C. P. Weiner

B. Gonik

High Risk Pregnancy

MANAGEMENT OPTIONS

David K. James
MA, MD, FRCOG, DCH
Professor of Fetomaternal Medicine
Director of Medical Education
Queen's Medical Centre
Nottingham
UK

Carl P. Weiner
MD, MBA, FACOG
Professor
Department of Obstetrics, Gynecology,
and Reproductive Sciences
Professor
Department of Physiology
University of Maryland School of Medicine
Baltimore, Maryland

Philip J. Steer
BSc, MD, FRCOG, FCOGSA (hon)
Professor
Faculty of Medicine
Imperial College London
Chelsea and Westminster Hospital
London
UK

Bernard Gonik
MD, FACOG
Professor and Fann Srere
Chair of Perinatal Medicine
Department of Obstetrics and Gynecology
Wayne State University
School of Medicine
Detroit, Michigan

NOTICE

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

CONTRIBUTORS

Oqba A. Al-Kuran, MD
Consultant
Maternal Fetal Medicine
Queen's Medical Centre
Nottingham
UK

Anthony Ambrose, MD
Associate Professor
Pennsylvania State University College of Medicine
Hershey, PA
USA

Christine Ang, MBChB, DFFP, ALSO, MD, MRCOG
University of Leicester
Leicester
UK

Marie-Cécile Aubry, MD
Associate
Université Paris V;
Consultant
Hôpital Necker Enfants Malades
Paris
France

John Anthony, MB, ChB, FCOG (SA)
Professor
Obstetrics and Gynaecology
University of Cape Town;
Groote Schuur Hospital
Capetown
South Africa

Vincent T. Armenti, MD, PhD
Professor of Surgery
Abdominal Organ Transplant Program
Temple University School of Medicine
Philadelphia, PA
USA

Robert D. Auerbach, MD
Yale University School of Medicine
New Haven, CT
USA

Loraine Bacchus, BSc, MA, PhD
Research Associate
Kings College London
School of Nursing and Midwifery
London
UK

May Backos, MBChB, MRCOG
Obstetrics and Gynaecology
West Middlesex University Hospital
Isleworth, Middlesex
UK

Philip Baker, BMedSci, BM, BS, MRCOG, DM
Professor
Academic Unit Obstetrics & Gynecology
   and Reproductive Health Care
St. Mary's Hospital
Manchester
UK

Ahmet Alexander Baschat, MB, BCh, MD
Assistant Professor
University of Maryland Medical School;
Attending Physician
University of Maryland Medical Center
Baltimore, MD
USA

Susan Bewley, MBBS, MA, FRCOG
Consultant Obstetrician
Maternal-Fetal Medicine
Guy's and St. Thomas' NHS Foundation Trust;
London
UK

Joseph R. Biggio, Jr., MD
Assistant Professor
Department of Obstetrics and Gynecology and
    Department of Genetics
University of Alabama at Birmingham
Birmingham, AL
USA

Ralph B. Blasier, MD
Professor and Associate Chairman for Orthopedic
    Research and Education
Orthopedic Surgery
Wayne State University;
Orthopedic Surgery
Sinai-Grace Hospital
Detroit, Michigan
USA

Renee A. Bobrowski, MD
Assistant Professor
Department of Obstetrics and Gynecology
University of Connecticut
Farmington, CT;
Attending Physician
Hartford Hospital
Hartford, CT
USA

D. Ware Branch, MD
Professor
Department of Obstetrics-Gynecology
University of Utah School of Medicine
Salt Lake City, UT
USA

Anneke Brand
Immunohematology and Blood Transfusion Service
Leiden University Medical Center
Leiden
The Netherlands

David Cahill, MD, MRCPI, FRCOG
Consultant Senior Lecturer in Reproductive Medicine
University of Bristol;
Consultant Gynecologist
St. Michael's Hospital
Bristol
UK

Alessandra Capponi
Department of Obstetrics and Gynecology
Università Roma Tor Vergata Ospedale Fatebenefreatelli
    Isola Tiberina
Rome
Italy

J. Ricardo Carhuapoma, MD
Assistant Professor
Departments of Neurology, Neurological Surgery,
    and Anesthesiology/Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, MD
USA

Tinnakorn Chaiworaponga, MD
Department of Obstetrics and Gynecology
Wayne State University
Detroit, MI
USA

Allan Chang, BS, PhD, FRCOG
Professor
University of Queensland;
Director
Mater Research Support Centre
Mater Health Services
South Brisbane
Australia

Frank A. Chervenak, MD
Professor and Chairman
Department of Obstetrics and Gynecology
Weill Medical College of Cornell University;
Obstetrician and Gynecologist-in-Chief
Weill Cornell Medical Center
New York, NY
USA

Lisa M. Cohen, MD
Clinical Assistant Professor
Department of Dermatology
Tufts University School of Medicine
Boston, MA;
Director
Cohen Dermatopathology
Newton, MA
USA

Joshua A. Copel, MD
Professor and Vice Chair
Obstetrics, Gynecology, and Reproductive Sciences
Yale University School of Medicine;
Attending
Obstetrics and Gynecology
Yale-New Haven Hospital
New Haven, CT
USA

Marc Coppens, MD
Consultant Gynaecologist–Obstetrician
Department of Obstetrics, Gynaecology, and Fertility
AZ Middelheim Hospital
Antwerpen
Belgium

Caroline A. Crowther, MBChB, MD, RCOG, Cert. MFM, FRANZCOG
Department of Obstetrics and Gynaecology
The University of Adelaide
Adelaide, South Australia
Australia

Peter Danielian, MA, MD, FRCOG
Honorary Senior Lecturer
Department of Obstetrics & Gynecology
Aberdeen University Medical School;
Consultant Obstetrician
Department of Obstetrics, Neonatology, and Gynecology
Aberdeen Maternity Hospital
Aberdeen, Scotland
UK

John M. Davies, MA, MD, FRCP, FRCPath
Honorary Senior Lecturer
University of Edinburgh;
Consultant Haematologist
Western General Hospital
Edinburgh, Scotland
UK

John M. Davison, MD
Professor of Obstetrics and Gynaecology
School of Surgical and Reproductive Sciences
University of Newcastle
Newcastle upon Tyne
UK

Isaac Delke, MD,
Chief, Division of Maternal-Fetal
Medicine, Director, Obstetrics, Professor,
Department of Obstetrics and Gynecology,
University of Florida College of Medicine Jacksonville,
Jacksonville, FL
USA

Philip Dennen, MD
Assistant Clinical Professor
Department of Obstetrics and Gynecology
Yale University School of Medicine
New Haven, CT
USA

Jan Deprest, MD, PhD
Consultant
Obstetrics and Gynecology
University Hospitals Leuven
Leuven
Belgium

Jodie M. Dodd, MBBS, FRANZCOG, Cert. MFM
Department of Obstetrics and Gynaecology
The University of Adelaide
Adelaide, South Australia
Australia

Jan E. Dickinson, MD
Associate Professor
Maternal-Fetal Medicine
School of Women's and Infants' Health
The University of Western Australia;
Maternal-Fetal Medicine Specialist
King Edward Memorial Hospital for Women
Perth, Western Australia
Australia

Marc Dommergues, MD
Professor
Service de Gynécologie Obstétrique
Groupe Hospitalier Pitié Salpétière
Paris
France

J. M. Ernest, MD
Professor
Department of Obstetrics and Gynecology
Wake Forest University School of Medicine
Winston-Salem, NC
USA

Peter A. Farndon, MSc, MD, FRCP, DCH
Professor of Clinical Genetics
University of Birmingham;
Consultant Clinical Geneticist
West Midlands Regional Clinical Genetics Service
Birmingham Women's Hospital
Birmingham
UK

Roy G. Farquharson, MD, FRCOG
Clinical Director
Obstetrics and Gynecology
Liverpool Women's Hospital
Liverpool
UK

Nicholas M. Fisk, PhD, FRCOG
Professor
Institute of Reproductive and Developmental Biology
Imperial College London;
Consultant
Centre for Fetal Care
Queen Charlotte's Hospital
London
UK

Breton C. Freitag, BS, MD
Clinical Instructor;
Fellow in Neonatal-Perinatal Medicine
Oregon Health and Science University
Portland, OR
USA

Harry Gee, MD
Medical Director
Birmingham Women's Health Care NHS Trust
Birmingham Maternity Hospital
Birmingham
UK

Reynir Tómas Geirsson, MD, PhD, FRCOG
Professor of Faculty of Medicine
Obstetrics and Gynecology
University of Iceland;
Chairman
Department of Obstetrics and Gynecology
Women's Clinic
Landspitali University Hospital
Reykjavík
Iceland

Robert Gherman, MD
Chairman
Department of Obstetrics and Gynecology
Washington Adventist Hospital
Takoma Park, MD
USA

Joanna Girling, MA, MBBS, MRCP, MRCOG
Honorary Senior Lecturer
Imperial College School of Medicine
London;
Consultant Obstetrician and Gynaecologist
West Middlesex University Hospital
Isleworth
UK

Luis F. Gonçalves, MD
Department of Obstetrics and Gynaecology
Wayne State University
Detroit, MI
USA

John M. Grant, MBChB, MRCP, MRCOG, FRCS (Glas)
Consultant Obstetrician and Gynaecologist
Wishaw General Hospital
Wishaw, Lanarkshire
Scotland

Michael G. Gravett, MD
Professor
Department of Obstetrics and Gynecology;
Chief
Division of Maternal–Fetal Medicine
Oregon Health and Science University
Portland, OR;
Senior Scientist
Division of Reproductive Sciences
Oregon National Primate Research Center
Beaverton, OR
USA

Michael Greaves, MBChB, MD, FRCPath, FRCP (Lon), (Edin), (Glas)
Head of School of Medicine
University of Aberdeen;
Honorary Consultant
Haematology
Aberdeen Royal Infirmary
Aberdeen, Scotland
UK

Clare Gribbin, BMedSci, BMBS, MRCOG, MI Psych Med
Specialist Registrar
Obstetrics and Gynaecology
Queen's Medical Centre
Nottingham
UK

David Griffin, MD, FRCOG
Consultant Obstetrician and Gynaecologist
West Herts Hospital HMS Trust
Waterford, Hertferdshire
UK

Mordechai Hallak, MD, MPA
Professor
Ben Gurion University,
Head of Feto-Maternal Medicine Unit
Soroka Medical Center
Beer Sheva
Israel

Roger F. Haskett, MD
Professor of Psychiatry
Department of Psychiatry
University of Pittsburgh;
Medical Director, Adult Services
Western Psychiatric Institute and Clinic
UPMC Presbyterian Shadyside;
Chief
Department of Psychiatry
Magee-Women's Hospital
Pittsburgh, PA
USA

Robert H. Hayashi, MD
J. Robert Willson Professor of Obstetrics
Director of Maternal-Fetal Medicine Fellowship
University of Michigan School of Medicine
Ann Arbor, MI
USA

Elizabeth Helen Horn, MD, FRCP, MRCPath
Consultant Haematologist
Department of Haematology
Royal Infirmary of Edinburgh
Edinburgh, Scotland
UK

David Howe, MD, MRCOG
University of Glasgow
Glasgow
Scotland

Alyson Hunter MD, MRCOG
Senior Lecturer
Department of Obstetrics and Gynaecology
Queen's University of Belfast;
Consultant in Fetal and Maternal Medicine
Royal Jubilee Maternity Hospital
Belfast
Northern Ireland

Jonathon Hyett, MD, MBBS, MRCOG
Harris Birthright Research Centre for Fetal Medicine
King's College Hospital
London
UK

David K. James, MA, MD, FRCOG, DCH
Professor of Fetomaternal Medicine
Director of Medical Education
Queen's Medical Centre
Nottingham
UK

Robin B. Kalish, MD
Assistant Professor
Weill Medical College of Cornell University;
Assistant Professor
New York Presbyterian Hospital
New York, NY
USA

Humphrey H. H. Kanhai, MD, PhD
Professor, Obstetrics
University Medical Center;
Head of Department of Obstetrics in Fetal Medicine
  and Leiden University Medical Center
Leiden
The Netherlands

Lucy H. Kean, MA, DM, MRCOG
Consultant in Fetal and Maternal Medicine
Department of Obstetrics
City Hospital
Nottingham
UK

Rohna Kearney, MB, MRCPI, MRCOG
National Maternity Hospital
Dublin
Ireland

Anna P. Kenyon, MBChB, MD
Department of Obstetrics
Maternal and Fetal Research Unit
Guys King's and St. Thomas' School of Medicine
London
UK

Lauren Kerzin-Storrar, BA, MS
Lecturer (honorary) MSC Programme Director
University of Manchester;
Consultant Genetic Counsellor
Regional Genetic Service and Academic Unit of
  Medical Genetics
Manchester
UK

Mark D. Kilby, MBBS (Lond.), MD, MRCOG
Professor of Fetal Medicine
Department of Obstetrics and Gynaecology
Birmingham Women's Hospital
Birmingham
UK

Justin C. Konje, MBBS, FMCOG, MRCOG
Professor
University of Leicester;
Consultant Obstetrician and Gynaecologist
Leicester Royal Infirmary
Leicester
UK

George Kroumpouzos, MD, PhD
Associate Faculty
Department of Internal Medicine
South Shore Hospital
South Weymouth, MA;
Courtesy Faculty
Division of Dermatology
Department of Medical Specialties
St. Vincent Hospital at Worcester Medical Center
Worcester, MA;
Staff Dermatologist
South Shore Medical Center
Norwell, MA
USA

Mark B. Landon, MD
Professor and Vice Chair
Director
Division of Maternal-Fetal Medicine, Obstetrics, and
    Gynecology
Ohio State University
College of Medicine and Public Health
Columbus, OH
USA

Steven R. Levine, MD
Professor of Neurology
Neurology and Stroke Program
The Mount Sinai School of Medicine;
Director, Cerebrovascular Education
Neurology and Stroke Program
The Mount Sinai Hospital
New York, NY
USA

Liesbeth Lewi, MD
Consultant
Obstetrics and Gynecology
University Hospitals Leuven
Leuven
Belgium

Bertis B. Little, PhD
Tarleton State University
Stephenville, TX
USA

Charles J. Lockwood, MD
The Anita O'Keefe Young Professor
Department of Obstetrics, Gynecology and
    Reproductive Sciences
Yale University School of Medicine;
Chief
Obstetrics and Gynecology
Yale-New Haven Hospital
New Haven, CT
USA

Mary Ann Lumsden, MB, MD, FRCOG, MRCOG
Department of Obstetrics and Gynaecology
University of Glasgow
Glasgow Royal Infirmary
Glasgow
Scotland

I. Z. MacKenzie, MA, MD, FRCOG, DSc
Reader in Obstetrics and Gynaecology
Nuffield Department of Obstetrics and Gynaecology
University of Oxford;
Honorary Consultant in Obstetrics and Gynaecology
John Radcliffe Hospital
Oxford
UK

**Kassam Mahomed, MBChB, MD, FRCOG,
FRANZCOG**
Associate Professor
Department of Obstetrics–Gynecology
University of Queensland;
Director
Department of Obstetrics and Gynecology
Toowoomba Hospital
Toowoomba
Australia

Michael Maresh, BSc, MD, FRCOG
Honorary Senior Lecturer
Department of Obstetrics and Gynaecology
University of Manchester;
Consultant Obstetrician
St. Mary's Hospital for Women and Children
Manchester
UK

Neil Marlow, DM, FRCPCH
Professor of Neonatal Medicine
University of Nottingham
Queen's Medical Centre
Nottingham
UK

Michael J. Mendelow, MD
Assistant Professor
Orthopedic Surgery
Wayne State University;
Orthopedic Surgery (Pediatric Orthopedic and Scoliosis
    Surgery)
Children's Hospital of Michigan
Detroit, Michigan
USA

Michael J. Moritz, MD
Professor of Surgery
Director of Abdominal Transplantation
Drexel University College of Medicine
Philadelphia, PA
USA

Robert T. Morris, MD
Associate Professor
Obstetrics and Gynecology
Wayne State University School of Medicine;
Gynecologic Oncology
Barbara Ann Karmanos Cancer Institute;
Director
Gynecologic Oncology
St. John Medical Center
Detroit, MI
USA

Adnan R. Munkarah, MD
Associate Professor
Obstetrics and Gynecology
Wayne State University;
Director
Obstetrics and Gynecologic Oncology
Karmanos Cancer Institute/Detroit Medical Center
Detroit, MI;
Director
Gynecologic Oncology
Oakwood Hospital Medical Center
Dearborn, MI;
USA

Catherine Nelson-Piercy, MA, FRCP
Consultant Obstetric Physician
Guy's and St. Thomas' Hospitals Trust
London
UK

**Robert Ogle, MBBS, FRANZCOG, FHGSA
(Clinical Genetics)**
Senior Staff Specialist
Physician in Molecular and Clinical Genetics
Department of Obstetrics and Fetal Medicine
Royal Prince Alfred Hospital for Women and Babies
Sydney, New South Wales
Australia

Colm O'Herlihy, MD, FRCOG, FRCPI
Professor and Head
Department of Obstetrics and Gynaecology
University College Dublin;
Consultant Obstetrician and Gynaecologist
National Maternity Hospital
Mater Misericordiae Hospital
Dublin
Ireland

Zoë Penn, MD, FRCOG
Honorary Senior Lecturer in Obstetrics
Faculty of Medicine
Imperial College London;
Consultant in Obstetrics
Chelsea and Westminster Hospital NHS Healthcare
    Trust
London
UK

T. Flint Porter, MD, MPH
Assistant Professor
Obstetrics and Gynecology
University of Utah Health Sciences;
Medical Director
Maternal-Fetal Medicine
LDS Hospital, Urban Central Region of Intermountain
    Healthcare
Salt Lake City, UT
USA

Raymond Powrie, MD, FRCPEC
Associate Professor of Medicine and Obstetrics and
    Gynecology
Brown University;
Academic Director Division of Obstetric and
    Consultative Medicine
Women and Infants Hospital of Rhode Island
Providence, RI
USA

Margaret Mary Ramsay, MA, MD, FRCOG, MRCP
Senior Lecturer in Fetomaternal Medicine
School of Human Development
Nottingham University;
Honorary Consultant in Fetomaternal Medicine
Queen's Medical Centre
Nottingham
UK

Lesley Regan, MD, FRCOG
Head of Department of Obstetrics and Gynaecology
Imperial College London;
Professor and Head Department of Obstetrics and
    Gynaecology
Director of Early Pregnancy and Recurrent Miscarriage
    Services
St. Mary's Hospital;
Honorary Consultant in Obstetrics and Gynaecology,
    Service Director for Gynaecology
Women and Children's Directorate
St. Mary's NHS Hospital Trust
London
UK

John T. Repke, MD, FACOG
Professor and Chairman
Department of Obstetrics and Gynecology
Pennsylvania State University College of Medicine;
Obstetrician–Gynecologist-in-Chief
The Milton S. Hershey Medical Center
Hershey, PA
USA

Laura E. Riley, MD
Assistant Professor Obstetrics and Gynecology and
    Reproductive Biology
Harvard Medical School
Cambridge, MA;
Medical Director of Labor and Delivery
Massachusetts General Hospital
Boston, MA
USA

Giuseppe Rizzo, MD
Professor
Department of Obstetrics and Gynecology
Università Roma Tor Vergata;
Ospedale Fatebenefreatelli Isola Tiberina
Rome
Italy

**Jeffrey S. Robinson, MB, BCh, BAO, FRCOG,
FRANZCOG**
Professor of Obstetrics and Gynaecology
University of Adelaide
Adelaide, South Australia
Australia

Stephen Robson, MD, MRCOG, MBBS
Professor of Fetal Medicine
School of Surgical and Reproductive Sciences
University of Newcastle upon Tyne
Newcastle upon Tyne
UK

Romaine Robyr
Consultant
Département de Gynécologie Obstétrique et Médecine
    de la Reproduction
Centre Hospitalier Intercommunal
Poissy
France

Michael S. Rogers, MBChB, FRCOG, FRCS, MD
Professor
Chinese University of Hong Kong;
Professor and Division Head
Department of Obstetrics and Gynaecology
Chinese University of Hong Kong
Shatin, Hong Kong
China

Roberto Romero, MD
Chief Perinatology Research Branch
Intramural Division, NICHD
Professor
Department of Obstetrics and Gynecology
Wayne State University/Hutzel Hospital, Department
    of Obstetrics and Gynecology
Detroit, MI
USA

Thomas Roos, MD
Assistant Professor
Department of Obstetrics and Gynecology
University of Regensburg
Attending
Department of Obstetrics
Sahlgrenska University Hospital—East
Gothenburg
Sweden

Jane M. Rutherford, DM, MRCOG
Consultant in Fetomaternal Medicine
Obstetrics and Gynaecology
Queen's Medical Centre
Nottingham
UK

Rodrigo Ruano, MD
Research Fellow
Université Paris V;
Consultant
Hôpital Necker Enfants Molades
Paris
France

Luis Sanchez-Ramos, MD
Professor
Obstetrics and Gynecology
University of Florida Health Science Center
Jacksonville, FL
USA

Veronica L. Schimp, DO
Wayne State University School of Medicine;
Assistant Professor
Wayne State University Karmanos Cancer Institute
Detroit, MI
USA

Neil S. Silverman, MD
Clinical Professor
Department of Obstetrics and Gynecology
Geffen School of Medicine at UCLA;
Medical Director
Inpatient Obstetric Services
Cedars-Sinai Medical Center
Los Angeles, CA
USA

Gordon C. S. Smith, MD, PhD, MRCOG
Professor and Head of Department
Obstetrics and Gynaecology
Cambridge University;
Consultant in Maternal-Fetal Medicine
Addenbrooke's NHS Trust
Cambridge
UK

John Stafan Smoleniec, BSc (Mech. Eng.,) MBBCh, MRCOG, FRACOG, FMFF (UK), DDU, MFMC (Aust.)
Conjoint Appointee
University of New South Wales
Sydney;
Director
Feto Maternal Unit
Liverpool Hospital
Liverpool
Australia

Christopher S. Snyder, MD
Head of Pediatric Electrophysiology
Ochsner Clinic Foundation
New Orleans, LA
USA

Peter William Soothill, BSc, MBBS, MD, FRCOG
Professor of Maternal and Fetal Medicine
Obstetrics and Gynaecology, Clinical Sciences South
    Bristol
University of Bristol;
Professor of Maternal and Fetal Medicine
Obstetrics and Gynaecology
St Michael's Hospital, UBHT
Bristol
UK

Philip J. Steer, BSc, MBBS, MD, FRCOG
Professor
Academic Department of Obstetrics and Gynaecology
Faculty of Medicine
Imperial College London;
Chelsea and Westminster Hospital
London
UK

Peter Stone, BSc, MBChB MD (Bristol), FRCOG, FRANZCOG, DDU, CMFM
Professor of Maternal Fetal Medicine
Department of Obstetrics and Gynecology
University of Auckland;
Professor of Maternal Fetal Medicine
National Women's Hospital
Auckland Hospital
Auckland
New Zealand

Jane Streltzoff, BS, RDMS
Division of Maternal—Fetal Medicine
Department of Obstetrics and Gynecology
Weill Medical College of Cornell University
New York, NY
USA

Jane Strong, MBChB, MRCP(UK), MRCPath
Consultant Haematologist
Leicester Royal Infirmary
Leicester
UK

John M. Svigos, MBBS, DRCOG, FRCOG, FRANZCOG
Senior Clinical Lecturer
Department of Obstetrics and Gynaecology
University of Adelaide;
Senior Visiting Medical Officer and Obstetric Unit Head
Women's and Children's Hospital
North Adelaide, South Australia
Australia

Myles J. O. Taylor, BA, MRCGP, MRCOG, PhD
Honorary Clinical Senior Lecturer
Peninsula Medical School
Universities of Exeter and Plymouth;
Consultant Obstetrician and Gynaecologist
Subspecialist in Fetal and Maternal Medicine
Royal Devon and Exeter NHS Foundation Trust
Devon
UK

Jim Thornton, MD, FRCOG
Professor in Obstetrics and Gynaecology
School of Human Development
University of Nottingham;
Honorary Consultant Obstetrician and Gynaecologist
Nottingham City Hospital NHS Trust
Nottingham
UK

Mark W. Tomlinson, MD
Clinical Assistant Professor
Obstetrics and Gynecology
Oregon Health and Sciences University;
Obstetrics and Gynecology
Providence St. Vincent's Hospital;
Women's Healthcare Associates
Portland, OR
USA

Lawrence C. Tsen, MD
Associate Professor in Anesthesia
Harvard Medical School;
Director of Anesthesia, Center for Reproductive Medicine
Department of Anesthesiology, Perioperative, and Pain
    Medicine
Brigham and Women's Hospital
Boston, MA
USA

Sarah Vause, MD, MRCOG
Consultant in Fetomaternal Medicine
St. Mary's Hospital
Manchester
UK

Rasniah Vigneswaran, MD*
Formerly Senior Staff Neonatologist
University of Adelaide
Adelaide Women's and Children's Hospital
Adelaide, South Australia
Australia

Yves Ville, MD, PhD
Professor
Department de Gynecologie Obstetrique et Medecine
de la Reproduction
Centre Hôspitalier Intercommunal
Poissy, Cedex
France

Anthony Vintzileos, MD
Professor and Chair
Department of Obstetrics, Gynecology, and
   Reproductive Sciences
UMDNJ-Robert Wood Johnson Medical School;
Chairman
Department of Obstetrics Gynecology, and
   Reproductive Sciences
Robert Wood Johnson University Hospital
New Brunswick, NJ
USA

Asnat Walfisch, MD
Instructor
Ben Gurion University;
Department of Obstetrics and Gynecology
Soroka Medical Center
Beer Sheva
Israel

Ann Walker, MBChB
Lead Clinician for Pregnancy
University of Leeds
Leeds
UK

James Walker, MD, FRCOG, FRCP
Professor of Obstetrics and Gynecology
University of Leeds;
Professor of Obstetrics and Gynaecology
St. James University Teaching Hospital
Leeds
UK

Peter Wardle, MD, FRCS (Lond.), FRCOG
Consultant Obstetrician and Gynaecologist
Southmead Hospital
Bristol
UK

D. Heather Watts, MD
Medical Officer
Pediatric, Adolescent, and Maternal AIDS Branch
National Institute of Child Health and Human
   Development
National Institutes of Health
Bethesda, MD
USA

Carl P. Weiner, MD, MBA, FACOG
Professor
Department of Obstetrics, Gynecology, and
   Reproductive Sciences;
Professor
Department of Physiology
University of Maryland School of Medicine
Baltimore, MD
USA

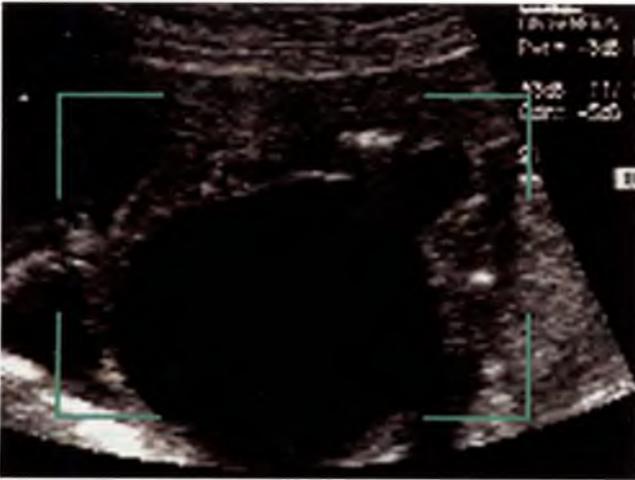
Katharine, D. Wenstrom, BA, MA, MD
Professor
Obstetrics and Gynecology
University of Alabama School of Medicine;
Director
Division of Maternal–Fetal Medicine and Reproductive
   Genetics
University of Alabama Hospital and Clinics
Birmingham, AL
USA

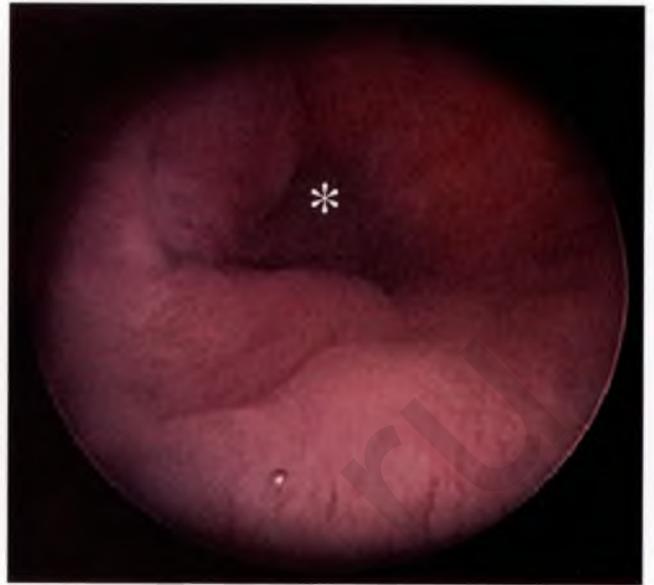
Hajo I. J. Wildschut, MD, PhD
Associate Professor of Obstetrics and Gynecology
Erasmus University Medical Center;
Consultant in Obstetrics and Gynecology
Erasmus University Medical Center
Rotterdam
The Netherlands

David Williams, MBBS, PhD
Senior Lecturer, Maternal Medicine
Imperial College London;
Consultant Obstetric Physician
Department of Obstetrics and Gynaecology
Chelsea and Westminster Hospital
London
UK

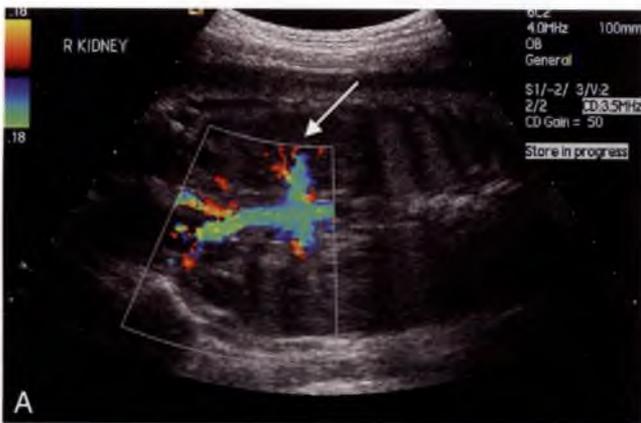
*(deceased)

Catherine Williamson, BSc, MBChB, MRCP
Senior Lecturer in Obstetric Medicine
Imperial College London;
Honorary Consultant Obstetric Physician
Queen Charlotte's Hospital
London
UK

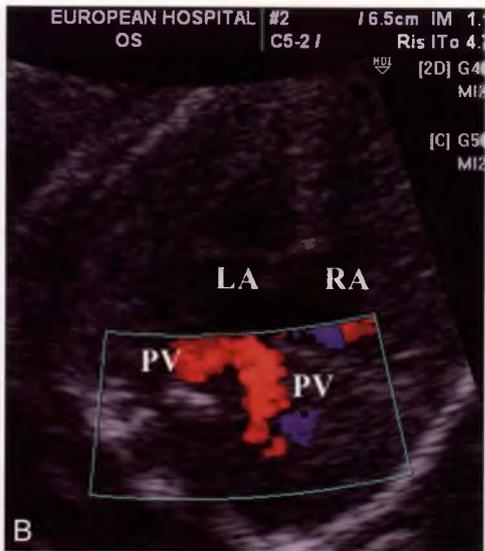
Lami Yeo, MD
Associate Professor
Department of Obstetrics, Gynecology, and
    Reproductive Sciences
UMDNJ—Robert Wood Johnson Medical School;
Director of Perintal ultrasound
Director of Fetal Cardiovascular Unit
Robert Wood Johnson University Hospital
New Brunswick, NJ
USA


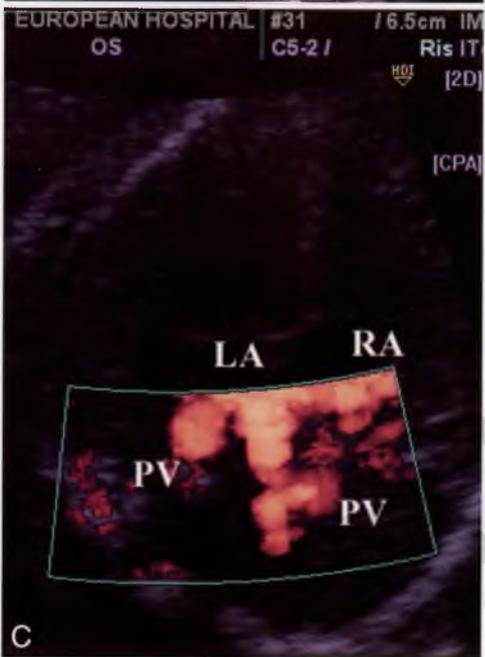
COLOR PLATE 1
A transverse view of lower fetal abdomen on ultrasound at 16 weeks, showing a dilated bladder with a keyhole sign (see Fig. 13–3).


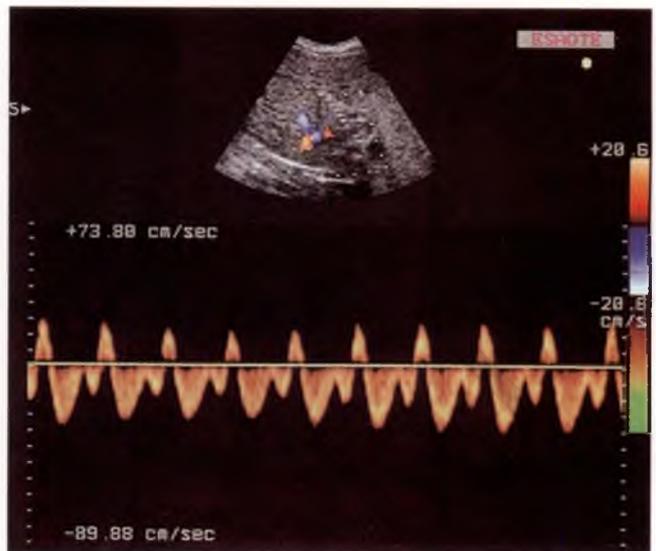
COLOR PLATE 3
Fetal cystoscopic view of a fetal bladder and the proximal urethra (*) (see Fig. 13–6).

COLOR PLATE 4
Flow in ductus venosus of a fetus with reentrant supraventricular tachycardia. Normal flow is unidirectional in contrast with bidirectional flow shown here (see Fig. 16–3).


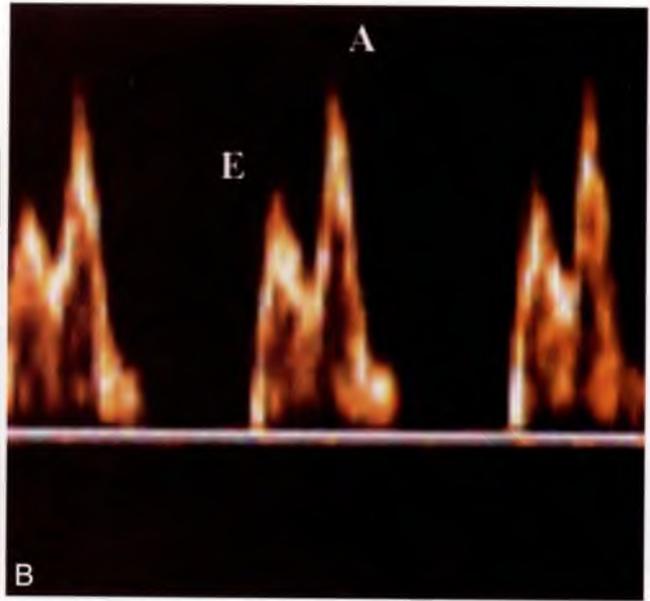
COLOR PLATE 2
Color Doppler/power Doppler showing renal arteries in a normal fetus (*A*) but absent from a fetus with renal agenesis (*B*) (see Fig. 13–5).

COLOR PLATE 5
B, Same section with power Doppler superimposed showing the arch with its three branches: innominate artery (I), left carotid artery (C) and subclavian artery (S) (see Fig. 17–5).


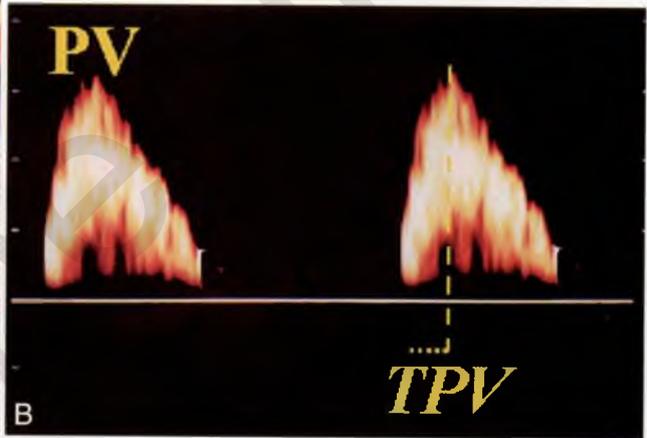


COLOR PLATE 6
Apical four-chamber view of the fetal heart showing the inlet of the pulmonary veins (PV) in the left atrium in real time (*A*) and with the help of color (*B*) and power (*C*) Doppler (see Fig. 17–11).


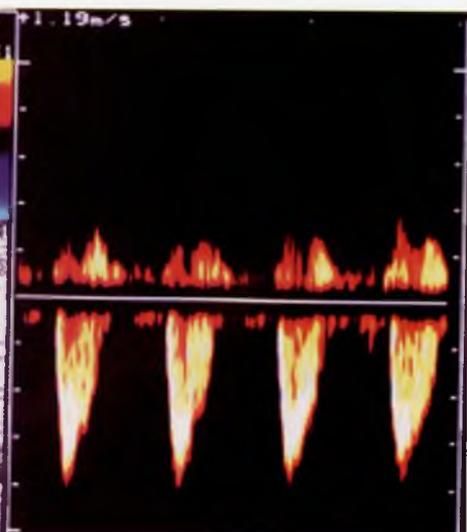
COLOR PLATE 7
Parasagittal view of the fetal trunk with the sample volume placed on the inferior vena cava. Note the typical triphasic morphology with the reverse flow (upper channel) during atrial contraction (A wave) (see Fig. 17–12).

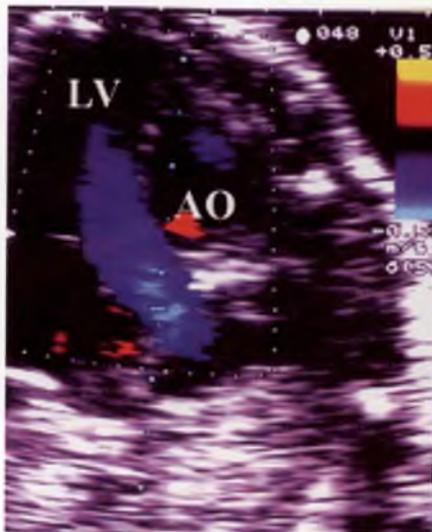
COLOR PLATE 8
Transverse section of the upper fetal abdomen with the sample volume placed on the ductus venosus. Note the typical biphasic morphology (see Fig. 17–13).


COLOR PLATE 9

*A*, Apical flow chamber view of the fetal heart showing the normal filling of the two ventricles (*red color*). *B*, Pulsed Doppler tracing from tricuspid valve. Note the typical morphology (E and A waves) and the absence of flow during systole (see Fig. 17–15).


COLOR PLATE 10

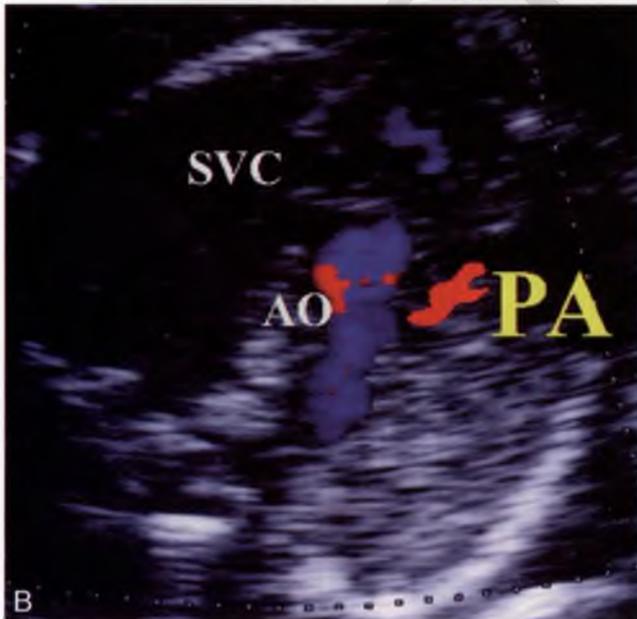
A, Short-axis view of the fetal heart with the color Doppler superimposed showing the outflow of the right ventricle (*blue*). *B*, Pulsed Doppler tracing at the level of the pulmonary valve and the typical velocity waveform recorded. PV, peak velocity; TPV, time to peak velocity (see Fig. 17–16).


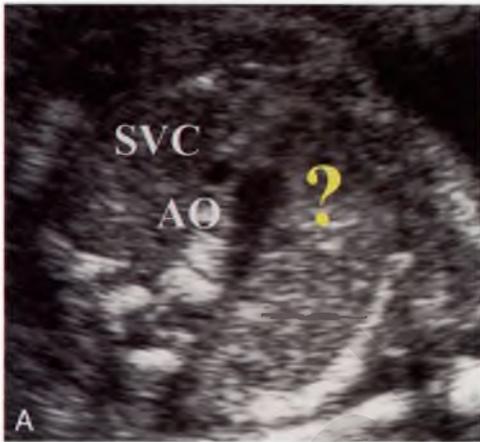


COLOR PLATE 11

Long-axis view of the fetal heart with the color Doppler superimposed showing the outflow of the left ventricle (*blue*). The sample volume is placed at the level of the aorta and the typical velocity waveform recorded (see Fig. 17–17).

COLOR PLATE 12
Three-vessel view with the color Doppler superimposed showing pulmonary artery (PA) and ascending aorta (AO) with the same flow direction (see Fig. 17–18).

COLOR PLATE 14
This small perimembranous septal defect is visualized with the help of color Doppler. High-velocity jet from the left to the right ventricle is due to the association of aortic stenosis (see Fig. 17–21).


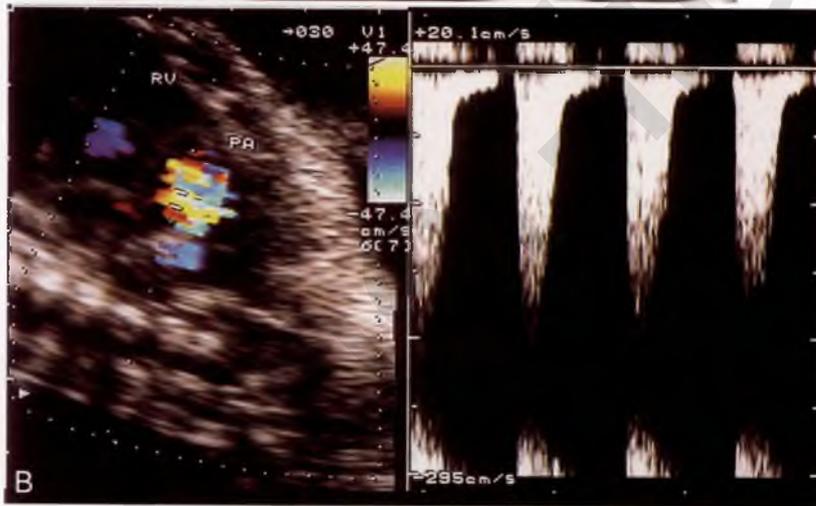


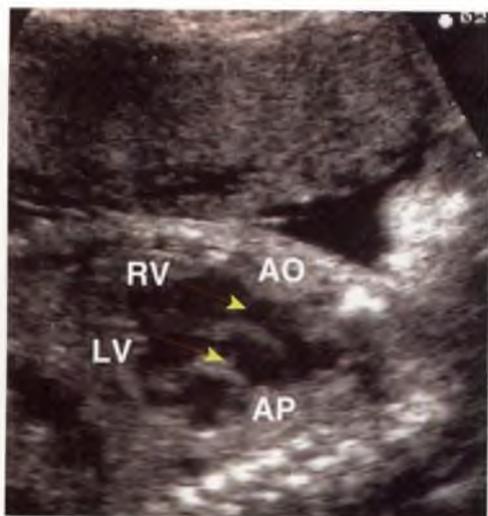
COLOR PLATE 13
Three-vessel view in a fetus with pulmonary atresia. *A*, The pulmonary artery is not evidenced (?) in real-time image. *B*, With the color Doppler superimposed, a small caliber pulmonary artery is identified with reversal flow (*red*) indicating retrograde perfusion from the systemic circulation to pulmonary circulation (see Fig. 17–19).

COLOR PLATE 15
The color Doppler shows the normal filling of the right ventricle (*red*) and the absent filling of the left ventricle (mitral atresia). LV, left ventricle; RV, right ventricle (see Fig. 17–25*B*).

COLOR PLATE 16
Color Doppler shows the absent filling of the right ventricle (tricuspid atresia). LV, left ventricle; RV, right ventricle (see Fig. 17–26B).

COLOR PLATE 18
Color Doppler image with the pulsed Doppler sample placed on the aortic valve showing high velocities (PV > 220 cm/sec) suggestive of aortic stenosis (see Fig. 17–28).

COLOR PLATE 17
Apical four-chamber view in the presence of a pulmonary atresia and intact septum. When the color Doppler is superimposed a high-velocity retrograde jet is seen (*blue*) (*B*) and a holosystolic high velocity (>2 m/sec) tricuspid regurgitation is measured by pulsed Doppler (*C*). LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle (see Fig. 17–27B,C).


COLOR PLATE 19
Short-axis view of the fetal heart in a fetus with pulmonary stenosis. *A*, Narrowing of the valve. *B*, Color Doppler superimposed showing high velocities in pulmonary artery (PA). Pulsed Doppler demonstrates high-velocity waveforms (180 cm/sec) consistent with pulmonary stenosis (see Fig. 17–30).


COLOR PLATE 20

Example of correct transposition of great artery with intact septum. The heart is seen in long axis, and in contrast to normal, both great arteries are seen in this projection. They arise in parallel orientation with the aorta (AO) from the anterior right ventricle (RV) and the pulmonary artery (PA) from the posterior left ventricle (LV) (see Fig. 17–31).

COLOR PLATE 21

Long-axis view of the fetal heart in a fetus with tetralogy of Fallot. *A*, The aorta (AO) is overriding the left (LV) and right ventricles (RV) in real time. *B*, The color Doppler shows the perfusion during systole from the left (LV) and right (RV) ventricles into the overriding aorta (AO) (Y sign) (see Fig. 17–34).

COLOR PLATE 22

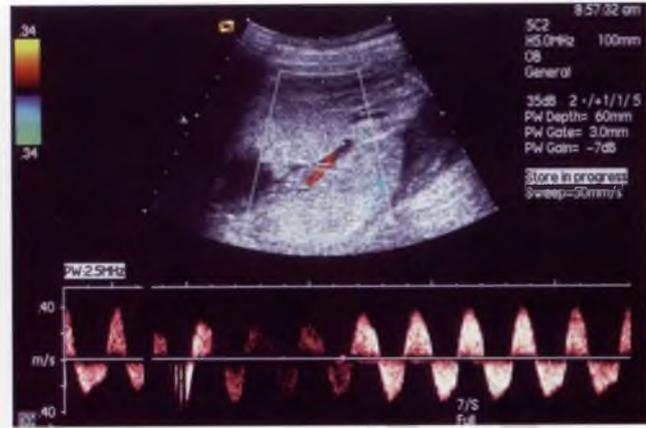
Tetralogy of Fallot. Color Doppler demonstrates the presence of the ventricular septal defect (*B*) and pulsed Doppler placed at the level of pulmonary valve demonstrates the presence of high velocities (>2 m/sec) consistent with pulmonary stenosis (*C*) (see Fig. 17–35*B,C*).

COLOR PLATE 23
Double outlet right ventricle. Both great vessels originate from the
right ventricle (RV). Furthermore the PA is atretic and a retrograde
flow (*blue*) is evident, suggesting that the pulmonary circulation
depends on the aorta (*B*) (see Fig. 17–36*B*).

COLOR PLATE 25
Arch view in presence of a hypoplastic left ventricle. The arch is
perfused in the reverse direction (blue color is seen instead of red)
suggesting that the brain and coronary circulation depend on the right
ventricle. AO, aorta (see Fig. 17–39).

COLOR PLATE 24
Truncus arteriosus. Color Doppler allows the visualization of the
origin of the right (RPA) and left (LPA) pulmonary arteries from the
truncus (TR) (see Fig. 17–37*B*).

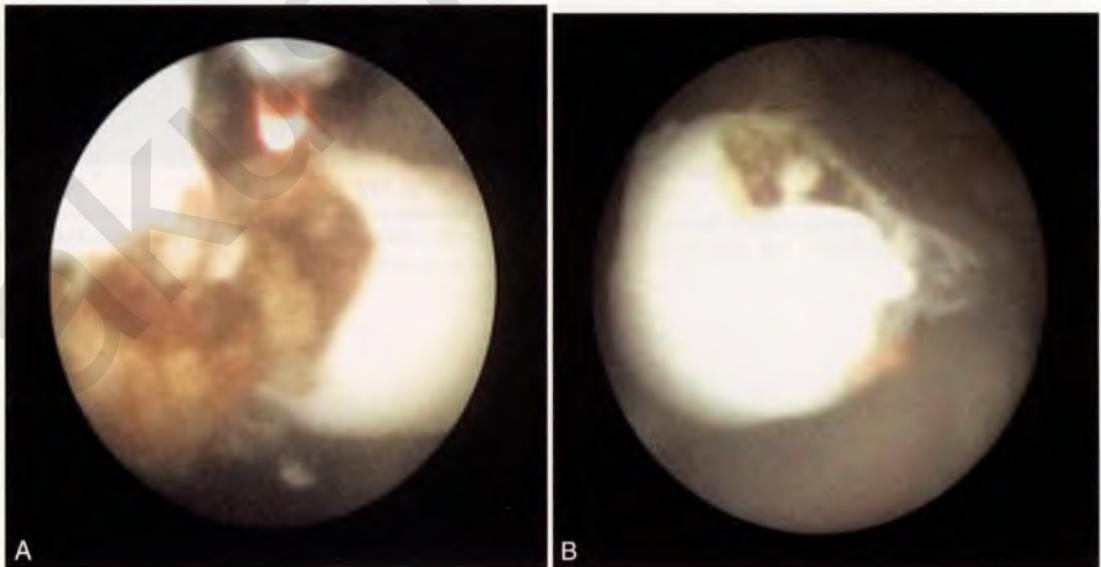
COLOR PLATE 26
Transverse section through fetal head using color Doppler
demonstrating blood flow in cystic structure, vein of Galen (see Fig.
18–15*C*).

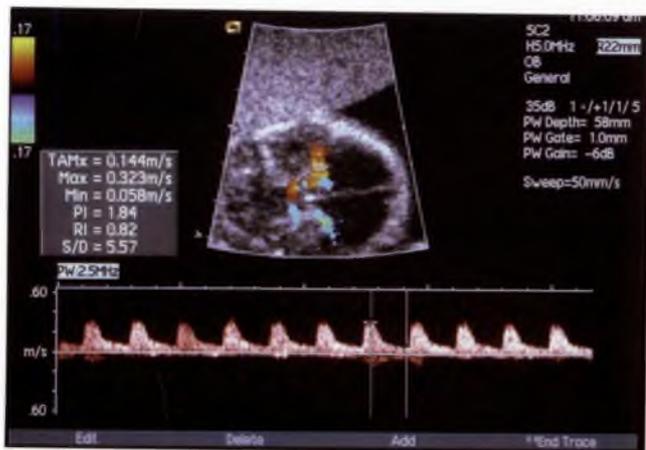
COLOR PLATE 27
Three-dimensional reconstruction of a CT-angiogram of a monochorionic placenta at term, showing an equal distribution of the placental mass and a large arterioarterial and venovenous superficial anastomosis (*arrows*). (see Fig. 24–2). (In collaboration with M. Cannie, UZ Leuven, Belgium.)


COLOR PLATE 29
Characteristic bidirectional Doppler pattern in an arterioarterial anastomosis, which confirms monochorionicity (see Fig. 24–8).

COLOR PLATE 28
Doppler pattern of intermittent absent end-diastolic flow as typically seen in the smaller twin of a monochorionic pair with discordant growth (see Fig. 24–7).

COLOR PLATE 30
Macroscopic image of large-diameter anastomoses and side-to-side insertion of the umbilical cords as typically seen in a monoamniotic twin pregnancy (see Fig. 24–9A).

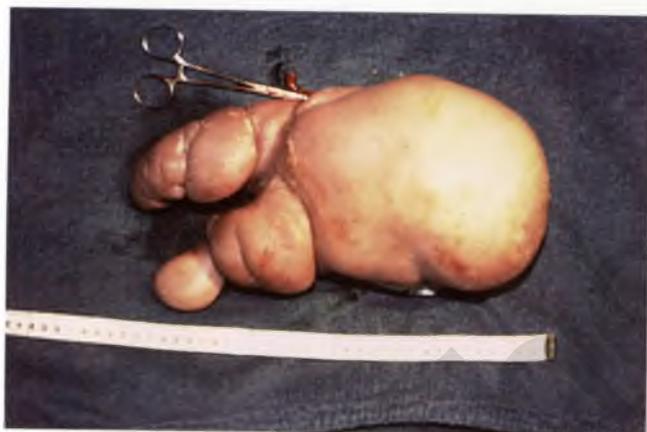
COLOR PLATE 31
Cord entanglement and knotting at birth in a monoamniotic twin pregnancy (see Fig. 24–12). (Courtesy of S. Dobbelaere, H. Hart Hospital, Lier, Belgium.)


COLOR PLATE 32
Fetoscopic image during (*A*) and after (*B*) umbilical cord transsection by laser in a monoamniotic twin pregnancy with a severe discordant anomaly (see Fig. 24–13).


COLOR PLATE 33

Doppler examination of the middle cerebral artery of the surviving twin of a monochorionic pair at 20 weeks' gestation, within 4 days after sIUFD of the growth-retarded co-twin (see Fig. 24–15).

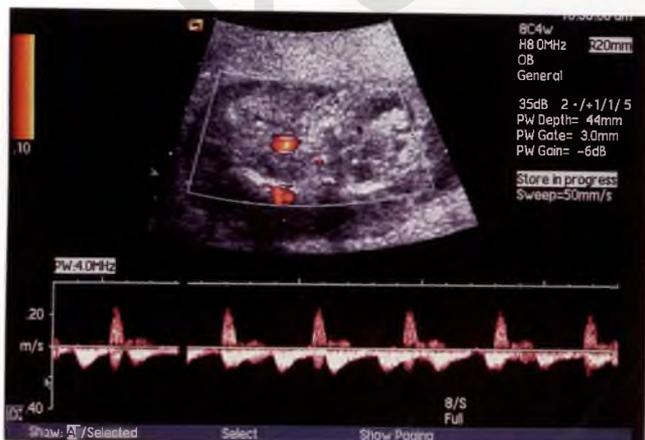
COLOR PLATE 36

Doppler examination at 15 weeks' gestation, demonstrating the typical, retrograde flow from the pump twin toward the acardiac twin over an arterioarterial anastomosis (*arrow*) (see Fig. 24–18*B*).


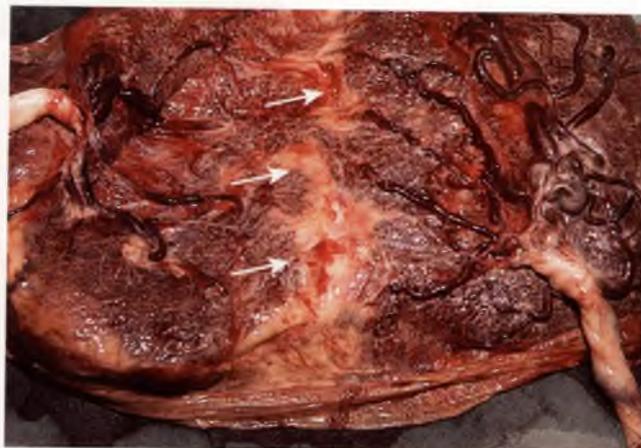
COLOR PLATE 34

Macroscopic image of an acardiac twin with absent head and partial development of lower limbs and abdomen. This acardiac mass weighed about 4 kg and was not diagnosed until the third trimester. The patient delivered at 37 weeks, and the pump twin survived (see Fig. 24–16).

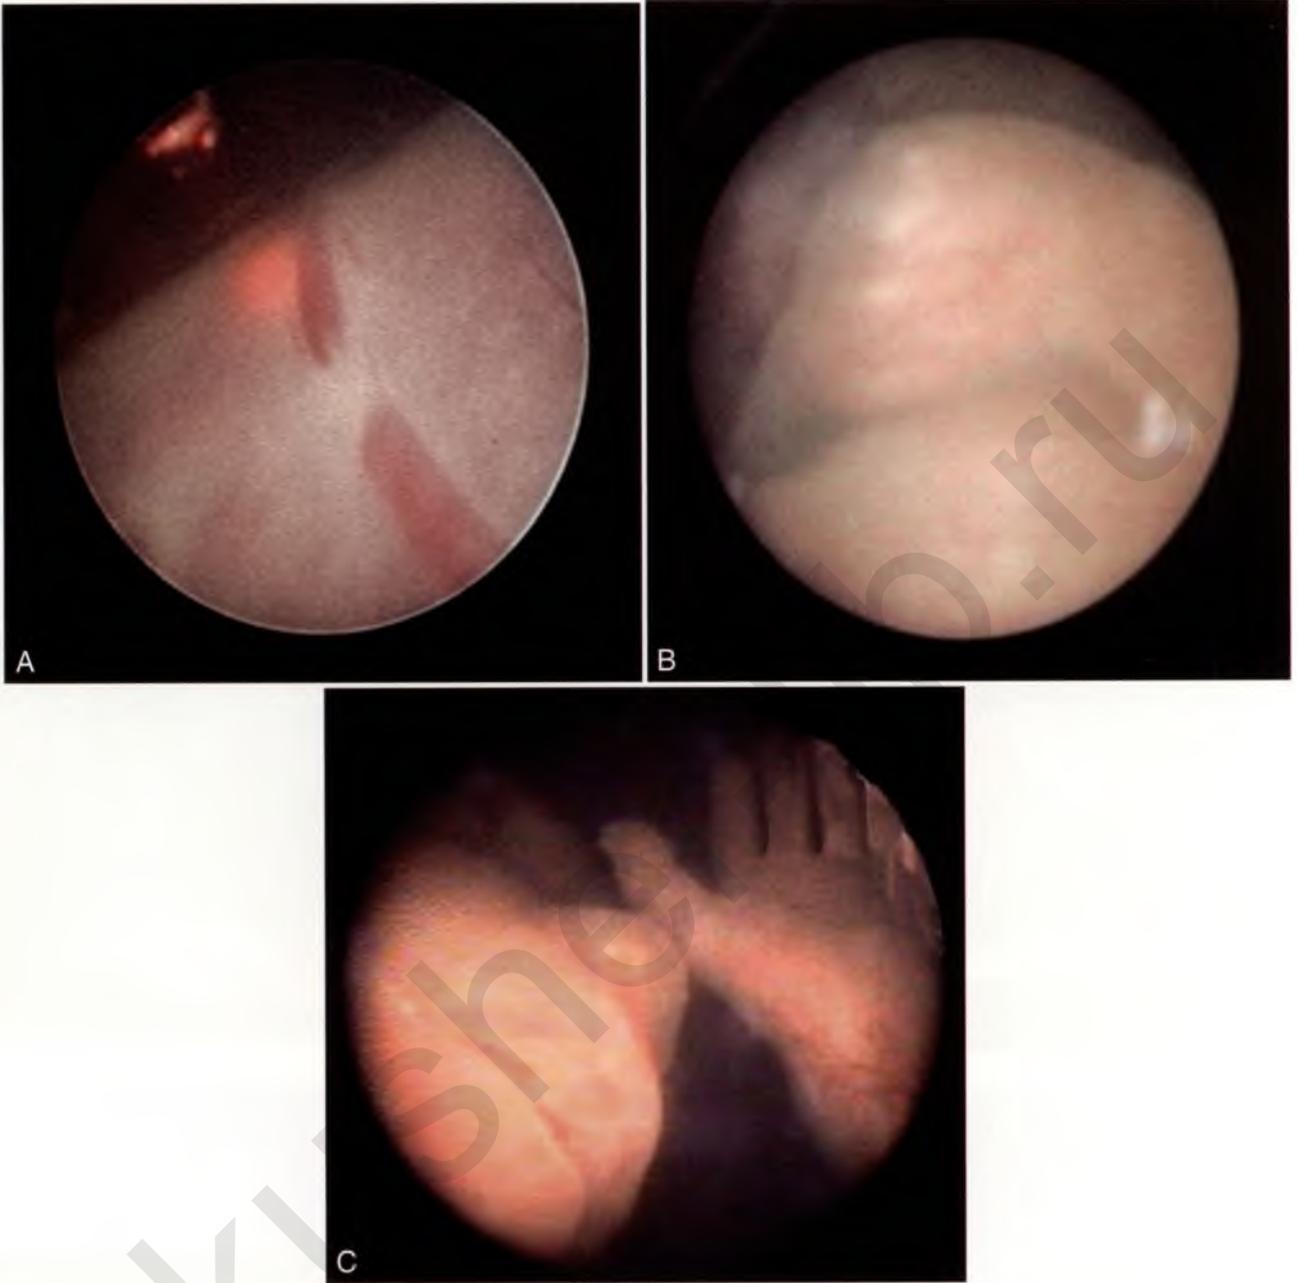
COLOR PLATE 37

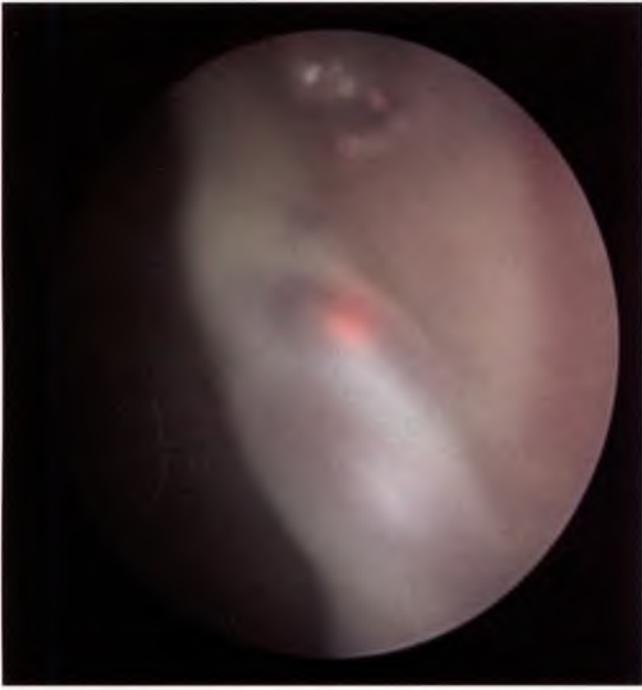
Ultrasound image of membrane folding in a monochorionic twin pregnancy, which reflects discordant amniotic fluid in a monochorionic twin pregnancy (see Fig. 24–23).


COLOR PLATE 35

Doppler examination demonstrating cardiac activity in the rudimentary heart (70 bpm) of the acardiac twin, with flow in the opposite direction in the aorta (140 bpm) (see Fig.24–17).


COLOR PLATE 38

Macroscopic image of a placenta at birth demonstrating "bichorionization" and laser impact (*arrows*) on the monochorionic placenta after laser coagulation for twin-to-twin transfusion syndrome (see Fig. 24–24).


COLOR PLATE 39
A, Fetoscopic image of laser coagulation of an arteriovenous anastomosis for twin-to-twin transfusion syndrome. *B*, Fetoscopic image of the hands of the donor twin, who is stuck behind the intertwin septum. *C*, Fetoscopic image of the face of the recipient, who moves freely in the hydramniotic sac (see Fig. 24–26).


COLOR PLATE 40
Fetoscopic image of laser cord coagulation (see Fig. 24–28).

COLOR PLATE 41
Dermatologic features observed in obstetric cholestasis cases:
Dermatitis artefacta (see Fig. 48–1).

COLOR PLATE 42
Spider angioma (telangiectasia) on the arm (see Fig. 52–1).

COLOR PLATE 43
Stretchmarks (striae gravidarum) on the lateral aspects of the
abdomen and hyperpigmentation of the linea alba, causing
development of the *linea nigra* (see Fig. 52–2).

COLOR PLATE 44
Telogen effluvium, which developed in the immediate postpartum
period, with typical temporal recession and thinning (see Fig. 52–3).

COLOR PLATE 45
Melasma of the entire central face (see Fig. 52–4).

COLOR PLATE 46

Pseudoacanthosis nigricans may develop in skin of color during pregnancy and manifests itself as hyperpigmented velvety plaques on the axillae (as shown) and neck (see Fig. 52–5).

COLOR PLATE 47

Grayish-brown ill-defined patches of dermal melanocytosis may develop in pregnancy and persist in the postpartum period (see Fig. 52–6).

COLOR PLATE 48

Extensive postinflammatory hyperpigmentation secondary to pruritic urticarial papules and plaques of pregnancy in an Asian female (see Fig. 52–7).

COLOR PLATE 49

A, Early impetigo herpetiformis: discrete group sterile papules at the periphery of erythematous patch. *B,* Generalized advanced lesions of impetigo herpetiformis show crusting or vegetations (see Fig. 52–8). (Photographs courtesy of Aleksandr Itkin, MD.)

COLOR PLATE 50

Hyperpigmented minimally scaly patches on the chest in a pregnant female with tinea versicolor (see Fig. 52–9).

COLOR PLATE 51
Malar erythema in a butterfly distribution in a pregnant woman with systemic lupus erythematosus (see Fig. 52–10). (Photograph courtesy of Cameron Thomas, Campbell Kennedy, and Phillipa Kyle from second edition.)

COLOR PLATE 52
Melanocytic nevus that became darker and developed a mild border irregularity during gestation (see Fig. 52–11).

COLOR PLATE 53
Pyogenic granuloma of pregnancy (*granuloma gravidarum*), typically seen on the gingivae, can also develop on extramucosal sites (see Fig. 52–12).

COLOR PLATE 54
Keloid that developed during pregnancy without previous trauma (see Fig. 52–13).

COLOR PLATE 55
Minimal residual skin lesions of sarcoidosis on the knee in a pregnant female who showed severe generalized skin sarcoidosis before gestation (see Fig. 52–14).

COLOR PLATE 56

A, Pruritic abdominal urticarial lesions usually develop in the early phase of herpes gestationis. *B*, Characteristic tense vesicles on an erythematous base on the forearm in a patient with herpes gestationis. (see Fig. 52–15). (Photographs courtesy of Jeffrey Callen, MD.)

COLOR PLATE 57

A, Early PUPPP showing typical urticarial lesions in the abdominal striae. *B*, Lesions with microvesiculated appearance on the forearm in PUPPP. *C*, Widespread PUPPP may resemble a toxic erythema (see Fig. 52–16). (Photograph courtesy of Helen Raynham, MD.)

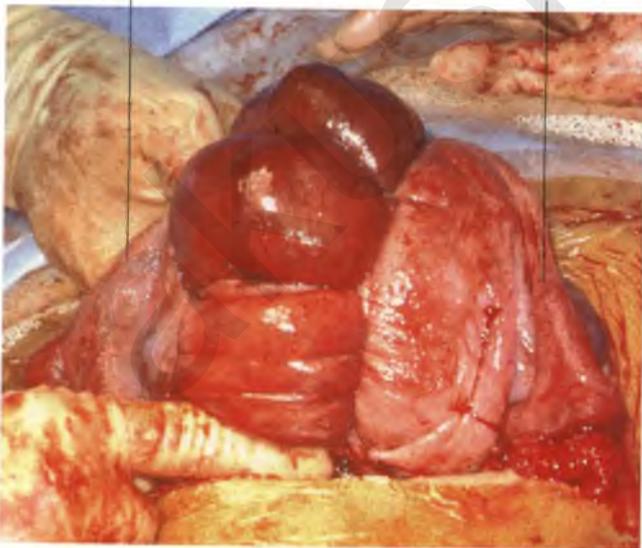
COLOR PLATE 58

Prurigo gestationis: excoriated papules and nodules on the extensor surfaces of the extremities (see Fig. 52–17). (Photograph courtesy of Cameron Thomas, Campbell Kennedy, and Phillipa Kyle from second edition.)

COLOR PLATE 59

A, Pruritic folliculitis of pregnancy: typical follicular erythematous or pigmented papules on the abdomen. *B,* Follicular acneform pustules and papules on the upper back in pruritic folliculitis of pregnancy (see Fig. 52–18).

Left fallopian tube

Right fallopian tube


COLOR PLATE 60

Posterior view of compression sutures (see Fig. 77–9). From Hayman RG, Arulkumaran S, Steer PJ: Uterine compression sutures: Surgical management of postpartum hemorrhage. Obstet Gynecol 2002;99:502–506.

EVIDENCE-BASED SUMMARY OF MANGEMENT OPTIONS BOXES

One of the most popular features of the first two editions of High Risk Pregnancy: Management Options was the "Summary of Management Options" (SOMO) Box. The SOMO Box was placed at the end of each chapter or section within a chapter and presented the reader with an *aide memoire* of the main points regarding the management options for a specific condition discussed in detail in the chapter.

In 2003, the SOMO Boxes were compiled into a separate publication: Evidence Based Obstetrics. For that book, however, the SOMO Boxes were expanded to include an evidence-based scoring system. Each management option was scored on the basis of the quality of evidence that underpinned that strategy. The strength of recommendation for a given management option would inevitably result from the quality of evidence, with the highest recommendation being linked with the best quality of evidence.

For the third edition of *High Risk Pregnancy: Management Options* the editors have agreed to include the same evidence-based approach in the SOMO Boxes.

The following is the evidence based scoring system that is used in this book for the SOMO Boxes.

Scoring System for Summary of Management Options Boxes

Quality (Level) of Evidence
Ia   Evidence obtained from meta-analysis of randomized controlled trials

Ib   Evidence obtained from at least one randomized controlled trial

IIa   Evidence obtained from at least one well-designed controlled study without randomization

IIb   Evidence obtained from at least one other type of well-designed quasi-experimental study

III   Evidence obtained from well-designed non-experimental descriptive studies, such as comparative studies, correlation studies, and case studies

IV   Evidence obtained from expert committee reports or opinions and/or clinical experience of respected authorities

Strength (Grade) of Recommendation
A   At least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation (Evidence Levels Ia or Ib)

B   Well-controlled clinical studies available but no randomized clinical trials on the topic of the recommendations (Evidence Levels IIa, IIb, or III)

C   Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities. Indicates an absence of directly applicable clinical studies of good quality (Evidence Level IV)

GPP   Good Practice Point: recommended best practice based on the clinical experience of the chapter authors and editors

PREFACE TO THE FIRST EDITION

This new international textbook in obstetrics will, we believe, be of major value to all practicing clinicians, be they trainees or established in practice.

It aims to assist with the questions: How do I manage this patient? or How do I perform this procedure?

It presents a wide range of reputable management options. Unlike many traditional texts, based on a single individual's experience and view, all the contributors to each section were asked to give their preferred management in all areas of their section. Each resulting chapter reflects that wide range of acceptable practice. This means you will have a *choice* about which option or combination of options suits you and your patient.

This book is designated to be practical. It addresses those difficult questions which arise in practice, which often stem not only from the medical facts, but from the constraints of time, facilities, finance, and patient acceptability. Moreover, we have standardized the presentation of each topic as far as possible (while still allowing the personality of the original authors to shine through!) to enable the reader to become familiar with the format.

We have deliberately chosen a panel of contributors who are both leaders in their field and who can represent practice in the USA, Europe, and Australasia and this we feel gives the text a unique universality.

Finally it is our intention that the book is comprehensive. We hope that we will have something to say on all the important problems you come across. If you find any exceptions, please let us know, with your comments, in time for the next edition.

PREFACE TO THE THIRD EDITION

Welcome to the third edition of *High Risk Pregnancy: Management Options*. We hope this edition will build on the success of the first two. In particular, we seek its continued growth in reputation as a true International Postgraduate Textbook. Although the majority of contributors come from the United States, the author list includes representatives from all over the world (UK, Ireland, Netherlands, France, Italy, Germany, Belgium, Israel, Iceland, South Africa, Hong Kong, Australia, and New Zealand).

We have made the following significant improvements to the third edition whilst maintaining the key characteristic features of previous editions:

- a major overhaul and revision of the book's appearance to further enhance readability
- a clearer presentation of the text while keeping to the original layout style of
  - "Introduction"
  - "Risks (Maternal and Fetal)"
  - "Management Options (Prepregnancy, Prenatal, Labor and Delivery, Postnatal)"
  - "Summary of Management Options" Box
- The Summary of Management Options Box includes evidence-based scoring for each management strategy proposed. It illustrates how strong the evidence is for your actions
- The majority of the 82 chapters are essentially new contributions designed to address changes in the field:

- The 14 new chapters are (Prepregnancy antecedents [1], Midpregnancy problems [6], Screening for fetal abnormality [7 and 8], Management of the abnormal screening test [9], Invasive procedures for prenatal diagnosis [10], Critical evaluation of prenatal fetal assessment methods [11], Intrauterine infection, preterm parturition, and the fetal inflammatory response syndrome [27], Pregnancy following transplantation [54], Psychiatric illness [56], Screening for prelabor membrane rupture and preterm labor [61], Shoulder dystocia [70], Perineal repair and pelvic floor injury [73], and Domestic violence [81]]
- 29 chapters were rewritten by new authors to bring a fresh view [4, 5, 12, 15, 16, 19, 28, 29, 30, 31, 33, 38, 39, 42, 43, 45, 46, 48, 50, 52, 58, 66, 68, 69, 75, 77, 78, 79, 80]
- The 39 remaining chapters were all extensively updated

As in prior editions, we have appreciated the comments of readers and reviewers and sought to respond to them wherever possible.

We hope you find the third edition of *High Risk Pregnancy: Management Options* an even more valuable but always practical reference manual for the management of problem pregnancies.

Pregnancy

Prepregnancy Antecedents of a High Risk Pregnancy

Hajo I.J. Wildschut

WHAT IS A HIGH RISK PREGNANCY?

Definition

In general, pregnancy should be considered a unique, physiologically normal episode in a woman's life. However, preexisting disease or unexpected illness of the mother or fetus can complicate the pregnancy. *Risk* is defined as the probability of an adverse outcome or a factor that increases this probability. A pregnancy is defined as *high risk* when the probability of an adverse outcome for the mother or child is increased over and above the baseline risk of that outcome among the general pregnant population (or reference population) by the presence of one or more ascertainable risk factors, or indicators. This classification does not take into consideration the magnitude of risk or the importance of the risk to the health outcome of the pregnant population at large.

The Concept of Risk

Risk is a reflection of the incidence of an adverse health outcome arising in a defined population during a given period. The magnitude of risk is usually expressed as a point estimate of probability (ranging from 0 to 1) or odds (ranging from 0 to $+\infty$ [infinity]) [Table 1–1].

Thus, for example, a risk of 20% of the occurrence of the target condition (e.g., incidence of a disease) equates to a probability (P) of 0.20 (1 of 5) or odds of 0.25 (the likelihood of one individual having an adverse outcome to four not having this outcome). Probability can be computed from odds by the following formula:

$$P \text{ (of the disease)} = \frac{\text{Odds (of the disease)}}{1 + \text{odds (of the disease)}}$$

Conversely, odds can be computed from probability by the following formula:

$$\text{Odds} = \frac{P}{1-P}$$

With lower values (<0.20), risk estimates based on probabilities approximate those based on odds (see Table 1–1).

The terms *relative risk* (or *risk ratio* [RR]) and *odds ratio* (OR) are alternative ways of expressing risk. RR is the likelihood of the target condition occurring in people exposed to a particular risk, compared with people who are not exposed.[1] It indicates how many more times likely exposed people are to have the target condition than nonexposed people. RRs are usually derived from prospective longitudinal studies. Case–control studies allow an estimate of risk as a result of exposure by assessing exposure among those who have been identified with the target condition and their controls. The OR is given by the ratio of the odds of exposure among those with the target condition (cases) and the odds of exposure among those without the target condition (controls). Thus, case–control studies measure the *prevalence*, not the *incidence*, of exposure among those with and without the outcome of interest. RR is not synonymous with OR, although for rare outcomes, these estimates approximate one another.[1] An RR or OR of 1 indicates no difference in the occurrence of the condition of interest between the two comparison groups (exposed and unexposed). An RR or OR of greater than 1 suggests that exposure is associated with increased risk of the target condition

TABLE 1–1	
The Relation between Probability and Odds	
PROBABILITY	**ODDS**
0.001	0.001
0.01	0.01
0.02	0.02
0.05	0.05
0.1	0.11
0.2	0.25
0.3	0.43
0.4	0.67
0.5	1
0.6	1.5
0.7	2.3
0.8	4
0.9	9
0.95	19
0.98	49
0.99	99
0.999	999

compared with nonexposure. Conversely, an RR or OR of less than 1 suggests that exposure is associated with decreased risk compared with nonexposure. In these contexts, however, the actual point estimation of risk should be considered together with the 95% confidence intervals. In epidemiology, a statistically significant difference between two groups can be shown only if the 95% confidence intervals do not include 1 (do not cross unity).

The importance of a specific risk factor for the incidence of the outcome of interest in a population is usually expressed as the *population-attributable risk* (i.e., the proportion of disease in a population that results from a specific risk to health). It also gives an indication of the proportion of incidence of disease that could be prevented by total elimination of that risk factor in the population (Fig. 1–1).[2]

Risk as a Proxy for Care

Focusing on risks to health is the key to preventing disease and injury. Over recent decades, the ability to predict and avert adverse reproductive health events has improved greatly. Women with high risk pregnancies can potentially benefit from increased care. The initial assessment of a woman's reproductive health risks may start well before pregnancy occurs (i.e., the preconception period). Ongoing assessment of a woman's health and that of her unborn child is the foundation of modern maternal and fetal care.

Preconception Health Care Model

Preconception care involves risk assessment, health promotion, and intervention.[3] Risk assessment includes questions about the woman's medical, obstetric, family, and genetic history; nutritional habits; drug use; environmental exposures; lifestyle; and social issues. Similar information is obtained about her partner.[4] The Appendix shows an example of a preconception questionnaire.

Primary care health professionals may be involved in providing preconception care, as may be obstetricians, midwives, nurses, clinical geneticists, and genetic counselors. The most common reasons for referral for preconception counseling include previous spontaneous abortion, chronic maternal disease, and previous fetal abnormality.[3,4]

Some women do not seek or receive preconception care. These include women with unplanned pregnancies and those without health insurance. Physicians are not always equipped to address the many time-intensive medical and social problems encountered in couples seeking preconception care.

Finally, few controlled trials show the effectiveness of preconception care (e.g., folic acid to prevent neural tube defects, normalization of blood glucose values in patients with diabetes). More research is needed in this area.

GENETIC AND CONSTITUTIONAL FACTORS

Genetic Factors

The enormous technologic progress in medical genetics in recent decades has enabled implementation of a novel form of prevention based on reproductive choice. The goal is to maximize the chances that individuals at increased risk for having affected offspring will have children free of the disorder. The prepregnancy management options for individuals who are at risk for genetic conditions are discussed in Chapter 2.

Ethnicity

Race and ethnicity are complex, controversial sociologic issues that are difficult to measure accurately. Race and ethnicity are often considered surrogate measures for standard of living and lifestyle.[5] However, both between and within ethnic populations, marked variations occur in cultural beliefs and practices, language, household structure, sexual behavior, contraceptive patterns, general health, perception of illness and disease, childbirth and child-rearing practices, postnatal customs, dietary habits, housing, education, employment, economic status, level of assimilation, stress, and access to health care services.[6–9] Some of these attributes have little to do with health or disease, whereas others may be important factors. In clinical research, the terms *race* and *ethnicity* are often defined inadequately, if at all. Therefore, epidemiologic associations with health problems should be interpreted cautiously. For example, for public health considerations, information about race or ethnicity could be relevant for the identification of specific health problems and medical needs.

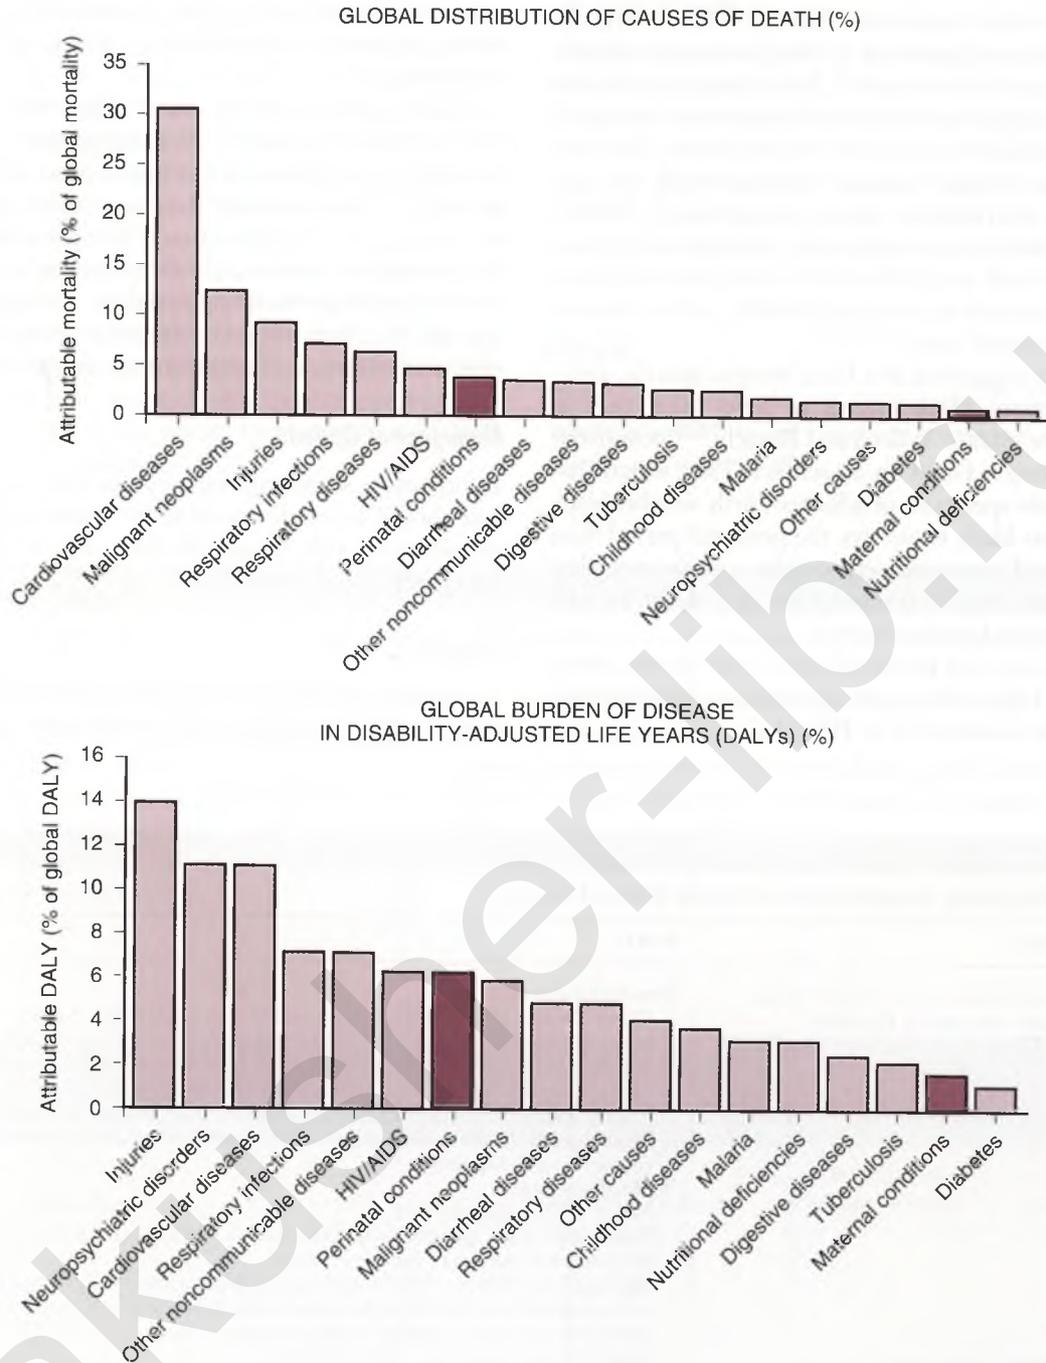
GLOBAL DISTRIBUTION OF CAUSES OF DEATH (%)


FIGURE 1–1
Attributable mortality (*A*) and burden of disease (*B*) as a result of leading global risk factors. The estimated relative mortality and disease burden are shown in terms of disability-adjusted life years (DALY) for each risk factor considered individually. These risks act in part through other risks as well as jointly with other risks. Consequently, the burden caused by groups of risk factors is usually less than the sum of individual risks. (Reproduced with permission.)

Risks

Ethnicity is one of the factors that is most strongly associated with low birth weight.[8–12] Low birth weight is closely related to infant mortality and childhood morbidity rates.[13] In the United States, preterm birth rather than growth restriction is implicated as the most important cause of low birth weight in black women.[12,14] Given

the high rates of preterm delivery, crude survival rates for black infants are less favorable than those for white infants.[12,15,16] The biologic explanation for the high preterm delivery rate among black women is unclear.

Apart from preterm delivery, newborns designated as white and black may show different patterns of intrauterine growth.[17,18] For example, at term, black infants are

on average smaller than white infants.[18,19] Moreover, the average duration of gestation in black women is slightly shorter than in white women.[18] It has been argued that birth weight distribution is an intrinsic genetic feature of ethnicity, just like the sex of the infant. Hence, for each ethnic group, different norms for gestational age and birth weight distributions should be applied.[20] Others, however, refute this assumption by claiming that ethnic disparities in birth weight distribution are most likely the result of disparities in maternal health, socioeconomic status, and prenatal care.[10,15,17,21]

It has been suggested that birth weight–specific mortality in preterm black infants is lower than that in preterm white infants. Wilcox and Russell[19,20] postulated that this finding is based on an artifact. They stated that over the whole spectrum of adjusted birth weight, black infants are less likely to survive the perinatal period than white infants. The excess birth weight–specific mortality in black infants may be compounded by a failure to seek or receive optimal medical care.[21]

Many diseases and problems that occur during pregnancy have both ethnic and geographic distributions. The risks are summarized in Table 1–2.

Female circumcision is still practiced in some parts of Africa, in particular the Horn of Africa, and may affect childbirth.[22]

Uterine fibroids occur more often in black women than in white women.[23] Nonengagement of the fetal head late in pregnancy is not uncommon in black primigravidae.[24] The available data on ethnic differences in the frequency of dysfunctional labor are inconclusive. Differences in duration of labor may be attributed to a wide range of confounding variables, including maternal age, stature, birth weight of the infant, poor communication, and unfavorable sociocultural circumstances.[23,25,26]

Management Options

Information, screening, and appropriate counseling services should be made available for communities that are considered at risk for specific diseases (see Table 1–2 and other relevant chapters).

PRENATAL

Communication is often a problem because of language barriers. Video displays and informative pamphlets or

---

TABLE 1–2

Risks in Pregnancy Associated with Certain Ethnic Groups

ETHNIC GROUP	RISKS

Mediterranean islands, parts of middle East, Southeast Asia, and parts of the Indian subcontinent	Beta-thalassemias:
	  Minor: Anemia in pregnancy, treated with oral iron and folate, but not parental iron
	  Major: Rare to survive to reproductive age, but those who do often have pelvic bony deformities and problems with labor and delivery; also iron overload with subsequent hepatic, endocrinologic, and myocardial damage
	  Major/minor: Possible risk of inheriting the disease, a requiring prenatal counseling and diagnosis
	Alpha-thalassemias:
	  Minor: Usually asymptomatic
	  Major: Rare, but a spectrum of presentation: in adults, usually manifests as a hemolytic anemia of variable severity
	  Major/minor: Possible risk of inheriting the disease, requiring prenatal counseling and diagnosis; homozygous alpha-thalassemias in the fetus can manifest as hydrops fetalis and associated severe preeclampsia in the mother

Afro-Caribbean, Mediterranean, Middle East, India	Sickling disorders (especially HbSS, HbSC):
	  Maternal: Infection, sickling crises, preeclampsia, renal compromise, jaundice; although HbSC tends to be a milder disease (Hb levels usually within normal limits), it can cause massive sickling crises if the diagnosis has not been made; HbAS (carrier state) mothers are rarely at risk for sickling crises with, for example, anoxia, dehydration, or acidosis
	  Fetus: Possible risk of inheriting the disease, requiring prenatal counseling and diagnosis; growth restriction is a risk with HbSS and HbSC

Mediterranean, American Blacks	Glucose-6-phosphate dehydrogenase deficiency:
	  Mother: Hemolytic anemia
	  Fetus: Risk of inheriting the disease, requiring prenatal counseling and diagnosis; fetal hydrops

Far East	Hepatitis B (chronic carriers): Risk of transmission to the fetus or neonate and health care workers
Africa, Caribbean, Hawaii	HIV infection: Risk to the mother of symptomatic infection; risk to the fetus and health care workers of acquiring the infection
Africa (especially Horn of Africa)	Female circumcision: Problems with vaginal delivery (dystocia, trauma, hemorrhage)
Developing countries	Varied effects of endemic infection on the mother or fetus

HbSC, hemoglobin SC; HbSS, hemoglobin SS.

brochures written in several languages should be made available.[27] Standard information should include guidelines for lifestyle and nutrition as well as preparation for parturition and parenthood, preferably in keeping with sociocultural features of the relevant ethnic communities.[27] The use of interpreters, either in person or by telephone, is advisable for dealing with specific problems.[27]

Once prenatal care has been initiated, women at risk for specific diseases, such as hemoglobinopathies, may be selected for further testing or treatment.[28,29] In parous women, it is important to obtain all necessary information about the course and outcome of previous pregnancies. Immunization status should be checked, and[30] fetal growth should be monitored.[8,10–12]

LABOR AND DELIVERY

The continuous presence of a supportive female companion during labor and delivery benefits maternal well-being by improving her emotional status, shortening labor, and decreasing the need for medical intervention.[31] Psychosocial support may also improve mother–infant bonding. It is unlikely that ethnicity in itself affects the duration of labor and delivery.

POSTNATAL

Breastfeeding should be encouraged.[32] Contraceptive advice should take into account individual sociocultural norms and values.[33,34]

CONCLUSIONS

- Large variations occur in health care coverage and reproductive outcome among different racial and ethnic groups.[5]
- The reasons for differences in pregnancy outcome between ethnic groups are not clear, although social environment, age, parity, and genetic and constitutional factors may play a role.[34]
- Several diseases show clear ethnic differences among pregnant women. These include genetic defects, such as the hereditary hemoglobinopathies; medical disorders, such as chronic hypertension; and specific conditions acquired in endemic areas, such as malaria, AIDS, and tuberculosis.[28,29]
- Each disease or condition requires a separate approach in pregnant women (see Table 1–2 and the Summary of Management Options).

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy in Women from Different Ethnic Backgrounds

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Provide education, screening, and counseling for communities at specific risk.	III	B	28
Prenatal			
Overcome language and cultural barriers.	IV	C	27
Offer screening and counseling where specific risk exists.	III	B	29
Offer prenatal diagnosis if appropriate.	III	B	28
Provide maternal and fetal surveillance for any specific risk.	IIa	B	8,10–12
Labor and Delivery			
Offer the continuous presence of a supportive companion during labor and delivery.	Ia	A	31
Postnatal			
Encourage breast-feeding.	IV	C	32
Offer contraceptive advice, taking account of individual sociocultural norms and values.	III	B	33,34

ENVIRONMENTAL FACTORS

Prescribed Drugs

The risks and management options for women who take prescribed drugs before pregnancy are discussed in Chapter 35.

Drug Abuse, Cigarette Smoking, and Alcohol

The risks and management options for women who abuse drugs, cigarettes, and alcohol before pregnancy are discussed in Chapter 34.

Vaccines

The risks and management options for individuals who receive vaccines are discussed later in this chapter (see "Air Travel during Pregnancy").

Ionizing Radiation (See also Chapter 53)

Definition

Ionizing radiation is any radiation capable of displacing electrons from atoms or molecules, thereby producing ions. Examples are α-, β-, γ-, and x-rays. Sources of radiation are given in Figure 1–2.[35]

Risks

Two categories of biologic effects of ionizing radiation are described, deterministic and stochastic.[36,37] Deterministic effects pertain to a decrease in or loss of organ function as a result of cell damage or cell killing (apoptosis).[37] Loss of organ function could lead to fetal malformation, mental retardation, or death. For these effects to occur, threshold doses exist. Fetal exposures of less than 100 mGy (historically termed "10 rad") do not increase the incidence of fetal malformation at birth. Doses of more than 100 mGy should be evaluated in the context of the type of radiation and the time of exposure relative to fetal development and may be associated with impaired cognitive development (IQ).[36] The risks of fetal growth restriction and major structural malformation seem small.[36] The 1986 nuclear reactor accident at Chernobyl did not result in a detectable change in the prevalence of major congenital anomalies in neighboring European countries, despite exposure to relatively high radiation doses (200–700 mSv) in the first year after the disaster.[38] Radiation doses greater than 500 mGy result in a significant risk of central nervous system damage, with severe mental retardation, especially when the fetus is exposed 8 to 15 weeks after conception.

Stochastic effects are those that result from radiation changes in cells that retain their ability to divide.[36,37] These modified cells sometimes initiate malignant transformation of a cell that eventually leads to clinically overt cancer. The period between initiation and manifestation of the disease may extend from a few years (e.g., leukemia) to several decades (e.g., colon and liver cancer). In addition, genetic effects may be initiated as a result of irradiation of germ cells. For stochastic effects, no threshold doses are assumed. The probability of their occurrence is believed to be proportional to the dose. Therefore, the probability of tumor induction should be reduced by keeping the dose as low as possible. The estimated mortality risk from radiation-induced cancer in childhood (0–15 years) is 0.06% per 10 mGy.[39]

Because of the low level of radiation exposure, prenatal exposure to ionizing radiation from diagnostic procedures is not associated with an increased risk of adverse pregnancy outcome in terms of perinatal death, congenital abnormalities, or mental retardation (see Table 1–3).[40]

The stochastic effects of radiodiagnostic examinations are typically very limited. For this reason, termination of pregnancy is not warranted when the mother is exposed to diagnostic procedures involving ionizing radiation.[40] Special attention should be given to nuclear examination

Pelvis	25	79
Nuclear Medicine		
^{99m}Tc bone scan	3.3	4.6
^{99m}Tc lung perfusion	0.2	0.4
^{99m}Tc kidney scan	1.5	4.0
^{99m}Tc thyroid scan	0.7	1.6
^{99m}Tc brain scan	4.3	6.5

*The estimated exposure to background radiation in the general population is on average 2 millisieverts (mSv) per year. The sievert is the unit for equivalent dose, which is the average absorbed dose in an organ or tissue multiplied by a radiation weighting factor. The unit for absorbed dose is the gray (Gy) [100 rad]. For almost all radiation used in medicine, the radiation weighting factor equals unity, making Sv and Gy numerically equal. ^{99m}Tc, radiopharmaceutical labeled technetium-99m.
(From www.europa.eu.int/comm/environment/radprot)

with radiopharmaceuticals and radionuclides. In nuclear medicine, unlike x-ray procedures, the woman may be a source of radiation for some time after the examination. For this reason, in certain circumstances, the woman should be advised to avoid pregnancy for an appropriate period after radionuclide administration.[41] Prenatal radiation exposure should be recorded to facilitate estimation of the fetal dose.

In a therapeutic setting, however, high doses of radiation during pregnancy (>100–200 mGy) are associated with an increased risk of impaired cognitive development (IQ).[36] The fetus is particularly vulnerable to the stochastic effects of high doses of ionizing radiation when exposed 8 to 15 weeks after conception. During this period, exposure to ionizing radiation at a dose of 1000 mGy (1 Gy) is associated with a 30-point decrease in IQ.[40]

In young women who have been exposed to radiation therapy below the diaphragm, reproductive problems include the risk of ovarian failure and significantly impaired development of the uterus. The magnitude of risk is related to the radiation field, total dose, and fractionation schedule.[42] Irradiation of either parental gonad in the preconception period is not associated with an increased risk of genetic defects, congenital malformations, or childhood or adulthood cancer.[43]

Management Options

RADIODIAGNOSTIC EXAMINATIONS

- Every woman of childbearing potential who is undergoing a radiodiagnostic examination should be explicitly asked, orally or in writing, whether she might be pregnant or have missed a period. If there is any uncertainty about pregnancy, the planned examination should be postponed or the woman should be treated as if she were pregnant.[36,40]
- There is no need to apply the 10-day rule (i.e., exposure during the first 10 days after the onset of the last menstrual period), unless the radiodiagnostic examination involves radionuclides or radiopharmaceuticals.[40]
- If the woman is pregnant, special attention should be given to the justification and urgency of the radiodiagnostic examination.[36,41,44]
- In pregnant women, alternative diagnostic methods, such as ultrasound or magnetic resonance imaging (MRI), should be considered.[36,40]
- Reduction of the radiation dose to the fetus may be achieved by lead-shielding the abdomen, where

feasible.[36,40] Moreover, reduction of radiation to the fetus can be achieved by adapting radiodiagnostic techniques and taking fewer images.[36,40,44]

- Every woman who is undergoing a nuclear medicine examination should be asked, orally or in writing, whether she is breastfeeding.[40]
- When a pregnant woman is undergoing a nuclear medicine examination, the dose of radionuclide is kept as low as possible without sacrificing radiographic information. The commonly administered radiopharmaceuticals used for lung, gallbladder, kidney, bone, and bleeding scans are labeled with technetium-99m. All deliver whole fetal doses of less than 5 mGy (see Table 1–3).[44]

RADIATION THERAPY

- The presence of pregnancy should be evaluated when radiation therapy is considered in women of reproductive age.[40]
- Appropriate lead shields should be used to protect the gonads of patients undergoing radiation therapy.[36,40]
- If the patient is pregnant, she must be involved in the discussion and decision about radiation therapy.[40]
- Termination of pregnancy should be considered if the radiation dose would lead to severe deterministic effects or a high probability of stochastic effects.[40]
- Patients who have had radiation therapy should not be discouraged from having children.[40]

Radiodiagnostic Examinations

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Postpone planned examination if pregnancy is unconfirmed.	IV	C	40
Prenatal			
If the patient is pregnant, explain the justification for and urgency of radiodiagnostic examination.	III	B	36,41
In a pregnant patient, keep the dose of radionuclide as low as possible without compromising the radiographic examination.	IV	C	40,44
Postnatal			
Ask every woman of reproductive age who is scheduled for nuclear medicine examination whether she is breastfeeding.	IV	C	40

Magnetic Resonance Imaging

Risks

MRI is a powerful imaging tool that does not expose patients to ionizing radiation. MRI requires powerful magnetic fields and a radiofrequency pulse to produce a diagnostic image. Under most circumstances, these fields do not appear to pose a health or safety risk.[45] Although generally considered safe, MRI has some maternal safety issues, including the effects of high magnetic fields on metallic biomedical implants or other metallic foreign bodies.[46] Foreign metallic materials embedded within patients can have ferromagnetic properties that present a potential hazard in the strong fields associated with MRI, precluding MRI examination in these patients. Other hazards of MRI include the potential side effects of contrast agents, anxiety, claustrophobia, and temporary hearing loss as a result of acoustic noise generated by MRI.

Postpone a planned examination if pregnancy is unconfirmed.	IV	C	47

SUMMARY OF MANAGEMENT OPTIONS
Magnetic Resonance Imaging *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Evaluate each patient with a written questionnaire followed by oral questioning before imaging to identify those with ferromagnetic foreign bodies or implants anywhere in the body that are electrically, magnetically, or mechanically activated.	IV	C	46
Maintain a high state of vigilance to prevent iatrogenic burns and injuries from ferromagnetic missiles.	IV	C	46
Prenatal			
Magnetic resonance imaging (MRI) is not recommended during the first trimester.	IV	C	48
The use of contrast material for MRI is not recommended in pregnancy.	IV	C	48
Ultrasonography is the initial imaging modality of choice for the evaluation of obstetric patients. In limited cases, however, when the results of ultrasonography are indistinct, MRI may be a clinically useful adjuvant for diagnostic evaluation. Indications for the complementary use of diagnostic MRI in pregnancy include the evaluation of adnexal masses, hydroureteronephrosis, placenta accreta, and fetal abnormalities, in particular those involving the central nervous system.	III	B	47–50

Ultrasound

Risks

Ultrasound has become a widely accepted and valuable diagnostic tool in standard clinical practice. Most ultrasound machines in obstetrics use phased-array real-time technology with a brightness-mode (B-mode) display. Although the potential biophysical effects of ultrasound, such as tissue warming and cavitation, are well established, diagnostic ultrasound in medicine is considered safe.[51,52] As to diagnostic ultrasound in pregnancy, there have been no reports of potential harmful effects in the offspring, other than a few studies showing a statistically significant association of ultrasound and left-handedness in male offspring.[53,54] It is unlikely that this association is the result of brain damage because there is no association between ultrasound exposure in pregnancy and other indicators of brain damage (i.e., impaired motor or speech development, impaired school performance, visual disturbances, or hearing loss).[55] In recent years, there has been a trend to use new diagnostic ultrasound techniques, such as color flow imaging, power Doppler, and pulsed Doppler. These techniques require higher acoustic exposures than those used in B- and M-modes, with pulsed Doppler associated with the highest levels. In pulsed Doppler ultrasound, the beam is focused onto a small volume and kept stationary so that the same tissues are insonated throughout the examination, thereby maximizing the heating effects. Data from animal studies show that pulsed Doppler ultrasound can produce significant thermal effects, particularly near bone.[52] To ensure the continued safe use of diagnostic ultrasound in medicine, modern obstetric ultrasound machines are subject to output regulation only in the United States.[56,57] Ultrasound machines with on-screen displays of "thermal index" and "mechanical index" encourage the ultrasonographer to protect the fetus or embryo from potential harmful levels of acoustic exposure. The thermal and mechanical output indicators, however, do not take account extraneous factors, such as dwell time, examination time, and patient temperature. Hence, thermal index and mechanical index are not perfect indicators of the risks of bioeffects to the fetus, but should be accepted as the most practical and understandable methods of estimating the potential for such risks.[51]

Management Options

For the safe use of diagnostic ultrasound in medicine, the following international recommendations and guidelines are advocated.[52–58]

B- AND M-MODES

Based on scientific evidence of ultrasonically induced biologic effects, there is no reason to withhold B- or M-mode scanning for any clinical application, including the routine clinical scanning of every woman during pregnancy.

DOPPLER FOR FETAL HEART MONITORING

Because low power levels are used for fetal heart rate monitoring (cardiotocograph, CTG), the use of this modality, even for extended periods, is not contraindicated on safety grounds.

DOPPLER MODES (COLOR FLOW IMAGING, POWER DOPPLER, AND PULSED DOPPLER)

Exposures used for Doppler modes are higher than those used for B- and M-modes. There is considerable overlap in the ranges of exposure that may be used for color flow imaging, power Doppler, and pulsed Doppler techniques. The clinical user should be aware that pulsed Doppler at maximum machine outputs and color flow imaging with small color boxes have the greatest potential for biologic effects.

USE OF DOPPLER STUDIES IN THE FIRST TRIMESTER

The embryonic period is particularly sensitive to external influences. Until further data are available, studies using pulsed or color Doppler ultrasound should be carried out with careful control of output levels and exposure times. With increasing mineralization of the fetal bone as the fetus develops, the possibility of heating fetal bone increases. The user should prudently limit exposure of critical structures, such as the fetal skull and spine, during Doppler studies.[52–59]

In general, the informed use of Doppler ultrasound is not contraindicated. However, at the maximum machine output settings, significant thermal effects at bone surfaces cannot be excluded. The user is advised to use the exposure information provided by the manufacturer (e.g., displayed safety indices) to determine the highest output conditions and to act prudently to limit exposure of critical structures, including bone, and regions, including gas. If an online display is not available, care should be taken to minimize exposure times.[52–59]

Caution should be exercised in febrile patients. Doppler ultrasound might present an additional embryonic and fetal risk.

Care should be taken to use the minimum output that will obtain the required diagnostic information and to minimize the duration of pulsed Doppler examinations in pregnancy.[57]

TRANSVAGINAL ULTRASONOGRAPHY

In the absence of long-term, large-scale, follow-up studies after first-trimester transvaginal ultrasound exposure, care is required in the application of transvaginal ultrasonography in early pregnancy. It should be performed only for valid medical reasons that benefit the mother or the embryo.[58]

NONMEDICAL USE IN PREGNANCY

The use of two-dimensional or three-dimensional ultrasound only to view the fetus, obtain a picture, or determine fetal sex, without a medical indication, is inappropriate and contrary to responsible medical practice. Although there are no confirmed biologic effects on patients caused by exposures from current diagnostic ultrasound instruments, such biologic effects may be identified in the future. Thus, ultrasound should be used prudently to provide medical benefit to the patient.[59]

NEW DEVELOPMENTS

Echo-contrast agents can be useful in diagnostic ultrasound, may decrease the threshold for cavitation. As a consequence, the use of echo-contrast agents may change the risk-to-benefit ratio substantially in various clinical applications. Given the increased use of ultrasound, the introduction of new techniques, and a broadening of the medical indications for ultrasound examinations, continuous vigilance is essential to ensure its continued safe use.[58]

Video Display Terminals

Several studies show that exposure to the magnetic fields emitted by video display terminals does not constitute an appreciable risk to the reproductive health of women or a risk to their children.[60,61]

Environmental Health Hazards

From the public health point of view, environmental health hazards can be categorized into five distinct groups: chemical, physical, biologic, mechanical, and psychosocial. Their effects on pregnancy are discussed in other chapters (e.g., infection, prescribed drugs, drugs of abuse).

It is difficult to ascertain the clinical importance of each of these environmental influences on reproductive health. The adverse effect on pregnancy outcome is dependent on the prevalence of exposure and the dose and timing during pregnancy. Information of this kind is often lacking. Furthermore, confounding factors and the interaction of more than one factor hamper the interpretation of potentially adverse effects of a particular environmental agent on reproductive health. For example, increased genetic susceptibility of the individual and the use of medication could mediate the adverse effects of these agents. Moreover, the assessment of a cause-and-effect relationship is hampered because of a considerable time gap between exposure to the environmental risk factor and outcome in terms of disease, disability, or death.

Chemicals

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) have been produced commercially since the late 1920s. They have been used in pesticides, surface coatings, inks, adhesives, flame retardants, and paints.[62] Because PCBs resist both acids and alkali and are relatively heat-stable, they have been used in dielectric fluids in transformers and capacitors. Further environmental contamination may occur from disposal of old electrical equipment containing PCBs. Many countries have severely restricted or banned the production of PCBs.

Highly chlorinated PCB congeners are generally persistent in the environment. The general population is exposed to PCBs in the air, drinking water, and food, particularly meat, fish, and poultry. They are rapidly absorbed from the intestinal tract and distribute to and accumulate in the liver. They also cross the placenta and are excreted in breast milk. Detectable concentrations of PCBs have been found in amniotic fluid, placenta, and fetal tissue samples. Breast-fed infants can have blood levels greater than those of their mothers. Formula is free of PCBs. Much concern exists that PCBs transferred to the fetus across the placenta may induce long-lasting neurologic damage. Recent data from a Dutch cohort study among 418 infants showed that prenatal exposure to PCBs has subtle negative effects on the neurologic and cognitive development of the child up to 6 years of age. Half of the infants were fully breast-fed for at least 6 weeks. Despite higher PCB exposures from breast milk, breast-feeding had a beneficial effect on cognitive development in this cohort of infants.[63] Hence, the beneficial effects of breast-feeding outweigh the potentially adverse effects of PCB exposure from breast milk. Epidemiologic studies suggest that exposure to PCBs is associated with an increased risk of cancers of the digestive system, notably the liver, and malignant melanoma.[62] However, in many studies, the limitation of exposure data, the inconsistency of results,

and the presence of confounding factors preclude the identification of a true causal relationship.

Dioxins

Dioxins are a heterogeneous mixture of chlorinated dibenzo-*p*-dioxin and dibenzofuran congeners. The main sources of dioxins are emissions of industrial and municipal incineration processes. Dioxins accumulate in the food chain, and human exposure occurs mainly through contaminated food.[64] Few data are available on the effects of dioxins on female reproductive health. In animal models, dioxin has an antiestrogenic effect. Environmental chemicals have been implicated in the temporal decline in the age of onset of puberty, the development of polycystic ovarian syndrome, and shortened lactation. The prevalence of male reproductive disorders, such as cryptorchisms and hypospadias, need more careful study, particularly because they are linked to testicular cancer and show temporal changes in many countries. The effects of environmental chemicals on sperm quality are inconsistent. Because of methodologic shortcomings in epidemiologic studies, it is unknown whether dioxins affect spontaneous abortion rates or fetal growth restriction.

Pesticides

Pesticides, including fungicides, herbicides, insecticides, and rodenticides, are a reproductive health concern in many countries. They are often found in commercially available food products. However, the almost universal exposure to low concentrations of these compounds makes it very difficult to determine the effect of pesticides on the incidence of fetal abnormalities. Occupational exposure to pesticides has been implicated in increased birth defects rates.[65,66] Birth defects, however, are mostly multifactorial, meaning that other risk factors may also play an important role.

SOCIOECONOMIC STATUS

The importance of maternal social factors on the health and well-being of the offspring has been recognized for a long time. For example, infant mortality is closely associated with social inequality. Large differences in social conditions still exist. Caution should be exercised in interpreting studies of the effect of social conditions on pregnancy outcome. These include variations in definitions and practices associated with time and geographic area, availability of reliable data, and interpretation of the findings.[67–69]

The concept of *social index* is not simple. Various measures of social status are used, some of which tend to be crude and meaningless. In England and Wales, for example, the maternal social class index is traditionally derived from the Registrar General's Classification, which is based on the occupation of the father of the child (Table 1–4).

TABLE 1–4

Social Class by Occupation of the Father

CATEGORY	OCCUPATION
I	Higher professionals
II	Other professionals, including those in managerial positions
IIIa	Skilled workers, nonmanual
IIIb	Skilled workers, manual
IV	Semiskilled workers
V	Unskilled workers

Although there is a strong association between social class, thus defined, and infant mortality, this observation does not explain why some infants die and others do not. Other methods of categorization of socioeconomic status include those based on ranking of educational attainment, income, type of health care coverage, employment profile, legitimacy, family affluence, and household characteristics.[69] Accurate information of this kind is usually not readily available.

Social risk factors, however defined, are descriptive rather than explanatory. Social disadvantage in itself is unlikely to have a direct causal effect on the outcome of pregnancy.[70] Socioeconomic status should be considered merely a risk indicator, identifying high risk groups within the population.[71] Social adversity probably represents a wide range of behavioral, environmental, medical, and psychological factors that are causally related to pregnancy outcome, some of which are more amenable to intervention than others.[10,72–74] In this context, it is assumed that women of higher socioeconomic status have better financial, educational, and medical resources than women of lower socioeconomic status. Many social risk factors are interrelated. In the absence of logically structured multivariate analyses, the independence of their effects cannot be established.[17] In scientific research, correlations with socioeconomic status should be the impetus for further investigation, rather than the endpoint of an analysis.[75]

Risks

Lower socioeconomic status is associated with an increased risk of various adverse pregnancy outcomes, including perinatal mortality, preterm birth, and low birth weight. Smoking has been suggested as the key factor underlying socioeconomic differences in low birth weight and infant mortality.[69,76–78] Differences in care along the social strata may also account for some of the extra risks. The contribution of poor nutrition is discussed in the next section.

Management Options

Prenatal

Socially disadvantaged women are less likely to seek prenatal care and also have more pregnancy complications.

Some claim that apart from recognizing the increased risk associated with socioeconomic disadvantage, there is little to do in terms of prevention. Social support, however, benefits women psychologically, although the effect of social intervention on mean birth weight, low birth weight, and preterm delivery is limited.[31] From a public health point of view, the greatest reduction in adverse pregnancy outcome may be anticipated from prenatal services directed at socially disadvantaged women.[79,80] In this respect, widespread health education and serious antismoking measures are needed.[81]

Labor and Delivery

Intrapartum management need not be substantially modified if no other risk factors are present.

Postnatal

Women of higher socioeconomic status tend to breast-feed more often and longer than women of lower socio-economic status. Breastfeeding should be encouraged and social support provided, when indicated.[82] Contraception must be discussed when needed.[34]

CONCLUSIONS

- The maternal environment has a pronounced effect on birth weight and pregnancy outcome.
- Knowledge of a pregnant woman's socioeconomic status does not provide direct information about the circumstances in which she lives. Differences in socioeconomic status may reflect differences in material conditions in life and differences in behavior (e.g., smoking habits). Caution must be exercised in the extrapolation of associations between socioeconomic status, however defined, and pregnancy outcome, because the mechanisms underlying these associations are often unclear.
- Clinically, it is difficult to alleviate the effects of social deprivation. Social support may improve the patient's emotional well-being, but there is no evidence that it has any effect on any other outcome variable.[31]

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy in Women of Low Socioeconomic Background

	Provide specific and directed social support.	Ib	A	80
	Discuss contraception.	III	B	34

NUTRITIONAL FACTORS

Risks

General

Nutritional conditions during key periods in early pregnancy are believed to be of major importance in determining health in later life.[83,84] The long-term effects on adult health, such as type 2 diabetes, hypertension, and coronary heart disease, are considered consequences of fetal programming. This describes the phenomenon whereby a stimulus or an injury at a critical period in early fetal life can produce lasting changes in physiology and metabolism.[83,85] The central concept is that despite current levels of nutrition in western countries, intrauterine nutrition is suboptimal because the nutrients available are unbalanced or their delivery is constrained by changes in the structure and function of the placenta.[83] Evidence suggests that after an intrauterine lesion, regulatory mechanisms may maintain homeostasis for many years, until further damage, caused by age, obesity, or other effects, initiates a self-perpetuating cycle of progressive functional loss.[83] Follow-up studies of the war-induced Dutch famine of 1944–1945 showed a relative increase in placental weight in infants whose mothers' nutrition was compromised around conception or in the first trimester of pregnancy.[86] The increase in the placenta weight-to-birth weight ratio is interpreted as a compensatory mechanism after reduced caloric intake in early pregnancy.[87,88] An increased ratio is also seen with maternal anemia, tobacco use in pregnancy, and births at high altitude.[87] Fetal cardiovascular adaptations are a recognized feature of intrauterine growth restriction and divert nutrient-rich, highly oxygenated blood to spare the growth of the brain and other critical organs. Furthermore, reduced availability of micronutrients may affect fetal body composition. The relative amounts of fetal bone and lean and fat mass influence the risk of adult obesity and type 2 diabetes.[83] Placental size also has an important effect on fetal endocrinology and metabolism, with lasting effects on health in later life. When undernutrition during early development is followed by improved nutrition, many animals and plants have accelerated, or compensatory, growth.[83] Compensatory growth has costs, however; in animals, these risks may include reduced life span.[84] It has been reported in humans that undernutrition and small size at birth followed by rapid childhood growth may lead to cardiovascular disease and type 2 diabetes in later life.[83]

Caffeine

Caffeine has been a controversial topic in pregnancy nutrition for more than a decade. A 1980 study by the U.S. Food and Drug Administration (FDA) found that caffeine, when fed to pregnant rats, caused birth defects and delayed skeletal development in their offspring. At that time, although the human implications were unknown, the FDA advised pregnant women to eliminate caffeine from their diets.[89] Subsequent epidemiologic studies showed inconsistent results. Some studies found significant effects of caffeine on pregnancy outcomes, whereas others did not. Risks associated with maternal caffeine consumption during pregnancy and perinatal outcomes have proved difficult to estimate. Caffeine consumption is difficult to measure, and substantial misclassification occurs when consumption does not account for the actual cup size used. Moreover, cigarette smoking may confound the association of caffeine consumption with pregnancy outcomes.[89]

Vitamins

The current reference daily intakes (RDI) for vitamins are summarized in Table 1–5.[90] Pregnancy may increase vitamin requirements. Mechanisms underlying vitamin deficiency include inadequate dietary intake and abnormal metabolism.

FOLATE

Most evidence of the relation between maternal nutritional status and pregnancy outcome is derived from studies of the association between folate and neural tube defects. Folate is a water-soluble vitamin and is found mainly in polyglutamated form. Folic acid (folacin) is the synthetic form present as a monoglutamate in vitamin tablets and fortified foods. Folate is important for the biosynthesis of DNA and RNA. It also plays an important role in the conversion of homocysteine to methionine, an essential amino acid. An adequate level of folate should be established before conception and maintained during the first trimester to reduce the risk of neural tube defects. Fruits, green vegetables, beans, nuts, and bread are the primary sources of folate. Cooking may destroy some forms of dietary folate. The RDI is 400 µg/L.[90] In pregnancy, folate requirements are usually increased.

TABLE 1–5	
Current Reference Daily Intakes for Vitamins	
VITAMIN	**DAILY VALUE**
Vitamin A	1500 µg (5000 IU)
Vitamin C	60 mg
Vitamin D	10 µ (400 IU)
Vitamin E	20 mg (30 IU)
Vitamin K	80 µg
Vitamin B_6	2 mg
Vitamin B_{12}	6 µg
Folate	400 µg
Thiamin	1.5 mg
Riboflavin	1.7 mg
Niacin	20 mg

(From Fairfield KM, Fletcher RH: Vitamins for chronic disease prevention in adults: Scientific review. JAMA 2002;287:3116–3126.)

A low folate plasma concentration could be caused by inadequate dietary intake or the use of anticonvulsant drugs, such as phenytoin, phenobarbital, and carbamazepine, which are known folate antagonists. Moreover, folate deficiency could be the result of inherited metabolic disorders, associated, for instance, with methylenetetrahydrofolate reductase (MTHFR) gene polymorphism. MTHFR is a key enzyme in homocysteine metabolism.[91] The homocysteine plasma concentration is considered a sensitive biomarker of the levels of folate and vitamins B_6 and B_{12}. In pregnancies complicated by a fetal neural tube defect, maternal plasma homocysteine levels are elevated and plasma folate concentration is decreased, suggesting a defect in the folate-dependent homocysteine metabolism. Hyperhomocystinemia is also associated with various conditions characterized by placental vasculopathy, such as preeclampsia and abruption, and with recurrent pregnancy loss.[92]

OTHER VITAMINS

Vitamin A is the family of fat-soluble compounds called *retinoids* that have vitamin A activity.[90] The current RDI is 1500 µg/L (5000 IU).[90] Isotretinoin, a derivative of vitamin A, is a powerful prescription drug for the treatment of severe recalcitrant nodular acne. High doses of vitamin A can cause birth defects (e.g., heart defects, craniofacial anomalies), beginning at doses of only three times the daily allowance. Since its approval, isotretinoin has been labeled as pregnancy category X, meaning that it should not be used during pregnancy. Another derivative of vitamin A, etretinate, is a prescription drug for the treatment of psoriasis. This drug is also contraindicated in pregnant women and those who are likely to become pregnant while taking it. In adults, vitamin A toxicity results in hepatotoxicity and visual changes.[90] Xerophthalmia, night blindness, and increased susceptibility to disease characterize vitamin A deficiency.

Vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine) is water-soluble and is found in various plant and animal products. The current RDI for vitamin B_6 is 2 mg.[90] Vitamin B_6 is involved in many enzymatic reactions. Deficiency is uncommon.

Vitamin B_{12} (cyanocobalamin) is water-soluble and found in animal products only. The current RDI for vitamin B_{12} is 6 µg.[90] Cyanocobalamin has no known physiologic role, but must be converted to a biologically active form (i.e., methylcobalamin of adenosylcobalamin). Methylcobalamin is an essential cofactor in the conversion of homocysteine to methionine.[91] When this reaction is impaired, hyperhomocysteinemia occurs and folate metabolism is deranged. The cobalamins are involved in fat and carbohydrate metabolism, protein synthesis, and hematopoiesis. Deficiency can result from poor intake, including strict veganism, malabsorption from the absence of intrinsic factor, and rare enzyme deficiencies. Vitamin B_{12} deficiency results in macrocytic anemia and neurologic abnormalities. There are no consistent adverse effects of high intake.[90]

Vitamin C (ascorbic acid) is water-soluble and acts as a cofactor in hydroxylation reactions, which are required for collagen synthesis. It is also a strong antioxidant. The current RDI for vitamin C is 60 mg.[90] Vitamin C deficiency leads to bruising and easy bleeding (scurvy). Large doses (≤ 2000 mg) of vitamin C are generally well tolerated.

Vitamin D (calciferol) is not a true vitamin because humans can synthesize it with adequate sunlight exposure. The current RDI for vitamin D (1,25-dihydroxyvitamin D_3) is 0.01 mg (400 IU).[90] Vitamin D deficiency is associated with rickets in children. In adults, vitamin D deficiency leads to secondary hyperparathyroidism, with subsequent bone loss and increased fracture risk. There is evidence that genetic polymorphisms strongly affect fracture risk.[90] Inadequate vitamin D intake is more common than previously believed, particularly among housebound women of specific ethnic minority groups.[90] There is no documented evidence of vitamin D deficiency and adverse pregnancy outcome, apart from neonatal hypocalcemia. Given the relatively high prevalence of vitamin D deficiency in certain communities, vitamin D supplementation at a dosage of 0.01 mg (400 IU) is advocated. High intake of vitamin D (>0.05 mg or 2000 IU) results in hypercalcemia and soft tissue calcification.[90]

Vitamin E is a family of eight related compounds, the tocopherols and the tocotrienols. With the possible exception of hemolytic anemia and retinopathy in preterm infants, vitamin E deficiency as a result of dietary limitations has not been seen in humans. However, genetic deficiencies in apolipoprotein B or α-tocopherol transfer protein lead to severe vitamin E deficiency syndromes, with symptoms including hemolytic anemia, muscle weakness, and brain dysfunction.[90] The current RDI for vitamin E is 20 mg (30 IU).[90] With doses of 800 to 1200 mg/day, antiplatelet effects and bleeding may occur.[90] Because of its antioxidative properties, vitamin E is believed to prevent diseases associated with oxidative stress, such as cardiovascular diseases, cancer, chronic inflammation, and neurologic disorders. It is assumed, but not proven, that vitamin E requirements increase during pregnancy. Supplementation with vitamins C and E may help to prevent preeclampsia in women at risk for the disease. There is, however, insufficient evidence to recommend this strategy (see also Chapter 36).[93]

Vitamin K is fat-soluble and essential for normal clotting, especially for the production of prothrombin and factors VII, IX, and X, and protein C and S. Vitamin K has two subtypes, vitamin K_1 and K_2. Vitamin K_1, or phylloquinone, is found in most vegetables and dairy products. Vitamin K_2, or menaquinone, is synthesized by the intestinal flora and absorbed only in small amounts.[94] The current RDI for vitamin K is 80 µ/L.[90] Vitamin K

deficiency occurs when dietary intake is inadequate or intestinal bacteria, which synthesize vitamin K, are altered. Newborn infants are at risk for vitamin K deficiency because of poor placental transfer, lack of intestinal bacteria, and low content in breast milk.[94] The risk of vitamin K deficiency is higher in the breast-fed infant because breast milk contains lower amounts of vitamin K than modern formula or cow's milk.[94] A single dose of either oral or intramuscular vitamin K, 1 mg, to all infants is advocated to prevent hemorrhagic disease of the newborn in the first week after birth.[94] Women using antiepileptic drugs, including phenytoin, carbamazepine, and phenobarbital, are particularly at risk for vitamin K deficiency in their offspring. They are advised to use an oral dose of vitamin K, 10 mg daily, from the 36th week of gestation to prevent neonatal hemorrhagic disease.[95]

IODINE AND ZINC

Trace minerals, such as iodine, are needed in greater quantities during pregnancy. Deficiencies of trace minerals, such as iodine and zinc, are also implicated in low birth weight, perinatal mortality, mental retardation, childhood hearing and speech disorders, and birth defects.[96]

IRON

In Europe, iron deficiency is an important nutritional disorder, affecting large fractions of the population, particularly children, menstruating women, and pregnant women. Factors that affect iron deficiency include the type of contraception in women, blood donation, and minor pathologic blood loss (e.g., hemorrhoids, gynecologic bleeding). Moreover, women, especially vegetarians, vegans, and patients with malabsorption, are at increased risk for iron deficiency. A reduction in body iron is associated with a decrease in the level of functional compounds, such as hemoglobin (see also Chapter 39).

Management Options

General

From a recent overview of randomized controlled trials, no firm conclusions could be drawn about the implications of nutritional advice to prevent or treat impaired fetal growth.[88] Most physicians agree that RDIs, except those for iron and folic acid, can be obtained through a proper diet. Pregnant teenagers, smokers, drug users, alcohol drinkers, and strict vegetarians tend to be deficient in various vitamins.[97–99] Multivitamin supplements can be of value.

To reduce the incidence of neural tube defects, most countries advocate folic acid supplementation in a dosage of 0.4 mg/day to all women from at least 4 weeks before until 8 weeks after conception.[89]

Large quantities of caffeine consumption (>600 mg daily) should be avoided. Caffeine is associated with reductions in birth weight equivalent to those associated with smoking 1 to 10 cigarettes.[89]

SUMMARY OF MANAGEMENT OPTIONS

Nutritional Preparation for Pregnancy

Stage of Pregnancy	Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy				
	Offer counseling to women at risk for nutritional deficiency.	III	B	100, 103
	Recommend folate supplements (0.4 mg/day) for all women contemplating pregnancy.	Ia	A	101
	Offer continuing folate supplementation (0.4 mg/day) to all women at increased risk for neural tube defects in pregnancy.	Ia	A	101
Prenatal				
	The decision to recommend supplements is based on individual requirements.	Ia	A	102
	Routine iron supplementation is warranted in populations in which iron deficiency is common.	Ia	A	104

Nutritional Preparation for Pregnancy *(Continued)*

Stage of Pregnancy	Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal				
	Avoid excess vitamin A (i.e., more than the daily allowance).	III	B	90
	Advise supplemental vitamin K (10 mg/day from 36 weeks gestation) to women who take antiepileptic drugs to prevent neonatal hemorrhagic disease.	IIa	A	95
	Advise women to avoid large amounts of caffeine (>600 mg daily, which is equivalent to six 10-ounce cups of coffee).	III	B	84
Labor and Delivery				
Postnatal				
	Give a single dose (1 mg) of either intramuscular or oral vitamin K to the newborn to prevent classic hemorrhagic disease. Vitamin K prophylaxis improves biochemical indices of coagulation status at 1 to 7 days.	Ib	A	94

MATERNAL WEIGHT AND WEIGHT GAIN

Although routine weighing of pregnant women has become an important feature of prenatal care, surprisingly little is known about the effectiveness of weighing as a screening procedure for predicting fetal demise or about the clinical and practical implications of "abnormal" weight changes in pregnancy. Epidemiologically, prepregnancy weight may be considered a risk indicator, identifying women who are at increased risk for pregnancy complications and poor reproductive outcome. Prepregnancy weight is a crude reflection of nutritional status, which is largely determined by maternal genotype and environmental factors, including a woman's lifelong health status, beginning at her own conception. Weight gain is arguably directly related to birth weight and the subsequent health of the child.

Underweight Women

Definitions

Perhaps the best way to assess abnormalities of nutritional status, namely undernutrition and obesity, is to refer to standard height and weight tables, using infor-

mation on maternal height and prepregnancy weight. Body mass index (BMI), also known as Quetelet's index (weight $[kg]/height[m]^2$), is commonly used. Naeye[105] classified pregnant women into four categories according to arbitrary BMI values: "thin," less than 20; "normal," 20 to 24; "overweight," 25 to 30; and "obese," greater than 30. In clinical practice, however, these standard definitions of BMI are difficult to apply because information on prepregnancy weight is usually unavailable at the first prenatal visit. Therefore, many investigators have limited the definitions for abnormal nutritional status to information on body weight. In this regard, subjective criteria for "initial" body weight have been proposed. Values of 45 kg (99 lb) or less are used to describe "underweight" women and values of 85 kg (187 lb) or greater are used to describe "overweight" women.[106] Alternatively, skinfold thickness measurements are used to define maternal constitution in terms of body fat content. Estimates of skinfold measurements, however, are affected by alterations in maternal body composition during pregnancy.[107,108] Because it is impossible to rely fully on the accuracy of these measurements during pregnancy, the results should be interpreted carefully. Also, from a practical viewpoint, most institutions do not routinely record this measurement.

Nutritional deprivation may arise as a result of starvation, dieting, or chronic eating disorders, such as anorexia nervosa and bulimia. Eating disorders are a public health concern in affluent societies.[97]

Anorexia nervosa is a syndrome characterized by severe weight loss, a distorted body image, and an intense fear of becoming obese.[97,109] Anorexia nervosa is not synonymous with bulimia, although bulimic symptoms may occur in women with anorexia nervosa.

Bulimia is characterized by recurrent episodes of secretive binge eating followed by self-induced vomiting, fasting, or the use of laxatives or diuretics.[97] Depression and alcohol and drug abuse are also prominent features of this disorder.[110] Patients show frequent weight fluctuations, but are not likely to have significant weight loss, as seen in women with anorexia nervosa. Both syndromes, which primarily affect adolescents and young adults from middle-class and upper middle-class families, are often associated with oligomenorrhea and amenorrhea.[97] Despite menstrual irregularities, women with chronic eating disorders may become pregnant. Stewart and colleagues reviewed the outcome of pregnancies in women with anorexia and bulimia.[100]

Risks

Nutritional deprivation has a negative effect on birth weight.[86,111] Underweight women are more likely than women of normal weight to give birth to infants who are small for gestational age.[105,112,113] Poor fetal growth may result in birth asphyxia and complications, such as neonatal hypoglycemia and hypothermia.[114] Underweight women my be more susceptible to anemia.[76] In "thin" women (Quetelet's index <20), the perinatal mortality rate is increased.[105]

The outcome of pregnancy in women with anorexia and bulimia varies. If the eating disorder is in remission, then an uneventful pregnancy and a favorable pregnancy outcome can be anticipated. However, expectant women with active anorexia nervosa or bulimia at the time of conception may have a number of severe health problems, including electrolyte imbalances, dehydration, depression, social problems, and poor fetal growth. Appropriate psychiatric treatment is warranted.[100,109]

Management Options

PREPREGNANCY

Women who have anorexia or bulimia and wish to become pregnant are advised to wait until the eating disorder is in remission.[100] The treatment of underweight women with anovulatory infertility should be focused on restoration of weight by an integrated multidisciplinary approach rather than on ovulation induction.[97]

PRENATAL

In view of the increased risk of low birth weight, prenatal care should focus on early detection of impaired fetal growth.[109] Careful dating of gestation is important. Adequate weight gain should be ensured. However, the beneficial effects of dietary advice, with or without specific food supplements, are controversial.[88,97,115]

LABOR AND DELIVERY

If fetal growth restriction is suspected, the patient should be admitted to a specialist unit. Continuous electronic fetal heart rate monitoring is advised.[113] Emergency neonatal services should be readily available for resuscitation.

POSTNATAL

Approximately 40% of women with eating disorders have a history of affective disorders, which also puts them at risk for postpartum depression.[109] No additional specific management strategies need to be considered. Treatment with antidepressant drugs may be warranted.

Overweight Women

Definitions

According to the recommendations of the World Health Organization, overweight is defined as a BMI of more than 25.0 kg/m^2 and obesity is defined as a BMI of greater than 30 kg/m^2.[116] The degree of obesity is classified into three categories: grade I (BMI 30.0–34.9 kg/m^2), grade II (BMI 35.0–39.9 kg/m^2), and grade III (BMI > 40 kg/m^2).

Risks

Hypertensive disorders, including preexisting hypertension and pregnancy-induced hypertension, are more common in women with excess weight, although prevalence rates in different reports vary widely (7%–46%).[117] Gestational diabetes is also more frequent, affecting 7% to 17% of obese women.[117] Other problems associated with obesity include gallstones, urinary tract infections, postnatal hemorrhage, and possibly thrombophlebitis.[118,119] Obese women are more likely to give birth to large-for-gestational-age infants. Poor fetal growth is not usually seen in obese women.[118] Despite the higher mean birth weight of the infant, there is no clear evidence that obese women without prenatal complications are at increased risk for labor and delivery complications, such as dysfunctional labor, shoulder dystocia, and birth asphyxia.[118,120] Moreover, obese women without prenatal complications do not appear to be more prone to either augmentation with oxytocin for poorly progressing labor or cesarean section for dystocia when compared with matched nonobese control subjects.[118,119]

There is conflicting evidence about the effect of obesity on perinatal mortality. Based on the findings of the Collaborative Perinatal Study in the United States, Naeye[105] concluded that perinatal mortality rates are directly related to Quetelet index values, even when the effects of demographic factors, smoking, and prenatal complications were considered. He showed that nearly half the increase in perinatal mortality among obese women could be ascribed to preterm birth. The increased rate of twin births may also partially explain the relatively high rates of preterm birth and subsequent increased perinatal mortality rates among obese women.[105] Other investigators could not confirm this association between perinatal mortality and obesity. Such a lack of association could be the effect of prenatal care, through early recognition and appropriate management of prenatal complications in the obese woman.[117] Various studies suggested that the cesarean section rate for obese women is slightly higher than that for women of normal weight.[119] In fact, the increased need for abdominal delivery in obese women can be attributed mainly to the relatively high rate of prenatal complications and to factors such as advanced age and high parity. When surgical delivery is required, obese women are more prone to wound infection compared with nonobese women.[117,121]

Management Options

PREPREGNANCY

If an obese woman wishes to reduce her weight, she should be encouraged to lose weight before or after pregnancy. There are several potentially effective programs for weight loss.[122] It has been suggested that weight loss programs should aim initially at a reduction of body weight by 10% from baseline, at a rate of 1 or 2 pounds (approximately 0.5–1 kg) per week, for 6 months.[122] Diets with a deficit of 500 to 1000 kcal/day produce weight loss of 300 to 1000 g/wk, depending on the patient's weight.[123] Starvation diets, with energy intake of less than 200 kcal/day, are no longer used. Dietary manipulation should not be advocated during pregnancy. It is difficult to achieve, offers no benefit to the mother, and may have ill effects on fetal weight and the subsequent health of the child.[111,124] Apart from a balanced diet, daily exercise programs should be promoted[116,122] (see "Physical Activity"). If a woman insists on severe caloric restriction for weight reduction, the problem of maintaining reduced weight for prolonged periods should be addressed. The recurrence rate of obesity after weight reduction is high.[125] Massively obese women who cannot achieve dietary control sometimes opt for surgical treatment of obesity. Pregnancies that occur after intestinal bypass surgery are often complicated by fetal growth restriction.[125] In contrast, most pregnancies that occur after gastric bypass surgery appear to have a generally benign course; this procedure is seldom associated with nutritional and metabolic abnormalities.[126] Pregnancy should be avoided if electrolyte imbalance is present.

PRENATAL

Prepregnancy weight and maternal height should be documented routinely in the prenatal health records or medical records. Weight is usually recorded at each prenatal visit, using calibrated scales. Blood pressure should also be monitored with an appropriately sized cuff. Obese women may show artificially high readings when a standard cuff is used.[127]

In grossly obese women, it can be difficult to assess fetal growth and well-being. Ultrasonic measurements of fetal size may be untrustworthy if adipose tissue limits proper visualization of the fetus. Ascertainment of fundal height in overweight women by either palpation or measurement could also present problems in terms of accurate estimation of fetal size. There is no simple solution. Moreover, in massively obese women, it may be difficult to determine fetal presentation. Ultrasonography is particularly important in resolving problems of presentation. Before delivery, anesthesia consultation is needed if medical problems arise, such as hypertension, diabetes mellitus, or pulmonary dysfunction.

Obese women should be evaluated for gestational diabetes at the first prenatal visit. Testing should be repeated in the second or third trimester if the previous findings were normal.[119] Women should be screened for asymptomatic bacteriuria by culture and colony count of clean-catch voided urine.[128] Screening for asymptomatic bacteriuria, with subsequent treatment, reduces the risk of pyelonephritis and its consequences.[128]

LABOR AND DELIVERY

Fetal macrosomia is strongly associated with problems in labor, including poor progress as a result of cephalopelvic disproportion, shoulder dystocia, and birth asphyxia.[120] Attempts to derive a prediction score to identify large-for-gestational-age infants have been unsuccessful because of unacceptably high false-positive rates.[129]

PROCEDURE

CESAREAN SECTION IN THE OBESE PATIENT

Preoperative Considerations

Anesthesia

In view of technologic advances, there should no longer be a hesitancy to perform a cesarean section in morbidly obese women. In nonemergent deliveries, epidural anesthesia warrants serious consideration. Even in the massively obese woman, epidural anesthesia is technically possible and is preferred over general anesthesia, at least in experienced hands.[118,130]

Prophylactic Measures

The use of prophylactic antibiotics during both elective and emergency cesarean section significantly reduces the risks of maternal wound infection and febrile morbidity.[131] Additionally, prophylactic administration of low-molecular-weight heparin is recommended, beginning preoperatively and continuing until the patient is fully ambulatory.[132]

Type of Incision

In obese women, the type of incision for abdominal delivery, midline vertical versus low-transverse (Pfannenstiel), is often subject to debate. Gross[133] reviewed the benefits and risks of the two operative approaches in obese women. He concluded that the favorable aspects of the Pfannenstiel incision are: (1) less postoperative pain and early ambulation, thus avoiding atelectasis and embolism; (2) a more secure closure; and (3) less adipose tissue to incise. Moreover, the Pfannenstiel incision gives a better cosmetic result than the midline incision. The potential adverse effects of the Pfannenstiel incision are: (1) greater likelihood of infection because the incision is located in a warm, moist area; (2) potentially restricted access to the infant; and (3) more difficult exposure of the upper abdomen.

In theory, prolongation of surgery increases the risk of wound infection. The extent to which the type of incision affects the duration of surgery in overweight women is unknown. The total duration of the operation in obese women appears to be only marginally affected by the type of incision used. The interval from incision to delivery with the Pfannenstiel technique may be somewhat longer because extraction of the infant may be more difficult, particularly when the infant is large. Incision closure may be more difficult when a midline incision is used. Exteriorization of the uterus to facilitate repair of the uterine incision is commonly practiced when exposure is particularly difficult. The value of this technique, however, remains to be established.[134] Use of a "full-thickness" or "one-layer" closure technique (incorporating peritoneum together with rectus sheath) with nonabsorbable suture material could avoid the problem of wound dehiscence. Placing surgical drains at the time of closure of the abdomen in obese women is a matter of debate. There is no conclusive evidence about how the skin should be closed after cesarean section.[135]

POSTNATAL

Specific complications after abdominal delivery in obese women include wound infection, wound dehiscence, atelectasis, and pulmonary emboli. Prophylactic administration of anticoagulants should be continued until the patient is fully mobilized. Early mobilization appears to improve maternal outcome.

In newborn infants born to grossly obese women, especially those that are large for gestational age, the postnatal blood sugar level should be monitored during the first hours of life.

CONCLUSIONS

- Obese women are more likely to have prenatal complications, including hypertensive disorders, gestational diabetes, urinary tract infection, cesarean section, large-for-gestational-age infants, and intrapartum and postpartum complications.
- Maintaining awareness of the specific medical and obstetric problems associated with obesity will enable the clinician to maximize efforts to improve maternal health and fetal outcome.

Weight Gain in Pregnancy

The total weight gain of a healthy nulliparous woman eating without restriction is approximately 12.5 kg (27.5 lb).[108] However, large variations in weight gain are seen in women with normal outcomes.[108,136] In western societies, average total weight gain ranges from 10 to 16 kg (22–35 lb).[137] This variation is a function of prepregnancy weight, age, parity, and dietary habits during pregnancy. In healthy, well-nourished women with uncomplicated pregnancies, the proportional weight gain (i.e., total weight gain at term expressed as a proportion of the weight before pregnancy) is 17% to 20%.[107] The increase is mostly accounted for by an increase in total body water (averaging approximately 7.5 kg [16.4 lb] when no edema is present) and body fat mass (approximately 2.2–3.5 kg [5.0–7.7 lb]).[108,137,138] The rest, approximating 0.9 kg (2 lb), is caused by an increase in protein content, half of which is fetal. Mean weight gain in pregnancy, from conception to birth, does not show a linear trend. The normal, lean nulliparous woman, who eats to appetite, gains only a little weight during the first trimester (0.65–1.1 kg [1.4–2.4 lb] by 10 weeks).[108,137] In the second trimester, average weekly weight gain is approximately 0.45 kg (1 lb); thereafter, it is approximately 0.36 kg (0.8 lb).[118] Weight loss or failure to gain weight over a 2-week interval in the third trimester is not uncommon in both nulliparous and parous women. The average weight gain in parous women may be slightly less than in nulliparous women. The maximum rate of weight gain occurs between 17 and 24 weeks of pregnancy.[136] Subcutaneous fat is laid down over the abdomen, back, and upper thighs, mainly in the first and second trimesters.[117]

A study from the Netherlands showed that in a highly selective group of healthy women, postpartum weight was 2.9 kg (6.4 lb) greater than weight before pregnancy.[138] After delivery, the most rapid weight loss occurs between 4 and 10 days postpartum, mainly from loss of fluid. In the following weeks, weight loss is much more gradual, approximately 0.25 kg (0.55 lb) per week, consistent with a gradual mobilization of fat stores.[139] Eventually, the average woman loses most of the weight she gains during pregnancy, taking into account the effects of age and weight gain over time.[108,140] Pregnancy does not have a lasting effect on body fat mass. Breastfeeding for longer than 60 days has a favorable effect on the rate of postpartum weight loss because it is assumed that maternal caloric consumption is generally insufficient to meet the increased needs of lactation.[141]

Risks

There is a positive correlation between maternal weight gain and birth weight, regardless of maternal age and parity.[136,141] Women who gain little weight in pregnancy are at increased risk for having low–birth weight infants. The magnitude of the association between inadequate maternal weight gain and low birth weight depends on prepregnancy weight: women of low prepregnancy weight who have little weight gain during pregnancy are more likely to give birth to a low–birth weight infant than overweight women who have a similar net weight gain during pregnancy. Net weight gain in underweight women is strongly related to birth weight. In overweight women, net weight gain is only marginally related to birth weight.[142] The optimum weight gain in terms of minimum perinatal mortality is 7.3 kg (16 lb) for overweight women, 9.1 kg (20 lb) for women of normal weight, and 13.6 kg (30 lb) for underweight women.[108] The possibility of an eating disorder should be considered in women who do not gain appropriate weight or who have intractable vomiting.[100]

Management options

PRENATAL

Dietary policies vary markedly from hospital to hospital, but the rationale for dietary management of pregnant women with "inappropriate" weight gain is unclear. Over the last several decades, significant changes have been made in the recommendations made to women about weight gain during pregnancy. Until the 1970s, it was common practice to advise women to restrict food intake. These recommendations were aimed at curtailing weight gain to approximately 6.8 kg (15 lb) or 11.3 kg (25 lb) at most.[142] The main objectives for dietary restriction were threefold: (1) reduction of the incidence of preeclampsia, (2) promotion of easier labor, and (3) preservation of the woman's figure after birth.[142] Later, when the association between low birth weight and inadequate weight gain was recognized to be less strong than originally thought, and in view of the fact that dietary restriction could not avert preeclampsia, medical attitudes toward weight gain in pregnancy were relaxed.[124]

Caloric restriction in women cannot be recommended because there is no scientific evidence that such policy has a beneficial effect on maternal and fetal health, in terms of preventing preeclampsia, perinatal mortality, preterm birth, or impaired fetal growth.[88,102,124,143] By increasing energy intake, however, the pregnant woman can promote excessive fat accretion.[137] A modest reduction in nutrient intake may reduce the likelihood of retaining undesirable amounts of fat postpartum.[137] If a woman wishes to pursue this approach, a dietitian should advise her about a healthy, well-balanced diet, taking into account her background, assets, and lifestyle.

LABOR AND DELIVERY

Important considerations were discussed in the previous section.

CONCLUSIONS

- Mean infant birth weight is a function of maternal weight before pregnancy and weight gain during pregnancy.
- Weight gain during pregnancy seems to have a far greater effect on the birth weight of infants born to underweight women than on those born to overweight women.

PHYSICAL ACTIVITY

Definition

Physical activity is of two types: (1) daily activities, including household, occupational, and commuting-related activities; and (2) leisure activities, such as sports and exercise, including aerobics. Physical activity accounts for 15% to 40% of total energy expenditure. The magnitude of the physiologic response to physical activity is determined by age, fitness, body weight, body position, concurrent physical adaptations to pregnancy, and psychological factors.[145] Because physical activity has many interrelated dimensions, its quantification is complex. Indirect assessment of physical activity by questionnaire is the most practical and widely accepted approach in epidemiologic studies.[146]

Risks

General Health

There are clear associations between physical activity and health and between diet and health. These relationships are often linked through obesity.[116] Although obesity, an unhealthy diet, and physical inactivity are independent risk factors, they are often found together and are a common risk factor for type 2 diabetes, hypertension, cardiovascular disease, and stroke.[116]

Pregnancy

Research focused on physical activity in the workplace shows that physically and emotionally demanding work during pregnancy is associated with an increased risk of hypertension, low birth weight, and preterm birth[147] (see "Occupational Factors"). Research focused on leisure time physical activity during pregnancy has not identified similar associations.[147] Research findings indicate that the overall effect of regular recreational exercise on pregnancy outcome is positive for both mother and fetus, in terms of maternal cardiovascular reserve, placental growth, and functional capacity.[147–149] This also holds true for vigorous exercise, including aerobics and competitive sports.[150,151] Activities with a high risk of abdominal trauma should be avoided.[148] Scuba diving should be discouraged throughout pregnancy, because the fetus is not protected from decompression problems and is at risk for malformation and gas embolism after decompression disease.[148,152]

Management Options

A woman's overall health, including obstetric and medical risks, should be evaluated before an exercise program is prescribed.[148] The American College of Obstetricians and Gynecologists (ACOG) recommends healthy pregnant women to engage in 30 minutes or more of moderate exercise daily, provided there are neither medical nor obstetric complications.[148] Healthy pregnant women are allowed to exercise vigorously or take part in competitive sports, provided that there are no noticeable health hazards to themselves or their infants.[145,148,150,151]

SUMMARY OF MANAGEMENT OPTIONS Exercise in Pregnancy

OCCUPATIONAL FACTORS

Risks

The number of women in paid employment has increased over the last decades in both developing and developed countries.[153] With increasing participation in the workforce, many women have become vulnerable to unsafe and unhealthy conditions, such as exposure to toxic chemicals, radiation, and physically or mentally demanding work.

Women's occupations are multidimensional. They may undertake paid work at home or may combine part-time or full-time work with household activities and the care of children. They are likely to move in and out of the paid labor force during different life stages. For these reasons, a simple occupational category is seldom sufficient as a guide for establishing specific health risks.[69,154]

Determining both exposure and outcome may be problematic. Data on meaningful indicators of reproductive health hazards in the workplace are usually scarce, and occupational morbidity is frequently unquantified and largely invisible. The same is true for occupational hazards associated with household work, for instance, exposure to toxic chemicals, such as cleaning fluids, bleach, detergents, insecticides, and pesticides. Furthermore, little information is available on the physical effort and emotional strain associated with the daily care of young children, which may be demanding, especially when there is little support from the woman's partner, friends, or family. Despite considerable progress in integrating women into the labor force, many women are still found in jobs where employment conditions are relatively unfavorable. Many jobs often held by women (e.g., salesperson, hairdresser, teller, cashier) require static work, monotonous tasks, and repetitive movements

that may result in physical and mental health problems. Migrant workers are of special concern because they are often underpaid and work in exploitative conditions. The adverse effects of poor working environment can be magnified by problems of isolation, stress, tiredness, and depression.

Physical violence is a major contributor to women's health risks, either in the home or in the formal workplace. Unemployment and poverty have led many women to work in the sex industry. Although the occupational health risks of sex workers vary with the setting and context, these workers are at increased risk for violence and sexually transmitted diseases (see Chapter 81).

The list of occupational exposures suspected to be harmful to the fetus is long. For instance, occupational exposures to anesthetic agents, laboratory chemicals, organic solvents, and pesticides have been linked to adverse pregnancy outcomes.[155,156] However, interpretation of the findings of studies in occupational settings is often hampered by methodologic shortcomings. A recent meta-analysis of working conditions and adverse pregnancy outcomes concluded that physically demanding work is significantly associated with preterm birth (OR, 1.22; 95% CI, 1.16, 1.29), fetal growth restriction (OR, 1.37; 95% CI, 1.30, 1.44), and hypertension or preeclampsia (OR, 1.60; 95% CI, 1.30, 1.96). Other occupational exposures significantly associated with preterm birth include prolonged standing (OR, 1.26; 95% CI, 1.13, 1.40) and shift and night work (OR, 1.24; 95% CI, 1.06, 1.46).[157] No adverse outcomes are seen in women with less strenuous jobs or in those who can modify their work activity.[158] These data suggest that interventions to reduce physical exertion among pregnant women could improve birth outcomes. French investigators developed a useful scale for identifying strenuous working conditions. This "fatigue index" comprises five sources of potential occupational hazards:

posture, type of work, physical exertion, mental stress, and situational factors (e.g., exposure to noise and heat). They showed a strong relationship between preterm delivery and adverse working conditions, as reflected by the fatigue index.[159] Several studies noted an association between stress and fatigue related to the work or home environment and increased risk of adverse pregnancy outcome (pooled OR, 1.63; 95% CI, 1.33, 1.98).[157] The underlying mechanism of these adverse effects on pregnancy outcomes is unclear.

Legislation to protect women in the workplace has been enacted in most countries. Such legislation is frequently used to exclude women from specific industries, either because the work is too physically demanding or because it poses unwarranted risks to the outcome of pregnancy. Implementation of these protective health and safety measures is often problematic. For instance, informal sector employment is generally excluded from protective legislation, leaving women vulnerable to workplace hazards.

Management Options

A careful workplace history should be taken, including level of activity, hazardous exposures, and ease of workplace modification.[158] Precautions should be taken to protect women from specific occupational health risks, such as exposure to toxic chemicals or radiation.[153] Women whose work is physically or emotionally demanding should be monitored carefully throughout pregnancy for evidence of hypertension, intrauterine growth restriction, and symptoms of preterm labor.[157] It is important for health care professionals, family members, and employers to recognize the potential negative effect of adverse working conditions on pregnancy outcome.

The ultimate decision on continuation of employment during pregnancy should be made by the pregnant woman after careful counseling by her physician, involving the company medical officer and the employer, when indicated.

ADOLESCENT PREGNANCY

Definitions

The term *adolescent* is often used synonymously with *teenager*. In this sense, *adolescent pregnancy* is pregnancy in a girl or woman aged 10 to 19 years.[160] Epidemiologically, a distinction is often made between pregnancy (or birth) rates among adolescents aged 15 to 19 years and those among adolescents aged 10 to 14 years. Some investigators advocate the use of the terms *reproductive age* and *gynecologic age* as measures of physiologic maturity.[161-164] *Reproductive age* is the interval from the age of menarche (i.e., onset of first menses) to the chronologic age at conception, whereas *gynecologic age* is the time span from the age of menarche to the chronologic age at delivery. Conception or delivery within 2 years after the onset of menarche represents the lower extreme of the distribution of reproductive or gynecologic ages, respectively.

With the improvement of socioeconomic conditions, the median age of menarche has shown a downward trend. Currently, the median age of menarche among girls in developed countries is approximately 12.5 years.[160]

Incidence

The incidence of teenage pregnancy shows marked variation between developed countries. The lowest teenage pregnancy rates are found in the Netherlands (14/1000

among 15- to 19-year-olds), whereas in Sweden and England and Wales combined, they are considerably higher. According to recent figures for England and Wales, the teenage pregnancy rate (15–19 years) is 45/1000, the abortion rate is 19/1000, and the birth rate is 26/1000.[160] The highest pregnancy rates in developed countries are found in the United States. In the mid-1990s, among teenagers 15 to 19 years old, the pregnancy rate was 83.6, the abortion rate was 29.2, and the birth rate was 54.4.[165] In the United States, approximately 1 in every 11 girls aged 15 to 19 years becomes pregnant each year.

Risks

Teenage pregnancy is associated with both social and medical problems, in particular, preterm birth.[160,162,166] Many teenage mothers originate from working-class families and ethnic minorities. Many are themselves the children of teenage or very young parents.[167] Most teenage pregnancies are unplanned and unwanted. Consequently, in western societies, abortion rates among adolescents are quite high, ranging from 30% to 60% of all confirmed pregnancies in this age group.[168]

Reports on complications of pregnancy in adolescents are contradictory and difficult to interpret because of the confounding effects of adverse social circumstances and poor attendance for prenatal care. Typically, cigarette smoking and illicit drug use are common among pregnant adolescents.[160] Medical complications associated with adolescent pregnancy include preterm birth and low birth weight, perinatal mortality, short interval to next pregnancy, and sudden infant death syndrome. Moreover, adolescents who become pregnant are at particular risk for nutritional deficiencies, anemia, HIV infection, and other sexually transmitted diseases.[160] The increased incidence of pregnancy-induced hypertension among pregnant adolescents is largely explained by nulliparity.[160] It has been suggested that competition for nutrients between the fetus and the mother could affect pregnancy outcome in adolescents by interrupting the normal growth process.[169] However, contrary to common belief, biologic "immaturity" does not affect appreciably the reproductive performance of teenagers in terms of length of labor and route of delivery.[160,162,169] In facts, the likelihood of operative delivery is not increased.[160]

Management Options

Prevention and Prepregnancy Management

Primary prevention focuses on preventing pregnancy through sexual education in schools, with an emphasis on the importance of family planning and related issues.[168,170–172] Teenagers should be encouraged to discuss openly with their friends and classmates the realities of pregnancy and parenthood.[173] The media could play an important role in this area. Education should also include information about values, responsibilities, and the right to say "no." Secondary prevention is directed at sexually active women through a flexible approach to the use and provision of contraceptives for both males and females.[171] Some family planning clinics require parental notification if a teenager attends the clinic for birth control. Such policy may have a positive effect of including motivated parents in guiding their children's sexual behavior and contraceptive decision-making. However, such policy may also discourage teenagers from attending family planning clinics for fear of discovery and potential repercussions, in particular when they are raised with the idea that premarital sex is wrong. Motivation to use birth control is rarely hampered by negative attitudes toward contraception. In fact, positive ideas about "getting pregnant" and indifference toward "having a baby" are justifications that are frequently mentioned by childbearing teenagers for not having used contraceptives before conception.[172] Tertiary prevention involves adolescents who become pregnant. They are encouraged to seek early adequate prenatal care and to discuss options for the resolution of pregnancy.[174–176]

Prenatal

Compliance with prenatal care tends to be poor, especially among teenagers in their second pregnancy. Obviously, the provision and use of health care services is beneficial to both mother and child, although it is not clear to what extent prenatal care per se exerts a positive effect on pregnancy outcome. Routine ultrasonography during early pregnancy is advisable to confirm gestational age. Furthermore, timely identification of risk factors is important. Strategies for intervention should be focused on individual medical and social risk factors, in particular, poor nutritional status, adverse health habits, and perceived isolation. It is often difficult to determine the real needs of the pregnant teenager, her partner, and her family. Nevertheless, pregnant adolescents should be offered social support when feasible, preferably in close cooperation with the family physician, an empathetic midwife, or a social worker.[31] Also, information on pregnancy, delivery, and child-rearing should be made available.

Labor and Delivery

There are usually no specific programs for the intrapartum management of teenage pregnancies. The well-being of both the mother and the child must be monitored effectively. If possible, continuous emotional support during labor should be provided by a professional (e.g., nurse, midwife) or nonprofessional caregiver (e.g., spouse, friend, relative).[31] The patient may be hospitalized in a regular maternity unit if she has no risk factors other than age. In exceptionally young adolescents,

specialized care is advisable because of the increased likelihood of obstructive labor in patients with a small, immature pelvis.[177]

Postnatal

Infant feeding practices, infant growth, and infant safety should be reviewed. Symptoms of medical problems in the infant must be considered. Social and financial concerns should be discussed.[176] Teenage girls should be encouraged to continue secondary education.[173] Effective contraception should be implemented. A large percentage of teenagers who give birth before the age of 17 years have a repeat pregnancy before they are 19 years old.[178,179] Home visitation programs by public health nurses can have a positive effect on the health of the adolescent mother and her child.[178,179]

CONCLUSIONS

- Pregnancy has a tremendous effect on the adolescent and her family.
- Detrimental effects of age can be explained largely by poor social circumstances.
- Data indicate that most pregnant adolescents are biologically mature when they conceive.
- Teenagers tend to delay seeking prenatal care and typically do not use prenatal care facilities appropriately.
- Attention should be focused on individual risk factors.

ADVANCED MATERNAL AGE

Incidence

In the late 1960s and early 1970s, there was a decrease in the number of live births generally and a decrease in the proportion of mothers aged 35 years and older.[180,181] In the last three decades, there has been a trend toward deferred childbearing, especially among healthy, well-educated women with career opportunities.[182–184] The proportion of pregnant women aged 35 years and older varies from country to country. Both socioeconomic circumstances and the nature of the population of elderly women have changed with time. Formerly, pregnant women aged 35 years and older tended to have several unplanned children, whereas

today, the proportion of first births to "elderly" pregnant woman is growing.

Risks

Advanced maternal age is a risk indicator for several pregnancy complications, including spontaneous miscarriage; ectopic pregnancy; stillbirth; chromosomal abnormalities; twins; uterine fibroids; hypertensive disorders; gestational diabetes; prolonged labor; cephalopelvic disproportion necessitating operative delivery; bleeding disorders, including placenta previa; low birth weight; antepartum and intrapartum fetal loss; and neonatal mortality.[183–186] However, most reports of pregnancy outcome in elderly primiparous women have not taken into account effects other than age, such as details of general health, smoking habits, and reproductive history (including a history of miscarriage or infertility and its treatment).[182] Information about whether the first pregnancy was postponed deliberately is often lacking. In the early 1990s, Berkowitz and colleagues[184] reported that although pregnancy complications are more common in primiparous women aged 35 years and older, the risk of poor neonatal outcome is not appreciably increased. The women in their study represented a highly selected group of private patients who were predominantly white, married, college-educated, and nonsmoking, and who were delivered of a single infant in a tertiary care center. Hence, their study population was not representative of the population at large. The findings of this study should be interpreted with caution because they may not be applicable to other populations.

Maternal age at conception is highly correlated with the risk of spontaneous miscarriage, regardless of parity or the number of previous miscarriages (Fig. 1–3).[186]

It is assumed that the increased risk of spontaneous miscarriage among older women is a function of the age-related risk of chromosomal abnormalities. Approximately 40% to 60% of conceptions that abort are chromosomally abnormal.[182] The relative frequency of chromosomally normal miscarriages also increases with age, possibly resulting in a decline in uterine function with age.[182] Maternal age has no effect on the incidence of birth defects of unknown etiology.[187]

The topic of maternal age and chromosomal abnormalities is addressed in Chapter 2.

Advanced paternal age has little or no independent effect on the risk of autosomal trisomies when the effect of maternal age is taken into account.[188]

Management Options

Preconception and Prenatal

In clinical practice, maternal age normally refers to the age of the pregnant woman at the time she consults the physician or midwife for the first prenatal visit. This

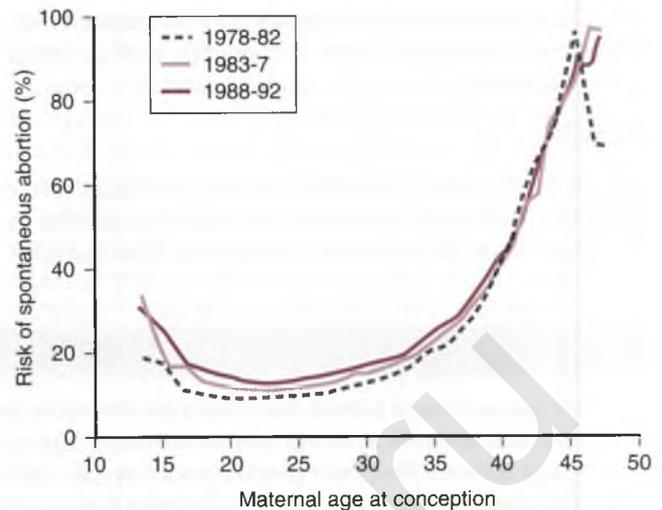

FIGURE 1–3

Risk of spontaneous abortion according to maternal age at conception, stratified according to calendar period, based on Danish civil registry data from 1978–1992. During this period, a total of 634,272 women had 1,221,546 pregnancies, of which 126,673 ended in fetal loss, 285,022 in an induced abortion, and 809,762 in a live birth. (From Andersen A-MN, Wohlfahrt J, Christens P, et al: Maternal age and fetal loss: Population-based register linkage study. BMJ 2000;320:1708–1712, with permission.)

information is particularly important for genetic counseling about the maternal age–specific risks of chromosomal abnormalities because these are typically based on maternal age at the time of delivery. Moreover, counseling should carefully distinguish the risk of a chromosomal abnormality in a live birth from the risk of a fetal chromosomal abnormality that is detectable in early pregnancy or midpregnancy.[189–191] This notion is also important for the proper interpretation of the risk estimates derived from first- and second-trimester screening tests for fetal abnormalities (see Chapters 7, 8, and 9). Fetal chromosomal abnormalities can be diagnosed with chorionic villus sampling or amniotic fluid sampling (amniocentesis) [see Chapter 10].The timing of chorionic villus sampling should take into account the higher baseline rate of spontaneous first-trimester miscarriages in women of advanced maternal age.[186,192]

Although medical and obstetric complications tend to be more common in women aged 35 years and older (discussed earlier), in practice, normal prenatal care usually is not modified unless another risk factor or complication is identified.

Labor and Delivery

Elderly women are usually advised to be delivered in a specialized unit because of the risk of dystocia during labor. However, the impression is often gained that the woman's age in itself contributes strongly to the decision to intervene.[184] Close monitoring of fetal condition (intermittent

monoaural auscultation or cardiotocography) and progress in the second stage of labor are warranted. However, intrapartum care is not modified substantially because of the extremes of maternal age.

Postnatal

Discussion of long-term contraception is recommended.[193,194]

CONCLUSION

- It is widely held clinically that advanced maternal age is associated with poor reproductive outcome. Only the increased risks of chromosomal abnormalities and spontaneous abortion are proven.

SUMMARY OF MANAGEMENT OPTIONS

Delivery in a unit that can manage dystocia and other complications.	III	B	183
Postnatal			
Discuss long-term contraception.	III	B	193,194

MATERNAL PARITY

Incidence

In western societies, nulliparous women constitute approximately half of all pregnant women.

Definitions

Definitions of parity differ from country to country. *Parity* is the number of times a woman has given birth to an infant, dead or alive. However, the gestational threshold may vary (e.g., 23 completed weeks' gestation vs. 27 completed weeks' gestation).

Risks

Differences in mortality risk between the offspring of primiparous and multiparous women are accounted for by birth weight.[17] Parity is closely correlated with maternal age and with socioeconomic status to a certain extent. It is often difficult to establish precisely how these factors are implicated in the etiology of adverse pregnancy outcome. On the whole, the risk of adverse outcome with parity does not show a consistent pattern. Mean birth weight for infants born to nulliparous women is consistently lower than that for infants born to multiparous women.[166] Some investigators suggested that differences in the mean birth weight of infants born to women of different parity could be explained by differences in maternal weight. It is well known that nulliparity is associated with an increased risk of pregnancy-induced hypertension, which in itself is strongly related to low birth weight. Further, in nulliparous women, there is an increased risk of perineal trauma as a result of either episiotomy or spontaneous tear, compared with multiparous women.

Women of high parity tend to receive inadequate obstetric care. They often delay seeking care and show poor attendance for prenatal care. Moreover, it is assumed that women with a history of rapid or precipitated childbirth have an increased risk of unattended out-of-hospital delivery. High parity is associated with an increased likelihood of abnormal fetal presentation and obstetric hemorrhage.[195] Parity, however, does not have a significant effect on the incidence of Down syndrome when the effect of maternal age is taken into account.[196]

Management Options

Prenatal

Nulliparity is a nonspecific risk factor. In this respect, no specific precautions need to be taken, provided the course of pregnancy is uneventful. There is no need for specialist care on the grounds of nulliparity alone.

In parous women, it is of fundamental importance to obtain all clinically relevant details of previous pregnancies. Reproductive history is a very informative predictor of pregnancy outcome. Consequently, this information has implications for the management of subsequent pregnancies. To facilitate the provision of prenatal care to parous women, it is useful to provide space and staff to accommodate the patients' children, who may accompany her.

Labor and Delivery

Empirically, there is a difference in the normal labor patterns of nulliparous and multiparous women. The median duration of the second stage of labor (i.e., from full dilation of the cervix to delivery) is approximately 45 minutes in nulliparous women versus approximately 20 minutes in multiparous women who have experienced a vaginal delivery previously. Clinically, however, the duration of the second stage of labor is highly variable. In both nulliparous and multiparous women, policies for imposing limits on the length of the second stage of labor tend to be subjective and are usually based on uncontrolled observational data. If the maternal and fetal condition is satisfactory and progress is occurring, with descent of the presenting part, obstetric intervention is not warranted. Cephalopelvic disproportion, however, must be considered when progress in labor is slow. To assure proper maternal and fetal surveillance during labor and prevent unattended out-of-hospital delivery, all women should be instructed to make the necessary arrangements for reaching the hospital in time. For women with a history of rapid or precipitated delivery, timely admission to the hospital and elective induction of labor may be considered, although there is no evidence that this approach is beneficial.

Postnatal

Discussion of long-term contraception is recommended.[193,194]

CONCLUSIONS

- First births have a statistically increased risk over second births, although the pattern of risk varies with age and in itself should not affect pregnancy care.
- Parity, age, and socioeconomic status are interrelated, and they all have an effect on birth weight and pregnancy outcome.
- Overall, the relative importance of parity is limited where fetal outcome is concerned.
- Nulliparity is associated with an increased risk of pregnancy-induced hypertension.
- High parity (traditionally five or more) is associated with abnormal fetal presentation and obstetric hemorrhage.
- Empirically, the duration of "normal" labor in multiparous women is shorter than that in nulliparous women.

SUMMARY OF MANAGEMENT OPTIONS
Women at the Extremes of Parity

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Discuss the risks, with emphasis on the effects of parity alone and nulliparity or high multiparity (≥5).	III	B	195,196
Prenatal			
Encourage regular attendance for care in those of high parity.	III	B	196
Look for pregnancy-induced hypertension in those of nulliparity.	III	B	196
Look for abnormal presentation from 36 weeks' gestation in those of high parity.	III	B	195
Labor and Delivery			
No specific recommendations are needed on the grounds of parity alone.	III	B	195,196
Postpartum hemorrhage is more likely with increasing parity.	III	B	195
Postnatal			
Discuss long-term contraception.	III	B	193,194

AIR TRAVEL DURING PREGNANCY

General Considerations

With commercial air travel becoming more global, health care providers are increasingly confronted with questions from travelers and airline crew members about the safety of long-distance flights. In this context, pregnant women and those contemplating pregnancy need special consideration because of the specific nature of the potential health risks of long-distance flights. These include exposure to cosmic radiation (see Fig. 1–2), reduced arterial oxygen pressure, immobilization, and unforeseen medical and obstetric emergencies encountered during the flight.[197] Little information has been published on this topic, and the recommendations made to airline crew members and travelers are typically based on common sense rather than scientific evidence.[197]

Risks

Radiation Exposure

The annual exposure dose limit for a member of the general public is 1 millisievert (mSv). The occupational limit is 5 mSv.[198] The exposure dose from cosmic radiation at flight altitudes is usually not higher than 0.005 mSv/hr (see also Fig. 1–2).[35] Rough estimates show that it takes a minimum of 200 flight hours to approach the annual dose limit for the general public. More radiation shielding is provided by atmospheric air at lower altitudes. The dose received from cosmic radiation is usu-

ally lower during short-haul flights than during long-haul flights because longer flights are usually flown at higher altitudes. The latitude of the flight route also makes a difference in the level of cosmic radiation exposure, with maximum exposures occurring near the equator. Airlines usually restrict commercial airline crew members from long-haul flights once pregnancy is diagnosed.

Fetal and Maternal Hypoxia

On long-distance commercial flights at an altitude of 32,000 feet, cabin pressure is set at the equivalent to an altitude of 6000 feet.[197] Acute ascent to 6000 feet produces transient cardiovascular and pulmonary adaptations, including decreased heart rate, increased blood pressure, and a significant decrease in aerobic capacity.[199,200] These changes are associated with a decrease in partial oxygen pressure that should not affect women with uneventful pregnancies. However, this decrease may affect those with compromised pregnancies. Therefore, pregnant women should be discouraged from air travel if they have a medical or obstetric problem that is exacerbated by a hypoxic environment.[197] If they must travel, supplemental oxygen should be prescribed during air travel.[201]

Venous Thrombosis

There is probably a link between long-distance air travel and deep venous thrombosis. The increased risk of venous thrombosis is ascribed to prolonged immobilization from

cramped seats ("economy class syndrome"). The risk, however, appears very small and is largely confined to those with recognized risk factors, such as a history of thrombosis, recent major surgery, hormone treatment, and malignancy.[202–206] However, the risk does not appear to be confined to those traveling in economy class. There are insufficient scientific data on which to base specific recommendations for prevention, other than leg exercise and the use of elastic compression stockings.[203,206,207]

Preterm Labor

There is no evidence that air travel itself increases the risk of preterm labor. However, 5% to 8% of pregnancies are complicated by preterm labor. Women with a history of preterm birth and those with multiple pregnancies are at increased risk for preterm birth. Recent recommendations from the ACOG suggest that pregnant women who have evidence of preterm labor or are at increased risk for preterm birth should avoid long-distance air travel.[201] Pregnant women who plan to travel should be aware that appropriate medical facilities may not be available in the country of destination.

Obstetric Emergencies

Obstetric emergencies, such as antepartum hemorrhage, cord prolapse, and placental abruption, are rare. However, the consequences are potentially fatal for the mother and child. Pregnant women should be aware that there is no guarantee that qualified medical personnel will be on board the flight and that medical equipment is limited.[197]

Seat Belts

Advice for airline seat belt use is the same as that for cars. A recent study showed that the likelihood of adverse pregnancy outcome among belted pregnant women who were involved in a passenger car accident is comparable to that of those who were not pregnant.[208] Because air turbulence cannot be predicted and this risk of trauma is not trivial, pregnant women are advised to use their seat belts continuously while seated.[201]

Vaccines

A woman who is contemplating pregnancy should receive vaccines that are safe and will protect her health and that of her child when she becomes pregnant. However, care must be taken to avoid inappropriate administration of certain vaccines that can be hazardous to an unborn child. This is particularly true for live vaccines. According to the recommendations of the World Health Organization, active vaccination with live attenuated measles, mumps, rubella, bacillus Calmette-Guérin, and yellow fever virus vaccines should be avoided in pregnancy (Table 1–6).[209,210]

The risks and benefits of vaccination should be examined in each case. For instance, women who are more than 13 weeks' pregnant are advised to be vaccinated against influenza virus because they are at increased risk for complications of influenza, including hospitalization for cardiorespiratory conditions, compared with nonpregnant women.[211]

TABLE 1–6

Vaccination in Pregnancy

VACCINE	USE IN PREGNANCY	COMMENTS
Bacille Calmette-Guérin	No	
Cholera	Yes, administer if indicated	Avoid unless high risk
Hepatitis A	Yes, administer if indicated	Safety not determined
Hepatitis B	Yes, administer if indicated	Safety not determined
Influenza	Yes, administer if indicated	Consult a physician
Japanese encephalitis	Yes, administer if indicated	Avoid unless high risk
Measles	No	
Meningococcal disease	Yes, administer if indicated	
Mumps	No	
Poliomyelitis	Yes, administer if indicated	Normally avoided
Rubella	No	
Tetanus and diphtheria	Yes, administer if indicated	
Rabies	Yes, administer if indicated	
Typhoid	Yes, administer if indicated	Avoid unless high risk
Varicella	No	
Yellow fever	Yes, administer if indicated	Avoid unless high risk

(From World Health Organization: International travel and health. Vaccine-preventable diseases. www.who.int/ith/chapter 06_16.html; Thomas RE: Preparing patients to travel abroad safely: Part 2. Updating vaccinations. Can Fam Physician 2000; 46: 646–652, 655–656.)

Malaria Prophylaxis

Four parasitic protozoa of the genus *Plasmodium* (*Plasmodium ovale, Plasmodium vivax, Plasmodium malariae,* and *Plasmodium falciparum*) cause human malaria. Of the four species, *P. falciparum* causes the most severe morbidity and mortality. All four species are transmitted through the bite of an infected female *Anopheles* species mosquito. At risk for contraction of malaria are nonimmune persons living in or traveling to areas of Central and South America, Hispaniola, sub-Saharan Africa, the Indian subcontinent, Southeast Asia, the Middle East, and Oceania. Resistance of *P. falciparum* to chloroquine is now common in nearly all malaria-endemic countries of Africa, especially in east Africa, thus posing increasing problems for the provision of suitable treatment. The clinical features of malaria in pregnancy depend to a large extent on the immune status of the woman, which in turn is determined by her previous exposure to malaria. In pregnant women with little or no preexisting immunity, such as those from nonendemic areas or travelers to endemic areas, infection is associated with a high risk of severe maternal anemia and low birth weight. These complications are more common in primigravidae than in multigravidae.[212] Preventive strategies include chemoprophylaxis, intermittent preventative treatment with antimalarials, and insecticide-treated bed nets.[212–215] These strategies reduce the risk of severe maternal anemia and low birth weight, in particular among women of low parity.[212–215] Recommendations for the most appropriate strategy depend on the country of destination, the length of stay, and individual preferences.[216] In the absence of medical attention, travelers to endemic areas are increasingly advised to carry emergency medication for self-treatment.[217]

Chemoprophylaxis should be started at least 1 week before the woman enters the endemic area, preferably 2 to 3 weeks before, so that side effects can be detected before travel occurs. If necessary, prophylaxis can be changed to an alternative drug. Chemoprophylaxis should be continued with unfailing regularity throughout the stay in the endemic area and for 4 weeks after the woman leaves the endemic area. Chloroquine, sulfadoxine–pyrimethamine, and mefloquine are considered safe for use in pregnancy. Normal precautions and contraindications should be observed.

Chemoprophylaxis is increasingly hampered by parasite drug resistance and poor patient compliance.[215] Moreover, chemoprophylaxis does not offer 100% protection, and health care professionals should be alert to the clinical symptoms of malaria.[218] Malaria, which can be fatal, must be suspected if fever, with or without other symptoms, develops at any time between 1 week after the first possible exposure and 2 months (or even later in rare cases) after the last possible exposure.[218]

Other Precautions

The risk of travelers' diarrhea is approximately 7% in developed countries and 20% to 50% in the developing world.[219] Routine prophylaxis of travelers' diarrhea, especially with antibiotics, should be discouraged. Oral rehydration is generally important in the treatment of diarrhea, but travelers' diarrhea is not usually dehydrating in adults.[219] Less severe disease can be treated with a variety of nonantibiotic agents, including bismuth subsalicylate-containing compounds and loperamide.[219,220] These drugs are considered safe for use in pregnancy.

MEDICAL FACTORS

The risks of specific medical conditions in pregnancy and the prepregnancy management options are discussed in the relevant chapters.

SUMMARY OF MANAGEMENT OPTIONS
Air Travel in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
In the absence of predictable obstetric or medical problems, long-distance air travel is safe in pregnancy.	IV	C	197,201
Long-distance flights are not recommended for women up to 36 weeks' gestation with singleton pregnancies and 32 weeks' with multiple pregnancies.	IV	C	201
Air travel is not recommended for infants younger than 7 days old.	IV	C	197
Update travelers on routine immunizations, including tetanus, diphtheria, polio, measles, mumps, rubella, hepatitis A and B, and influenza vaccines. Other immunizations are based on geographic risk.	IV	C	210

SUMMARY OF MANAGEMENT OPTIONS
Air Travel in Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Travel is not recommended at any time during pregnancy for women who have either medical or obstetric problems that could result in emergencies.	IV	C	201
Preventive measures (e.g., supportive stockings, periodic movement of lower extremities) can be used during long hours of air travel to minimize thromboembolic risk. Additional prophylaxis is advised in those with increased thromboembolic risk (see Chapter 43).	Ib	A	201,207
Travelers should be informed about how to protect themselves against mosquito bites in malarial endemic areas.	Ia	A	214
Drugs given to prevent malaria in pregnancy significantly reduce the likelihood of severe maternal anemia and low birth weight, in particular among women of low parity.	Ia	A	215
Malaria should be suspected in all patients who have symptoms after traveling to an area where malaria is endemic. These patients should undergo blood microscopy.	III	B	218

CONCLUSIONS

- The couple's health status, lifestyle, and reproductive and family history before conception may have a major effect on the likelihood of a successful pregnancy.
- The initial assessment of a woman's reproductive health risks may start well before pregnancy occurs (see Appendix).
- The developing fetus is most vulnerable to maternal conditions and environmental exposures in the first trimester of pregnancy.[83,84]
- Preconception health care may improve reproductive outcome.[4,221]
- The key elements of preconception services include the following:
- Identification of women at increased risk for adverse pregnancy outcome, with subsequent counseling about the necessary preventive measures to ensure an optimal outcome
- Provision of health education to all women, regardless of their risk status, to increase the likelihood of optimal reproductive outcome
- Preconception health care services should include a discussion of contraception and timing of pregnancy, nutritional information, and the patient's infection and immunization history.[4]
- A recent systematic review found evidence of the effectiveness of preconception care in the following three areas[221]:
- Screening women who are seeking family planning for high risk conditions
- Folate supplementation in sexually active women of reproductive age
- Women affected with certain metabolic conditions (e.g., diabetes and hyperphenylalaninemia)
- When couples are systematically provided with information and skills to reduce health risks, they are more likely to reduce substance use, stop using tobacco products, practice safe sex, eat healthy foods, and engage in physical activity.[222]
- Physicians who provide primary care to women should include prepregnancy care in their routine encounters with women of reproductive age.[221]

Genetics, Risks, and Genetic Counseling

Peter A. Farndon / Mark D. Kilby

INTRODUCTION

An abnormal fetal phenotype can be caused by environmental factors, chromosomal abnormalities, specific genes, or more complex genetic mechanisms. For most couples, the finding of fetal anomalies is unexpected, but some have identifiable factors that suggest a high risk of fetal anomaly. These include the following:

- A previous child affected with a single-gene disorder
- A family history of a single-gene disorder
- A parent with a chromosomal anomaly
- Structural anomalies found on ultrasound examination

Because families with single-gene disorders or parental chromosomal anomalies are at increased risk, it is important to identify couples from such families before they undertake pregnancy. An assessment of an individual's risk can often be made by a combination of pedigree analysis, precise clinical diagnosis, and genetic testing, which is available for an increasing number of conditions.

Although the main effect of genetics on current obstetric practice may be aiding the prediction and understanding of fetal anomaly, in the future, it is likely that screening for maternal genetic susceptibility to conditions such as eclampsia will be feasible.

DETERMINING THE GENETIC BASIS OF A CONDITION

To give a family accurate genetic information, it is recommended that the following steps (which are discussed in greater detail later) are undertaken:

- Examine the family tree to detect a pattern of inheritance.
- Refine and confirm the diagnosis by clinical examination and testing.

- Perform karyotype analysis or DNA testing, as appropriate.
- Assess the genetic risks to family members.
- Explain the genetic information to the family ("genetic counseling").
- Discuss the available options.
- Support the family while they make decisions appropriate to their situation.

IDENTIFICATION OF FAMILIES AT INCREASED GENETIC RISK

The couple may have realized that the family tree suggests a genetic disorder and volunteer this information. In other cases, the high risk is appreciated only when a formal history is taken.

The best and easiest way to record genetic information is to draw a pedigree. The standard notation is shown in Figure 2–1. Guidelines include the following:

- Create the tree from the "bottom," starting with the affected child and siblings: "Please give me the names of your children and their dates of birth, in order of age, starting with the oldest."
- Choose one parent (usually the mother) and ask about her siblings and their children, and then her parents, moving from generation to generation.
- Add information about the paternal side of the family.
- Use clear symbols (e.g., circles for females, squares for males). Fill in the symbol if the person is affected.
- Put a sloping line through the symbol (from the bottom left to the top right corner) if the person has died.
- Record all names, dates of birth, and maiden names.
- Ask about miscarriages, stillbirths, or deaths in each partnership: "How many children have you had? Have you lost any children? Have you had any previous partners?"

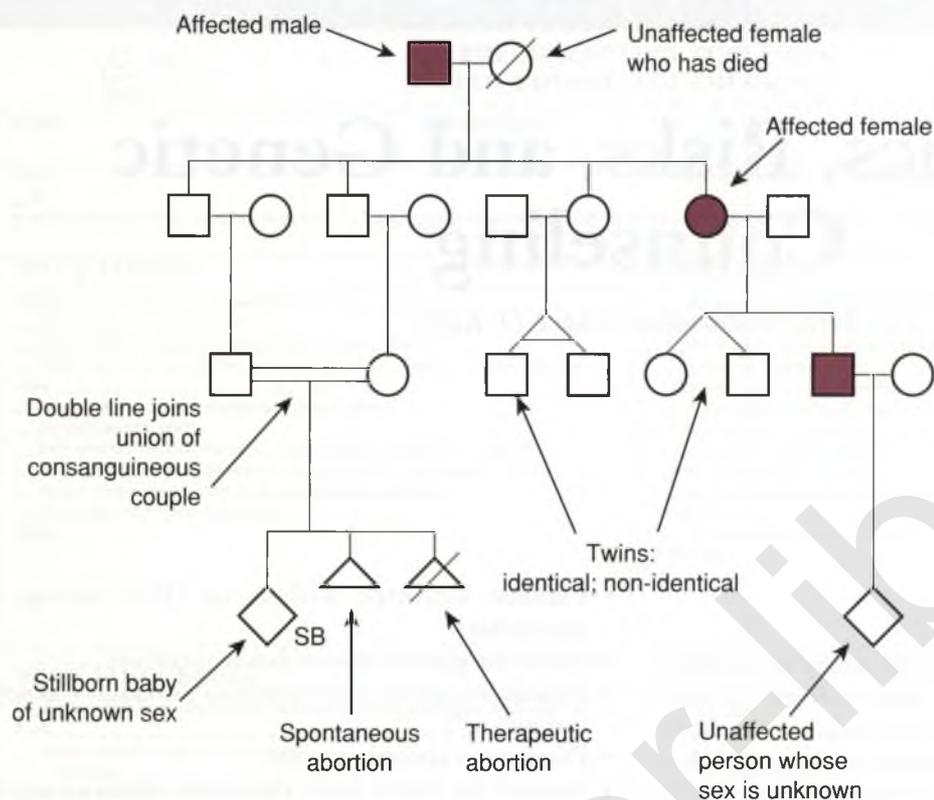
PEDIGREE SYMBOLS


FIGURE 2–1
Symbols used in drawing a pedigree.

- Note parental occupations, medical and drug history, and pregnancy and birth history, especially when a child has a dysmorphic syndrome.
- Record at least basic details for both sides of the family, even when it appears that a disorder is segregating on one side.
- Ask about consanguinity: "Are you and your partner related? Are there any surnames in common in the family?"
- Date and sign the pedigree.

When the mode of inheritance is certain from the diagnosis (e.g., a known autosomal recessive condition), it may not be necessary to record personal details about all family members in as much detail as would be required for an unknown disease.

It is recommended to seek the couple's consent to share their medical information and test results with other family members.

Interpretation of the Pedigree

The precise pattern of affected members may suggest dominant, recessive, or X-linked inheritance, as discussed later. Inherited chromosomal anomalies may show a pattern of unaffected members having children with multiple anomalies and/or several pregnancy losses (Table 2–1).

Consanguinity does not prove autosomal recessive inheritance, but makes it more likely. An isolated case can still have a genetic cause. Illegitimacy may explain discrepancies.

Confirmation of the Diagnosis

Accurate genetic information requires a precise diagnosis. The diagnosis may need to be confirmed by referral to a specialist, who may be able to identify clinical subtypes that have different modes of inheritance. Confirmatory documents, such as specialists' letters and laboratory or necropsy results, may also be required. Apparently unaffected individuals may need to be assessed to exclude mild or early disease, especially in autosomal dominant disorders, such as neurofibromatosis, tuberous sclerosis, myotonic dystrophy, retinitis pigmentosa, and adult polycystic kidney disease.

Genetic Counseling

Genetic counseling is not solely giving a risk figure. Harper[1] defined it as "the process by which patients or relatives at risk of a disorder that may be hereditary are given information about the consequences of the disorder, the probability of developing and transmitting it and the ways in which it may be prevented or ameliorated."

Providing Genetic Counseling

The provision of clinical genetic services varies between countries. In the United Kingdom, trained clinical

TABLE 2–1

Establishing the Mode of Inheritance

Autosomal Dominant Inheritance

Males and females affected in equal proportions
Transmitted from one generation to next ("vertical transmission")
All forms of transmission are observed (i.e., male to male, female to female, male to female, and female to male)

Autosomal Recessive Inheritance

Males and females affected in equal proportions
Individuals affected in a single sibship in one generation
Consanguinity in the parents provides further support

X-Linked Recessive Inheritance

Males affected almost exclusively
Transmitted through carrier females to their sons ("knight's move" pattern)
Affected males cannot transmit the disorder to their sons

X-Linked Dominant Inheritance

Males and females are affected but affected females occur more frequently than affected males
Females are usually less severely affected than males
Affected females can transmit the disorder to male and female children, but affected males transmit the disorder only to their daughters, all of whom are affected

Inherited Chromosomal Anomalies

May give a pattern of unaffected family members having children with multiple abnormalities with growth and developmental retardation
The hallmarks of chromosome anomalies are multiple organ systems affected at different stages in embryogenesis
May give a pattern of multiple pregnancy losses

Mitochondrial Inheritance

If all the children of affected mothers are affected, but no children of affected fathers, consider the possibility of mitochondrial inheritance.

An Apparently Isolated Case

Could be caused by a:

- Phenocopy (caused solely by environmental factors)
- New dominant mutation
- More severe expression in a child of a dominant disorder in a parent
- Recessive condition
- X-linked condition (if a male)
- Chromosome anomaly (either inherited or spontaneous)
- A combination of environmental influences on a genetic predisposition

geneticists, usually supported by a team of genetic counselors, are usually based in tertiary referral centers, but most have clinics in district hospitals.

As part of clinical care, most obstetricians give genetic information about common chromosomal trisomies found at prenatal diagnosis, for instance, but seek advice from a clinical geneticist for DNA diagnosis, familial chromosomal disorders, single-gene disorders, and malformation syndromes.

Giving Genetic Information

Genetic information should be given in a nondirective manner, presenting facts, discussing options, and helping couples and families to reach their own decisions. It may

not be easy to be completely nondirective because the professional's views can affect the tone and manner of presentation of the information. There is no "right" or "wrong" decision; a couple must make a decision that they believe is right for them. Whenever possible, the partners should be seen together when discussing genetic information or abnormalities found at prenatal diagnosis.

Timing

Couples who consider themselves to be at potentially high risk for a genetic disorder and who have sought genetic information before embarking on a pregnancy have time to decide which option is the most appropriate.

The diagnosis of a serious genetic disorder or malformation syndrome during pregnancy may require difficult management decisions to be made relatively quickly. The family may have little time to understand the severity and consequences of the disorder, identify the options (including available treatments), and discuss the genetic implications. Families want to know whether the condition is lethal or severely disabling, whether there is a high risk that a future pregnancy will be affected, and whether specific prenatal diagnosis would be available.

Genetic information may play an important role in the consideration of options for future pregnancies and clinical management of the current pregnancy. Options include the following:

- Having no (more) children
- Accepting the risk
- Undertaking prenatal diagnosis, if available
- Seeking adoption
- Having gamete donation
- Seeking preimplantation diagnosis

A couple's choice will depend on social, economic, moral, and practical factors, among others.

DETERMINING RISKS

The mathematical "risk of recurrence" can usually be derived with certainty for a single-gene (mendelian) disorder. For other conditions, empirical figures must be used (discussed later).

Explaining Risks (See also Chapter 1)

Although some people perceive risks only as "high" or "low," most wish to understand how a figure has been reached, when a discussion about modes of inheritance and mechanisms of genetic disease may be helpful. Expressing a risk figure as a fraction (e.g., 1 in 2, 1/2), as odds (50:50), or as a percentage (50%) is less likely to lead to confusion. The perception of what constitutes "high" or "low" risk varies with the individual. Some

families find it easier to understand risk figures presented as odds, whereas others prefer to discuss these figures as percentages. Most clinical geneticists use both odds and percentages during a consultation, concentrating on the one that the patients find easiest to understand.

The decision as to what constitutes an "acceptable" risk varies with the disorder and the individual. However, providing some reference points (Table 2–2) may be helpful.

Genetic Risk: Burden and Probability

A "risk" figure has two components: the probability that the condition will occur and the burden of the disease. Families may view the same mathematical figure entirely differently. For example, for autosomal dominant conditions with a "1 in 2" risk, the family may view the effect of the disease as mild (e.g., brachydactyly) or very severe (e.g., Huntington disease). Their view may also be affected by whether screening and treatment are available (e.g., bilateral retinoblas-

toma, adenomatous polyposis coli). Such issues may need to be discussed during the genetic consultation.

TABLE 2–2

Examples of Approximate Reproductive Risks in Developed Countries

	RISK	
REPRODUCTIVE OUTCOME	ODDS	%
Infertility	1 in 10	10.0
Pregnancy ending in a spontaneous miscarriage	1 in 8	12.5
Perinatal death	1 in 30 to 1 in 100	1.0
Birth of a baby with a congenital abnormality (major and minor)	1 in 30	3.3
Birth of a baby with a serious physical or mental handicap	1 in 50	2.0
Death of a child in the first year after the first week	1 in 150	0.7

SUMMARY OF MANAGEMENT OPTIONS
Genetics, Risks, and Genetic Counseling

Management Options	Quality of Evidence	Grade of Recommendation	References
Population Genetic Screening			
Policies vary on the basis of:	IV	C	2, 3
• Financial constraints			
• Prevalence and health burden of the conditions			
• Political issues			
If screening is implemented, patients should be given the following information:	IV	C	2,3
• Nature of the medical condition			
• Mode of inheritance			
• Reliability of the screening test			
• Procedures for giving results			
• Implications for their future, their existing children, and their family members if the screening test result is positive			
• Possibility that genetic screening may result in unexpected information being revealed			
General (Prepregnancy, Prenatal, and Postnatal)			
Families with single-gene disorders and parental chromosomal anomalies have the highest risks and may be detected by taking a family pedigree.	IV	C	1
Adequate time should be made available in a quiet setting that is free from interruptions.	IIa	B	40
Both partners should be seen together whenever possible.	IIb	B	41
Obtain accurate and comprehensive information to make a secure diagnosis, including taking a family pedigree.	IIa	B	40
Provide nondirective and supportive counseling.	III	B	42, 43
Ensure that stated risks are accurate and up-to-date.	IIa	B	40
What constitutes an "acceptable" risk to an individual varies with the disorder because a risk figure has two components: The probability of occurrence and the burden of disease.	III	B	43
Consider referring complex cases to a clinical geneticist.	III	B	42

TYPES OF GENETIC DISORDERS: MECHANISMS AND RISKS

Humans have approximately 23,000 genes arranged on 23 pairs of chromosomes that allow their physical transmission from cell to cell and generation to generation. Generally, gain or loss of gene function is the underlying mechanism for single-gene and chromosomal disorders. However, isolated congenital anomalies are often the result of multifactorial inheritance. In multifactorial disorders, the condition develops in individuals with a liability above a particular threshold. The liability is composed of "environmental" components that act with a genetic predisposition caused by the summation of the effects of several genes.

CONDITIONS WITH MENDELIAN INHERITANCE: SINGLE-GENE DISORDERS

General

Single-gene (mendelian) disorders behave as though they are under the control of only one pair of genes. They have high risks of recurrence. This mode of inheritance is usually recognized by a combination of clinical diagnosis and pedigree pattern.

Risks can usually be determined from knowledge of the mode of inheritance of a particular condition. However, some conditions, such as retinitis pigmentosa, have dominant, recessive, and X-linked forms, so care is needed.

For many mendelian conditions, DNA tests are available for presymptomatic diagnosis, carrier detection, and prenatal diagnosis (Table 2–3). Up-to-date information should be sought from a clinical genetics department because advances are too rapid for published literature to remain current. In addition, access to online databases is helpful (Appendix). Prenatal diagnostic possibilities may have changed by the time a couple is considering having another child.

Autosomal Dominant Inheritance (Fig. 2–2)

A dominant trait manifests in a heterozygote (a person with both the abnormal and the normal alleles) and is usually transmitted from one generation to the next ("vertical transmission") [see Fig. 2–2]. Each offspring of a parent with an autosomal dominant trait has a 1 in 2 chance of inheriting the disease gene. Autosomal dominant traits can exhibit variable expressivity, reduced penetrance, and sex limitation. The effects on a fetus from a dominant disorder may be more difficult to predict than suggested by the straightforward simple probability of 1 in 2 of inheriting the disease gene.

Some dominant conditions are so variable in their expression that careful physical examination is needed to detect the minute signs that a parent has the gene. For

TABLE 2–3
Examples of Common Single-Gene Disorders* Detected by DNA Diagnosis

Dominantly Inherited Disorders

Achondroplasia
Adult polycystic kidney disease
Breast cancer (some families)
Familial adenomatous polyposis coli
Familial hypercholesterolemia
Hereditary motor and sensory neuropathy
von Hippel-Lindau disease
Huntington's disease
Marfan syndrome
Multiple endocrine neoplasia
Myotonic dystrophy
Neurofibromatosis
Tuberous sclerosis

Recessively Inherited Disorders

α-1 Antitrypsin
Congenital adrenal hyperplasia
Cystic fibrosis
Friedreich's ataxia
Sickle cell disease
Spinal muscular atrophy
Tay-Sachs disease
Thalassaemia

X-Linked Disorders

Alport syndrome
Becker muscular dystrophy
Duchenne muscular dystrophy
Fragile X syndrome
Hemophilia A and B

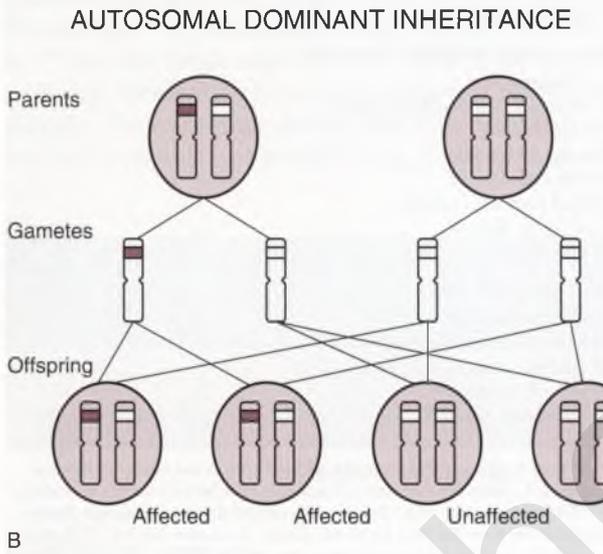
*For gene tracking, DNA from the affected person and family studies are required. Consult the Regional Clinical Genetics Service for the availability of DNA diagnosis in other diseases; it is potentially possible for all diseases in which the gene has been localized. Online databases that list DNA tests provided by genetic laboratories are increasingly available. To ensure clinical reliability and validity, it is important to confirm that laboratories that offer testing are part of recognized quality control programs and to ask about the experience of the laboratory with the particular test.

instance, freckles in the axilla may be the only sign of neurofibromatosis. For some disorders, a fetus may be considerably more affected than the affected parent. For example, the increase in size during maternal transmission of a trinucleotide repeat associated with the gene causing myotonic dystrophy can result in the congenital form of myotonic dystrophy: The parent has minor signs of the disease but the child is severely affected. However, the phenotypes of other dominant conditions never vary (e.g., achondroplasia).

Very rarely, a person who carries the gene for an autosomal dominant condition (with an affected parent and an affected child) has no physical signs of the condition. The gene is said to be "nonpenetrant" in the person who has no signs of the disease.

Some autosomal dominant conditions appear to occur sporadically. If there is no family history and both parents are found to be unaffected after appropriate examinations and investigations, then the child's disease is likely to be caused by a new mutation. The recurrence risk for parents is low, but the child has a 50% risk of passing on the

AUTOSOMAL DOMINANT INHERITANCE

AUTOSOMAL DOMINANT INHERITANCE


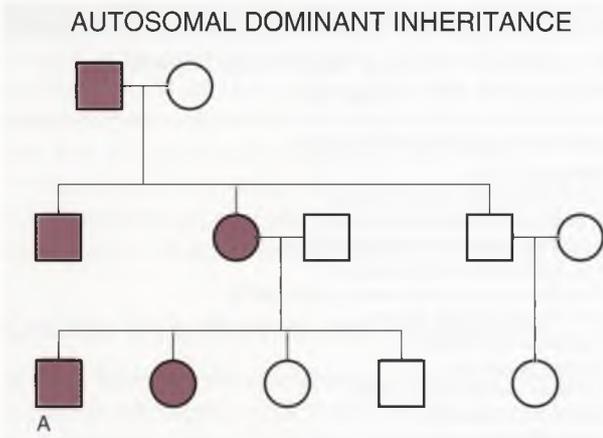


FIGURE 2–2
Single-gene disorders: examples of pedigrees and modes of inheritance. *A*, Autosomal dominant inheritance. Three generations are affected, and male-to-male transmission is shown. *B*, Autosomal dominant inheritance. If one parent is affected by a dominant condition, each offspring has a 50% (1 in 2) risk of inheriting the gene.

disease to offspring. There is a slight chance that a parent of a child with an apparently new dominant mutation has gonadal mosaicism. In this case, the germ line contains two populations of cells: one with the mutation and one with the normal gene. This situation explains the rare cases in which unaffected parents have two children with the same autosomal dominant condition.

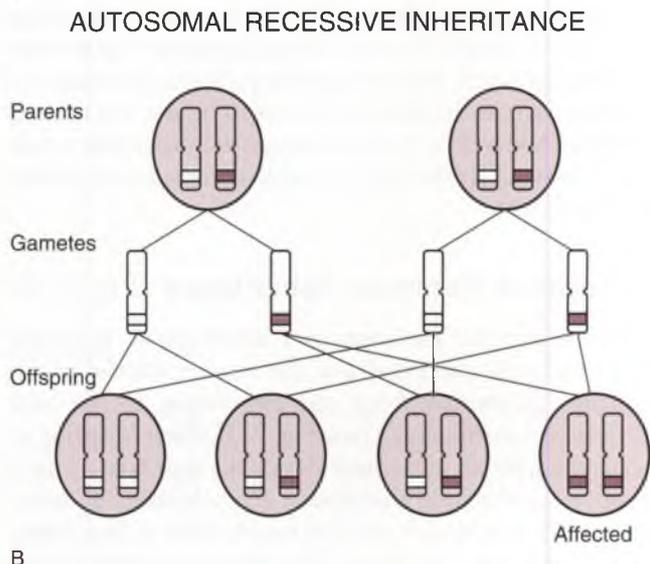
Autosomal Recessive Conditions (Fig. 2–3)

Autosomal recessive disorders are manifest only in the homozygous state: the affected person has two copies of the abnormal gene. Heterozygotes (carriers) are normal. When parents are heterozygous for the same autosomal recessive condition, each offspring has a 1 in 4 chance of being affected. An unaffected sibling of an affected person has a 2 in 3 chance of being a carrier (see Fig. 2–3). If an affected person reproduces, the children will be at risk only if the partner is a carrier for the same autosomal recessive condition.

Carriers for some inborn errors of metabolism can be identified by biochemical tests. Unfortunately, for many disorders, the range of results for carriers overlaps with the range of results for noncarriers, with test results generating a probability of being a carrier rather than giving a definitive answer. DNA techniques allow diagnosis of the carrier state for some autosomal recessive conditions in some families. This "genetic testing" is offered when other evidence (usually being closely related to an affected person or a known carrier) suggests increased risk.

For some conditions, DNA diagnosis can be offered to members of a general population with a high proportion of carriers for a specific mutation. In this case, carrier risks can be altered for couples who have no family history. This "genetic screening" is discussed in more detail later.

AUTOSOMAL RECESSIVE INHERITANCE

AUTOSOMAL RECESSIVE INHERITANCE


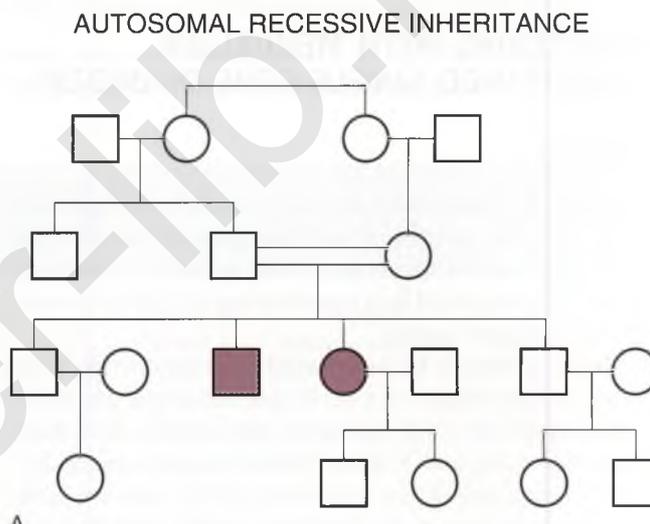


FIGURE 2–3
Single-gene disorders: examples of pedigrees and modes of inheritance. *A*, Autosomal recessive inheritance. Siblings in only one generation are affected. In this family, the parents are first cousins. *B*, Autosomal recessive inheritance. If both parents carry the same abnormal gene for a recessive condition, their offspring have a 25% (1 in 4) risk of inheriting the abnormal gene from both parents and therefore being affected.

Unless the disorder is very common or unless consanguinity is present, the risks for half-siblings, children of affected individuals, and especially children of unaffected siblings are minimally increased over the risks in the general population. The precise risk depends on the frequency of heterozygotes in the population and can be calculated using mendelian principles.

Some couples request sterilization after the birth of a child with an autosomal recessive condition. Very sensitive handling of this request is needed. If the parents separate, either parent may form a new relationship with an unrelated partner; in this case, it is likely that the risk of recurrence would be low.

X-Linked Recessive Inheritance (Fig. 2–4)

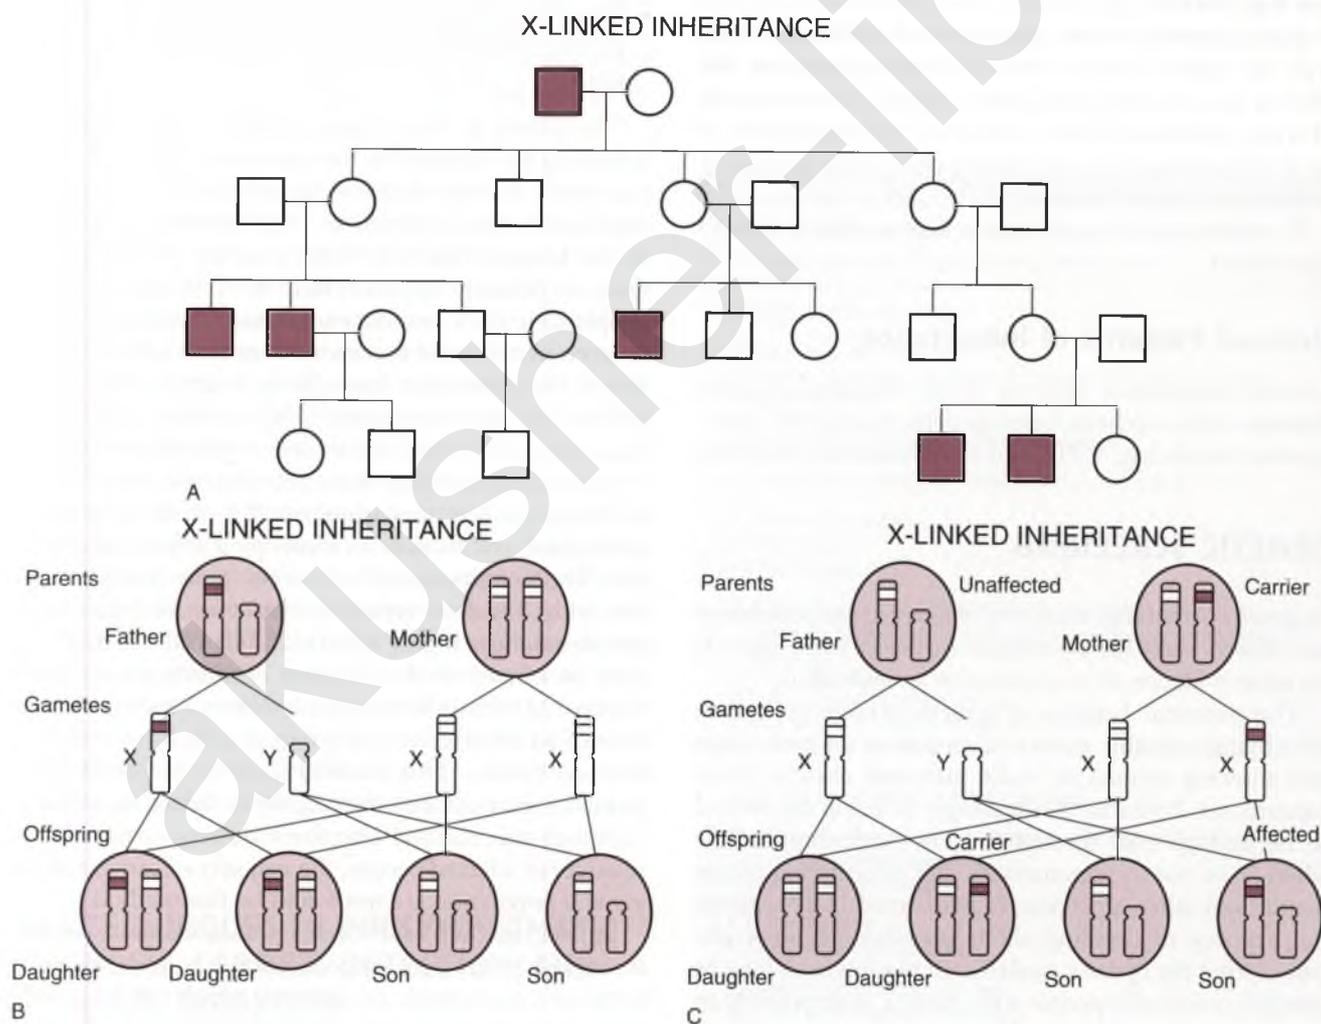
Although males and females have similar sets of the 22 pairs of autosomes, the sex chromosome pair is different. Females have two X chromosomes, whereas males have one X chromosome and a Y chromosome. Because sex-linked recessive traits are determined by genes on the X chromosome, they usually manifest only in males because males have a single copy of the genes on the X chromosome. Although females have two copies of the X chromosome, one is inactivated at random early in gestation. In an individual female cell, the genes from either the paternal or the maternal X chromosome are active and most of the genes on the other X chromosome are silenced. Therefore, a female who is heterozygous for an X-linked condition will be a mosaic of normal and affected cells. The proportions of each type in a given tissue are related to the chance pattern of X inactivation. For this reason, carrier detection in X-linked recessive disorders may be difficult. For example, approximately 30% of known carriers of Duchenne muscular dystrophy have biochemical carrier test results within the normal range,


FIGURE 2–4

Single-gene disorders: examples of pedigrees and modes of inheritance. *A*, X-linked inheritance. In this family, the grandfather has a nonlethal X-linked disorder (e.g., hemophilia). Males affected in several generations are linked through unaffected females. Daughters of affected men are obligatory carriers. *B*, X-linked recessive inheritance in which a father is affected. If a father has an X-linked condition, all of his daughters will be carriers, but none of his sons will be affected. (Sons inherit his Y chromosome; that is why they are male!) *C*, X-linked recessive inheritance in which a mother is a carrier. If a woman carries a gene for a recessive condition on one of her X chromosomes, each of her sons has a 1 in 2 risk of being affected and each of her daughters has a 1 in 2 risk of being a carrier.

presumably because, by chance, relatively few muscle cells express the abnormal gene in these women. Many cases of the more serious X-linked diseases are caused by new mutations, which makes counseling difficult unless reliable techniques for carrier detection are available. However, DNA techniques may be able to answer these questions with high precision, either by direct detection of a mutation or by gene tracking (discussed later).

A son of a woman who is heterozygous for an X-linked recessive disorder has a 1 in 2 chance of inheriting the disease allele from his mother and of being affected (see Fig. 2–4C). A daughter also has a 1 in 2 chance of inheriting the disease allele, but would be expected to be an unaffected carrier. (Women who are carriers for the fragile X mental retardation syndrome can have daughters who are mentally handicapped; because of the complexities involved, patients should be referred for genetic counseling.)

Daughters of affected males are obligate heterozygotes (see Fig. 2–4B).

Rarely, females show signs of an X-linked recessive trait or disease because they are homozygous for the allele (e.g., color blindness), have a single X chromosome (Turner syndrome), have a structural rearrangement of an X chromosome, or are heterozygous with skewed or nonrandom X inactivation.

If male-to-male transmission is shown, then X linkage is excluded.

Unusual Patterns of Inheritance

Unusual inheritance patterns can be explained by phenomena such as genetic heterogeneity, mosaicism, anticipation, imprinting, UPD, and mitochondrial mutations.

GENETIC SCREENING

In genetic screening, members of a particular population are offered a test for a condition or defect when there is no prior evidence of its presence in an individual.

The potential benefits of genetic screening include identifying treatable genetic disorders at an early stage and allowing couples to make informed choices about parenthood. Potential disadvantages of being discovered to be at high risk through genetic screening include whether or not to communicate the information to the family, and when screening is performed in pregnancy, the urgency of deciding about prenatal diagnosis and considering the options available. In the future, it may be possible to identify people with genetic susceptibility to common serious diseases. However, the advantages of early identification will need to be weighed against possible adverse effects on employment prospects and the ability to obtain insurance.

Guidelines for genetic screening programs have been recommended by several organizations.[2–5] These are helpful in determining the aims, limitations, scope, and ethical aspects of a genetic screening program as well as considerations for the storage and registration of data or material, the need for follow-up (including social consequences), and the risk of side effects.

People undergoing genetic investigations are entitled to receive sufficient information about what is proposed and about substantial risks in a way they can understand. They should be given time to decide whether or not to agree to what is proposed. They must be free to withdraw at any time.

Specifically, they should receive information about the following:

- Nature of the medical condition
- Mode of inheritance
- Reliability of the screening test
- Procedures for giving results
- Implications for their future, their existing children, and family members if the result is positive
- Possibility that genetic screening may result in unexpected information being revealed (e.g., non-paternity)

The debate in the United Kingdom over population screening for carriers for the autosomal recessive condition cystic fibrosis illustrates many of these points. The disease is common, with 1 in 25 of the white population in the United Kingdom being a carrier. Routine DNA tests can identify approximately 85% of carriers; these people have the common mutations. A "negative" result for commonly tested mutations does not exclude a member of the population from being a carrier, but greatly reduces the risk. In contrast, DNA testing for sickle cell disease would be expected to detect virtually all carriers.

The current program for screening newborns for cystic fibrosis covers approximately 18% of the population of England and focuses on identifying affected individuals. The incorporation of direct gene analysis into screening based on serum immunoreactive trypsinogen measurement is highly effective.[6] "Cascade testing" can then be offered to the relatives of affected individuals. Compared with other methods, offering testing to relatives of an affected person produces a high ratio of positive test results. This method is up to ten times more powerful than unfocused screening in detecting carriers.[7] Although this method effectively detects carriers in the relatives of affected people, the majority of carriers in the general population are not found by this method.

Indeed, making a CF carrier test available to anyone interested in the general population has been shown to result in a low uptake. In contrast, a high uptake (>70%) followed an invitation during pregnancy to be screened by an interested health professional. However, screening during pregnancy may not allow people to be fully informed or high-risk couples to have the choice of all options.[8] A "two-step" approach in pregnancy has been studied,[9] in which the woman was tested first and test-

ing was offered to men whose partner was found to be a carrier. However, considerable anxiety may occur when the woman is determined to be a carrier and the man is not. An alternative procedure is to regard the couple as the screened unit and to provide information on carrier status only when both partners are carriers.[10]

When the mutations that cause cystic fibrosis in an affected person have been identified, definitive carrier testing is available for family members.

The term "genetic testing" is used when an individual is tested for a condition or defect that other evidence suggests may be present. This may be to confirm a diagnosis or to test for carrier status within a family. Although the same laboratory procedure may be used for both genetic screening and genetic testing, there are important clinical conceptual differences. Those undergoing genetic testing are likely to have more knowledge about the genetic implications because they were identified as being at high risk because of their family history. This is unlikely to be the case in a genetic screening program, where education and information have been shown to be key factors in successful programs (e.g., a carrier screening program for thalassemia in Cyprus, screening for Tay-Sachs disease in Montreal).

The optimal timing of the testing procedure changes as a community becomes more informed. For example, a screening program that is designed to detect newborns affected with a recessive disorder so that treatment may be instituted may encourage relatives to undergo carrier testing. This can increase awareness of the benefits of antenatal screening and may lead to an offer of testing to couples or individuals in the general population[4] before pregnancy. Some communities encourage individuals leaving school to be tested.[5]

It is widely accepted that predictive genetic testing of children should be offered when the condition occurs in childhood or when treatment can be offered, but children should not be tested for adult-onset genetic disease (unless specific preventive measures are available) nor for carrier status until they are old enough to decide whether to undergo testing.[11] However, the U.K. national neonatal screening program to identify people with sickle cell disease will also detect carriers; clinical practice in the United Kingdom for the carrier testing of children in families with genetic disorders may need to be reviewed.

DNA TECHNIQUES IN PRESYMPTOMATIC DIAGNOSIS, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

DNA techniques can be used in single-gene disorders to allow the following:

- Confirmation of the diagnosis, especially when the clinical features can be equivocal

- Confirmation that a family member has not inherited the disease
- Carrier testing, especially when biochemical testing is not available or the results are equivocal
- Presymptomatic diagnosis so that surveillance can be instituted (e.g., familial adenomatous polyposis coli, some types of breast cancer)
- Prenatal diagnosis, especially for conditions for which biochemical or hematologic testing or ultrasound detection of associated structural anomalies were formerly the only possibilities

Identification of Families for DNA Diagnosis

Families are often identified from the pattern of affected members or when a precise diagnosis is made. Each family must be assessed individually because some techniques rely on the family structure and availability of the necessary DNA samples. Therefore, DNA diagnosis may require considerable time. Families are best referred to a clinical genetics unit before pregnancy for completion of the steps outlined in Table 2–4.

TABLE 2–4

Practice Points for Prenatal Diagnosis by DNA Techniques for Single-Gene Disorders*

Identify families through:

- Previously affected child
- Carrier screening programs for autosomal recessive disease
- Family history

Do they wish to proceed to further testing?

Consider the techniques available for prenatal diagnosis:

- Biochemical assays
- Ultrasound
- DNA diagnosis

Is DNA diagnosis possible? Consult the regional Genetics Services. Check before each pregnancy because of the rate of advances.

- Is the clinical diagnosis secure?
- Has the gene been localized or cloned?
- Is the family structure suitable, and are samples available for testing?
- Is sufficient time available for testing?

Explain procedures and the accuracy of results to family.
Collect appropriate samples.
Order laboratory testing:

- Gene tracking
- Direct mutation detection

Explain the results and options.
Proceed with diagnostic testing:

- Presymptomatic
- Prenatal

---

*A clinical genetics unit can advise and arrange for much of the above. The genetics of some single-gene disorders may be complicated (e.g., retinitis pigmentosa can be inherited as autosomal dominant and autosomal and X-linked recessive).

The Principles of Diagnosis: Gene Tracking and Mutation Detection

Gene Tracking: The Use of Linked DNA Markers

Gene tracking can be used when the chromosomal localization of the disease is known, but the gene has not been isolated. The goal is to identify a DNA marker that is inherited with the disease gene in a family.

The chromosomal region that contains the gene has usually been identified through a linkage study in which many DNA markers spread throughout the genome have been analyzed in families with the disease. After statistical analyses of results from all the families are completed, the chromosomal region that is most likely to contain the gene is identified. This information can be used prospectively for diagnosis in individual families by identifying a familial DNA pattern that is inherited with the disease gene. DNA sequences that vary in length naturally in the population ("polymorphisms") and are next to or within the disease gene are used to

generate these "markers" in a family. A class of highly variable CA repeat markers is usually used (Fig. 2–5). The markers are detected by their different positions on a gel after electrophoresis. Figure 2–6 shows an example of an autosomal recessive disease. The fragment "tracking" with the disease gene can be identified by observing which fragment pattern is common to affected family members. An error is associated with the use of linked markers because recombination may occur between the DNA marker and the disease gene. To minimize the risk of misdiagnosis, markers that show no more than 1% recombination with the disease gene are used whenever possible.

Diagnosis by Direct Detection of a Mutation

The definitive diagnostic test is to show a change in DNA that is predicted to disrupt gene function, and this cause disease. When a mutation is predicted to cause truncation of the protein product (usually through a frameshift mutation

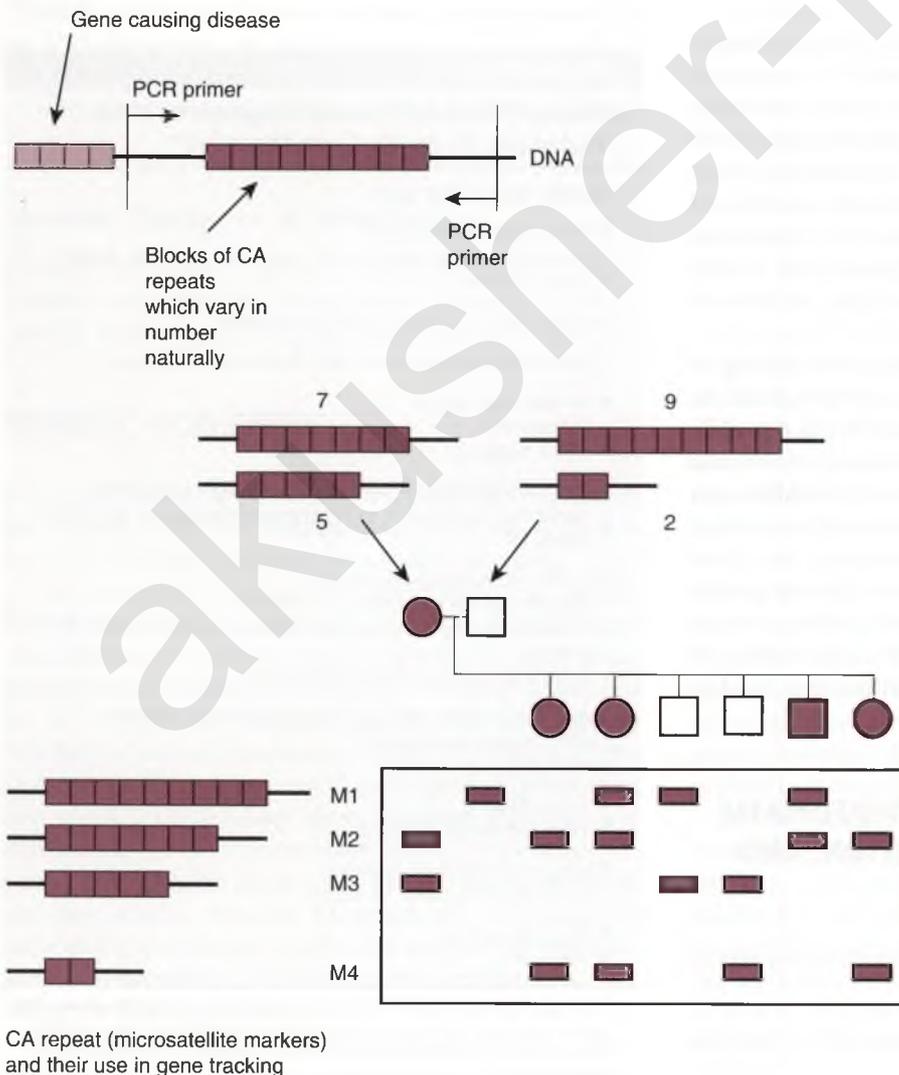
CA repeat (microsatellite markers) and their use in gene tracking


FIGURE 2–5
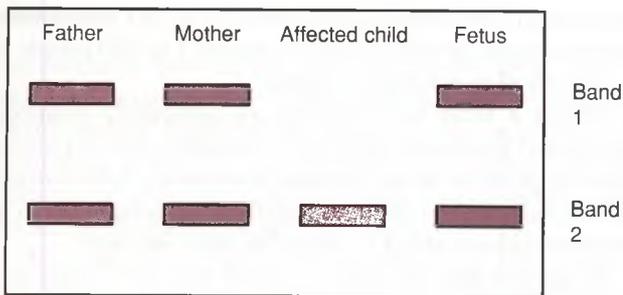
Principles of gene tracking with CA repeat markers. A variable DNA sequence (consisting of two DNA bases, CA, repeated several times) is fortuitously situated immediately in front of a gene that is known to cause a particular disorder. The length of the $CA_{(n)}$ sequence varies from individual to individual and is usually of no significance. Variation in its length is used as a marker tracking the gene of interest in a family. Members of this family whose symbols are blocked in are affected with an autosomal dominant disorder. DNA is extracted from lymphocytes, and the DNA segment containing the CA repeat is amplified by polymerase chain reaction (PCR) so that there are sufficient copies to be visualized. The different $CA_{(n)}$ lengths are separated by electrophoresis. In this family, the father has CA repeats of lengths 9 and 2, and the mother affected by the dominant disorder has repeats of lengths 7 and 5. Because the CA repeat sequence is acting as a marker of the parental disease gene alleles, all affected children have inherited the same maternal $CA_{(n)}$ allele. This marker allele could be used for diagnosis in other family members. In other families with the same condition, however, the disease will be associated with this CA marker system, but the mutated allele that causes the disease could be tracking with a different length of CA repeat. When using gene tracking, a study of each family is needed to determine which allele is associated with the disease gene.


FIGURE 2–6
DNA diagnosis of an autosomal recessive condition by gene tracking. In this family, both parents have two detectable fragments (*1* and *2*) but their son, who is affected with spinal muscular atrophy (SMA), shows only one (*2*). Therefore, the SMA gene must be located on the parental chromosomes that give the fragment labeled *2*. In the next pregnancy, the fetus had two fragments, *1* and *2*, and therefore is predicted to be a carrier, but is not affected with SMA.

or the introduction of a stop codon), this is strong evidence that a pathogenic mutation has been identified. Other sequence changes may be more difficult to interpret, especially missense mutations that result in replacement of one amino acid by another. Additional studies may be needed to determine the likelihood of pathogenicity. These may include testing members of the population to determine if this is a polymorphism or performing a family study to determine whether the DNA change is being inherited with the disease in the case of a dominant disorder, for instance.

For some diseases, common mutations are known (e.g., δ-F508 mutation in cystic fibrosis, G380R mutation in achondroplasia). For most diseases, however, the precise mutation causing the disease in the family must first be identified. Identification may take months, depending on the structure of the gene and the laboratory techniques used. Many laboratories use an initial screening test, but techniques such as single-strand conformation polymorphism (SSCP) appear to detect only approximately 80% of mutations, depending on the gene. It has been argued that direct DNA sequencing of a gene is the "gold standard," but although this method should detect coding sequence variants, it does not detect deletions or large rearrangements. After the mutation is identified, other family members can be offered definitive diagnosis. Even when the genetic code of a gene is known, gene tracking may have to be used if technical constraints make direct mutation testing impractical.

CHROMOSOMAL ABNORMALITIES

The Karyotype Report: Nomenclature

Karyotyping is labor-intensive because high-resolution (extended) chromosome preparations reveal more than 850 bands. These bands are usually analyzed by light microscopy, although computer imaging is beginning to have a major effect. Occasionally, only limited analysis may be possible because of poor elongation of the chromosomes.

The human chromosome composition is reported in an internationally agreed format that gives a precise description of an abnormality. The format has three parts that are separated by a comma: the total number of chromosomes seen, the sex chromosome constitution, and the abnormalities or variants.

- The first figure gives the total number of chromosomes (e.g., 46, 45, 47).
- The second part gives the sex chromosome complement (e.g., XX, XY, X, XXY).
- The third part describes abnormalities or variants affecting the following:
  - Whole chromosomes
  - Arms of chromosomes

The short arm of a chromosome is designated "p" (for *petit*), and the long arm is designated "q" (the next letter in the alphabet). Each arm is further subdivided into bands and subbands.

Breakpoints involved in structural rearrangements are described according to the arm involved, the region of the arm, and then by band and subbands within that region. For example, band Xq27.3 is found on the long arm of the X chromosome, in region 2, band 7, and subband 3. Further examples are given in Table 2–5.

Molecular Cytogenetic Techniques

Some syndromes are caused by submicroscopic deletions of chromosomal material. Molecular techniques (usually fluorescence in situ hybridization, FISH) can be used for diagnosis when the loss or gain of material is beyond the limit of light microscopy. This technique is also helpful for determining the origin of chromosomal material.

This method can also be applied to interphase nuclei to determine the numbers of copies of specific chromosomes, particularly as a rapid screening test for common trisomies.

A Parent with a Chromosome Anomaly

Chromosomal Translocations

A translocation is formed when there has been transfer of material between chromosomes, requiring breakage of both chromosomes, with repair in an abnormal arrangement. If the exchange results in no loss or gain of DNA, the individual is clinically normal and is said to have a "balanced translocation." Such a translocation carrier is, however, at risk of producing chromosomally unbalanced gametes, which may result in a chromosomally abnormal baby, miscarriages, still birth, or infertility depending on the origin and amount of chromosome material involved.

When a translocation is found, other family members should be offered testing for carrier status because of the potentially high risks of having offspring with unbalanced forms of the translocation. Clinical genetics services are used in contacting and dealing with such families.

TABLE 2–5

Examples of Cytogenetic Nomenclature

Normal

46,XX Normal female

Sex Chromosome Aneuploidies

45,X Monosomy X (Turner syndrome)
47,XXY Klinefelter syndrome
45,X/46,XX Mosaic Turner syndrome

Autosomal Aneuploidies

47,XY, +21 Male with trisomy 21 (Down syndrome)
47,XX, +13 Female with trisomy 13 (Patau syndrome)

Polyploidy

69,XXY Triploidy

Deletions

46,XX,del(18)(q21) Deletion of part of the long arm of one
    chromosome 18 from band q21 to the end of the long arm
    (qter)
46,XX,del(17)(p13) Female karyotype with a deletion of part of
    the short arm of chromosome 17, from band p13 to the end
    of the short arm (pter)

Translocations

46,XY,t(2;12)(p14;p13) Male with a balanced reciprocal
    translocation between chromosomes 2 and 12, with
    breakpoints on the short arms, at p14 on chromosome 2 and
    at p13 on chromosome 12
46,XX,der(2)t(2;12)(p14;p13)mat Female with an unbalanced
    complement, having received the derivative chromosome 2
    from her mother, who carries a translocation between
    chromosomes 2 and 12; this child would have too little
    material from chromosome 2 (from p14 to pter) and an
    additional copy of material from chromosome 12 (from p13
    to pter), making her effectively monosomic for 2p and
    trisomic for 12p
45,XY,rob(14;21)(q10q10) Carrier of a Robertsonian
    translocation between one chromosome 14 and one
    chromosome 21

Other

46,XY,inv(5)(p14;q15) Pericentric inversion of one
    chromosome 5
46,XX,r(15) Female with one normal and one ring
    chromosome 15
46,XY,fra(X)(q27.3) Male with a fragile site in subband 27.3 on
    the X long arm
46,XX,add(20)(p13) Additional material of unknown origin
    attached to band p13 on one chromosome 20

Generally, the smaller the segment involved, the greater the chance of viable offspring. The cytogenetic literature may show whether the birth of a viable child with the potential unbalanced products of the particular translocation has been reported. It may be possible to calculate a theoretical risk figure, so the clinical genetics or cytogenetics services should be consulted. For most couples, the precise risk figure is not the vital consideration because fetal karyotyping in future pregnancies can determine whether the fetus has inherited an abnormal arrangement of chromosomal material.

There are two types of translocations:

RECIPROCAL TRANSLOCATION

In reciprocal translocations, chromosomal material distal to (i.e., beyond) the breaks in two chromosomes is exchanged. The long or short arms of any pair of chromosomes may be involved. Approximately 1 in 500 people is a reciprocal translocation carrier.

When a fetus has inherited an apparently balanced reciprocal translocation from a clinically normal parent, there appears to be no increased incidence of phenotypic abnormality in the child, especially if the translocation is present without effect in several family members.

It appears that the risk of a child with the "balanced" parental karyotype having phenotypic abnormalities due to theoretical possibilities (such as the translocation having a cryptic unbalanced component beyond the resolution of conventional cytogenetics, or uniparental disomy) is remote in practice. A cryptic unbalanced complement is more likely if the parental translocation is de novo.

ROBERTSONIAN TRANSLOCATION (CENTRIC FUSION)

A Robertsonian translocation is one in which effectively all of one chromosome is joined end-to-end to another. Robertsonian translocations involve the acrocentric chromosomes (13, 14, 15, 21, and 22) and are among the most common balanced structural rearrangements in the general population, with a frequency in newborn surveys of approximately 1 in 1000.

Centric fusion may arise from breaks at or near the centromere in two acrocentric chromosomes, with the two products fusing together. This usually results in the production of a single chromosome and most frequently involves chromosomes 13 and 14. Next in frequency are chromosomes 14 and 21. Clinically, the most important fusions are those involving chromosome 21, which give rise to familial Down syndrome.

For female carriers of a Robertsonian 14;21 translocation, the risk of having a liveborn infant with Down syndrome is approximately 10%. The risk is approximately 1% for a male carrier.

A Robertsonian translocation involving both copies of chromosome 21 is rare, but all children of a carrier will have Down syndrome.

Where a Robertsonian translocation involves chromosome 15 and a balanced translocation karyotype is detected at prenatal diagnosis, it is appropriate to offer testing for uniparental disomy (UPD). This is to exclude Angelman syndrome or Prader-Willi syndrome in the fetus caused by UPD for chromosome 15. This can occur by postzygotic "correction" of trisomy 15 when one parental chromosome 15 that is not involved in the Robertsonian translocation is lost during mitosis.

Deletions and Duplications of Chromosomal Material

When a patient with partial autosomal monosomy or trisomy is sufficiently unaffected to have children, the risk that the child will inherit the parental chromosomal abnormality is theoretically 50%, as the child can inherit either the normal homologue or the chromosome with the deletion or duplication.

Inversions

An inversion (inv) affects just one chromosome, with a segment between two breaks inverted and reinserted. Inversions are found in fewer than 1 in 100 individuals. A pericentric inversion has one break in the short arm and one in the long arm. A paracentric inversion has both breaks in the same chromosome arm.

An inversion carrier is usually phenotypically normal, but the inversion may cause chromosomally unbalanced gametes. For the normal and inverted chromosomes to pair at meiosis, they have to adopt an unusual physical configuration. If a crossover occurs between the inverted and the normal chromosomes, in the inverted segment unbalanced products will result. In theory, the larger the inverted segment, the greater the risk of recombination and the greater the risk of having abnormal liveborn children. In contrast, a viable recombinant product is unlikely to come from a chromosome with an inverted segment that is less than one third the length of the chromosome.

The overall risk of having an abnormal child is approximately 1% when there is no family history of the recombinant form, but the individual risk depends on the precise inversion. If the family is identified through the birth of an individual with a recombinant chromosome, then the risk of having an abnormal liveborn child is 5% to 10%.

An otherwise normal carrier of an inversion that involves one chromosome arm and not the centromere (paracentric inversion) has virtually no increased risk of having a chromosomally abnormal child. There are common inversion variants of chromosomes 1, 9, 16, and Y that do not imply an increased risk.

Parents with Trisomies

Few data are available on the risks associated with the rare occurrence of an individual with trisomy 21 having a child. Affected individuals rarely reproduce. From a literature review of approximately 30 pregnancies, an approximate empiric risk of 1 in 3 of having a child with trisomy 21 has been quoted for females, but the risk of a chromosomally normal fetus having a birth defect or being mentally handicapped could be as high as 30%.[12]

Fetal Chromosomal Anomaly Found on Karyotyping during Pregnancy

Aneuploidies

Most structural chromosomal abnormalities are aneuploidy, numerical abnormalities that involve the loss or gain of one, two, or even whole chromosome sets. These anomalies are most commonly caused by nondisjunction, a process that is more common with increased maternal age. Fraser and Mitchell[13] noted a lack of hereditary factors but an association with advanced maternal age in cases of Down syndrome. Subsequently,

in a study of 350 cases, Shuttleworth[14] reported a considerable proportion of affected infants born to women approaching the climacteric. Bleyer[15] proposed an association with degeneration of the ovum. Antonarakis and associates[16] examined DNA polymorphisms in infants with Down syndrome and showed that 95% of nondisjunction trisomy 21 is maternal in origin.

In the late 1970s and early 1980s, when prenatal diagnosis was in its infancy, eight large studies were carried out to assess the age-specific prevalence of trisomy 21 in live births.[17-24] Some of these studies had incomplete ascertainment and little information about the distribution of maternal age and the effect of selective abortion after prenatal diagnosis.

However, two studies[19,22] had nearly complete ascertainment. Cuckle and colleagues[25] combined the data from these eight surveys on a total of 3,289,114 births to determine the prevalence of trisomy 21 at each maternal age. Regression analysis was applied to smooth out fluctuations in the observed data.

In the 1970s and 1980s, genetic amniocentesis at 16 to 20 weeks was offered to women 35 years of age or older. This group was considered to be at increased risk for aneuploidy. Similarly, these groups were targeted for chorionic villus sampling between 9 and 14 weeks.

Data from these prenatal studies confirmed that the prevalence of trisomy 21 increased with maternal age and that the prevalence was higher during pregnancy than at birth.

Combined data from two multicenter studies of amniocentesis (one in the United States and one in Europe) showed that the prevalence of trisomies 13, 18, and 21 was approximately 30% higher at 16 to 20 weeks than at birth.[26,27] Similarly, data from fetal karyotyping by chorionic villus sampling showed that the prevalence of these aneuploidies was approximately 50% higher between 9 and 14 weeks than at birth (Fig. 2–7).[28]

Ultrasound studies have demonstrated that major chromosomal defects are often associated with multiple fetal abnormalities. Conversely, in a fetus with multiple abnormalities, the frequency of chromosomal defects is high and the relative risk increases with the number of anomalies identified. However, prenatal karyotyping is often performed because the prognosis for the baby may be dictated not only by the combination of structural anomalies identified but also by marked neurodevelopmental morbidity associated with aneuploidy. The frequency of chromosomal defects, such as aneuploidy, increases with maternal age. Traditionally, counseling of patients about the risk of fetal chromosomal defects depends on the provision of live birth indices of trisomy 21. However, with ultrasound screening, the prevalence must be established for all chromosomal defects that are associated with structural and biometric anomalies.

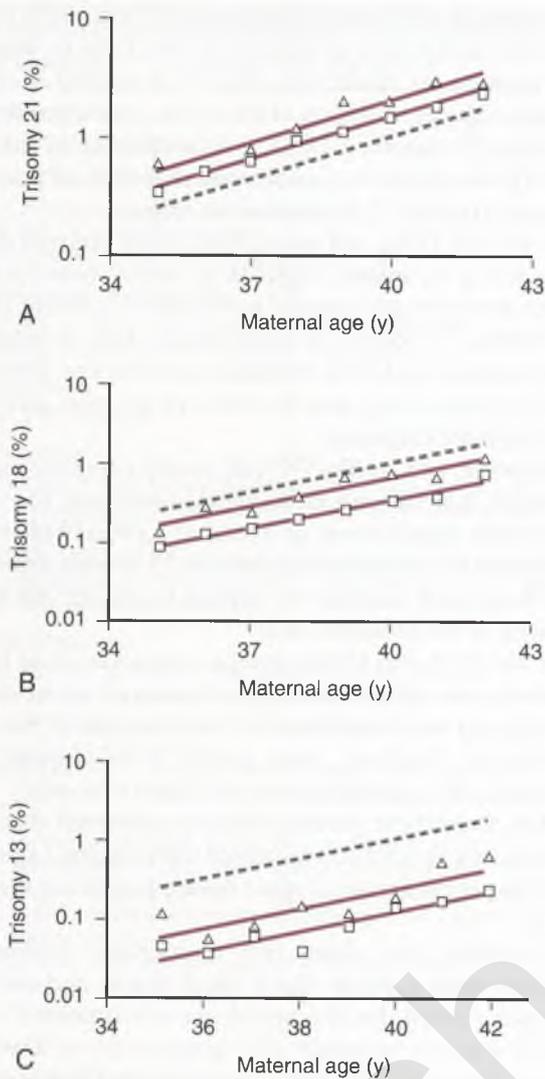
Chromosome anomalies differ in the rate of intrauterine attrition, and it is important to establish maternal and


FIGURE 2–7
The prevalence of trisomy 21 (A), trisomy 18 (B), and trisomy 13 (C) at 9 to 14 weeks' gestation (△) and the prevalence of these trisomies at 16 to 20 weeks (□) compared with the prevalence of live births affected with trisomy 21 (–) in women 35 to 42 years old. (From Snijders RJM, Nicolaides KH: Assessment of risk in ultrasound markers for fetal chromosome defects. In Nicolaides KH (ed): Frontiers in Fetal Medicine. London, Parthenon, 1996.)

gestational age-specific risks for each of the common aneuploidies. Data from a subgroup of women 35 to 42 years old have been used to examine the radiance of regression lines that describe the relationship between maternal age and the prevalence of aneuploidy. For trisomy 21 (see Fig. 2–7A), trisomy 18 (see Fig. 2–7B), and trisomy 13 (see Fig. 2–7C), the increase in frequency is nearly parallel, suggesting that there are no maternal age-related differences in the rate of intrauterine loss. If the prevalence of each of the common trisomies in live births is considered to be 1, then the relative prevalence of other gestational ages can be calculated and relative prevalence curves calculated.

The identification of fetal structural abnormalities leads to a stepwise increase in prevalence risk with each

additional abnormality. A detailed discussion is beyond the scope of this chapter, but may be found elsewhere (See Snijders and Nicolaides, listed in Further Reading). In the last 10 years, the use of first-trimester scanning to measure nuchal translucency (as related to fetal crown–rump length), combined with maternal serum free βHCG and pregnancy-associated plasma protein A, has been used to screen for aneuploidy (see Chapter 7).

Triploidy

Survival to term of fetuses with triploidy is rare, and those born alive die shortly after birth. Most have partial hydatidiform mole, and the rest are nonmolar, with a normal or hypoplastic trophoblast. It is reasonable to offer prenatal karyotyping in future pregnancies. The phenotypes of the fetus and placenta depend on whether the additional set of chromosomes is paternally or maternally derived. The overall recurrence risk is usually low, but diandric triploidy associated with partial hydatidiform mole has a 1% to 1.5% risk of recurrence, and some women appear to have a predisposition for digynic triploidy.

Structurally Abnormal Chromosomes

When an unexpected structural chromosomal abnormality is found, the first step should be to examine the parental chromosomes. If neither parent has the chromosomal abnormality, gain or loss of chromosomal material may have occurred during gamete formation, with consequent severe clinical effects. If the structural anomaly is present in one parent who is otherwise normal, it is unlikely that a similar anomaly in the child will cause severe problems. Exceptions may occur when chromosomes known to be imprinted are involved, principally chromosome 15. Further cytogenetic advice should be sought.

Structurally Abnormal Additional Chromosomes ("Marker Chromosomes")

If a structurally abnormal extra chromosome (marker, supernumerary, accessory chromosome) or a ring chromosome is discovered, parental karyotyping should be performed urgently. Further advice should be sought in counseling these patients because specialized cytogenetic tests (e.g., painting with chromosome-specific fluorescent probes) may be able to determine whether the fetus is at high or low risk by showing the chromosomal origin and nature. These chromosomes are often found in mosaic form with a normal cell line. The ratio of cell lines in tissue used for prenatal diagnosis cannot be used prognostically. There is no accurate information relating to the residual risk of mental retardation when ultrasound examination shows no fetal anomalies.

Mosaicism

Mosaicism occurs when an individual's tissues or organs contain more than one genetic line of cells. The mutant line of cells may contain a chromosomal anomaly or sometimes a mutant single gene. This is a difficult situation because the phenotype lies somewhere between that of a full disorder and that of a normal individual, and further testing is needed. Even so, the proportion of abnormal cells in one tissue may not be the same as the proportion elsewhere. Similarly, exact figures cannot be given for the risk to offspring of individuals with chromosome or single-gene mosaicism because of the very nature of mosaicism. The risk depends on the numbers and disposition of mutant cells in the gonads.

Placental mosaicism with a chromosomally normal fetus is a well-recognized phenomenon (see Chapter 10). Mosaicism for chromosomes 13, 18, and 21 often predicts fetal abnormality. A high incidence of fetal abnormality is associated with mosaic trisomy 9 and mosaic trisomy 22. Mosaicism for a structurally abnormal additional chromosome appears to carry a greater risk than autosomal trisomy mosaicism. However, another concern when autosomal trisomy mosaicism is found at prenatal diagnosis is that a trisomic fetus may have "lost" one of the three copies of the chromosome in some cells to "correct" the imbalance. If both remaining copies of the chromosome originated from the same parent (UPD), this too could give an abnormal phenotype (discussed later).

De Novo Apparently Balanced Structural Rearrangements

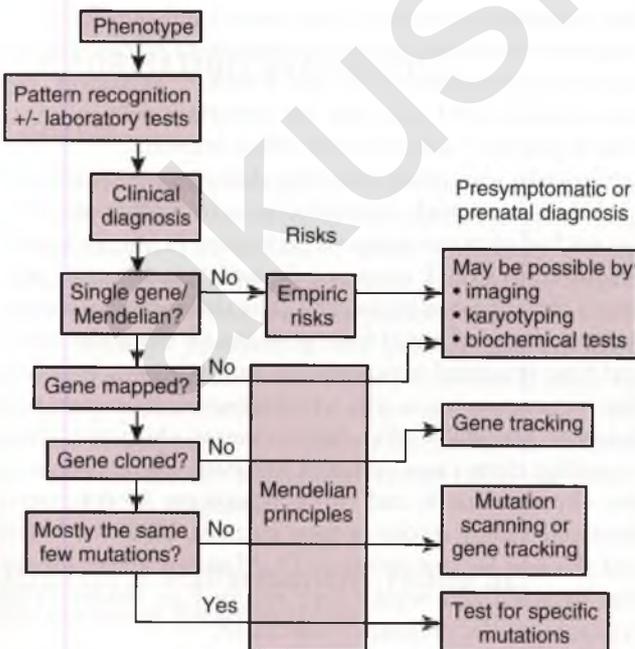
The concern is that there may be a submicroscopic abnormality, either deletion, duplication, or gene disrup-


FIGURE 2–8
A flow chart to assist in determining risks and the appropriate type of presymptomatic or prenatal diagnosis.

tion, involving the breakpoints. Molecular techniques, such as comparative genomic hybridization, may help to determine whether there is cryptic gain or loss of material in apparently de novo rearrangements found at prenatal diagnosis.

De Novo Apparently Balanced Reciprocal Translocation

In a very large study, Warburton[29] found that serious malformations were detected in 6.1% of pregnancies at elective termination or in liveborn infants, which is approximately 3% greater than the background risk of malformation that applies to all pregnancies. No prospective data on the risks of cognitive impairment or mental retardation are available. A figure of 5% to 10% is often used to include malformations and neurologic and developmental deficiencies. Negative scan findings may reduce the risks, but cannot predict cognitive outcome. Congenital malformations found on ultrasound indicate likely chromosomal imbalance.

De Novo Robertsonian Translocation

Because the formation of Robertsonian translocations does not disrupt coding sequences, the risk of phenotypic abnormalities is low. When a Robertsonian translocation involves chromosome 14 or 15, fetal UPD studies may be indicated to exclude the small chance that the fetus inherited both copies of chromosome 14 or 15 from the same parent, resulting in dysmorphic and developmental features because of imprinting effects (discussed later).

De Novo Apparently Balanced Inversions

The risk of phenotypic abnormality is increased if the inversion is de novo. Empirically, the risk appears to be approximately 9%. Figures for cognitive impairment are not available.

Other Chromosomal Abnormalities

Duplication is the presence of two copies of a segment of a chromosome. It may originate from unequal crossing-over during meiosis, with the other product of that cell division being a deletion. Duplications are more common than deletions and are generally less harmful. Specific syndromes are associated with certain deletions, but few phenotypes associated with duplications have been given names.

Loss or duplication of part of a chromosome can result in congenital malformations and mental retardation. The precise features depend on the amount of chromosomal material involved and the chromosome from which it was derived.

The clinical effects of the likely chromosomal imbalance may be found from similar cases in the literature. The recurrence risk for a de novo deletion is very low, but not

zero. Rare recurrences are likely to be caused by parental mosaicism, which is not usually detected by routine karyotyping. Although recurrence is extremely rare, many couples request prenatal diagnosis for reassurance. When the deletion is caused by an unbalanced product from a familial translocation, the risk of recurrence can be high.

Hereditary fragile sites can occur on several chromosomes, giving the appearance of breakage at a specific point. On autosomes, they appear to be harmless. However, a fragile site near the end of the long arm of the X chromosome at Xq27.3 is a marker for fragile X syndrome, an X-linked mental retardation syndrome. Because of the high risks and complex genetics of this single-gene disorder, families should be referred to the clinical genetics department.

OTHER MECHANISMS OF GENETIC ABNORMALITY: UNIPARENTAL DISOMY AND GENOMIC IMPRINTING

Uniparental Disomy (UPD)

The genomic stimulus for fetal growth is affected by the constant constraints of maternal size, placental function, and nutritional sufficiency. However, the expression of certain genes in both the fetus and the placenta is probably crucial to growth potential. It is probable that the placenta can control not only its own size, but through a variety of mechanisms, that of the fetus. Few studies of the genetic control of fetal and placental growth have been done. However, UPD may be a cause of abnormal fetal growth, especially when it occurs without classic risk factors.

Abnormal growth in utero predisposes the fetus to increased perinatal and neonatal morbidity and mortality. In mammals, reproduction requires the fusion of two haploid chromosome sets, one paternal and the other maternal. The fertilized egg then contains two copies of each chromosome. It is usual, and previously has been assumed invariable, for one member of each chromosome pair to be derived from each parent. However, in UPD, one homologous chromosome pair comes from the same parent (in isodisomy, the chromosomes are identical, but in heterodisomy, the two different maternal or paternal chromosomes are inherited). Catanach and Kirk in 1985 showed UPD in mice that resulted in specific abnormal phenotypes associated with growth disturbance.[30] The progeny of mice with maternal disomy of chromosome 11 were smaller than their normal litter mates. Those with paternal disomy 11 were considerably larger than their litter mates.

Recently, cases have been described in human pregnancies where UPD for specific chromosomes have caused a clinical disorder. The first example was an individual with maternal isodisomy 7 and homozygosity for the cystic fibrosis gene.[31] A similar case was subsequently described by Vosse et al, the progeny showing phenotypically short stature.[32]

Other conditions may be associated with UPD and show the following characteristics:

- Occurrence that is usually sporadic
- No consistent cytogenetic abnormalities
- Abnormal growth patterns and rates of growth

Three separate mechanisms have been postulated for UPD:

- Chromosomal duplication in a monosomic somatic cell after postzygotic loss of a homologous chromosome
- Fertilization of a nullisomic gamete by a disomic gamete
- Loss of a supernumerary chromosome from a trisomic cell, leaving two homologues from the same gamete (trisomic rescue)[33]

Supporting the evidence for this has been provided in recent publications.[34,35] The paper by Purves-Smith reported a confined placental mosaicism for trisomy 15, but an apparently normal karyotype on amniotic fluid cytogenetic and postnatal blood analysis.[34] However, at the age of 2 years, Prader-Willi syndrome was diagnosed clinically and maternal disomy 15 confirmed on molecular studies. The second study reported confined placental mosaicism for trisomy 16 in 4 fetuses with severe intrauterine growth restriction.[35] Subsequent skin karyotyping and molecular studies showed a normal karyotype with maternal disomy of chromosome 16.

Alternatively, postzygotic mitotic recombination could result in "mosaic" UPD. This phenomenon was recently identified in four patients with Beckwith-Wiedemann syndrome.

Further mechanisms for UPD include gamete complementation or monosomic zygote correction; the latter has supporting evidence from some isodisomy cases of Angelman syndrome when no evidence of recombination between chromosome 15 was found.[36] Whatever the mechanism, UPD may play an important role in unresolved genetic syndromes that affect growth.

Similarly, we carried out pilot chromosomal studies of 11 babies born with idiopathic growth restriction. The fetuses had prenatal diagnosis performed before 26 weeks' gestation. In the 11 cases, we showed 5 instances of placental chromosomal mosaicism. The chromosomal abnormalities identified varied from trisomies for chromosomes 7 and 8 to structural abnormalities and deletions. In a further six pregnancies in which chromosomal mosaicism was detected prenatally after first-trimester chorionic villus sampling, three cases occurred involving chromosome 7, one chromosome 8, and two chromosome 15 for uteroplacental disomy. In one of these six cases, UPD was found and this was for chromosome 15. Maternal heterodisomy was detected and would have resulted in Prader-Willi syndrome if the pregnancy continued.[37]

Fewer than 100 well-documented pregnancies are reported as having intrauterine growth restriction or fetal death associated with confined placental mosaicism. To date, only 12 chromosomes have been involved: 2, 3, 7, 8,

9, 13, 14, 15, 16, 18, 22, and X.[35] Trisomy 16 is the most common trisomy associated with pregnancy loss and confined placental mosaicism in intrauterine growth restriction. A prospective study investigated the incidence of UPD associated with growth restriction in 35 infants born between 25 and 40 weeks.[38] However, only two fetuses were born before 28 weeks, and both had chromosomal UPD of chromosome 16 plus confirmed placental mosaicism. No other UPD was found for the 12 chromosomes tested. It was concluded that UPD for the chromosomes tested did not explain the etiology of most cases of intrauterine growth restriction. However, many of these cases occurred after 32 weeks, and a higher detection rate is likely in fetuses with severe intrauterine growth restriction before 28 weeks.

Genomic Imprinting

The concept that male and female genomes do not contribute equally to mammalian development derives from observations made in mice two decades ago.[39] In these experiments, the development of uniparental diploid embryos was severely disrupted. Pathogenetic conceptuses developed embryos up to the 25-cell stage but showed only very rudimentary extraembryonic tissues. Androgenic conceptuses were characterized by relatively well-developed extraembryonic membranes and severely perturbed embryos. These reciprocal uniparental phenotypes probably resulted from disruption of the normal parental-specific expression patterns of a subset of imprinted genes. A detailed discussion is outside the scope of this chapter (See Further Reading, Georgiades et al, 2001).

MALFORMATION SYNDROMES

General

The term "dysmorphology" has been applied to the study of birth defects occurring in recognizable syndromic combinations. The causes of these syndromes include chromosomal abnormalities, genetic defects, and teratogens (e.g., drugs, infections, metabolic causes). The cellular pathways involved in the pathogenesis of some malformation syndromes are being delineated, often by analyzing genes identified in other species as vital for normal development. Confirming that mutations in these genes cause specific human syndromes offers the possibility of DNA diagnosis.

Structural Malformations Found at Ultrasound Examination

A detailed screening fetal ultrasound examination may show a pattern of major anomalies that suggests a specific diagnosis (see Chapters 7 and 8). Recognizable patterns are most likely to be caused by chromosomal anomalies, but rare single-gene or dysmorphic syndromes may be diagnosed in utero in the absence of a history of the syndrome. In addition to major structural abnormalities, careful evaluation of the fetus may show other dysmorphic features that are not commonly sought in a routine "screening" ultrasound examination. These abnormalities include micrognathia, hypotelorism, and hypertelorism as well as subtle abnormalities of the hands (e.g., clinodactyly) or feet (e.g., sandal gap of the toe). Careful evaluation of the fetal posture or attitude when the fetus is stationary and moving may also give important diagnostic information.

Evaluation of the features with a clinical geneticist or perinatologist who has a special interest in fetal dysmorphology may aid in the prospective diagnosis of a dysmorphic syndrome. The use of computer databases (see Further Reading) may be helpful in obtaining a diagnosis. It is important to look at photographs in original reports because a description may sound identical but the reported case may look entirely different from the patient.

As with all aspects of genetic counseling, accuracy of the diagnosis is paramount. Information obtained prenatally should be supplemented by information from postnatal examination, or from a detailed examination by a perinatal pathologist if the couple opts for termination or if the fetus is stillborn. Photographs of the main features are helpful when seeking the diagnostic advice of a clinical geneticist.

Syndromes

For many common disorders, empirical risk tables are available (see Further Reading and Harper, P, 1998). If the diagnosis is not clear or no accurate data on which to base a recurrence risk are available, it is advisable to refer the case to a clinical geneticist.

ISOLATED ORGAN AND SYSTEM ANOMALIES

Many disorders that affect specific organ systems appear to have a genetic or inherited component but show no clear pattern of mendelian inheritance or identifiable chromosomal abnormality. The term "multifactorial" has been used to describe this group. In some cases (e.g., Hirschsprung disease, congenital heart disease), the disorder is not a single entity but a heterogeneous group of indistinguishable disorders. Some of these may be inherited in a mendelian fashion, others may result from interplay of an inherited component and environmental factors, and others may be "acquired" in the sense that environmental factors are largely influential. Empiric risk data, obtained from observing recurrences in population studies, are available for many of these conditions (see Further Reading), but a clinical geneticist should be consulted.

Counseling Points for Common Conditions

Management Options	Quality of Evidence	Grade of Recommendation	References
Mendelian Inheritance			
High recurrence risks	IV	C	I
Establish an accurate diagnosis and the mode of inheritance before counseling.	IV	C	I
Seek the latest information about carrier detection tests.	IV	C	I
Plan invasive procedures requiring DNA methods in consultation with a laboratory.	IV	C	I
Autosomal Dominant Conditions			
50% risk to offspring of the affected parent	IV	C	I
Potential pitfalls in conditions with variable expression	IV	C	I
Autosomal Recessive Conditions			
25% risk of an affected child when both parents are carriers	IV	C	I
Prenatal diagnosis is possible for some	IV	C	I
Donor gametes may be an acceptable therapeutic option for some; much discussion is required.	IV	C	I
X-Linked Recessive Conditions			
Male-to-male transmission never occurs.	IV	C	I
Daughters of an affected male are carriers.	IV	C	I
Unaffected males never transmit the disease.	IV	C	I
For female carriers, each son has a 1 in 2 risk of being affected and each daughter has a 1 in 2 risk of being a carrier; affected homozygous females are rare.	IV	C	I
Chromosome Abnormalities			
Refer families with translocations to a clinical geneticist so that family studies can be performed to identify the risk of an unbalanced karyotype (which may lead to miscarriage or a child with abnormalities).	IV	C	I
With an unexpected structural chromosome abnormality, examine the parents' chromosomes.	IV	C	I
Duplication or deletion of chromosomal material can result in congenital malformation or mental retardation.	IV	C	I
Predicting the clinical effects of mosaicism is difficult; it may require karyotyping other cell lines.	IV	C	I
De novo chromosomal disorders have a low risk of recurrence; offer fetal karyotyping for reassurance.	IV	C	I
Check karyotype reports with a laboratory if the meaning is in doubt.	IV	C	I
Clarify whether risks relate to "at amniocentesis" or "at delivery".	IV	C	I
Specific Syndromes			
Ensure the accuracy of diagnosis and risks.	IV	C	I
Empiric risk figures are available for some conditions (see "Further Reading").	IV	C	I
Prenatal diagnosis is available for some with a biochemical basis, where a gene has been found, or where a microdeletion or duplication is the cause.	IV	C	I

SUMMARY OF MANAGEMENT OPTIONS
Counseling Points for Common Conditions *(Continued)*

Management Options	Quality of Evidence	Grade of Recommendation	References
Specific Syndromes (Continued)			
If the diagnosis or risks are in doubt, refer the patient to a clinical geneticist.	IV	C	I
Organ and System Abnormalities			
For many conditions, information should be obtained from a clinical geneticist.	IV	C	I
Empiric risk figures for siblings and children are available for some conditions (see "Further Reading").	IV	C	I

CONCLUSIONS

- Fetal abnormality is not uncommon, affecting 1% to 2% of newborns.
- Not all abnormalities have a genetic basis or a risk of recurrence in a future pregnancy.
- Families with single-gene disorders and parental chromosomal anomalies have the highest risks and may be detected by taking a family pedigree.
- The more distant the pregnant woman's relationship from a blood relative with a gentic disorder, the lower the risk of the condition.
- For women who have had trisomies, the risk of recurrence applies only to further siblings.
- Accurate and comprehensive information is needed to make a secure diagnosis, including taking a family pedigree before undertaking counseling.
- Close liaison with clinical geneticists is advisable.

Useful Genetics Web Links

Genetics knowledge, both clinical and scientific, is expanding so rapidly that it is necessary to rely on international databases to ensure that patients have the most up-to-date information. This section lists a selection of useful websites, and many more can be found on the websites of the European and American Societies of Human Genetics. *(www.eshg.org; www.ashg.org)*

OMIM (On-line Mendelian Inheritance in Man)

OMIM is a catalog of mendelian disorders in humans. It was initiated by Victor McKusick at Johns Hopkins Hospital. *(http://www.ncbi.nlm.nih.gov/Omim/searchomim.html)*

GeneClinics

GeneClinics is a clinical information resource that relates genetic testing to the diagnosis, management, and genetic counseling of individuals and families with specific inherited disorders. There is also a listing of laboratories and the tests that they provide. *(http://www.geneclinics.org/)*

EDDNAL (European Directory of DNA Diagnostic Laboratories)

EDDNAL, which is supported mainly by funding from the European Commission, provides standardized information on molecular diagnostic services for heritable syndromes and disorders offered by laboratories in 17 European countries. *(http://www.eddnal.com/)*

UK GTN (United Kingdom Genetic Testing Network)

The UK GTN website lists the diseases and available molecular tests in UK GTN laboratories. (http://www.ukgtn.org).

Public Health Genetics Unit

This site provides news and information about advances in genetics and their effect on public health and the prevention of disease. Its information database has reports, summaries, literature references, and other information about the genetic basis of disease, genetic testing and screening, policy development for genetic services, and ethical issues. *(http://www.phgu.org.uk/index.php)*

AIDS TO LEARNING GENETICS AND GENETICS INFORMATION

The Genetics Education Center at the University of Kansas Medical Center has an excellent listing of resources and is highly recommended. *(http://www.kumc.edu/gec/)*

DNA from the Beginning

DNA from the Beginning is an online learning text that is organized around key concepts of classical genetics, molecules of genetics, and genetic organization and control. The science behind each concept is explained by animation,

images, video interviews, problems, biographies, and external links. *(http://vector.cshl.org/dnaftb/)*

Clinical Genetics: A Self-Study for Health Care Providers

This self-study guide from the United States has two sections. The first consists of four lessons designed to increase knowledge about genetics and assist in identifying families for genetic referral. The second section includes reasons for referral, a glossary, a list of resources, and educational tools to use when working with patients and families. *(http://www.vh.org/Providers/Textbooks/ClinicalGenetics/Contents.*

ETHICAL ISSUES

Nuffield Council on Bioethics

The Nuffield Council on Bioethics offers published reports on the ethics of research into genetics, genetics and human behavior, and ethical issues associated with genetic screening. *(http://www.nuffield.org/bioethics/index.html)*

International: Centre for Public Law Research at the University of Montreal

The HumGen site provides information on a wide range of legislation, policy, guidelines, and recommendations of government and nongovernment organizations worldwide. *(http://www.humgen.umontreal.ca/intro.htm)*

INFORMATION FOR PATIENTS

Contact-a-Family

Contact-a-Family is an umbrella group that lists many patient support groups in the United Kingdom. *(http://www. cafamily.org.uk/)*

NORD (National Organization for Rare Disorders)

NORD is a federation of voluntary health organizations that is dedicated to helping people with rare "orphan" diseases and assisting the organizations that serve them. NORD is committed to the identification, treatment, and cure of rare disorders through programs of education, advocacy, research, and service. NORD has an index and a database of rare diseases and information about support groups and other sources of help. *(http://www.rarediseases. org/)*

GIG (Genetics Interest Group)

GIG is an organization in the United Kingdom that represents more than 120 charities that support children, families, and individuals affected by genetic disorders. Its primary goal is to promote awareness and understanding of genetic disorders. The website has video clips of patients discussing their diagnoses, discrimination and stigma, understanding and public awareness, and the prospects for research. *(http://www.gig. org.uk/)*

Early Prenatal Care

Planning Prenatal Care and Identification of Risk (Screening)

Marc Coppens / David K. James

INTRODUCTION

Definition of Risk

A pregnancy is defined as "high risk" when the likelihood of an adverse outcome for the woman or infant is greater than the incidence of that outcome in the general population.[1]

Aims of Prenatal Care

According to this definition, most pregnancies are not high risk. The aims of care for women with normal "low-risk" pregnancies are as follows[2]:

- To provide advice, reassurance, education, and support for the woman and her family
- To treat minor symptoms associated with pregnancy
- To provide an on-going screening program (clinical and laboratory-based) to confirm that the pregnancy continues to be low risk

For the minority of women who are identified as high risk before, during, or after pregnancy, these aims of prenatal care still apply. However, in addition, there is a fourth aim[2]:

- To prevent, detect, and manage problems and factors that adversely affect the health of the mother or infant

Is Prenatal Care Worthwhile?

Over the last 50 years, many studies of prenatal care, including major national surveys, showed worse pregnancy outcome in women who receive no prenatal care.[3–6] The association between prenatal care and improved pregnancy outcome has been suggested in several European epidemiologic studies.[7,8] Studies in developing countries have also indicated a causal relationship between enhanced prenatal care and a decrease in perinatal and maternal mortality rates.[6,9,10]

In light of these associations, some argue erroneously that prenatal care must be beneficial. However, this argument is flawed.[11,12] Further, what constitutes "prenatal care" varies considerably in practice (discussed later). The controversy over the real effect of prenatal care on pregnancy outcome was reinforced by recent studies. A critical review of studies conducted between 1966 and 1994 showed no conclusive proof of improved pregnancy outcome as a result of prenatal care programs.[13] More recent data have not resolved this controversy.[14] A recent regional audit of perinatal deaths in the Netherlands showed that many deaths were unrelated to women's use of prenatal care.[15]

A much stronger case for prenatal care can be made by examining whether individual components of care have proven benefit in achieving the four aims of prenatal care.[2,16–19] Each suggested strategy for prenatal care can be critically examined and categorized as follows[20]:

- Measures of proven benefit
- Measures for which further evidence is needed
- Measures for which the available evidence shows no benefit or even harm; it is reasonable to argue that this group of strategies should no longer be used in prenatal care

Space does not allow a detailed discussion of the evidence for classifying management strategies into these three groups; this information is available elsewhere.[21] Tables 3–1 through 3–4 show summaries of the evidence of the value of certain management strategies for prenatal care. Evidence for and against specific management options is discussed in greater detail in other chapters.

TABLE 3-1

Evidence That Advice, Reassurance, Education, and Support in Preparation for Childbirth is Effective (Aim No. 1 of Prenatal Care)

Proven Strategy	Level of Evidence	Grade of Recommendation	Benefit
Improved social and psychological support from caregivers	Ia	A	Better communication, satisfaction with care; less anxiety, less postnatal illness, and fewer feeding problems
Antismoking interventions	Ib	A	Reduced smoking and higher mean birthweight
Antenatal classes	III	B	Fewer intrapartum analgesia requirements
Routine ultrasonography with positive feedback	IIb	B	Positive feeling toward baby; lower post-term induction rate
Strategy Needing More Study			
Modifications of work patterns			Possible improvements in maternal and perinatal morbidity
Carbohydrate supplements for malnourished women			Possible higher mean birthweight
Antenatal classes			Possible increase in self-esteem and satisfaction with pregnancy; less pelvic floor trauma after delivery
Iron, folate, multivitamin, and nutritional supplementation for all women			Possible improvements in maternal and perinatal morbidity; higher birthweight, fewer neural tube defects, less preeclampsia
Strategy of No Proven Benefit or Proven Harm			
Failure to involve women in decision-making			
Failure to provide continuity of care			
Physicians involved in the care of all pregnant patients			
Prescribing high-density protein supplements			
Advising restriction of weight gain			
Advising restriction of salt intake			
Prescribing high doses of vitamin A (>4000 IE/day) or vitamin E			

(From Cochrane Pregnancy and Childbirth Group: Abstracts of Cochrane Reviews. The Cochrane Library, issue 2. Oxford, UK, Update Software, 2003.)

CRITICAL REVIEW OF THE EVIDENCE TO JUSTIFY THE OPTIONS AND VARIATIONS IN THE PROVISION AND USE OF PRENATAL CARE

Different measures are used to quantify the use of prenatal care (e.g., percentage of women receiving care, timing of the first visit, percentage of women receiving late or no care, frequency of visits, and indices of adequacy of prenatal care).[20] Data on the use of prenatal care show distinct socioeconomic, ethnic, and geographic differences.[20,22] These differences, also present within western countries, such as the United Kingdom, have led to important differences in perinatal and maternal mortality. For example, it is estimated that the perinatal mortality rate in Pakistani-born mothers in the United Kingdom is twice the national average.[23] In both developed and developing countries, there is great variation in the provision and content of prenatal care. However, there is little evidence to justify the different methods of providing prenatal care.

The Changing Childbirth report[24] explicitly stated that women should be the focus of maternity care. The main goal is to enable women to make informed decisions, based on their needs, after discussing the options fully with the professionals involved.

Reviews of women's views on antenatal care suggest that the aspects of care that women value most are respect, competence, communication, support, and convenience.[25]

Providers

The respective roles of obstetricians, family physicians (general practitioners), and midwives in the delivery of prenatal care vary from one country to another.[20] There is no evidence that physicians need to be involved in the prenatal care of every patient.[26–28] For specific problems, especially social concerns, midwives, family physicians, or other professionals may actually offer more benefit than specialists.[27,29] Midwives and general practitioners are primarily oriented to the care of women with normal pregnancies and, arguably, are more responsive to their needs than specialist obstetricians, whose care is concentrated on problems.[30] Incorporating different medical professionals into one shared antenatal care program can be effective in providing appropriate care for women with low-risk pregnancies.[31,32] Recent studies in Australia showed that continuity of midwifery care can realistically be achieved in a tertiary obstetric referral center without an increase in perinatal mortality and morbidity rates and with increased patient satisfaction.[28] The World Health Organization (WHO) Antenatal Care Trial Research Group evaluated

TABLE 3–2

Evidence That Minor Symptoms Can Be Relieved (Aim No. 2 of Prenatal Care)

Proven Strategy	Level of Evidence	Grade of Recommendation	Benefit
Antiemetics (e.g., antihistamines)	Ia	A	Reduced nausea and vomiting
Antacids	Ib	A	Reduced heartburn
Increased dietary fiber intake	IIb	B	Reduced constipation
Bulking agents and stool softeners	III	B	Reduced constipation
Strategy Needing More Study			
Magnesium supplements			Possible reduced leg cramps
Dilute hydrochloric acid			Possible reduced heartburn
Prostigmine			Possible reduced heartburn
Sodium chloride			Possible reduced leg cramps
Calcium			Possible reduced leg cramps
Quinine			Possible reduced leg cramps
Vitamin D			Possible reduced leg cramps
Strategy of No Proven Benefit or Proven Harm			
Saline cathartics or lubricant oils for constipation

the effectiveness of different antenatal care programs for women with low-risk pregnancies (reduced frequency of prenatal visits, different prenatal care providers).[32] The data showed no differences in selected perinatal outcomes for low-risk pregnant women, regardless of the different prenatal care programs. However, there were differences in satisfaction with the prenatal care provider. When care provided by a midwife and a general practitioner was com-

pared with care provided by an obstetrician and a gynecologist, women's response regarding the continuity of care favored midwife-led shared care.[33] Financial constraints on national medical budgets have reopened the discussion of optimizing the cost-effectiveness of health care delivery. A physician-based prenatal care model for low-risk pregnancies appears to be more expensive without actually improving pregnancy outcome.[27,28,34,35] From a health

TABLE 3–3

Evidence That Antenatal Screening Identifies Women at Risk (Aim No. 3 of Prenatal Care)

Proven Strategy	Level of Evidence	Grade of Recommendation	Risk Identified
Selective fetal ultrasonography or invasive procedure	Ia	A	Fetal abnormality
Maternal serum α-fetoprotein testing or biochemical screening (first or second trimester)	III	B	Neural tube defects, Down syndrome
Fundal height in high-risk pregnancies	Ib	B	Pathologic fetal growth
Regular ultrasound measurements of fetal size	Ia	A	Pathologic fetal growth
Maternal kick charts	Ib	A	Fetal death
Biophysical tests of fetal well-being	III	B	Fetal death
Doppler ultrasound of fetal circulation in high-risk pregnancy	Ia	A	Fetal compromise
Rhesus antibody screening	III	B	Rhesus hemolytic disease
Selective use of ultrasonography	IIa–IIb	B	Fetal viability, gestational age, placental site, fetal presentation
Regular blood pressure measurements and urinalysis	III	B	Preeclampsia
Screening for impaired glucose tolerance	IV	C	Gestational diabetes
Screening for bacteriuria	Ia	A	Asymptomatic bacteriuria and sequelae
Screening for infectious diseases (syphilis, HIV, gonorrhea)	III	B	Maternal, fetal, or neonatal infection
Screening for group B streptococcus carrier status near term	IV	C	Neonatal sepsis
Strategy Needing More Study			
Fundal height in low-risk pregnancies			Pathologic fetal growth
Doppler ultrasound of uteroplacental circulation			Fetal compromise, preeclampsia
Routine screening for toxoplasmosis, cytomegalovirus, chlamydia			Fetal or neonatal infection
Regular herpes swabs in women with a history of herpes			Neonatal infection
Risk scoring, monitoring of uterine activity, screening for vaginal sepsis, cervical assessment (digital, ultrasound)			Spontaneous preterm labor
Maternal and fetal screening			Risk of placental abruption
Maternal and fetal assessment in postdates pregnancy			Maternal and fetal risk

(From Cochrane Pregnancy and Childbirth Group: Abstracts of Cochrane Reviews. The Cochrane Library, issue 2. Oxford, UK, Update Software, 2003.)

TABLE 3-4

Evidence That When a Specific Risk Is Identified, the Subsequent Intervention and Management Improves the Outcome (Aim No. 4 of Prenatal Care)

Proven Strategy	Level of Evidence	Grade of Recommendation	Benefit
Multivitamins and folate supplements in patients with a previous fetus with a neural tube defect	Ia	A	Reduced incidence of neural tube defects in subsequent pregnancy
Amniocentesis vs chorionic villus sampling	Ia	A	Lower miscarriage rate with amniocentesis in the second trimester vs chorionic villus sampling in the first trimester
Anti-D for Rhesus-negative women after delivery of a Rhesus-positive child	Ia	A	Reduced subsequent isoimmunization
Intravascular fetal blood therapy for Rhesus hydrops	IIa	B	Improved perinatal outcome
Routine ultrasound	IIb	B	Reduced postdates induction
Doppler ultrasound of fetal circulation	Ia	A	Reduced perinatal morbidity and mortality
Antihypertensive therapy in women with hypertension	Ia	A	Reduced severe hypertensive pregnancy
Tight control of diabetes (rather than moderate)	Ia	A	Reduced urinary infection, preterm delivery, cesarean section, macrosomia, respiratory distress, congenital anomaly, perinatal mortality
Various antifungals	Ia	A	Reduced persistent candidiasis
Metronidazole after the first trimester	Ib	A	Reduced *Trichomonas* infestation
Intrapartum antibiotics for patients with maternal group B streptococcal vaginal infection	Ia	A	Reduced neonatal colonization and sepsis
Rubella vaccination postpartum	IV	C	Reduced rubella embryopathy subsequently
Cervical cerclage with previous second-trimester miscarriage	III	B	Reduced delivery before 33 weeks, miscarriage, or perinatal death
Intravenous tocolytics (β-mimetics or oxytocin antagonists) in patients with preterm labor	Ia	A	Reduced delivery within 24 hr or 48 hr, and before 37 weeks
Steroids before preterm delivery	Ia	A	Reduced respiratory distress syndrome, periventricular hemorrhage, necrotizing enterocolitis, early neonatal death
Use of antibiotics with steroids after preterm premature rupture of the membranes	Ia	A	Reduced infectious morbidity (maternal and fetal); delay delivery >7 days after initiating antibiotic therapy
Cesarean section for breech presentation at term	Ia	A	Reduced neonatal morbidity and mortality
Antiviral therapy and cesarean section when mother is HIV-positive	Ia	A	Reduced fetal and neonatal infection
Strategy Needing More Study			
Diagnosis of fetal abnormality by ultrasound, biochemical methods, and invasive procedures			Possible reduced incidence of fetal abnormality at birth and reduced maternal morbidity
Identification of pathologic fetal growth			Possible reduced perinatal morbidity and mortality
Maternal kick charts			Possible reduced perinatal morbidity and mortality
Biophysical tests of fetal well-being			Possible reduced perinatal morbidity and mortality
Plasmapheresis in severe Rhesus disease			Possible reduced perinatal morbidity and mortality
Antiplatelet agents in women at risk for preeclampsia and fetal growth deficiency			Possible reduced recurrence risk
Plasma expansion for severe preeclampsia			Possible reduced severe hypertension and renal failure
Hospital admission for nonproteinuric hypertension			Possible reduced development of proteinuria or severe hypertension, and maternal and perinatal morbidity and mortality
Strict bed rest for proteinuric hypertension			Possible reduced fulminating preeclampsia, and maternal and perinatal morbidity and mortality
Treatment of mycoplasma colonization			Possible reduced maternal and perinatal morbidity
Antiviral agents for patients with active genital herpes			Possible reduced persistent infection, and neonatal infection
Cesarean section for patients with herpes with no active disease			Possible reduced neonatal infection
Cervical cerclage for patients with a history other than previous second-trimester miscarriage			Possible reduced preterm delivery and perinatal mortality

TABLE 3–4—(cont'd)

Evidence That When a Specific Risk Is Identified, the Subsequent Intervention and Management Improves the Outcome (Aim No. 4 of Prenatal Care)

Proven Strategy	Level of Evidence	Grade of Recommendation	Benefit
Strategy Needing More Study—cont'd			
Tocolytics (β-mimetics or oxytocin antagonists) after preterm premature membrane rupture			Possible reduced maternal and perinatal morbidity
Use of fibronectin swabs			Possible reduced recurrence of preterm labor in subsequent pregnancy
Use of antibiotics in patients with toxoplasmosis seroconversion			Possible reduced severity of toxoplasmosis-induced congenital abnormality
Oral β-mimetics after inhibition of preterm labor			Possible reduced recurrence of preterm labor
Strategy of No Proven Benefit or Proven Harm			
Prescribing ethanol for inhibition of preterm labor			
Inducing labor routinely at less than 42 weeks			
Biochemical tests of fetal well-being			

(From Cochrane Pregnancy and Childbirth Group: Abstracts of Cochrane Reviews. The Cochrane Library, issue 2. Oxford, UK, Update Software, 2003.)

economics perspective, there is evidence of cost reduction if antenatal care is provided by staff other than obstetrician-gynecologists, without an increase in perinatal and maternal risks.[33,35] However, in many countries, the conceptual framework for prenatal care today is not based on good economics or evidence-based practice. Local and professional habits and traditions, political motives, and cultural and ethical beliefs all contribute.

Within the European community, Denmark and the Netherlands give a pivotal responsibility to midwives, with family physicians playing a supportive role and obstetricians being involved only in problem pregnancies and labor and delivery. In contrast, most of the care is provided by obstetricians in Belgium, Luxemburg, and Germany. In France and the United Kingdom, the sources of care are more diversified; however, in general, family physicians and midwives share the responsibility for prenatal care, with obstetricians involved marginally, if at all, in normal pregnancies. This pattern of care is also seen in Australia and New Zealand. In North America, midwives are uncommon, although there are several pilot studies examining an increasing role for these professionals. Most prenatal care in the United States and Canada is provided by family physicians or obstetricians, and some care is provided by nurse practitioners. Traditional birth attendants (TBAs) do not contribute significantly to prenatal care in developed countries. Involvement of TBAs in more than 5% of pregnancies has been reported in Guatemala, Honduras, and Mexico only.[20] In contrast, in some developing countries, up to 70% of all pregnancy care, including delivery, is provided by TBAs. Properly trained TBAs can serve as an inexpensive additional, yet effective, provider of prenatal care in developing countries without profound economic constraints.[22,36] Apart from the economic advantages of training TBAs, surveys in developing countries show that, during pregnancy and childbirth, many women prefer to receive care from a TBA rather than from other medical professionals.[36]

Education and Use of Prenatal Care

There is great variation in the form, content, and amount of education and advice that women receive during pregnancy, both between and within countries. Women receive much information about pregnancy not from medical professionals but from relatives and friends. One determinant of the quantity and quality of such information may be the professional's qualifications and experience.[37] Communication skills training for midwives and physicians appears to improve their ability to inform patients about pregnancy.[38] Trials in which women were given extra information prenatally in a variety of formats suggest that this information is valued and may reduce anxiety.[39] Providing knowledge (both oral and written) to health care providers can improve preventive measures in common practice (e.g., educating women about preterm labor and delivery).[40] Women tend to absorb information that is provided verbally by health care professionals better than information provided by standard evidence-based leaflets.[40]

On the other hand, in developed countries, specific barriers to free access to prenatal care persist and the number of women who do not seek or receive antenatal care is increasing.[41] The relationship between socioeconomic factors and poor use of prenatal care is well documented.[20,42–45] Providing financial incentives alone does not overcome these barriers to receiving prenatal care.[20,46,47] Additional efforts are needed to facilitate enrollment and enhanced social support services for these specific categories of women.[20,29,48] Home visits by prenatal care providers can be beneficial for women of

low socioeconomic status, improving their medical knowledge, health habits, support level, and satisfaction.[48,49] Further research is needed to substantiate its value on a large scale.

In developing countries, these barriers play an even greater role in the low use of prenatal care. The major barriers identified are economic, cultural, and those related to women's perception of their condition.[50–52] Reduction of poverty and economic empowerment of rural women are prerequisites for tangible improvement in the use of antenatal and obstetric delivery services in developing countries.[52] There may be an even greater need to create awareness about obstetric complications through targeted community-based health education interventions to promote early recognition of obstetric emergencies.[52] There is no sound evidence that removing user fees alone increases the use of prenatal care in developing countries.[53] Another major constraint experienced by women seeking health services is lack of satisfaction with the quality of care (e.g., long waiting lists in health centers, no combined maternal–child care, inappropriate communication, lack of transportation).[54]

Frequency of Visits

There is no agreement about the ideal number of prenatal visits. For example, the American College of Obstetricians and Gynecologists recommends a visit every 4 weeks until 28 weeks, every 2 weeks until 36 weeks, and then weekly until delivery.[55] This amounts to 13 visits if the first visit is at 8 weeks and the last is at 40 weeks. In contrast, a recent expert committee suggested a reduction to eight visits for women with normal pregnancies.[56] This is also the proposed number of antenatal visits for women with uncomplicated pregnancies in the United Kingdom.[25] In European countries, the recommended number of prenatal visits varies from 5 to 15.[57] It is likely that the number of prenatal visits can be reduced considerably in normal pregnancies.[58–61] The large WHO Antenatal Care Randomised Trial and a critical review of recent randomized controlled trials of reduced-visit programs in developed and developing countries clearly show that a reduction in the use of resources is possible without adversely affecting prenatal care process variables, pregnancy outcome, or patient satisfaction.[60,62,63] A reduction in the number of antenatal visits, with or without an increased emphasis on the content of the visits, could be implemented without an increase in adverse biologic maternal and perinatal outcomes. Some dissatisfaction with care, especially among women in western countries, has been reported when women receive fewer visits. Women who had fewer visits reported that their expectations were not fulfilled.[33] However, an opposite trend was reflected when these women were asked their preference for the type of care for future pregnancies.

Clinical and Laboratory Screening Programs

Despite much variation in other aspects of prenatal care, the clinical and laboratory-based screening that occurs during pregnancy is similar in most developed countries. Variations are often determined by the prevalence of local problems. Factors that are commonly checked during pregnancy are summarized in Table 3–5. Worldwide, large and unjustified variations in prenatal clinical and laboratory screening services have been observed.[64] This variation is due in part to the unavailability of certain services in some prenatal care units. More important is the observation that in clinics in which screening tests are available, few women are receiving these services. The variation and heterogeneity of antenatal services cast doubts on the rationale for routine antenatal care.[63]

CRITICAL REVIEW OF THE EVIDENCE SUPPORTING DIFFERENT APPROACHES TO RISK MANAGEMENT IN PREGNANCY

The third aim of prenatal care (discussed earlier) is to provide an ongoing screeening program to confirm that the pregnancy remains at low risk (and also to identify women at risk). This identification is based on the woman's history and findings on examination or tests performed before pregnancy, at the first prenatal visit, or during subsequent visits. The fourth aim of prenatal care is effective and appropriate management of women at risk. The goal of management is prevention, amelioration, or treatment of the adverse outcome.

In practice, risk in pregnancy can be identified in two ways:

- General risk scoring
- Specific risk scoring

General Risk Scoring

The main aim of a formal risk scoring system in pregnancy is to permit the classification of women into different categories for which different and appropriate management strategies can be implemented. Other benefits of general risk scoring include aiding teaching and audit, defining populations for epidemiologic purposes, and allocating resources. The main adverse outcome measures for which risk scores have been developed and evaluated to aid management care are as follows[64,65]:

- Perinatal death
- Small-for-gestational age or low-birth-weight fetus
- Preterm labor and delivery
- Perinatal asphyxia
- A combination of these

TABLE 3-5

Risk Factors Commonly Documented in Prenatal Screening

Demographic General Factors

Maternal age
Ethnicity
Socioeconomic status
Marital status
Paternal influences (age, habits, drugs, alcohol, ethnicity)
Nutritional history (vegetarian, anorexia, diet, vitamins)
Occupational and possible exposure dangers
Poor grasp of the English language

Obstetric History

Parity
Ectopic pregnancy or miscarriage
Mode of delivery
Baby pregnancy outcome, gestation, size, normality
Other complications of pregnancy
Postpartum depression

Medical History

Cigarette smoking
Alcohol abuse
Other drug abuse
Maternal medical disorders
Maternal prescribed medication
Previous surgery
Previous anesthetic problems
Previous blood transfusions

Gynecologic History

Subfertility
Contraception
Menstrual regularity
Specific problems
Infections (HIV, syphilis, human papilloma virus, gonorrhea, hepatitis B and C, chlamydia)

Family History

Congenital anomalies
Diabetes
Hypertension
Renal disease
Thromboembolic disease

Physical Examination

Maternal weight
Maternal height
General examination
Pelvic examination (not performed by all obstetricians, especially if there is no indication and routine pelvic ultrasound is offered)

Pregnancy Factors

Multiple pregnancy
Vaginal bleeding
Reduced or abnormal fetal movements
Abnormal uterine size or amniotic fluid volume
Other problems (weight gain in pregnancy is not universally recorded)

Tests

Urinalysis (glucose, protein, blood, ketones)
Complete blood count, blood typing, and antibody screen
Serologic screening for rubella, syphilis, and other infections, depending on local prevalence (e.g., hepatis B and C, HIV, toxoplasmosis, cytomegalovirus)
Biochemical screening for congenital anomalies (Down syndrome, neural tube defects)
Screening for thyroid function
Routine ultrasonography
Cervical smear (depending on local screening policy)
Blood pressure
Group B streptoccocal carrier status

The risk can be calculated in the following three ways[65,66]:

- According to the number of risk factors present
- According to the sum of the mathematically weighted risk for each individual factor
- By correcting the weighted risk by a further mathematical process, such as Bayes' theorem[66]

In primigravidae, the use of weighted risk factors, with or without Bayes' theorem, was superior to the use of unweighted factors. In multigravid women, the difference between the three approaches was marginal.[67]

Theoretically, formal risk scoring may be unsatisfactory in practice. Applying Bayes' theorem to risk assessment in prenatal care has the following limitations[68]:

- Geographic variations and the treatment paradox reduce the reliability of any assessment.
- Most obstetric variables are interdependent.

Formal risk scoring also leads to a simplistic and inflexible view of pregnancy management. "Risking systems" often include risk factors that have little predictive usefulness. The changing risk status during the prenatal period, in labor, and at delivery poses problems for the clinician who relies on risking systems to characterize the likelihood of adverse events. Risk scoring systems are not sufficiently robust for this task.[69] Formal risk scoring carries the inherent danger of ignoring low-risk women. It also requires computerized calculation of scores. These factors contribute to the limited use of risk scoring systems. However, another explanation for their limited use is that, although many formal scoring systems predict the likelihood of an adverse outcome, there is little evidence that their use is associated with a reduction in adverse pregnancy outcome.[64] Further, when risk scoring is applied in practice, there is a real danger that a potential, yet imprecise, risk of an adverse outcome will be replaced by increased surveillance and possible intervention and treatments, many of which may be of unproven value and carry their own risks. Examples include fetal monitoring and measures reported to reduce the risk of preterm labor and delivery.[64,70,71] However, the West Los Angeles Preterm Birth Prevention Project showed a significant reduction in preterm birth among women with high-risk pregnancies who were enrolled in a formal risk scoring program.[72] Since the late 1960s, a formal risk scoring program to evaluate the risk of preterm delivery has been conducted in France, with promising results.[73] However, outside France, these results have not been repeated.[74,75] The conflicting evidence of the efficacy of primary preterm birth prevention programs emphasizes the long-recognized difficulties in implementing and assessing effective primary prevention strategies. Finally, risk scores vary with different populations and for reasons other than prevalence or specific adverse outcomes.[75] The limitations of performance and potential disadvantages mean that formal risk scoring lacks many characteristics of effective screening tests. Recent

attempts to use risk scoring models at clinics in Africa did not identify women at risk for pregnancy complications.[76] Despite promising results from Australia,[77,78] formal risk scoring should not be introduced into routine pregnancy care until results from a well-designed randomized trial are available.

Recognition of Specific Risks

In practice, the most common way in which risk in pregnancy is identified is by the recognition of specific risk factors. After a woman is identified as having a risk factor for a specific adverse outcome, she receives specific additional management that may prevent, ameliorate, or treat the specific outcome. This management is in addition to the routine prenatal care received by all women. For example, a woman who weighs more than 85 kg is at increased risk for hypertension and gestational diabetes and, accordingly, the clinical and laboratory-based prenatal screening program must be amended to look specifically for these complications. In practice, the main problem with this approach is that although there may be agreement about what constitutes a risk factor and what the adverse outcome may be, there is less consensus about the appropriate management strategy. For many interventions, scientific proof of benefit is lacking, as discussed earlier (see Tables 3–1 through 3–4). The way in which additional care is provided on the basis of identification of risk factors may be empirical or schematic.

Empirical

After a specific risk factor is identified, the obstetrician chooses additional management strategies. Thus, if the patient weighs more than 85 kg, given the known risk of hypertension and gestational diabetes, the obstetrician may screen for hypertension in several ways, including the following:

- No measures other than paying strict attention to routine blood pressure recordings at routine prenatal visits and using a large sphygmomanometer cuff to obtain the measurements
- Increased frequency of clinic attendance for blood pressure readings
- Giving the woman a self-assessing sphygmomanometer and guidelines for self-referral

Similarly, the obstetrician may screen for gestational diabetes in the following ways:

- Performing random blood glucose testing on one or more occasions
- Performing a fasting glucose test on one or more occasions

- Performing a modified 50-g glucose tolerance test on one or more occasions
- Performing a formal 75-g glucose tolerance test on one or more occasions

Schematic

Every time a given risk factor is identified, the obstetrician implements a specific preagreed management strategy (Tables 3–6 through 3–11).[2] No studies have compared the outcomes of the schematic approach with those of the empirical approach. However, the schematic approach has several advantages, including the following:

- It provides consistent management of specific risk factors.
- It allows comparison of the effectiveness of one management strategy with another.

An implicit requirement of the schematic approach is that the underlying basic prenatal care program for all pregnant women should be documented (Table 3–12).[2]

Decision Analysis

In the future, some form of decision analysis may be applied to the provision of prenatal care.[71,79] This is likely to occur in the following two ways:

- Providing counseling about management options
- Determining the benefits of alternative management strategies on the basis of the literature, but without a randomized trial

Providing Counseling About Management Strategies

A simple example is a 40-year-old woman who seeks advice at 11 weeks about prenatal diagnosis of Down syndrome. In this patient, the likelihood of delivering a baby with the diagnosis is 1:100; the risk of miscarriage is approximately 1:100 for amniocentesis at 16 weeks and 1:50 for chorionic villus sampling at 11 weeks. She is asked to place a relative score, or weighting, on her view of Down syndrome versus miscarriage.

- If she fears Down syndrome three times more than she fears a miscarriage, then she can have either invasive procedure.
- If she fears Down syndrome two times more than she fears a miscarriage, than she should opt for amniocentesis.
- If she fears a miscarriage more than she does Down syndrome, then she should not have an invasive procedure.

TABLE 3–6

Schematic Management of Risk Factors: General Factors

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Vegetarian	Poor nutritional intake	Multivitamins, folate, iron, and other nutritional supplements
Age <18 yr	Poor antenatal attendance, education, and screening	Social worker involvement, home visits
	Hypertensive disease, IUGR	Vigilance for increased blood pressure, grade I fetal check
Age >35 yr	Chromosomal abnormalities	Early consideration for prenatal diagnosis
	Hypertensive disease, IUGR	Vigilance for increased blood pressure, grade I fetal check
Parity >4	IUGR	Grade I fetal check
	Anemia	Iron and folate supplementation
	Further pregnancies	Discuss contraception
	Malpresentation	Check presentation at 36 wk
	Postpartum hemorrhage	Vigilance for uterine atony and hemorrhage
Non-white	Hemoglobinopathy	Hb electrophoresis
	HB-Ag carrier (Far East) or HIV carrier (Africa)	If positive, then clear labeling of notes and implementation of policy guidelines
	Poor English, education, and screening	Interpreter
Single parent, financial and social	Poor antenatal attendance, education, and screening	Home visits if necessary, discussion of plans for labor and delivery, social worker
	IUGR	Grade I fetal check

Grade I fetal check, careful check of fetal growth by fundal height measurements and questioning about fetal activity; Hb, hemoglobin; HB-Ag, hepatitis B antigen; IUGR, intrauterine growth restriction.
(From James DK, Smoleniec J: Identification and management of the at-risk obstetric patient. Hosp Update 1992; 18:885–890.)

Many argue that these decisions are being made intuitively by women and their partners when given the relevant information in a nondirective way and without the need to complicate the issue with mathematical models. For more difficult decisions, there are good reasons to believe that decision analysis rather than intuitive methods will result in decisions that match patient prefer-

ences.[71] Changing the age of the woman in this example from 40 years to 37 years and incorporating the results of recent developments in noninvasive antenatal testing into the discussion (first-trimester ultrasound, measurement of nasal bone length or nuchal translucency, first-trimester or second-trimester biochemical testing) will lead to a far more complex decision analy-

TABLE 3–7

Schematic Management of Risk Factors: Obstetric History

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Previous ectopic pregnancy	Recurrence, maternal anxiety	Early ultrasound to confirm intrauterine pregnancy
Previous still birth or neonatal death	Risk depends on cause (not all are recurrent)	Try to establish cause; early review and specific management
Baby weight < 2 SD	Intrauterine growth restriction	Grade II fetal check
Baby weight > 2 SD	Gestational diabetes	Random glucose testing at 28 and 32 wk
	Further large fetus	Grade II fetal check, vigilance in labor
Congenital anomaly	Possible recurrence	Obtain details and diagnosis; possible prenatal diagnosis
Antibodies	Hemolytic disease	Specific protocol
Proteinuric preeclampsia	Recurrence	Assess renal function, grade II fetal check, carefully check blood pressure
Preterm delivery	Recurrence	Specific plan depending on cause
Uterine scar	Uterine rupture, cesarean section	Review of mode of delivery at 36 wk
Short labor	Recurrence and neonatal problems (trauma, asphyxia, hypothermia)	Specific management plan at 36 weeks
Postpartum hemorrhage	Recurrence	Specific plan at 36 wk
Other labor or delivery problems	Recurrence	Specific plan at 36 wk
Problems with baby	Recurrence, maternal anxiety	Obtain details and make a specific plan

< 2SD, less than 2 standard deviations below mean for gestation; > 2 SD, more than 2 standard deviations above mean for gestation; grade II fetal check, careful check of fetal growth by ultrasound every 2–4 wk and use of a fetal movement chart.
(From James DK, Smoleniec J: Identification and management of the at-risk obstetric patient. Hosp Update 1992; 18:885–890.)

TABLE 3-8

Schematic Management of Risk Factors: Medical, Surgical, Gynecologic, and Family History

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Smoking	IUGR, placental problems (placenta previa, solutio placentae)	Advice to reduce or stop smoking, grade I fetal check, ultrasound check of placenta
Excess alcohol	IUGR, fetal alcohol syndrome	Offer specific help, grade II fetal check, alert pediatricians
Chronic disease and prescribed drugs	Possible adverse effects of disease on pregnancy and pregnancy on disease	Obstetric and physician joint care with preagreed specific protocols
Drug abuse	HB-Ag, HC-Ag, HIV, IUGR, neonatal withdrawal	Counseling and serologic testing, grade II fetal check, alert pediatrician
Hemoglobinopathy	Sickle or thalassemia trait: risk of affected fetus Sickle disease: crisis or IUGR	Test partner, offer prenatal diagnosis, encourage hydration, check renal function, regular midstream urine, grade II fetal check
Anesthetic problems	Recurrence	Consultant anesthetist
Family history of diabetes	Gestational diabetes	Random glucose testing at 28 and 32 wk
Family history of congenital anomaly	Possible recurrence, maternal anxiety	Obtain details and diagnosis, consult obstetrician for possible prenatal diagnosis
Subfertility	Anxiety, multiple pregnancy, hypertension, or gestational diabetes with polycystic ovaries	Reassure, vigilance for hypertension, random glucose testing at 28 and 32 wk if polycystic ovaries
IVF/ICSI pregnancy	Congenital anomalies, chromosomal abnormality, IUGR	Consult obstetrician for possible prenatal diagnosis, grade II fetal check
Intrauterine contraceptive device in situ	Miscarriage, preterm labor	Remove if threads visible; if not, check at delivery

Grade I fetal check, careful check of fetal growth by fundal height measurements and questioning about fetal activity; grade II fetal check, careful check of fetal growth by ultrasound every 2–4 wk and fetal movement chart; HB-Ag, hepatitis B antigen; HC-Ag, hepatitis C antigen; IUGR, intrauterine growth restriction; IVF/ICSI, in vitro fertilization/intracytoplasmic sperm injection.

sis for the woman and her partner. The decision will be based on weighing the specificity and sensitivity of different noninvasive tests for Down syndrome and balancing these against procedure-related and age-specific risks.

DECIDING BETWEEN ALTERNATIVE MANAGEMENT STRATEGIES WITHOUT A RANDOMIZED TRIAL

No management strategy should be implemented without the benefit of a randomized trial. An example of how a randomized trial can affect clinical practice is provided by the study of Hannah and colleagues[80] on the mode of delivery of infants with breech presentation at term. Before this study, clinicians had to rely on circumstantial evidence in the literature.[81] The study by Hannah and coworkers shows that the optimal mode of delivery is planned cesarean section after the woman has been offered external cephalic version.[82] A survey of obstetricians showed that most now choose cesarean section as a result of the study.[83] However, attempts to resolve other management options have not been successful. An example is the management of compromised preterm fetuses. It is unlikely that a sufficiently large study could be con-

TABLE 3-9

Schematic Management of Risk Factors: Factors from Examination

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Weight >85 kg	Hypertension, gestational diabetes	Dietary advice, vigilance for increased blood pressure, random glucose testing at 28 and 32 wk
Weight <45 kg	Intrauterine growth restriction	Grade I fetal check
Primigravida and height <1.52 m	Cephalopelvic disproportion, asymptomatic heart disease	Plan for labor if fetal head is unengaged at 40 wk
Cardiac murmur	Maternal clinically significant heart disease, fetal congenital heart disease	Consider cardiologic opinion

Grade I fetal check, careful check of fetal growth by fundal height measurement and questioning about fetal activity.

TABLE 3–10

Schematic Management of Risk Factors: Factors Arising in Pregnancy

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Vaginal bleeding	<20 wk: miscarriage	Acute referral to hospital, no long-term additional action
	>19 wk: placenta previa, placental abruption	Acute referral to hospital, long-term grade II fetal check
Blood pressure >140/90	Preeclampsia, IUGR	• If blood pressure >160/100 or proteinuria, refer for hospital admission and care with preagreed protocol
		• If blood pressure <160/100 and no proteinuria, refer for day care with preagreed protocol
Multiple pregnancy	Anemia, hypertension, IUGR, preterm delivery, congenital anomalies	Iron and folate supplement, vigilance for increased blood pressure, preterm uterine activity, grade II fetal check, more frequent visits
Fetus small for dates	IUGR	Fetal assessment with preagreed protocol
Fetus large for dates	Big baby and complications, gestational diabetes, hydramnios, multiple pregnancy	Fetal assessment with preagreed protocol, random glucose testing
Polyhydramnios	Big baby and complications, abnormal fetus, diabetes	Fetal assessment with preagreed protocol, random glucose testing
Malpresentation after 35 wk	Delivery problems	Look for cause, make plan for labor
Reduced fetal movement	Poor maternal perception, fetal disease	Immediate nonstress tests, fetal assessment
Preterm rupture of membranes	Preterm labor, amnionitis	Hospital admission, manage with preagreed protocol
Urinary tract infection	Pyelonephritis, preterm labor	Treat (5 days), monthly midstream urine
Group B streptococcus–positive vaginal culture	Neonatal sepsis	Intrapartum intravenous antibiotics

Grade II fetal check, fetal growth by ultrasound every 2–4 wk and fetal movement chart; IUGR, intrauterine growth restriction.

TABLE 3–11

Schematic Management of Risk Factors: Factors from Studies

RISK FACTOR	TYPE OF RISK	MANAGEMENT
Proteinuria	Infection, renal disease, preeclampsia	Midstream urine, blood pressures studies if proteinuria persists
Glycosuria	Decreased renal threshold, gestational diabetes	Random glucose testing at 28 and 32 wk
Hematuria	Infection, renal disease	Midstream urine, renal hematuria studies if persists
No rubella antibodies	Susceptible to rubella	Warn mother, offer puerperal vaccination
Rhesus-negative status	Potential for sensitization	Check antibodies at first visit, 28, and 34 wk; give anti-D at potential sensitization
Antibodies	Fetal hemolytic disease	Specific protocol of management
Increased α-fetoprotein level	Fetal abnormality	Careful ultrasound scan at 18 wk
	If normal, intrauterine growth restriction, placental bleeding, preeclampsia	Grade II fetal check, vigilance for increased blood pressure
Low Hb (<10 g/dL)	Pathologic anemia	Investigate; treat cause with oral therapy; refer to hematologist if uncertain cause, intolerance of therapy, no response to therapy
Increased random glucose level (>7 mM)	Gestational diabetes	Formal 75 g oral glucose tolerance test
Abnormal cervical smear	Possible invasive carcinoma	Refer for colposcopy
Group B streptococcus-positive vaginal swab	Neonatal infection	Intrapartum intravenous antibiotics

TABLE 3-12

Schematic Approach to Prenatal Care: Basic Care (Suggested Minimum Program)

GESTATION (WK)	AIMS AND ACTION TAKEN	GESTATION (WK)	AIMS AND ACTION TAKEN
8–14 (wk)	Confirm pregnancy Check medical, family, social, and obstetric histories General physical examination Pelvic examination if indicated Tests: • Urinalysis (glucose/protein/blood) • Midstream urine specimen • Complete blood count • ABO/Rhesus grouping and antibody screen • Serologic tests (rubella, syphilis, toxoplasmosis, cytamegalovirus, HIV) • Ultrasound: nuchal translucency; confirm or correct estimated date of delivery Discuss pregnancy, including the offer of screening for neural tube defect or Down syndrome (first trimester or second trimester) and ultrasound scan at 18 wk General advice on diet and hygienic measures if toxoplasmosis or cytomegalovirus-negative (if performed), exercise, breast care, infant feeding, parentcraft classes, smoking, alcohol, family planning, and maternity benefits Complete case notes		Check results from 16-wk ultrasound serum screening Confirm or amend estimated date of delivery (if not performed in first trimester)
		22–24	Routine check (history of symptoms, especially vaginal bleeding, reduced or absent fetal movements), measurement of blood pressure, urinalysis, fundal height with tape measure (charted)
		28	Routine check (as before, but including fetal heart rate and liquor volume), especially blood pressure and fundal height Complete blood count, Rhesus antibody screen if Rhesus-negative
		32	Routine check (as before), especially of blood pressure, fundal height, and the of the 28-wk test Discuss labor and parentcraft
		35–37	Routine check (as before), especially of blood pressure, growth, and possible malpresentation Check group B streptococcus-carrier status Complete blood count, Rhesus antibody screen if Rhesus-negative
16	Serum screening for neural tube defects or Down syndrome (if not performed in first trimester) Check all test results	38–39	Routine check (as before), especially of blood pressure, growth, and possible malpresentation
18	Detailed ultrasound scan	40	Routine check (as before), especially of blood pressure, growth, and possible malpresentation Discuss labor
		41	Review and discuss induction of labor Routine check (as before)

ducted in the near future to determine the optimum mode and timing of delivery. An attempt to answer these questions was started in 1996 (Growth Restriction Intervention Trial).[84] A 2003 update of the results did not provide conclusive answers.[85] Nevertheless, it has been argued from decision analysis of the available literature that cesarean section without a trial of labor is indicated when there is evidence of acidemia before delivery. Otherwise, a careful trial of labor (including maternal oxygen supply, use of the left lateral decubitus position, and cervical ripening before the use of oxytocin) should be considered.[85]

CONCLUSIONS

- There is great variation in the provision and use of prenatal care both between and within countries in terms of who sees pregnant women, when they are seen, and what testing is done. There seems to be more consistency in terms of screening programs empolyed.
- Of the four aims of prenatal care, arguably the most important is the prevention, detection, and management of problems and factors that adversely affect the health of the mother, infant, or both.
- In managing these problems, the obstetrician should know which strategies have proven benefit and which are unproven.

SUMMARY OF MANAGEMENT OPTIONS
Planning Prenatal Care

Management Options	Quality of Evidence	Strength of Recommendation	References
Aims of Prenatal Care			
For the Majority of Pregnancies (Normal to Low Risk)			
Provide advice, reassurance, education, and support (see Table 3–1)			
Improved social and psychological support from caregivers	Ia	A	86
Antismoking interventions	Ib	A	87
Antenatal classes	III	B	29
Routine ultrasound with positive feedback	IIb	B	88
Treat minor symptoms (see Table 3–2)			
Antiemetics (e.g., antihistamines)	—	GPP	—
Antacids	Ib	A	89
Increased dietary fiber intake	IIb	B	90
Bulking agents and stool softeners	III	B	91
Implement an ongoing screening program (clinical and laboratory) to ensure continuing low-risk status (see Table 3–3)	—	GPP	—
Using risk scoring systems in pregnancy predicts the likelihood of adverse outcomes, with little evidence of a reduction in these outcomes	IV	C	64,65
A schematic approach is arguably more scientific than an empirical approach (see Tables 3–6 to 3–11 for examples)	—	GPP	—
For the Minority of Pregnancies (High Risk)			
Implement the above three aims in addition; prevent, detect, and manage risk factors (arguably the most important aim)			
There is no proof that prenatal care per se improves neonatal outcome	III	B	13
Specific interventions that are effective for specific risks can reduce mortality and morbidity (see Table 3–4)	III	B	95
Routine or Normal Prenatal Care			
What constitutes routine or normal prenatal care for a given population varies with the available resources:	—	GPP	—
• Personnel			
• Buildings and accommodations ("plant")			
• Laboratory			
Considerations (see Table 3–12 for example):			
• Who will see the pregnant women			
• When they will be seen			
• What will be done when they are seen			
The relative role of obstetricians, family physicians (general practitioners), and individuals in the delivery of prenatal care varies between countries.	III	B	20,63
There is no evidence that doctors need to be the medical professionals involved in the prenatal care of every pregnant patient.	Ib	A	27,35,38,48

Continued

Planning Prenatal Care *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
For specific problems, especially social ones, midwives or general practitioners may offer more benefit than specialist obstetric care.	Ia	A	27–29
Incorporating different medical professionals into one shared antenatal care program can be effective in providing appropriate care.	Ia	A	31,32
A physicians based prenatal care model appears to be more expensive without improving pregnancy outcome.	Ia	A	34,35
The frequency of prenatal visits can safely be reduced in low-risk pregnancies.	Ia	A	58,59
Socioeconomic factors and poor use of prenatal care are correlated.	III	B	20,42
Women report that midwife-led care provides better continuity of care.	Ia	A	27,32
In developing countries, well-trained traditional birth attendants can serve as an additional effective, yet inexpensive provider of prenatal care.	IV	C	36
There is great variation in the form, content, and amount of education and advice that women receive during pregnancy.	IV	C	37
Better communication skills by health care providers improve their ability to inform patients.	IV	C	38,39
Western women report dissatisfaction when they receive fewer prenatal visits.	Ia	A	33
Clinical and laboratory-based prenatal screening is similar in European countries.	—	GPP	56
Unjustified variation in clinical and laboratory-based prenatal screening exists worldwide.	III	B	63
The main aim of a formal risk scoring system in pregnancy is to permit the classification of women into different categories for which different and appropriate management options can be implemented.	IV	C	64
Overall risk can be calculated by: • Number of risk factors present • Sum of weighted risk factors • Correcting this weighted risk by mathematical processes, such as Bayes' theorem	IV	C	65
Formal risk scoring leads to a simplistic and inflexible view of pregnancy management.	IV	C	64
When risk scoring is used in practice, there is a real danger that a potential, yet imprecise risk of an adverse outcome is replaced by the introduction of increased surveillance and treatments of unproven value.	IV	C	69
Formal risk scoring should not be introduced into routine pregnancy care.	IV	C	64
The most common way in which risk in pregnancy is identified is by specific risk recognition; this can be done on an empirical basis or on a schematic basis.	—	GPP	—
The schematic approach has advantages over the empirical approach:	—	GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Planning Prenatal Care (*Continued*)

Management Options	Quality of Evidence	Strength of Recommendation	References
• It allows consistency of management for given risk factors. • It allows comparison of the effectiveness of one management strategy with another.			
Decision analysis will be applicable in the future and is likely to occur in two ways: • Providing counseling about management options • Determining the benefits of alternative management strategies on the basis of published literature, but without the benefits of a randomized trial	IV	C	71,79

Bleeding and Pain in Early Pregnancy

David J. Cahill / Peter G. Wardle

INTRODUCTION

Complications arise more frequently during the first trimester than at any other stage of pregnancy. Most patients have bleeding, pain, or both. Vaginal bleeding occurs in approximately 20% of clinically diagnosed pregnancies.[1] It causes considerable anxiety for the woman and her partner. In most cases, no intervention will alter the outcome. The main aim of clinical management is a prompt, accurate diagnosis, with reassurance if the pregnancy is appropriately developed and viable, or appropriate intervention if not. The differential diagnosis is shown in Table 4–1.

Most studies estimate that 15% to 20% of clinically recognized pregnancies end in miscarriage.[2] When bleeding occurs in the first trimester, approximately 30% of patients have a miscarriage, 10% to 15% have an ectopic pregnancy, approximately 0.2% have a hydatidiform mole, and approximately 5% have termination of the pregnancy. The remaining 50% of pregnancies continue beyond 20 weeks.[3]

Ectopic pregnancy is the most important cause of maternal mortality in the first trimester of pregnancy in the United Kingdom[4] and other western countries[5] and is the single largest cause of death in pregnancy among black American women. The most recent United Kingdom Confidential Enquiry into Maternal Mortality reported 13 deaths as a result of ectopic pregnancy (in contrast to 7 women who died after spontaneous miscarriage and 5 who died of sepsis).

When family size was larger, the loss of a pregnancy, particularly in the first trimester, was often accorded less importance by society and the medical profession. Now, with most couples having fewer children, the loss of an individual pregnancy or child has assumed greater signif-icance. The understanding and appreciation of the psychological effects of early pregnancy loss have lagged behind that of perinatal bereavement.[6] However, there is now greater recognition of the psychological and psychiatric sequelae and the consequent need for support.[7] These considerations should be taken into account in the management of couples who experience early pregnancy loss.

INITIAL MANAGEMENT

Resuscitation and Triage

Heavy bleeding in early pregnancy should never be ignored and should be assessed urgently. The rate and amount of blood loss should be assessed as accurately as possible, including a speculum examination to estimate additional concealed loss from intravaginal blood and clotting. Most women with first-trimester bleeding are young and fit and can maintain their blood pressure, even after substantial blood loss. When the woman's initial blood pressure is low, it is important to visualize the cervix carefully and remove any products of pregnancy, which may be lying within the cervical canal. It is important to differentiate between cervical shock (which responds rapidly to this removal of retained products of conception) and vascular decompensation, which is more likely to be the result of catastrophic hemorrhage requiring rapid resuscitation.

If the patient is in shock and there are no products of conception in the cervical canal, she should be managed as if a major blood loss has occurred, regardless of the amount of bleeding seen.

When severe blood loss is evident or suspected, adequate staff should be available for resuscitation. Pulse and

blood pressure should be recorded frequently, and large-bore intravenous access should be established. Blood should be obtained for a complete blood count, clotting screen, and type and crossmatch. A minimum of 4 units of blood would be required for a patient who is in shock. The woman should be assessed rapidly based on her clinical history and examination while resuscitation is proceeding. If this assessment suggests a catastrophic intraperitoneal hemorrhage from a ruptured ectopic pregnancy, it is unlikely that resuscitation will make her clinically stable. Under these circumstances, an emergency laparotomy should be undertaken.

If the woman responds promptly to appropriate resuscitation, or if she is not in shock (most patients), a careful history and examination should be undertaken and investigations arranged.

Diagnosis (See Table 4–1)

History

The date of the woman's last menstrual period, the usual length of her usual menstrual cycle and any variations, and the date of her first positive urinary pregnancy test should define the likely gestational age. The severity of early pregnancy symptoms, particularly nausea and breast discomfort, may be of diagnostic value. Nausea and vomiting in the first trimester are more frequently associated with a positive pregnancy outcome,[8] even among women with a threatened miscarriage.[9] The loss of early pregnancy symptoms around the time of vaginal bleeding is a bad prognostic sign. Increased early pregnancy symptoms also may be associated with molar pregnancies and multiple pregnancies.

The outcome of previous pregnancies should be noted and is an important indicator of the risk of miscarriage, ectopic pregnancy, or gestational trophoblastic disease (GTD). Primigravidae and women with previous live births have a lower risk of miscarriage. The risk of miscarriage increases cumulatively according to the number of previous miscarriages.[10,11] Similarly, women with a previous ectopic pregnancy are at substantially increased risk of another ectopic pregnancy.[12] There is approximately a tenfold increased risk of another hydatidiform mole in women with a history of an affected pregnancy.[13]

The nature and distribution of associated pain can be helpful. Unilateral pelvic pain is not necessarily related to an ectopic pregnancy; it may simply be caused by ovarian capsule distention from a corpus luteum of pregnancy, particularly if the pain radiates to the anterior thigh from irritation of the adjacent cutaneous nerves. Shoulder tip pain suggests diaphragmatic irritation as a result of intra-abdominal bleeding. Although it is more likely with an ectopic pregnancy, it can also occur with retrograde bleeding from a miscarriage. The extent of first-trimester vaginal bleeding provides a useful prognostic guide. Pregnancy is rarely successful if the loss is equivalent to or greater than a woman's normal menstrual blood loss.[14] A common exception is the loss of one of a twin pregnancy, although spontaneous reduction to a single pregnancy often is not accompanied by bleeding (the "vanishing twin" phenomenon).[15]

Examination

The aims of examination should be to differentiate between an early pregnancy complication and a coincidental abdominal pathology and to identify women who need prompt surgical intervention. Pulse and blood pressure should be monitored frequently to identify developing clinical shock early. The abdomen may be distended because of intraperitoneal bleeding or bowel dilation. Rarely, Cullen's sign (bluish tinge of the periumbilical skin or an umbilical "black eye") may be present in cases of ruptured ectopic pregnancy. Generalized lower abdominal guarding or rebound tenderness on abdominal palpation suggest intraperitoneal bleeding. Localized unilateral iliac fossa tenderness may be present with an unruptured ectopic pregnancy but can also be caused by a physiologic corpus luteum cyst of pregnancy.

Vaginal examination with a Cusco speculum should identify any local cause of bleeding due to trauma or cervical bleeding as a result of a polyp or physiologic ectropion (where bleeding can frequently be related to coitus). An open cervical os suggests either incomplete or inevitable miscarriage. Blood loss through the cervical os should be noted, including whether it is fresh or "old." If products of conception are extruding through the cervix, these can be removed with sponge forceps, which may relieve pain and correct reflex shock as a result of cervical

distention. If indicated, removed products of conception should be sent for histologic assessment.

Bimanual examination should be done to assess cervical dilation and identify cervical excitation tenderness as a clinical sign of an ectopic pregnancy. The size and shape of the uterus should be assessed. If it is larger than expected based on menstrual dates, the patient may have a multiple pregnancy, a hydatidiform mole, or coincidental uterine pathology, most frequently fibroids. Adnexal palpation may identify a tender mass that may be either an ectopic pregnancy or a normal corpus luteum cyst.

Special Investigations

A urinary βhCG pregnancy test should always be done if not checked previously. Commercial tests are now very sensitive and specific and can be expected to yield a positive result even 2 or 3 days before a missed period. If the result is positive, the critical and complementary diagnostic tests are a transvaginal pelvic ultrasound scan (TV USS) and quantitative serum βhCG measurements.

Ultrasound and βhCG Level

TV USS usually gives more immediate information, but is generally unhelpful in women who are less than 7 days past their missed period (a missed period is conventionally taken to be 4 weeks after the last period). Rapid changes in appearance occur between 4 and 7 weeks of amenorrhea (Table 4–2). Five weeks after the woman's last menstrual period (assuming a regular 28-day cycle), a gestation sac 2 to 5 mm in diameter should be visible (see Table 4–2). However, this sac can be difficult to differentiate from a pseudogestational sac associated with an ectopic pregnancy (where there is simply a small collection of fluid secretions within the uterine cavity) or a decidual cast (when the pregnancy has failed and decidual separation from the basal endometrium has

occurred). A genuine intrauterine gestation sac has two recognizable concentric decidual rings surrounding it, whereas a decidual cast or pseudogestation sac has only one ring. Even in practitioners with considerable ultrasound scanning experience, these subtle differences are easily missed.

Confirmation of an intrauterine sac can be made when the yolk sac or fetus becomes visible. The yolk sac is the first structure that becomes identifiable within the gestation sac, usually by 5½ weeks (Fig. 4–1). It usually measures 2 to 5 mm in diameter. Initially, up to about 6 weeks, it is larger than the fetus. However, an excessively large yolk sac (>5.6 mm in diameter) is often an early sign of impending miscarriage.[16] Other early indicators of almost certain miscarriage are a gestational sac whose diameter exceeds 20 mm without a visible yolk sac and a sac that exceeds 25 mm without a visible fetus.

When an intrauterine pregnancy is clearly visible, a useful formula to calculate approximate gestational age (in days from the last menstrual period) is as follows:

$$[\text{Gestational age (days)} = \text{Mean sac diameter (mm)} + 30].[17]$$

This formula is valid up to 9 weeks' gestation. A second, more accurate, but more complex, formula that is valid to at least 12 weeks gestation is as follows:

$$[\text{Mean sac diameter (mm)} = 0.986 \text{ (days after ovulation/conception)} - 17.1].[18]$$

The presence of an ongoing intrauterine pregnancy with a live fetus is a good prognostic finding. When a live embryo or fetus is seen on ultrasound, the overwhelming evidence is that the pregnancy is likely to continue (>95% of cases).[19,20] In addition to ultrasound structures, fetal circulation becomes evident at 5½ weeks and is visible in all viable pregnancies by 6 weeks.[18] Initially, the fetal heart rate is slower than normal, but it increases over time, from 85 to 90 beats/min at 6 weeks to up to 180 beats/min at

TABLE 4–2

9 weeks.[21] Rates persistently slower than 100 beats/min are more likely to be associated with a poorer outcome.[21]

Serum βhCG concentrations complement the information available from TV USS in assessing early pregnancy problems. In this chapter, all references to values and ranges of βhCG levels relate to the Third International Standard Preparation (WHO Preparation 75/735). Absolute levels may be helpful in recognizing when a woman with a normal intrauterine pregnancy should be evaluated with TV USS. Levels of βhCG greater than 1500 to 2000 IU/L (depending on local laboratory variations) are almost always associated with the finding of a gestation sac in the uterus if the pregnancy is intrauterine.[22] If it cannot be seen in the uterus, then it should be assumed that there is a pregnancy elsewhere (Fig. 4–2).

This maxim is not universally accepted and is the subject of debate. Caution should be exercised when women have had assisted conception treatment (by in vitro fertilization or ovulation induction). In these situations, more than one embryo might be present; therefore, an intrauterine and an extrauterine pregnancy might coexist (i.e., heterotopic pregnancy) or two intrauterine pregnancies might exist, giving rise to higher βhCG levels without a visible pregnancy on TV USS. Excessively high serum βhCG levels are also found with GTD (≥20 times normal values), and levels up to twice the normal values can be found in pregnancies affected by Down syndrome. Generally, βhCG levels are lower at any given gestational age with ectopic pregnancies than with normal intrauterine pregnancies. However, the overlap in values between the two clinical conditions is too great for this difference to be a diagnostic criterion.

Changes in βhCG levels are more useful clinically. Usually βhCG values are best tested at intervals of 48 hours or longer. A decreasing βhCG concentration in the first few weeks identifies a pregnancy as abnormal. If the

Age Points in Early Fetal Life

CROWN RUMP LENGTH (AFTER HOLLANDER, 1972[26] AND MILLS, 1992[18])	FETAL HEART (RATE) (AFTER MERCHIERS, 1991[21] AND ROBINSON, 1973[27])	SERUM βhCG (IU/L) (MEDIAN VALUES FOR βhCG ASSAY) (FROM THE THIRD INTERNATIONAL STANDARD PREPARATION)

3–4 mm	–	
4 mm	85–100	5200
7 mm	–	–
10 mm	125	26,700

βhCG level decreases by more than one half within 48 hours, it suggests that residual trophoblastic activity has ceased and that the pregnancy is likely to resolve without intervention. With a viable intrauterine pregnancy, βhCG values should increase by at least 66% in 48 hours.[23] If the rate of increase is less than 66% or if the βhCG doubling time is more than 2.7 days, there should be a strong suspicion of an ectopic pregnancy. A βhCG doubling time of more than 7 days is never found in a normal pregnancy.[23]

SUMMARY OF MANAGEMENT OPTIONS
Bleeding in Early Pregnancy—Initial and General Management

Management Options	Quality of Evidence	Strength of Recommendation	References
Identify the cause of bleeding by a combination of history, examination, βhCG assay, and transvaginal ultrasound.	III	B	9,11–14,18–21,23–27
Assess the amount and rate of blood loss.	III	B	14
Obtain regular recordings of pulse and blood pressure.	–	GPP	–

FBC for all. Perform a clotting screening if coagulopathy is suspected or excess blood loss occurs. Crossmatch blood if excessive blood loss occurs.	–	GPP	–

FBC, full blood count.

SPONTANEOUS ABORTION OR MISCARRIAGE

Definition

Now used synonymously, the terms *spontaneous abortion* and *miscarriage* imply the natural loss of a pregnancy before viability. Until recently, the term *abortion* was generally used in professional communication and *miscarriage* was used in discussion with patients. However, because the term *abortion* (which many patients find offensive) has pejorative connotations of "elective termination of pregnancy," there has been an overall shift away from using *abortion* to describe the spontaneous loss of a pregnancy.[28] Viability implies the ability of the fetus to survive extrauterine life. This is generally considered to occur at approximately 24 weeks' gestation. Rarely, fetuses born before that gestation survive for a short time or at least show some signs of life. The cutoff point for the use of the term *miscarriage* might lie at 22 weeks' gestation (154 days), as recommended by the World Health Organization (WHO).[29] The WHO also includes in this definition the fetus's weight (<500 g). In the United Kingdom, the legal definition changed in 1992 to 24 weeks' gestation (168 days), whereas in North America, the gestational age limit for a miscarriage is 20 weeks.[30]

In addition to these changes in terminology, there has been a marked alteration in the way in which early-pregnancy bleeding and pain are managed. Many of these changes are attributable to the following:

- Availability of rapid access to serum βhCG measurements
- High-resolution TV USS
- Introduction of fast-track referrals to early pregnancy assessment units or clinics (EPU/EPC)

In EPCs, access to integrated evaluation by ultrasonography, serum sampling for βhCG, and the presence of experienced medical and nursing staff has permitted women to be managed as outpatients or in the office, providing a more streamlined service.

Table 4–3 provides a summary of requirements for an EPC service. EPCs have improved the quality of care and produced considerable savings in financial and staff resources. However, as a tool in patient management, EPC services have not been fully evaluated.[31] Management of women through an EPC service is not without its drawbacks. Inappropriate delays in diagnosis of true ectopic pregnancies and overmanagement by laparoscopy of suspected ectopic pregnancies both occur, despite rigid adherence to protocols.

A pregnancy loss may be clinically evident after a patient has bleeding or pain or may be clinically silent and identified on a routine ultrasound scan. The introduction of nearly routine scanning to confirm gestational dates has had a dramatic effect on the

TABLE 4–3

Requirements for an Early Pregnancy Assessment Clinic

Appropriate resources for rostering of ultrasonographic, medical, and nursing staff (Exact calculation of time required is not evidence-based; experience suggests that for a hospital with 5000 deliveries/yr, 3 hours of patient contact time daily for all disciplines and 1 hour of telephone contact time later in the day is reasonable.)

Dedicated clinic space, with rooms for ultrasonography, clinical assessment and investigation, counseling, and a waiting area

Good-quality ultrasound machines with transvaginal capability

Availability of same-day βhCG estimation

A senior member of the clinical staff who is responsible for the development of guidelines and the resolution of diagnostic conflicts and problems

PROPORTION OF UNRECOGNIZED PREGNANCIES LOST TO RECOGNIZED MISCARRIAGES AND LIVE BIRTHS (AFTER CHARD, 1991)

FIGURE 4–3
Proportion of unrecognized pregnancies lost to recognized miscarriages and live births. (From Chard T: Frequency of implantation and early pregnancy loss in natural cycles. Baillieres Clin Obstet Gynaecol 1991;5:179–189.)

management of early pregnancy loss. Bleeding occurs in one fifth of recognized pregnancies before the 20th week of gestation. However, it is likely that far more pregnancies are lost before they are suspected, recognized, or confirmed (giving rise to the term *pregnancy loss iceberg*[32,33]; Fig. 4–3).

In one study, 12% of pregnancies in which bleeding occurred ended in miscarriage.[34] Other studies reported higher rates (≥16%),[34] but these studies did not include women who did not know they were pregnant (≥22%)[35] or those who did not seek medical advice about their bleeding, knowing that they were pregnant (approximately 12%).[34]

Risks

The maternal risks are blood loss, infection, and the psychological effects of pregnancy loss.

Presentation and Diagnosis

Most women seek care at a hospital, family physician's office, or EPC with one of the following concerns:

- Bleeding without pain
- Bleeding with pain, with possible passage of pregnancy tissue vaginally
- Bleeding with pain, with symptoms and signs of blood loss
- Absence of bleeding, with decreased symptoms of pregnancy

The amount of bleeding can vary from very slight to significant and has some prognostic value. Bleeding without pain is more likely to be associated with a threatened miscarriage. Patients seen at an EPC service often have painless bleeding. Once ongoing pregnancy is confirmed by ultrasound, the practitioner can provide reassurance. In most of these cases, bleeding has a local cause, such as physiologic changes in the cervix. The additional presence of pain is often associated with cervical opening or distention as a result of the passage of tissue or a blood clot, which may

be painful. Blood loss can give rise to symptoms in itself, and the passage of tissue through the cervical os can promote a vagal response that causes shock, which is rapidly relieved if the products are removed from the os.

Management Options

Threatened miscarriages are managed expectantly. If bleeding is slight and is not associated with pain, then the woman can be reassured that the pregnancy is likely to continue. Of all pregnancies in which bleeding occurs, more than 50% continue.[3] If bleeding occurs at 10 weeks' gestation, more than 90% continue; at 13 weeks, 99% continue.[36] If the menstrual or gestational age is greater than 6 weeks, then ultrasound may show a healthy, ongoing pregnancy. In such cases, the likelihood of pregnancy loss is less than 3%.[20] Ultrasonography before 6 weeks is less likely to be helpful. If a patient needs the reassurance of an ongoing pregnancy by ultrasound scan, then this evaluation should be undertaken after 6 weeks.

The management options for the loss of an early intrauterine pregnancy are

- Expectant
- Medical
- Surgical

Spontaneous complete miscarriage can be managed expectantly. Most difficulty in the management of bleeding in early pregnancy involves missed or incomplete miscarriage.

In most western countries, the surgical approach (evacuation of retained products of conception [ERPC]) historically has been the most common emergency gynecologic procedure. The procedure was traditionally carried out with ovum forceps and curettage and evolved to vacuum aspiration. Vacuum aspiration is associated with

less blood loss and pain and is a shorter procedure than surgical curettage.[37]

Expectant management avoids a surgical procedure and allows the woman to continue her normal daily routine. It is more acceptable to women and causes fewer effects on the quality of life.[38] Primary care physicians in the Netherlands and elsewhere strongly favor the use of expectant management, and it is likely that many miscarriages are managed expectantly in primary care.[39] However, expectant management is associated with more prolonged bleeding than either surgical[40] or medical management.[41] Reports from secondary care settings are less encouraging about expectant management; in one report, the incidence of prolonged bleeding and the success rate of expectant management were so low that its use was considered unjustified in clinical practice.[41]

Medical management has been advocated as an intermediate approach. The treatment regimens used have included misoprostol (often in combination with mifepristone),[42,43] sulprostone,[44] and gemeprost.[45] Women who have medical treatment have greater analgesic needs and more vaginal bleeding compared with those who have surgical management.[45,46] The treatment did not achieve success (ERPC was still required) in 50% to 80% of women in most studies,[45,47,48] although in one uncontrolled study, a success rate of 100% was reported.[44] The authors concluded that although medical treatment reduced the need for surgical evacuation, a significant proportion of patients who underwent medical treatment still needed ERPC. This approach hardly seems an effective treatment or an appropriate use of resources. When medical management is compared with expectant management, no differences are found in the number of days of bleeding, pain scores, blood loss, or complications. Women having medical treatment had a longer convalescence than those treated by expectant management.[42] Medical treatment is not innocuous; 45% of women in one study had gastrointestinal upset.[49]

In the absence of an adequately powered randomized controlled trial evaluating surgical, medical, and expectant management, how should incomplete miscarriages be managed? Can we rationalize the evidence from the assorted studies already undertaken? Gradation of the quality of evidence supporting the choices is provided in the Summary of Management Options. Expectant management should be used for women in the first instance, providing that they are stable. Given a choice, most women favor this approach.[50] It appears difficult to predict for which women expectant management will be effective.[51] Patients must understand that they may bleed for slightly longer,[52] and they must have ready access to hospital services should they require them. Women who choose medical management appear to have better mental health scores subsequently.[38] Perhaps if there is no clear option on clinical grounds, then medical management

should be the treatment of choice. Future fertility does not appear to be compromised by adopting this route.[53]

For those who do not want medical or expectant management, surgical management remains an option. Vacuum aspiration is preferred over surgical curettage; it is quicker, safer, and less painful.[37] Whether any women should electively have surgical treatment rather than any other is not clear, although in terminations, women of high parity (more than para 3) are more likely to have a complete abortion after surgical management.[54] Should tissue be sent from all miscarriages for histologic examination? Obvious practical problems arise with medical and expectant management, but it certainly should be requested for patients who undergo surgical curettage. Suspicious findings on ultrasound should direct management to surgery.

Some have suggested that the management option can be determined on the basis of ultrasound and biochemical evaluation. The volume of tissue remaining in the uterine cavity on ultrasound may be a useful guide in management. No intervention is required if there is no tissue or if the products of conception have a mean diameter of less than 15 mm. Medical or expectant management may be considered if the tissue mass is between 15 and 50 mm, and ERPC is probably required if the tissue diameter exceeds 50 mm.[42] More complications (37% vs. 3%) occurred when women with significant intrauterine tissue (intrauterine sac >10 mm in diameter) were managed expectantly compared with surgically.[55] Evidence to recommend the routine use of serum βhCG levels[55,56] or progesterone[56] to determine the need for surgical intervention is insufficient. When color Doppler imaging of uterine blood flow and the intervillous space was examined in missed miscarriages,[57] uterine blood flow could not differentiate between women whose miscarriage resolved spontaneously and those who required ERPC. Intervillous space blood flow was associated with an 80% chance of spontaneous resolution compared with 23% in those for whom flow was absent.[57] Although this technique shows promise, it requires validation. These adjuvant techniques are of little value in determining which women should be managed expectantly or otherwise. Should women undergoing surgical evacuation of the uterus have *Chlamydia* screening in line with other invasive interventions in the uterine cavity? One inadequately powered randomized trial showed no benefit, but because *Chlamydia* screening and selective antibiotic treatment reduces infection in induced abortion, this practice is worth continuing until evidence suggests otherwise.[58]

Thus, much of the management of bleeding in early pregnancy may be in the hands of general practitioners[39] or midwives,[1] but accurate diagnosis of ectopic pregnancies[55] and molar pregnancies[51] remains of particular concern. Rapid access to ultrasound and βhCG assays should remain a fundamental part of the management of bleeding in early pregnancy.

ECTOPIC PREGNANCY

The management of ectopic pregnancy has changed over the last 20 years. The changes that have led to these improvements in management are summarized in Table 4–4.

In line with this shift in practice, there has been a fourfold decrease in the mortality rate associated with ectopic pregnancy over the last 25 years, although the incidence of ectopic pregnancies has increased twofold.[4] The current rate of ectopic pregnancy (ectopic pregnancies per 1000 pregnancies) in the United Kingdom is 11.1 (approximately 1%), and in the United States, it is 20.[65] The mortality rate as a result of ectopic pregnancies in the United Kingdom is 4 per 10,000 (estimated) ectopic pregnancies.[4] In the United States, the rate is 3.4 per 10,000.[65] Complacency would be inappropriate, however, because ectopic pregnancy remains the leading cause of maternal death in early pregnancy.[4] Factors that predispose to ectopic pregnancy are listed in Table 4–5.

Definition

An ectopic pregnancy is one that occurs outside the uterine cavity, usually at an adjacent site, generally, the fallopian tube. In more than 98% of ectopic pregnancies, the primary site is in the fallopian tube. The rest occur in the abdominal cavity, on the ovary, or in the cervix. In the fallopian tube, approximately 80% of pregnancies occur in the ampullary region.

Risks

Risks are blood loss and its consequences, implications for future reproductive performance, and the psychological effects of the loss of the pregnancy.

Diagnosis

Symptoms

Diagnosis of an ectopic pregnancy can be difficult. Some, all, or none of the following symptoms may be elicited in a woman with an ectopic pregnancy:

TABLE 4–4

Changes Leading to Improved Management of Ectopic Pregnancy

Recognition of high-risk individuals (see Table 4-5)
Increased sensitivity of home pregnancy tests
Early referral to dedicated (early pregnancy) clinics in hospitals
Development and refinement of high-resolution transvaginal ultrasound
Accurate and rapid estimation of serum βhCG
Laboratory techniques allowing 24-hour access to automated sample processing

---

TABLE 4–5

Specific Risk Factors Predisposing to Ectopic Pregnancy

Peak age-specific incidence 25–34 years
Infertility (fourfold increased risk)
Sexually transmitted disease, especially chlamydia
Increased *Chlamydia* antibody titer
Tubal sterilization and reconstruction
Intrauterine contraceptive device
Endometriosis

- Amenorrhea
- Abdominal pain
- Vaginal bleeding
- Fainting
- Shoulder tip pain

Signs

At presentation to an EPC, many women with an ectopic pregnancy have few or no signs on examination. Unilateral iliac fossa pain is in keeping with ectopic pregnancy, but bilateral pain is not uncommon. Guarding, rigidity, and signs of peritonism may be elicited on abdominal palpation. Guarding may be reduced if the knees are drawn up to relax the abdominal muscles.

On vaginal examination, it may be possible to elicit pain on the affected adnexal side by manipulating the cervix laterally. Because the uterus moves in the opposite direction as a result of rotation around the fulcrum of the transverse cervical ligaments, there is increased tension on the side of the ectopic pregnancy. This is described as the pain of cervical excitation.

The uterus may be softer and even enlarged slightly in the presence of an ectopic pregnancy as a result of the softening effect of increased levels of progesterone on the endometrium and myometrium.

It is now rare in the United Kingdom for women to be admitted with an ectopic pregnancy presenting with hypovolemic shock or severe pain.

Investigations

Ectopic pregnancy must be differentiated from other causes of lower abdominal pain in a woman of reproductive age (see Table 4–1).

Critical to the diagnosis of ectopic pregnancy are TV USS and serum βhCG and, to a lesser extent, serum progesterone. Confirmation of the diagnosis by laparoscopy is not always necessary. Laparoscopy is not even the absolute answer because it has a false-negative rate of 3% to 4% (if done too early) and a false-positive rate of 5% (because of retrograde uterine bleeding).[66]

The complementary roles of TV USS and βhCG measurements were discussed earlier. Serum progesterone is also considered to have a role in the differentiation of an ectopic pregnancy. Its use is not as widespread as βhCG and TV USS. Serum progesterone concentrations well into the normal range for early pregnancy (>80 nmol/L) are associated with a high probability of the pregnancy being normal and intrauterine in site.[25] Conversely, values less than 15 nmol/L are highly likely (98%) to be associated with a nonviable pregnancy.[67] Most ectopic pregnancies have progesterone concentrations between these values that make the test of little value for routine clinical practice. Algorithms have been devised with and without the use of serum progesterone and can be referred to and integrated into local practice

guidelines if considered appropriate.[22,68] Figure 4–4 shows an example of a practical algorithm.

The patient who has obvious intra-abdominal bleeding can be diagnosed without difficulty. The less acute clinical scenario, in which a woman has little or no pain, vague symptoms, slowly increasing βhCG levels, and nonspecific findings on ultrasound, is more challenging.

Management Options

Management of the acutely ill woman differs from the more common presentation of a woman who is clinically stable.

The acute presentation that includes hypotension, tachycardia, pain, and other signs of shock, usually, but not always, associated with amenorrhea, is generally treated with laparotomy. The acute symptoms are usually caused by fallopian tube rupture or significant intraperitoneal bleeding. Surgical treatment usually requires partial or total salpingectomy, securing hemostasis, and removing blood and products of conception from the abdominal cavity.

In the less acute situation, there are several treatment options, which include surgical (conservative and radical), medical, and expectant management. The gradation of the quality of evidence is shown in the Summary of Management Options. The algorithm in Figure 4–4 shows the critical criteria that affect management; the trend in serum βhCG and the findings on TV USS. A serum βhCG level that increases above a critical threshold in the absence of an intrauterine gestation sac is usually an indication for surgical intervention. The choice of laparoscopy or laparotomy depends on the patient's surgical history, the findings on TV USS, and the absolute level of βhCG and its rate of increase.

Expectant Management

As shown in Figure 4–4, this management is most appropriate when the woman is hemodynamically stable, with no symptoms of pain. Some authors have suggested exclusion criteria, such as gestation sac size (>4 cm) or the presence of a fetal heartbeat on TV USS.[69] Expectant management is more likely to be effective if the initial serum βhCG concentration is less than 1000 IU/L and decreases thereafter and if a gestation sac is not seen on TV USS.[69] The serum βhCG level (both the initial level and the trend) is generally the most important predictor of successful expectant management.[69] Recent publications suggest that of vaginal bleeding, endometrial thickness, serum βhCG, and serum progesterone, the most useful modality to predict spontaneous resolution was serum progesterone, with a cutoff level of less than 20 nmol/L.[70]

Practically, expectant management involves establishing a reliable diagnosis of early extrauterine pregnancy

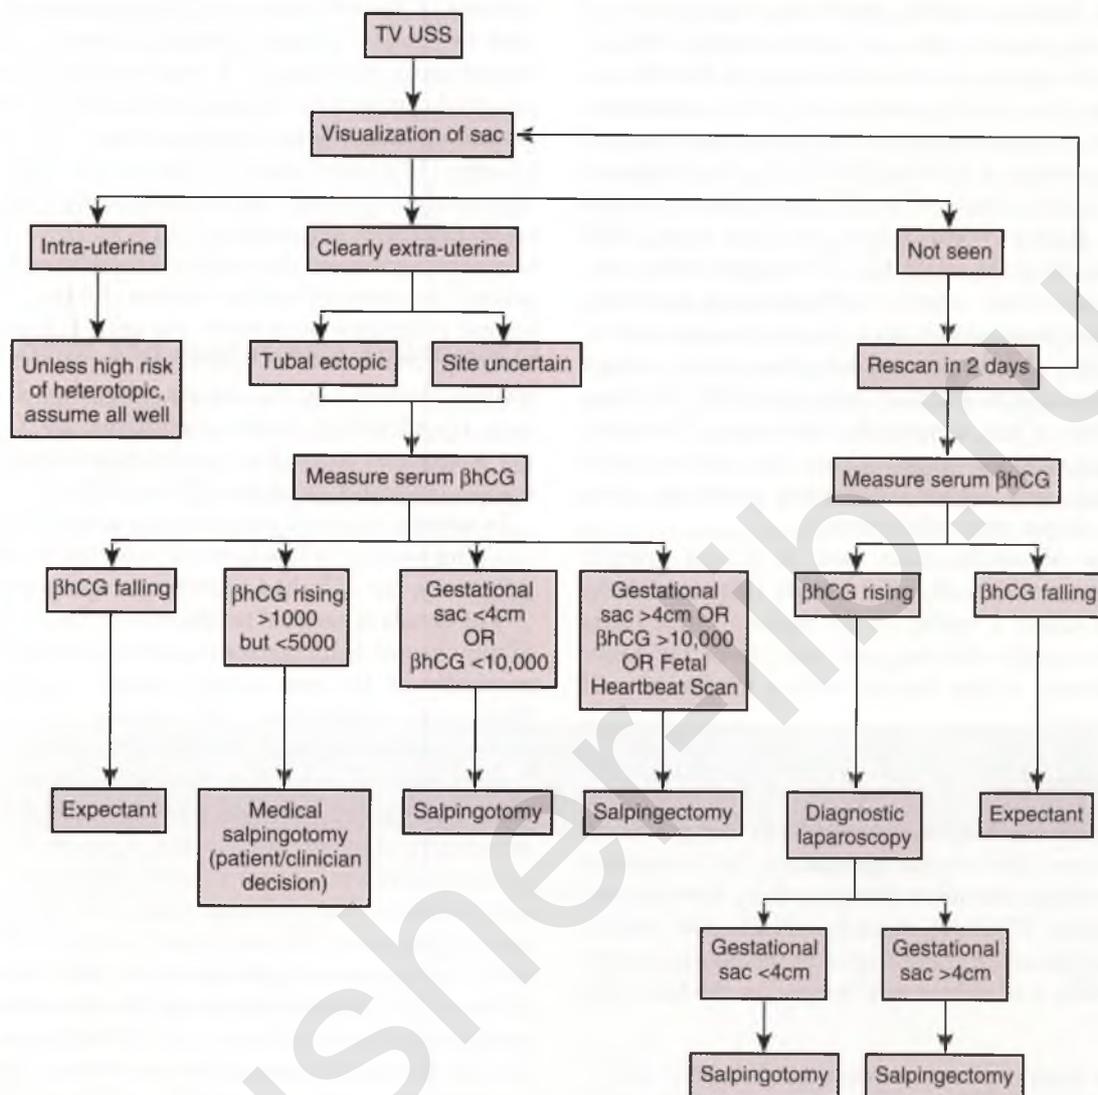
ALGORITHM FOR THE MANAGEMENT OF A POSSIBLE EXTRA-UTERINE PREGNANCY,
IN THE ABSENCE OF SUFFICIENT SYMPTOMS TO WARRANT SURGERY


FIGURE 4–4

failure, informing the patient of other treatment options, and obtaining consent that this method of management is acceptable. Serum βhCG levels should be monitored every 3 to 4 days until they decrease to less than 10 to 15 IU/L.[67]

Success rates for this approach range from 70% to 75% for βhCG levels of less than 1000 IU/L,[69,70] decreasing to 25% if levels are greater than 2000 IU/L.[71]

Medical Treatment

Current methods of medical management focus on the use of methotrexate, generally as a single dose. Multiple-dose regimens are less commonly used. Methotrexate is a

folic acid antagonist. As a chemotherapeutic agent, it is active against rapidly dividing tissues, such as those in the placental trophoblast. Methotrexate can produce side effects through its actions on other tissues, such as the gastrointestinal tract and the hematologic system. Adverse symptoms include stomatitis, gastritis, diarrhea, transient liver enzyme disorders, and rarely, bone marrow suppressive disorders. Single-dose use rarely gives rise to symptoms; daily or alternate-day multiple doses do so more commonly. Folinic acid is given to counteract this effect. Folinic acid is not required when doses are given at greater than weekly intervals.[72] Medical management is particularly appropriate when surgical intervention would be difficult (e.g., cervical and interstitial pregnancies).

Medical treatment has been available for more than 20 years,[73] but has not been adopted extensively. This is lamentable because studies involving large series of women show success rates of approximately 90%.[74] Predictors of success of medical treatment include sac size, fetal cardiac activity, and serum βhCG concentration; βhCG concentration is the most important of these.[74] For values of 2000 to 5000 IU/L, the likelihood of success is 92% (86%–97%; 95% confidence interval [CI]) and higher when values are less than 1000 IU/L (98%, 96–100%; 95% CI).[74] Compared with conservative laparoscopic surgery, methotrexate is associated with a shorter hospital stay but a longer return to normal βhCG levels.[75] In the United Kingdom, most women might be expected to attend an outpatient EPC for diagnosis, so this is not a particular advantage. However, future reproductive expectations are better with methotrexate, with higher intrauterine pregnancy rates and lower ectopic rates subsequently.

The dose of methotrexate used in clinical practice varies. Given systemically, and usually intramuscularly, the dose is either 1 mg/kg or 50 mg/m². These doses seem to be equally effective, and most favor the easier dose calculation of the former, with a minimum total dose of 50 mg.[76]

Surgical Treatment

Salpingectomy has long been considered the gold standard treatment for ectopic pregnancy. In emergency treatment of rupture of the fallopian tube, this may still be unavoidable. However, recently, considerable emphasis has been placed on conservation of the fallopian tubes when possible, and debate now hinges on the following questions:

- When is it appropriate to conserve a fallopian tube?
- Does fallopian tube conservation significantly affect subsequent fertility rates?

CONSERVATION OF THE FALLOPIAN TUBE

The Royal College of Obstetricians and Gynaecologists recommends that surgical treatment by laparoscopic salpingectomy is the preferred method of treatment for an ectopic pregnancy when the fallopian tube on the other side is normal.[77] However, until recently, most women in the United Kingdom were having open surgery, not laparoscopy, for the management of ectopic pregnancy.[78] Laparotomy may be the more appropriate route. A meta-analysis, based on the combined results of three studies involving women with unruptured tubal pregnancies, suggests that laparoscopic conservative surgery had more failures than an open surgical approach, when failure was defined as persistence of trophoblastic tissue and increased βhCG levels (relative risk [RR], 0.90; 95% CI, 0.83–0.97).[79]

There is not sufficient evidence from randomized controlled trials to answer the questions raised in the salp-ingectomy–salpingotomy debate. Opinions vary on this matter. In the management of an ectopic pregnancy, removal of the fallopian tube (salpingectomy) is considered the safest,[80] most clinically effective,[81] and most cost-effective technique.[82] A meta-analysis of nine well-designed comparative studies showed similar intrauterine pregnancy rates whether salpingectomy (49%) or salpingotomy (53%) was used.[76] That report and a separate meta-analysis showed higher subsequent ectopic pregnancy rates after salpingotomy (15% vs. 10%).[76,83] There is general agreement that salpingectomy would be appropriate if a women desired no further children, if a second ectopic pregnancy occurred in the same fallopian tube, if bleeding could not be controlled, or if the tube was severely damaged by the ectopic pregnancy. If salpingotomy is undertaken, further quantitative βhCG monitoring is required to confirm successful treatment because ectopic pregnancy persists in 8% to 19% of cases.[76,84]

In women who had one fallopian tube and underwent a salpingostomy, 54% achieved a subsequent intrauterine pregnancy, but 21% had a further ectopic pregnancy.[76]

The details of surgical techniques are beyond the scope of this chapter. Salpingectomy may be undertaken laparoscopically or by open surgery. Open surgery is more likely to be undertaken if the woman is in shock or is otherwise showing signs of hemodynamically instability. Laparoscopic salpingectomy techniques include resection with diathermy and scissors, loop ligatures, or single-use proprietary stapling instruments. Conservative surgery generally involves a linear incision along the antimesenteric border of the fallopian tube, over the site of the ectopic pregnancy. The pregnancy is removed by flushing with high-pressure hydrodissection, and hemostasis is achieved by (bipolar) diathermy. In two small studies, prophylactic local infiltration of dilute vasopressin was used in 40 hemodynamically stable women with a small unruptured ectopic pregnancy,[85] and diluted oxytocin was used in 25 similar women.[86] These interventions reduced the need for electrocoagulation for hemostasis (RR, 0.36; 95% CI, 0.14–0.95) without side effects, resulting in a significantly shorter operation time, reduced intraoperative and postoperative blood loss, and easier removal of the tubal pregnancy without side effects. However, neither study showed any benefit in reducing the likelihood of persistent trophoblastic disease.

FERTILITY AFTER SURGERY

After salpingectomy, in a woman who has a normal fallopian tube on the contralateral side, the likelihood of any pregnancy being intrauterine is still greater than 50%.[87] After salpingotomy, the likelihood of an intrauterine pregnancy is approximately 65%.[76,88]

Any study of fertility after radical or conservative treatment must consider the fact that there is a higher chance of salpingectomy if the initial ectopic pregnancy ruptured. In studies that considered this important factor, no appreciable difference was found in the subsequent

intrauterine pregnancy rates.[89] The factors that altered the likelihood of conception included the woman's age, previous tubal damage, and infertility.[89] This holds true even if the previous ectopic pregnancy ruptured.[90] The reported likelihood of a future ectopic pregnancy after 3 years of follow-up varies. It is 18% to 23% after conservative treatment and 28% after radical treatment.[89,91]

On economic and fertility outcome grounds, there are no clear indicators as to whether salpingectomy or salpingostomy is more appropriate for women who have both fallopian tubes.

Future Advice and Appropriate Treatment

After an ectopic pregnancy, many women are concerned about their future and the likelihood of recurrence. Regardless of the initial form of treatment, the likelihood of a further ectopic pregnancy varies little. Previous tubal rupture does not appear to have a detrimental effect on future fertility. Smoking is an independent risk factor for fertility, and the likelihood of a future intrauterine pregnancy appears to be increased by stopping smoking.[89] Future fertility also decreases if the woman is older (>35 years)[90] or has had previous tubal damage or infertility.[89] For these women, assisted conception may offer a better chance of an intrauterine pregnancy. The risk of a further ectopic pregnancy is strongly increased (three to four times) if the woman was previously nulliparous, if this was not her first ectopic pregnancy, if she has had previous tubal surgery,[91] or if there are adhesions around either fallopian tube.[89]

If a woman has had a previous ectopic pregnancy, any subsequent pregnancy is more likely to be ectopic. Under these circumstances, early review by high-resolution TV USS in a special EPC is advisable so that evaluation can be made of the site and viability of the pregnancy as soon as possible. This will either provide reassurance or allow timely intervention.

GESTATIONAL TROPHOBLASTIC DISEASE

GTD is an uncommon cause of vaginal bleeding in the first half of pregnancy. The disease encompasses a wide range of conditions that vary in their clinical presentation, their propensity for spontaneous resolution, local invasion and metastasis, and their overall prognosis. These conditions include complete or partial hydatidiform mole, invasive mole, choriocarcinoma, and placental site trophoblastic tumors.[95–97] The worldwide incidence of GTD is approximately 0.6 to 2.3 per 1000 pregnancies. Most cases are complete or partial hydatidiform moles.[98–100] The most invasive form of GTD, choriocarcinoma, has an incidence of 0.2 to 2.0 per 10,000 pregnancies.

The incidence of all types of GTD is reported to be up to twice as high in the Far East, particularly in Korea and Japan.[99,101] The woman's age is a consistently demonstrated risk factor for hydatidiform mole. Compared with women aged 25 to 30 years, there is approximately a 6-fold excess risk in women who become pregnant before 15 years of age and approximately a 300-fold excess risk in women who become pregnant after 45 years of age.[98,102] This age association is much greater for complete, rather than partial, hydatidiform mole. However, because women at these extremes of reproductive age represent such a small proportion of all pregnancies, more than 90% of molar pregnancies still occur in women aged 18 to 40 years. A history of a previous molar pregnancy is also a risk factor. Women with a history of one hydatidiform mole have at least a 10-fold greater risk of a repeat molar pregnancy, usually the same type of mole as in the preceding pregnancy, which equates to an incidence of approximately 18 per 1000 pregnancies.[103,104]

A complete hydatidiform mole is usually diploid and entirely androgenetic in origin. Most have a 46,XX karyotype; a few have a 46,XY karyotype. A complete molar pregnancy consists of diffuse hydropic chorionic villi with trophoblastic hyperplasia, forming a mass of multiple vesicles. There is usually no evidence of a fetus and minimal embryonal development.

A partial hydatidiform mole is usually triploid, with one maternal and two paternal haploid sets, either from dispermic fertilization or from fertilization with an unreduced diploid sperm. There is usually a fetus and a large placenta. The hydropic villi show a less florid appearance than is seen with a complete hydatidiform mole and are interspersed with normal chorionic villi. The fetus usually dies within a few weeks of conception, and a recent review did not identify any case in which a fetus of paternal (diandric) origin survived to term.[105] Very rarely, a partial molar pregnancy develops with two maternal and one paternal haploid set (digynic). In these cases, the placenta is small, the villi show minimal hydropic changes, and the fetus is growth-restricted. Some of these pregnancies have been reported to result

in live births, with subsequent early neonatal death.[106] One study suggested that diandric partial molar pregnancies have a greater malignant potential than digynic partial molar pregnancies. Of 3000 women with partial hydatidiform moles, 0.1% had a choriocarcinoma. All were genetically diandric.[107]

Persistent trophoblastic disease or malignant complications are much more common with a complete molar pregnancy than with a partial hydatidiform mole. The incidence of these complications is approximately 8% and 0.5%, respectively, compared with a risk of approximately 1:50,000 after a full-term pregnancy.

Diagnosis

Presentation and Clinical Features

Abnormal vaginal bleeding in early pregnancy, usually between 8 and 16 weeks' gestation, is the most common presentation. The diagnosis of a molar pregnancy might be suspected based on a number of clinical features (Table 4–6). These features are usually more prominent and develop at an earlier gestational age in women with a complete hydatidiform mole. The mean gestational age at diagnosis 40 years ago was 16 weeks, and this is still the case in many developing countries. In developed countries, most molar pregnancies are now diagnosed before 12 weeks, probably because of the increased use of high-resolution TV USS. With a complete mole, previously, ultrasound scan findings were reported characteristically as a "snowstorm" appearance of mixed echogenicity, representing hydropic villi and intrauterine hemorrhage (Fig. 4–5). This appearance is apparent only in later ultrasound scans when there has been some intrauterine hemorrhage. With increasing resolution and earlier use of ultrasound, a mole often shows a fine vesicular or honeycomb appearance rather than the classic description. The ovaries often contain multiple large theca-lutein cysts as a result of increased ovarian stimulation by excessive βhCG. Ultrasound diagnosis of a partial mole is more difficult. The fetus may still be viable, but may show signs consistent with triploidy, such as unusually

---

TABLE 4–6

Symptoms and Signs Suggestive of Gestational Trophoblastic Disease and Their Approximate Frequency

Irregular first-trimester vaginal bleeding (>90%)
Uterus large for dates (25%)
Pain from large benign theca-lutein cysts (20%)
Vaginal passage of grapelike vesicles (10%)
Exaggerated pregnancy symptoms:
  Hyperemesis (10%)
  Hyperthyroidism (5%)
  Early preeclampsia (5%)

FIGURE 4–5

early growth restriction or developmental abnormalities. There may be only scattered cystic spaces within the placenta, and ovarian cystic changes are usually much less pronounced. When there is diagnostic doubt, the scan should be repeated in 1 to 2 weeks.

The quantitative serum βhCG level is higher than expected in women with a complete mole, often exceeding 100,000 IU/L. This is much less likely in women with a partial mole; in these women, the level is often within the wide range associated with normal pregnancy. Partly as a result of the less elevated βhCG levels, the symptoms and signs of a partial mole are often delayed and mild enough to be missed. These women more often have a missed miscarriage or a spontaneous miscarriage, with the passage of a recognized fetus. The diagnosis of a partial mole is often missed clinically and is frequently made from subsequent histologic assessment of the products of conception. The clinical and pathologic differences between complete and partial hydatidiform moles are summarized in Table 4–7.

Investigations

Investigations directed at disease assessment include a complete blood count, measurement of creatinine and electrolytes, liver function tests, thyroid function tests, and a baseline quantitative βhCG measurement. A careful pelvic and abdominal ultrasound scan should be done to look for evidence of an invasive mole, exclude a coexisting pregnancy, and look for possible metastatic disease. Computed tomography or magnetic resonance imaging of the abdomen and pelvis may provide supplementary information. Chest radiography or computed tomography should be considered if there are symptoms that suggest pulmonary metastases. Computed tomography or magnetic resonance imaging of the brain should also be considered. If cerebrospinal metastases are suspected despite normal findings on imaging, a lumbar puncture may be done to measure βhCG levels in the cerebrospinal fluid. A plasma-to-cerebrospinal fluid ratio for βhCG of greater than 1:60 is strongly suggestive of occult cerebral metastases.[108,109]

Studies that relate to the prognosis include the ABO and Rhesus blood type of the woman and her partner, the ethnic origin of both partners, and a careful history of previous pregnancies and the duration of sex-steroid use by the woman.

TABLE 4–7

Clinical and Pathologic Differences between Complete and Partial Hydatidiform Moles

	COMPLETE MOLE	PARTIAL MOLE
Clinical		
Symptoms	Often severe and early	Often mild, similar to miscarriage
Diagnosis	Usually suspected from clinical and ultrasound features	Often missed clinically and diagnosed histologically from conception products
Persistent trophoblastic disease or tumor	8% of cases	0.5% of cases
Pathologic		
Macroscopic appearance	Grapelike vesicles often recognized; no fetal tissues	Often normal or suspected hydropic miscarriage; fetal tissue may be seen
Microscopic appearance	Diffuse hydropic villi; trophoblastic proliferation	Focal hydropic villi; variable mild trophoblastic proliferation; often focal; microscopic diagnosis sometimes difficult
Karyotype	Usually diploid; paternal chromosomes only	Usually triploid; diploid paternal and haploid maternal contribution

Risks

Risks include hemorrhage, persistent trophoblastic disease, malignant changes, psychological problems related to the loss of pregnancy, and the risks and need for follow-up of persistent or malignant disease.

Management Options

An algorithm for the management of GTD is shown in Figure 4–6.

Evacuation of Molar Pregnancy

Complete and partial molar pregnancies are managed differently.

Suction curettage is the method of choice for uterine evacuation of complete molar pregnancies. A suction catheter of up to 12 mm in diameter is usually sufficient because of the absence of fetal parts. It is best to avoid prior cervical preparation, the routine use of patient oxytocic drugs and sharp curettage, or medical evacuation with a complete mole, to minimize the risk of

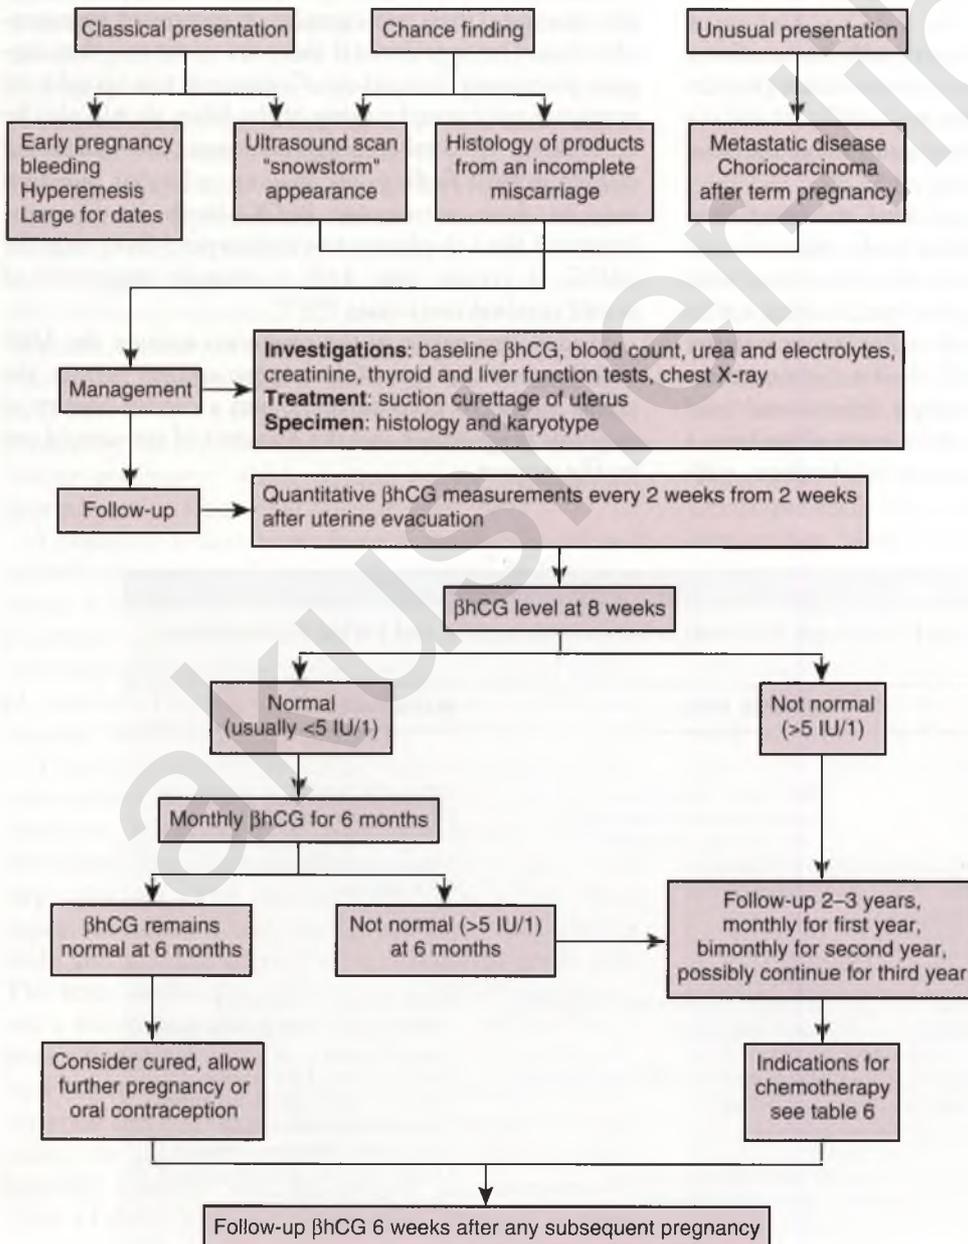
ALGORITHM FOR THE MANAGEMENT OF GESTATIONAL TROPHOBLASTIC DISEASE


FIGURE 4–6
Algorithm for the management of gestational trophoblastic disease.

dissemination of tissue leading to metastatic disease.[110,111] Oxytocic agents and prostaglandin analogues are best used only after uterine evacuation when there is significant hemorrhage.

In partial molar pregnancies that are recognized before uterine evacuation, suction curettage is the method of choice. However, when pregnancy is more advanced and the size of any fetal parts may reduce the chance of complete suction evacuation, medical termination can be used.

Total abdominal hysterectomy, with the molar pregnancy in situ, can be considered for older women whose families are complete. This approach reduces the risk of persistent trophoblastic disease by up to 50%.[112]

Follow-up After Uterine Evacuation

The aims of follow-up are to confirm successful treatment and to identify women with persistent or malignant GTD who may require adjuvant chemotherapy or surgery at an early stage. Persistent clinical symptoms, particularly vaginal bleeding, and continuing elevation of serum βhCG levels are the main indicators of residual disease. The approach to follow-up and the criteria for initiating chemotherapy vary around the world. The most effective systems are based on regional or national registries that involve experienced specialist oncologists.

Clinical follow-up and βhCG surveillance after uterine evacuation of a molar pregnancy vary in different countries and according to the different prognosis for persistent or malignant GTD between complete and partial hydatidiform moles. The clinical course for women who have had a partial hydatidiform mole is almost always benign after uterine evacuation. Persistent disease occurs in 1.2% to 4% of cases. Metastatic disease occurs in only 0.1% of cases.[113,114] In complete moles, these risks are approximately five times greater after treatment with uterine evacuation and two to three times greater after treatment with hysterectomy.[112,115] The risk of persistent or recurrent GTD is greatest in the first 12 months after evacuation, with most cases evident within 6 months.

In North America, current recommendations for surveillance after uterine evacuation of a molar pregnancy are for βhCG monitoring 48 hours after surgery and then weekly until three normal levels (<5 IU/L) have been obtained. Levels of βhCG are monitored at 2-week intervals for 3 months and monthly for 6 to 12 months for partial and complete molar pregnancies, respectively.

In the United Kingdom, there is a central registry for patients with molar pregnancies. Monitoring is supervised by a small number of screening centers. Monitoring of βhCG levels usually begins 2 weeks after uterine evacuation. The frequency and duration of monitoring is dependent on serum or urinary βhCG levels. With successful treatment by uterine evacuation alone, the serum βhCG level decreases to normal (<5 IU/L) after 8 weeks. Subsequent follow-up is usually by monthly serum or urinary βhCG monitoring for 6 months (for partial hydatidiform mole) or 12 months (for complete hydatidiform mole). If βhCG levels remain normal for 6 months, the risk of malignant GTD is very small, approximately 1:300, and the woman can consider a further pregnancy from that stage.[116]

Use of a combined oral contraceptive is best avoided until after the βhCG levels have returned to normal. Limited data suggest that this slows the rate of decrease of the βhCG level and may increase the risk of persistent GTD. However, the risk associated with an unplanned early pregnancy is greater, and the use of oral contraception is considered acceptable by some North American clinicians.[114,115]

Adjuvant chemotherapy may be required in approximately 10% of women after uterine evacuation. The indications for chemotherapy are shown in Table 4–8. The WHO scoring system uses a point score for different prognostic indicators, such as the woman's age, the hCG level, the ABO blood group of both partners, and the number and site of metastases. This allows the differentiation of women with low risk disease (who are usually treated with single-agent methotrexate and folinic acid rescue) from women with high risk disease (who require multiagent chemotherapy with etoposide, methotrexate, and actinomycin D [EMA], alternating with cyclophosphamide and vincristine [CO]).

After the completion of chemotherapy, serial βhCG measurements are usually assessed monthly for 1 year and then every 2 months for a second year. Cure rates are high, sometimes with additional salvage surgery, and more than 80% of women who wish to conceive are successful in achieving a pregnancy.[117] Monitoring of βhCG is advisable after any subsequent pregnancy, regardless of gestational age or outcome, to exclude recurrent GTD.

Women who have had a previous molar pregnancy should expect to have a normal chance of conception subsequently, even after chemotherapy. There is no evidence of an increase in the risk of fetal abnormalities, miscarriage, ectopic pregnancy, premature delivery, or stillbirth, compared with the normal population.[118–120]

In a subsequent pregnancy after chemotherapy for GTD, an ultrasound scan should be performed at 8 weeks' and 14 weeks' gestation. The risk of further GTD is 1.4% to 2.4%.[120] Monitoring of βhCG levels should be performed 6 weeks and 3 months after delivery.

TABLE 4–8

Indications for Adjuvant Chemotherapy in Gestational Trophoblastic Disease

Serum βhCG levels >20,000 IU/L more than 4 weeks after uterine evacuation
Static or rising βhCG levels at any time after uterine evacuation
Increased βhCG level 6 months after uterine evacuation
Metastases in liver, lung, brain, or gastrointestinal tract
Histologic diagnosis of choriocarcinoma

SUMMARY OF MANAGEMENT OPTIONS
Gestational Trophoblastic Disease

Management Options	Quality of Evidence	Strength of Recommendation	References
Presentation			
Complete moles cause more exaggerated symptoms and signs than partial moles.	III	B	121,122
Partial moles are often missed clinically and by ultrasound scan and are often diagnosed histologically after uterine evacuation of an incomplete miscarriage.			
Surgical Evacuation			
Primary treatment of choice for all moles	III	B	123
Suction curettage for uterine evacuation is safer than sharp curettage, particularly for evacuation of complete moles.	IIb	B	124
Oxytocics, cervical preparation, and medical termination are better avoided, particularly for evacuation of complete moles.	IV	C	116
Medical (for partial moles)			
Methotrexate	III	B	125
Actinomycin-D	III	B	125
Combination therapy	III	B	126,127
Follow-up			
If βhCG levels remain normal 8 weeks to 6 months after evacuation, a woman can be considered cured and further pregnancy allowed.	–	GPP	–
βhCG should be measured 6 weeks after any subsequent pregnancy because of the risk of further trophoblastic disease.	–	GPP	–

RHESUS PROPHYLAXIS

Guidelines from the Royal College of Obstetricians and Gynaecologists and the British Blood Transfusion Society[128] recommend that women who have a miscarriage after 12 weeks' gestation should be given anti-D. Between 12 and 20 weeks' gestation, a Kleihauer test to quantify fetomaternal hemorrhage is not required; treatment with 250 IU anti-D immunoglobulin is adequate.

For miscarriages and ectopic pregnancies earlier than 12 weeks' gestation, the evidence for decision-making is poor. There is general consensus that complete spontaneous miscarriages without surgical intervention do not require anti-D prophylaxis.[128] When surgical evacuation of the uterus is required, even before 12 weeks' gestation, it is associated with a higher chance of transfer of fetal cells to the maternal circulation.[129] Under these circumstances, 250 IU anti-D immunoglobulin should be given to all Rhesus-negative women.[130]

With a threatened miscarriage before 12 weeks' gestation, anti-D is generally not required. However, Rhesus prophylaxis may be prudent if the patient has very heavy bleeding or considerable abdominal pain. If a threatened miscarriage occurs later than 12 weeks, anti-D (≥ 250 IU) should be given. If bleeding is persistent, this may be repeated at intervals of no more than 6 weeks. The half-life of anti-D is 2 weeks. Prophylaxis may be needed at 2-week intervals if bleeding is heavy or if it is indicated by the results of a Kleihauer test.[128]

Most religious groups who have concerns about the use of blood products do not object to the use of anti-D prophylaxis.

If it is indicated, anti-D prophylaxis should be given within 72 hours of the sensitizing episode.[131] A 250-IU dose is sufficient for fetomaternal hemorrhage before 12 weeks' gestation. The use of anti-D immunoglobulin in Rhesus-negative women in later pregnancy is addressed in Chapter 14.

SUMMARY OF MANAGEMENT OPTIONS

Rhesus Prophylaxis

Management Options	Quality of Evidence	Strength of Recommendation	References
Bleeding associated with threatened miscarriage before 12 weeks gestation does not require anti-D.	IV	C	128
Anti-D is required for an incomplete miscarriage only when surgical evacuation is required.	III	B	130

CONCLUSIONS

- Complications, usually vaginal bleeding and pain, are more common in the first trimester than at any other stage of pregnancy.
- These symptoms may be dramatic, and quick assessment, accurate diagnosis, and prompt management are necessary to minimize maternal morbidity and mortality.
- When the symptoms are less acute, careful assessment with high-resolution ultrasound and serum βhCG measurements is critical.
- TV USS and βhCG together usually allow the differentiation of a normal, viable intrauterine pregnancy from the complications of miscarriage, ectopic pregnancy, and hydatidiform mole.
- Management considers the woman's future reproductive expectations. In the case of hydatidiform mole, other specialists may need to be involved and longer-term follow-up may be required.

Recurrent Miscarriage

May Backos / Lesley Regan

INTRODUCTION

Miscarriage is the most common complication of pregnancy. Approximately 50% of all conceptions[1] and 15% of all recognized pregnancies[2] result in miscarriage. The World Health Organization[3] defined miscarriage as the "expulsion or extraction from its mother of an embryo or fetus weighing 500 g or less." The more accepted definition of miscarriage is "spontaneous expulsion of the conceptus before viability has been achieved."

Recurrent miscarriage, which is defined as the loss of three or more consecutive pregnancies, affects 1% of couples who are trying to achieve a successful pregnancy.[4] Because the incidence of recurrent miscarriage is higher than that expected by chance alone (0.34%),[5,6] a proportion of couples with recurrent miscarriage have a persistent underlying cause for their pregnancy losses. Careful studies are needed to identify potentially treatable factors. Most clinicians agree that there is sufficient justification to initiate diagnostic evaluation of couples after three miscarriages. However, some argue that even two miscarriages warrant investigation because the possibility of finding an underlying causal factor is similar after two or three miscarriages (approximately 50%).[7] A further argument is that couples with two miscarriages should not be subjected to the trauma of another miscarriage before undergoing testing. The contrary argument is that most (80%) of these couples achieve a successful pregnancy outcome without undergoing stressful and expensive investigations.

RISK FACTORS FOR RECURRENT MISCARRIAGE

Recurrent miscarriage is a heterogeneous condition, and more than one factor may underlie recurrent pregnancy loss.

Epidemiologic Factors

Maternal Age

The risk of miscarriage increases with advancing maternal age, regardless of reproductive history, as a result of an age-related increase in chromosomally abnormal conceptions or a decline in uterine and ovarian function. A large prospective register linkage study[8] reported the following age-related risks of miscarriage in recognized pregnancies:

- 13.3% at 12 to 19 years
- 11.1% at 20 to 24 years
- 11.9% at 25 to 29 years
- 15% at 30 to 34 years
- 24.6% at 35 to 39 years
- 51% at 40 to 44 years
- 93.4% at 45 years or older

More recently, advanced paternal age was identified as a risk factor for miscarriage. A large multicenter European study[9] reported that the risk of miscarriage is highest for couples in which the woman is 35 years or older and the man is 40 years of age or older.

Reproductive History

Reproductive history is an independent predictor of future pregnancy outcome. The risk of a further miscarriage increases after each successive pregnancy loss, reaching approximately 40% after three consecutive pregnancy losses. A prospective study[2] concluded that a woman's risk of miscarriage can be quantified by her obstetric history. The single most important predictor is a previous miscarriage. For example, primigravidae and women with a history of live births have a 5% chance of miscarriage in their next pregnancy, a significantly lower risk than that in women whose last pregnancy ended in miscarriage (19%). Similarly, a large Danish study[10] in

an unselected population reported a 10% risk of miscarriage in primigravidae. The risk increased to 15%, 24%, 43%, and 54% after one to four previous consecutive miscarriages, respectively. These observations may be partly explained by reproductive compensation. Women whose pregnancy ends in miscarriage tend to embark on more pregnancies at progressively later ages, until they achieve the desired family size. Data from populations with recurrent miscarriage suggest that a previous live birth does not preclude subsequent recurrent miscarriage.[11,12]

Genetic Factors

Chromosomal abnormalities of the embryo account for at least 50% of first-trimester sporadic miscarriages[13] and 29% to 57% of further miscarriages in couples with recurrent miscarriage.[14,15] However, most published studies used conventional cytogenetic analysis, which identifies only gross chromosomal aberrations. Conventional cytogenetic analysis depends on tissue culture before karyotyping and is limited by external contamination, culture failure, and selective growth of maternal cells.[16] More recently, analysis of miscarriage tissue by comparative genomic hybridization (a technique that detects chromosomal abnormalities without the need for culture) showed that conventional cytogenetic analysis underestimates the incidence of chromosomal anomalies and that the contribution of chromosomal abnormalities to first-trimester miscarriage is nearly 70%.[17]

Parental Chromosomal Rearrangement

In approximately 3% to 5% of couples with recurrent miscarriage, one partner carries a balanced structural chromosomal abnormality.[18,19] Women are more likely than men to carry most types of chromosomal rearrangements.[18] The most common types of parental chromosomal abnormalities are balanced translocations, either reciprocal or Robertsonian (Fig. 5–1). In reciprocal translocations, segments distal to breaks in two chromosomes are exchanged. In Robertsonian translocations, two acrocentric chromosomes fuse at the centromeric region, with loss of the short arms. Although carriers of a balanced translocation are usually phenotypically normal, their pregnancies are at increased risk for miscarriage and may result in a live birth of a child with multiple congenital malformations or mental handicaps because of an unbalanced chromosomal arrangement. The risk of miscarriage is affected by the size and genetic content of the rearranged chromosomal segments.

A less common chromosomal abnormality that may cause recurrent miscarriage is a chromosome inversion. This has been reported in 0.2% of couples with recurrent miscarriage.[18]

Embryonic Aneuploidy and Polyploidy

Aneuploidy is caused by nondisjunction during meiosis that leads to the production of an extra chromosome (trisomy) or the deletion of a chromosome (monosomy). Triploidy occurs when there is a complete set of extra chromosomes. This usually arises from fertilization of the oocyte by two spermatozoa or from failure of one of the maturation divisions of either the oocyte or the spermatozoon. Tetraploidy (four times the haploid number) is usually caused by failure to complete the first zygotic division. In couples with recurrent miscarriage, conventional cytogenetic analysis reports the incidence of trisomy, polyploidy, and monosomy X in miscarriage tissue as 30%, 9%, and 4%, respectively.[15] Most trisomies are the result of meiotic error as a result of advanced maternal age[20]; however, gonadal mosaicism and sperm aneuploidies also increase the risk of trisomic conceptions. The risk of sex chromosome monosomy and polyploidy conceptions do not increase with maternal age.[21]

Some couples with a history of recurrent miscarriage are at risk for recurrent aneuploidy. The embryonic karyotype in a previous pregnancy may help to predict the future miscarriage rate. Women with a previous normal

embryonic karyotype miscarry more frequently than those with an abnormal embryonic karyotype,[14,22] suggesting that mechanisms other than fetal chromosomal abnormalities may account for some cases of recurrent miscarriage.

Molecular Mechanisms

Recent advances in molecular genetic technology highlighted the importance of certain mechanisms, such as single-gene mutations and skewed X chromosome inactivation, in the etiology of pregnancy loss. The role of single-gene mutations, which cause abnormalities in embryonic, placental, or cardiac development, is the subject of current research.[23]

Skewed X chromosome inactivation (preferential expression of either the maternal or paternal X chromosome in most maternal cells) is significantly more common in women with recurrent miscarriage compared with control subjects.[24] These findings suggest that women with skewed X chromosome inactivation may carry an X-linked recessive fetal-lethal trait that makes them susceptible to recurrent miscarriage. Future research may identify the specific X-linked and autosomal genes that are linked to pregnancy loss.

Anatomic Disorders

Congenital Uterine Malformations

Congenital uterine malformations (Fig. 5–2) are the result of disturbances in müllerian duct development, fusion, canalization, and septal reabsorption. The contribution of congenital uterine anomalies to recurrent pregnancy loss is unclear because the true prevalence and reproductive implications of uterine anomalies in the general population are unknown. In patients with recurrent miscarriage, the reported frequency of uterine anomalies varies widely, from 1.8% to 37.6%.[25] This variability may reflect differences in the criteria and techniques used for diagnosis and the fact that available studies included women with two, three, or more miscarriages at both early and late stages of pregnancy. The prevalence of uterine anomalies is highest in women with a history of late miscarriages, which probably reflects the greater prevalence of cervical incompetence in women with uterine malformation.[26]

Using three-dimensional ultrasound as a diagnostic tool, a recent large prospective study[27] reported that the frequency of uterine anomalies was 23.8% in women with recurrent first-trimester miscarriage (three or more consecutive pregnancy losses) compared with a frequency of 5.3% in low-risk women who were referred

for ultrasound for a variety of reasons unrelated to reproductive outcome. Further, distortion of uterine anatomy was more severe in women with recurrent miscarriage. These findings suggest that congenital uterine anomalies may contribute to pregnancy loss in a small proportion of women with recurrent miscarriage.

A retrospective review[25] of reproductive performance in patients with untreated uterine anomalies suggested that these women have high rates of miscarriage and preterm delivery and a term delivery rate of only 50%. However, retrospective studies are biased by patient selection. Until well-controlled prospective data become available, the role of uterine anomalies in recurrent miscarriage will be debatable.

Cervical Incompetence

Cervical incompetence is a well-recognized cause of recurrent midtrimester miscarriage. It is defined as the inability to support a term pregnancy because of a functional or structural defect of the cervix. Cervical incompetence occurs along a spectrum of severity. Severe incompetence leads to midtrimester miscarriage, and lesser degrees underlie some cases of preterm delivery.[28] The true incidence of cervical incompetence is unknown, because the diagnosis is essentially clinical and there are no agreed objective criteria for the diagnosis. Crude estimates from epidemiologic studies suggest an approximate incidence of 0.5% in the general obstetric population[29] and 8% in women with previous midtrimester miscarriages.[30]

Although some cases involve mechanical incompetence, such as congenital hypoplastic cervix, previous cervical surgery, and extensive trauma, most women with a clinical diagnosis of cervical incompetence have normal cervical anatomy. When considered as a continuum, premature cervical ripening may represent a final common pathway of a variety of pathophysiologic processes, such as infection, colonization, inflammation, and hormonal or genetic predisposition.[31] The cervix is the main mechanical barrier separating the pregnancy from the vaginal bacterial flora. Many patients who have asymptomatic midtrimester cervical dilation have evidence of subclinical intrauterine infection.[32] It is unclear whether this high rate of microbial invasion is the result or the cause of premature cervical dilation. When premature cervical ripening occurs, the mechanical barrier is disrupted, which may further stimulate processes (e.g., colonization of the upper genital tract) that culminate in spontaneous preterm birth. When cervical incompetence is associated with mechanical weakness, supportive measures such as cerclage may prevent ascending infection and hence may prolong pregnancy. In contrast, if cervical changes result from nonmechanical processes, then cerclage would be less effective, and even harmful in some cases, because of possible inflammatory and infectious complications.

Fibroids

Uterine fibroids have long been associated with a variety of reproductive problems, including pregnancy loss. The extent of the association is affected by the size and location of the fibroids. Although the exact mechanisms are unclear, the presumed theories of pathophysiology include mechanical distortion of the uterine cavity, abnormal vascularization, abnormal endometrial development, endometrial inflammation, abnormal endocrine milieu, and structural and contractile myometrial abnormalities.[33] Evidence of the association between uterine fibroids and recurrent miscarriage is retrospective[34] and insufficient to determine differences in pregnancy outcome or assess the effect of the size and location of the fibroids. Recent data from patients with infertility suggest that only fibroids with a submucosal or an intracavitary component are associated with a reduced implantation rate and an increased rate of miscarriage.[35] Subserous fibroids have no deleterious effect, and the role of intramural fibroids that do not distort the cavity is controversial.[35-37]

Intrauterine Adhesions

Intrauterine adhesions (Asherman's syndrome, an acquired uterine defect of varying severity) result from intrauterine trauma after vigorous endometrial curettage or evacuation of retained products of conception. Intrauterine adhesions are associated with recurrent miscarriage. The presumed mechanisms are decreased uterine cavity volume and fibrosis and inflammation of the endometrium that predispose the patient to abnormal placentation and pregnancy loss. However, evidence of the association is mostly retrospective[38,39] and conflicting,[40] and no robust prospective evidence confirms a causal relationship.

Endocrine Factors

Luteal Phase Defect and Progesterone Deficiency

Luteal phase defect is an entity in which the corpus luteum is defective, with insufficient progesterone production resulting in retarded endometrial development. Because progesterone is necessary for successful implantation and the maintenance of early pregnancy, progesterone deficiency during the luteal phase is associated with recurrent miscarriage. However, standard diagnostic criteria required to assess the true incidence and effect of luteal phase defect as a cause of recurrent miscarriage are lacking. Diurnal variations and pulsatile secretion make serum progesterone measurements unreliable, and the interpretation of the results of endometrial biopsy is susceptible to sampling and interobserver variation.[41] Additionally, serum progesterone levels are not predictive of pregnancy outcome; low progesterone levels in early pregnancy appear to reflect a pregnancy that has already failed.

Moreover, no convincing studies show that treatment of luteal phase defect improves pregnancy outcome in women with recurrent miscarriage.[42,43]

Polycystic Ovary Syndrome, Hypersecretion of Luteinizing Hormone, and Hyperandrogenemia

Polycystic ovary syndrome (PCOS) is linked to infertility and miscarriage. Polycystic ovaries, a high luteinizing hormone (LH) level, and hyperandrogenemia are classic features of PCOS and have been reported as risk factors for recurrent miscarriage. Although polycystic ovaries are found significantly more often among women with recurrent miscarriage than among parous control subjects, polycystic ovaries themselves do not appear to predict future pregnancy outcome in ovulatory women with recurrent miscarriage.[44] A high level of LH or testosterone does not correlate with pregnancy outcome in ovulatory women with recurrent miscarriage.[45] Further, a prospective randomized placebo-controlled trial[46] reported that prepregnancy suppression of high LH does not improve the live birth rate, and the outcome of pregnancy in women in the placebo group was similar to that in women with a normal LH level.

More recently, the association between PCOS and insulin resistance leading to compensatory hyperinsulinemia has come under scrutiny as a risk factor for recurrent miscarriage. Insulin resistance is associated with a higher rate of miscarriage among women with PCOS undergoing ovulation induction compared with those who are not insulin resistant.[47] Preliminary reports[48,49] suggest that metformin treatment (which increases sensitivity to insulin) in women with PCOS during induction of ovulation and early pregnancy may improve endometrial receptivity and implantation and reduce the risk of future miscarriage. However, the role of insulin resistance and the effectiveness and safety of metformin in women with polycystic ovaries and recurrent miscarriage remain to be established in prospective controlled trials.

Systemic Endocrine Factors

Diabetes mellitus and thyroid disease are associated with miscarriage, but there is no direct evidence that they contribute to recurrent miscarriage. Women with diabetes who have high hemoglobin A_{1c} levels in the first trimester are at risk for miscarriage and fetal malformation.[50] In contrast, well-controlled diabetes mellitus is not a risk factor for recurrent miscarriage, nor is treated thyroid dysfunction.[51,52] The prevalence of diabetes mellitus and thyroid dysfunction in women with recurrent miscarriage is similar to that expected in the general population.[19,53,54]

Thyroid autoantibodies are not associated with recurrent miscarriage. Women with recurrent miscarriage are no more likely than fertile control subjects to have circulating thyroid antibodies.[55] The presence of thyroid antibodies in euthyroid women with a history of recurrent miscarriage does not affect future pregnancy outcome.[56]

Coagulation and Immunologic Factors

Thrombophilia

The hemostatic system plays an important role in the establishment and maintenance of pregnancy. A thrombophilic defect is an abnormality in the coagulation system that predisposes an individual to thrombosis. During the last few years, the role of antiphospholipid syndrome (APS), an acquired thrombophilic defect, has become an established and treatable cause of recurrent miscarriage and the potential role of other thrombophilic defects (acquired or inherited) has been explored. The presumed hypothesis is that some cases of recurrent miscarriage and later pregnancy complications are caused by an exaggerated hemostatic response during pregnancy, leading to thrombosis of the uteroplacental vasculature and subsequent fetal demise.

Antiphospholipid Antibodies

Antiphospholipid antibodies (aPLs) are a family of heterogeneous autoantibodies that react with epitopes on proteins that are complexed with negatively charged phospholipids. In the etiology of recurrent pregnancy loss, the two most clinically important aPLs are lupus anticoagulant and anticardiolipin antibodies.

APS is the association between aPLs and pregnancy morbidity or vascular thrombosis.[57] Pregnancy morbidity includes recurrent first-trimester miscarriage, one or more morphologically normal fetal deaths after the 10th week of gestation, and one or more preterm births before the 34th week of gestation as a result of severe preeclampsia, eclampsia, or placental insufficiency. APS in patients with chronic inflammatory diseases, such as systemic lupus erythematosus, is referred to as "secondary APS." In contrast, "primary APS" affects patients with no identifiable underlying systemic connective tissue disease.

A major characteristic of APS is recurrent miscarriage. In 15% of women with recurrent miscarriage, aPLs (lupus anticoagulant and anticardiolipin IgG or IgM antibodies) are present.[58] In comparison, the prevalence of aPLs in women with a low-risk obstetric history is less than 2%.[59] In untreated pregnancies, the chance of successful pregnancy outcome in women with aPLs is exceedingly poor and the live birth rate may be as low as 10%.[60] The mechanisms by which aPLs cause adverse pregnancy outcome are varied, reflecting in part their heterogeneity. Historically, the pathogenesis of aPL-related pregnancy loss focused on placental thrombosis.[61,62] However, thrombosis is neither specific nor universal, and recent research provides new insights into the mechanisms of aPL-related pregnancy failure. Defective decidualization of the endometrium and

abnormal early trophoblastic function and differentiation may be the primary pathologic mechanisms.[63-66]

Inherited Thrombophilic Defects

Inherited thrombophilic defects are established causes of systemic thrombosis. These defects include activated protein C resistance (most commonly caused by the factor V Leiden [FVL] gene mutation); protein C, protein S, and antithrombin III deficiencies; hyperhomocysteinemia; and prothrombin gene mutation. Recently, these defects were reported to be associated with fetal loss and late pregnancy complications. Evidence of this association is largely retrospective, and prospective data are inadequate to prove a causal relationship. A recent meta-analysis[67] of pooled data from 31 retrospective studies suggested that the magnitude of the association between inherited thrombophilia and fetal loss varies according to the type of fetal loss and the type of thrombophilic disorder. In that meta-analysis, FVL mutation, an inherited activated protein C resistance, was associated with a history of both early and late recurrent fetal loss and late nonrecurrent fetal loss. Acquired activated protein C resistance was associated with early recurrent fetal loss, and the prothrombin gene mutation was associated with early recurrent and late nonrecurrent fetal loss. Protein S deficiency was associated with late nonrecurrent fetal loss. Methylenetetrahydrofolate mutation, protein C, and antithrombin III deficiencies were not significantly associated with fetal loss. However, because protein C and antithrombin III deficiencies are rare, the number of women available for study was too small to show a difference in pregnancy outcome.

Only one small prospective study[68] showed that women with recurrent miscarriage who carry the FVL mutation are at significantly increased risk for miscarriage compared with those with a normal factor V genotype. However, carrying the FVL mutation did not preclude an uncomplicated pregnancy delivered at term. No test can reliably discriminate between women with recurrent miscarriage and FVL mutation who are destined to miscarry and those who are destined to have a successful pregnancy.

Disorders of Maternofetal Alloimmune Relationships

The hypothesis that successful pregnancy depends on maternal immunologic tolerance of the fetus and that some cases of recurrent miscarriage result from failure of maternal alloimmune recognition of the pregnancy has not been substantiated. No alloimmune mechanisms have been shown unequivocally to cause recurrent miscarriage in humans. No clear evidence supports the hypothesis that HLA incompatibility between couples, the absence of maternal leukocytotoxic antibodies, or the absence of maternal blocking antibodies is related to recurrent miscarriage. These tests should no longer be offered routinely to women with recurrent miscarriage. The role of endometrial immunity in recurrent early

pregnancy loss is under investigation. Immune effector cell dysfunction and defects in immunosuppressive factors, cytokines, and growth factors at the local maternofetal interface may be implicated in the pathogenesis of implantation failure and recurrent early pregnancy loss.[69,70] However, further studies are needed.

A Cochrane systematic review[71] found that various forms of immunotherapy, including paternal cell immunization, third-party donor leukocytes, trophoblast membranes, and intravenous immune globulin (IVIG), are of no benefit in women with unexplained recurrent miscarriage. Further, immunotherapy is expensive and has potentially serious side effects, including transfusion reaction, anaphylactic shock, and hepatitis, and it should no longer be offered to women with unexplained recurrent miscarriage outside the context of approved clinical research projects.[72]

Other Factors

Infections

The role of infection in recurrent miscarriage is weak. Any severe infection that leads to bacteremia or viremia can cause sporadic miscarriage. However, for an infective agent to be implicated in the etiology of repeated pregnancy loss, it must persist in the genital tract and avoid detection or cause insufficient symptoms to disturb the woman. Toxoplasmosis, rubella, cytomegalovirus, herpes, and Listeria infections do not fulfill these criteria.[73] Although bacterial vaginosis in the first trimester has been reported as a risk factor for second-trimester miscarriage and preterm delivery,[74] evidence of an association with first-trimester miscarriage is inconsistent.[75,76] In women with a history of midtrimester miscarriage or preterm birth, detection and treatment of bacterial vaginosis early in pregnancy may reduce the risk of preterm, prelabor rupture of the membranes and low birth weight, but it did not reduce the risk of preterm birth.[77] Whether this treatment improves neonatal outcome is unclear.

Environmental Factors

Most data on environmental risk factors concentrated on sporadic rather than recurrent miscarriage. The results have been conflicting and undoubtedly biased by difficulties in controlling for confounding factors, the inaccuracy of exposure data, and the measurement of toxin dose. Most studies[78] agree that maternal cigarette smoking is associated with a dose-dependent increased risk of spontaneous miscarriage. Interestingly, however, a recent study challenged these findings.[79] Heavy alcohol consumption is toxic to the embryo and the fetus. Even moderate consumption of five or more units* per week may increase the risk of sporadic miscarriage.[80] Caffeine consumption is associated with a dose-dependent increased risk of miscar-

---

*1 unit of alcohol is equal to approximately 8g of absolute alcohol, or one small glass of wine.

riage. The risk becomes significant when caffeine intake exceeds 300 mg (3 cups of coffee) daily.[79,81,82] Working with or using video display terminals does not increase the risk of miscarriage.[83] Evidence on the effect of anesthetic gases among theater workers is contradictory. Earlier studies suggested an increase in the risk of spontaneous miscarriage, but more recent studies have reported that exposure to waste anesthetic gases did not increase the risk of miscarriage among theater workers.[84,85]

Psychological Factors

Miscarriage is a stressful life event, and recurrent miscarriage may affect the patient's mental health. A recent study[86] indicated that 33% of women with recurrent miscarriage were clinically depressed, and 21% had levels of anxiety that were equal to or higher than those in typical psychiatric outpatient populations. Animal data[87] indicate that stress may induce miscarriage. A recent small prospective study[88] indicated that among 14 psychological parameters studied, only a high depression scale affected the miscarriage rate in women with a history of two previous miscarriages. Larger prospective studies are needed to address the scope of psychological disorders and their contribution to recurrent miscarriage.

MANAGEMENT OPTIONS

"Prepregnancy" When the Third Miscarriage Occurs

A detailed history of the previous miscarriages is important to identify the underlying etiology. When the third miscarriage occurs, it is important to consider the following factors:

- The underlying causes of first-trimester miscarriage are different from those responsible for midtrimester loss. Therefore, it is important to determine the accurate gestational age, confirmed by ultrasound wherever possible, when the miscarriage occurred.
- If a first-trimester miscarriage occurred, determine whether the loss was biochemical, anembryonic (blighted ovum), embryonic (6–8 weeks), or fetal (>8 weeks). Different pathologic factors affect the various stages of early pregnancy. For example, biochemical and anembryonic losses are more likely to be associated with chromosomally abnormal embryos.
- Note whether fetal heart activity was detected before the miscarriage. Most first-trimester miscarriages associated with APS occur after the establishment of fetal heart activity.
- When surgical evacuation of the products of conception is performed, it is important to document suspected uterine abnormalities, such as a bicornuate or subseptate uterus or fibroids. Tissue should be collected and sent for both histologic examination (to confirm the diagnosis and exclude trophoblastic disease) and fetal karyotype (Table 5–1).
- If a second-trimester miscarriage occurred, note whether the pregnancy loss was preceded by intrauterine fetal death, spontaneous rupture of the membranes, vaginal bleeding, painful uterine contractions, or painless cervical dilation. This information is particularly useful in identifying or excluding a presumed diagnosis of cervical incompetence. The couple should be encouraged to consent to a full fetal postmortem examination, fetal karyotyping, and placental histologic examination.
- Ensure that a follow-up appointment is scheduled for the couple.

TABLE 5–1

Chromosome Analysis of the Products of Conception: Tissue Collection

General	It is a good practice, and in some countries a legal requirement, to obtain patient consent before tissue collection for diagnostic testing. Ensure aseptic technique in tissue handling.
Collection: first-trimester miscarriage	Collect all fetal tissue and placental villi.
Collection: second-trimester miscarriage	Obtain a small sample of full-thickness fetal skin with subepidermal layers. It is important, particularly in cases of intrauterine fetal death and macerated fetus, that in addition to a fetal sample, a placental biopsy is also sent, because culturing of the fetal sample is often unsuccessful. The placental biopsy specimen should be a wedge from the cord insertion site and should include membranes.
Container	Use a sterile universal container containing sterile saline or transport media provided by the cytogenetic laboratory. Do not add formalin. The transport media should be regularly renewed.
Labeling	Record patient details, including name, date of birth, and hospital number on the sample container label. Include a completed referral form. The laboratory should be informed that the sample will be sent.
Transport and storage	Send samples to the laboratory immediately after collection. Transport them at room temperature. Sample can be refrigerated at 4°C if they are not sent until the next day. Do not freeze samples.
Causes for rejection	Samples may be rejected because of gross contamination, necrotic tissue, or the use of fixative.
Limitations	Some products of conception may contain only maternal tissue. Trophoblasts may contain mosaicisms or aneuploidy not present in the fetus.

Prepregnancy Assessment and Counseling after the Third Miscarriage

The loss of a pregnancy at any stage is a tragic event, and sensitivity is required in assessing and counseling couples with recurrent miscarriage. A dedicated recurrent miscarriage clinic is often a better environment in which to provide this care rather than a busy postnatal or general gynecologic clinic. Ideally, the couple should be seen together and given accurate information to facilitate decision-making about future pregnancies (see "Risk Factors for Recurrent Miscarriage"). When possible, the couple should be given written information to take home.

History

A comprehensive history should be obtained from both partners, noting their age and obstetric, gynecologic, medical, surgical, social, psychological, and family histories. Seeking the cooperation of the patient's family physician and other physicians may be necessary to obtain relevant information.

Physical Examination

The physical examination should include height, weight, blood pressure, and a general assessment of signs of endocrine disease. Pelvic examination should assess signs of previous cervical trauma or surgery, genital tract anomalies, and uterine size.

Investigation of Recurrent Miscarriage (Table 5–2)

Testing should include the following:

- Parental karyotyping of both partners is performed to determine abnormal chromosome rearrangements, translocations, or inversions.
- Two-dimensional pelvic ultrasound is performed to identify polycystic ovaries and assess the uterine anatomy. Suspected uterine anomalies may require further studies with hysterosalpingography, hysteroscopy, laparoscopy, or three-dimensional pelvic ultrasound.
- Early follicular phase (days 2–4 of cycle) LH, follicle-stimulating hormone, and testosterone levels are measured for evidence of LH hypersecretion, hyperandrogenemia, and possible high levels of follicle-stimulating hormone.
- All women with recurrent miscarriage should be screened for aPLs before pregnancy. The diagnosis of APS requires at least two positive test results 6 weeks apart of either lupus anticoagulant or anticardiolipin IgG or IgM antibodies in medium or high titers. Women with one positive test result and a second negative test result should have a third aPL test to confirm

TABLE 5–2	
Investigation of Recurrent Miscarriage	
All patients	Karyotype
	Parental

HSG, hysterosalpingography; MTHFR, methyleretetrahydrofolate reductase.

or refute the APS diagnosis. The detection of aPLs is subject to considerable interlaboratory variation because of temporal fluctuation of aPL titers in individual patients, transient positivity as a result of infection, suboptimal methods of sample collection and preparation, and lack of standardization of laboratory tests for their detection.[89] Therefore, laboratory assays should be performed according to international guidelines.[57] Because maternal aPLs may be down-regulated during pregnancy,[90] tests are best performed preconceptually. Testing for aPLs other than lupus anticoagulant or anticardiolipin antibodies is uninformative.[57] Although no single test detects all lupus anticoagulant, the dilute Russell viper venom time test, together with platelet neutralization, is more sensitive and specific than either the activated partial thromboplastin time or the kaolin clotting time test.[58] Anticardiolipin antibodies are detected with a standardized enzyme-linked immunosorbent assay.

- Screening for APC resistance should include coagulation tests for both unmodified and modified APC resistance and factor V genotyping with polymerase chain reaction.

Other studies are determined by positive findings on history, examination, and laboratory tests. Table 5–2 shows a complete list of possible tests. It is unlikely that a cause will be found in more than half of the cases of recurrent miscarriage.[7]

Prepregnancy Treatment Options

General Approach

Couples should be treated sensitively and sympathetically. It is important to avoid recommending unproven treatments.

Epidemiologic Factors

Advanced maternal age and the number of previous miscarriages are two important independent risk factors for further miscarriage that should be considered.

Genetic Factors

When a parent carries a balanced chromosome rearrangement, the risk of producing chromosomally unbalanced offspring depends on the specific chromosomes involved, the size of the segments involved in the rearrangement, and the sex of the transmitting parent. The risk of miscarriage in couples with reciprocal translocation is approximately 50%. With robertsonian translocation, the risk is approximately 25%.[91,92] Most couples with balanced chromosome rearrangements have healthy children; however, homologous robertsonian translocations always result in fetal aneuploidy.

The finding of an abnormal parental karyotype warrants genetic counseling. Genetic counseling offers the couple a prognosis for future pregnancies, prenatal diagnostic options, and the opportunity to perform familial chromosomal studies, if desired. If a subsequent miscarriage occurs, karyotyping of the products of conception is essential, regardless of the parental karyotype. Table 5–1 summarizes the procedure for collecting the products of conception for chromosome analysis.

Traditionally, reproductive options in couples with chromosomal abnormality have included proceeding to a further natural pregnancy, with or without prenatal diagnostic tests, chorionic villus sampling, or amniocentesis; gamete donation[93]; and adoption. More recently, preimplantation genetic diagnosis has been explored as a treatment option for translocation carriers[94,95] and couples with unexplained recurrent miscarriage.[96] Preimplantation genetic diagnosis is a technically demanding procedure, and clinical experience is limited. The technique requires the couple to undergo in vitro fertilization to produce embryos. Therefore, couples with proven fertility must be made aware of the high financial cost and low implantation and live birth rates per cycle after in vitro fertilization. Further, the couple should be informed that they have a 40% to 50% chance of a healthy live birth in future untreated pregnancies after natural conception.[92]

Anatomic Factors

As a screening test for uterine anomalies, noninvasive two-dimensional pelvic ultrasound assessment of the uterine cavity, with or without sonohysterography,[19,97] when performed by skilled and experienced staff, is as informative as invasive hysterosalpingography. Because three-dimensional ultrasound offers diagnosis and classification of uterine malformations,[98,99] its use may obviate the need for hysteroscopy and laparoscopy.

A minor defect does not warrant surgical correction. In the past, abdominal metroplasty was advocated for a uterine septum; however, open uterine surgery has not been assessed in prospective trials, is associated with postoperative infertility, and carries a significant risk of scar rupture during pregnancy.[100] These complications are less likely to occur after transcervical hysteroscopic resection of uterine septa, and experience from case series appears promising.[101] However, before a clear judgment can be made, the procedure must be evaluated in a prospective controlled trial. These procedures must be performed by clinicians with appropriate training and experience in hysteroscopic surgery. Metroplasty has been traditionally advocated for bicornuate uterus and uterus didelphys, even though it is of unproven benefit and carries a significant risk of morbidity. Unicornuate uterus is rare and has limited treatment options. Cervical cerclage has been proposed, but is of uncertain value.[102] Uterine anomalies resulting from in utero diethylstilbestrol exposure are rarely amenable to surgical correction, but prophylactic cervical cerclage has been advocated.[103]

Intrauterine adhesions can be corrected by hysteroscopic lysis, placement of an intrauterine device, and administration of estrogen after surgery.

Occasionally, abdominal or hysteroscopic myomectomy is warranted for recurrent miscarriage associated with significant submucous fibroids that distort the uterine cavity or occupy a large subendometrial area. A 3-month course of a gonadotropin-releasing hormone analog preoperatively facilitates surgery by reducing the size and vascularity of the fibroids. More recently, percutaneous thermal ablation of uterine fibroids under real-time magnetic resonance control was studied and appears to be a promising alternative treatment.[104]

Traditionally, the diagnosis of cervical incompetence has been clinical because it relies on a history of late miscarriage preceded by spontaneous rupture of the membranes or painless cervical dilation. The clinical diagnosis has not been evaluated in terms of it its ability to predict future pregnancy outcome. Although hysterosalpingography (HSG) and painless passage of an 8 Hegar dilator have been used to confirm the diagnosis before pregnancy, neither procedure has been studied prospectively. There is no satisfactory objective test to identify nonpregnant women with cervical incompetence. Prepregnancy cervical cerclage is advocated in some cases of assumed cervical incompetence, although its benefit is unproven.

Endocrine Factors

There is no value in performing glucose tolerance tests in women with recurrent miscarriage who have no history suggestive of diabetes mellitus. In women with established diabetes, poor glycemic control increases the risk of pregnancy loss. Consequently, these women require prepregnancy counseling with the aim of obtaining optimal periconceptual glycemic control.[105]

The contribution of luteal phase defect to recurrent miscarriage is controversial, and a review of pregnancy rates after hormonal treatments for luteal phase deficiency concluded that the benefits are uncertain.[43] One meta-analysis[42] reported that progesterone support for pregnancy in women with recurrent miscarriage may have a beneficial effect, but this meta-analysis was based on three small studies. A multicenter placebo-controlled study of hCG supplementation in early pregnancy showed no benefit in pregnancy outcome.[106] Subsequently, a small placebo-controlled study cited that the benefit of hCG is confined to a small subgroup of patients with recurrent miscarriage and oligomenorrhea.[107] Prepregnancy suppression of high LH levels with an LH-releasing hormone analog followed by low-dose ovulation induction in ovulatory women with recurrent miscarriage does not improve pregnancy outcome. Further, the live birth rate without pituitary suppression is excellent.

The role of insulin resistance and the safety and effectiveness of metformin treatment in women with recurrent miscarriage and polycystic ovaries require further study. Metformin should be used only in the context of prospective controlled trials.

Infections

All women with recurrent miscarriage should be screened routinely for rubella antibody status to determine and afford immunization before the next pregnancy. The empirical use of antimicrobial drugs in the treatment of women with recurrent pregnancy loss cannot be justified.

Antiphospholipid Antibodies

Antiphospholipid antibodies are associated with a wide spectrum of pregnancy complications, including recurrent miscarriage, late fetal loss, fetal growth restriction, preeclampsia, placental abruption, preterm birth, and maternal thromboembolic disease.[108–110] Several treatment modalities have been used to improve the pregnancy outcome of these women. The use of steroids during pregnancy leads to significant rates of maternal and fetal morbidity and does not improve pregnancy outcome compared with other treatment modalities.[111,112] The combination of low-dose aspirin and low-dose heparin significantly reduces pregnancy loss by 54% compared with aspirin alone.[113] Further, a recent ran-

domized trial found that aspirin plus heparin is superior to IVIG[114] in the treatment of women with aPL-related pregnancy loss.

The use of low-dose aspirin during pregnancy is considered safe.[115] Because heparin does not cross the placental barrier, it is not teratogenic and does not cause fetal hemorrhage. However, heparin can be associated with maternal complications, including bleeding, hypersensitivity reactions, heparin-induced thrombocytopenia, and when used long term, osteopenia and vertebral bone fractures. However, two prospective studies[116,117] showed that the loss in bone mineral density at the lumbar spine associated with long-term, low-dose heparin therapy is similar to the loss that occurs physiologically during normal pregnancy. Risk–benefit assessment of aspirin plus heparin treatment appears to support its use in women with APS.

After the diagnosis of APS is made, women should be advised to start aspirin and heparin treatment after confirmation of their next pregnancy (at 4–5 weeks). No evidence suggests that preconceptual treatment of APS improves pregnancy outcome.

Hereditary Thrombophilia

The pregnancy outcome for women with a history of recurrent miscarriage associated with FVL mutation is poor when no pharmacological treatment is offered during pregnancy. The efficacy of thromboprophylaxis during pregnancy in women with recurrent miscarriage and inherited thrombophilic defects, who are otherwise asymptomatic, has not been assessed in prospective randomized controlled trials. Uncontrolled studies[118,119] suggest that heparin therapy may improve the live birth rate in these women. Until further evidence becomes available, the poor pregnancy outcome associated with FVL mutation, coupled with the maternal risks during pregnancy, probably justifies routine screening for FVL and antenatal thromboprophylaxis for those with the FVL mutation or evidence of placental thrombosis. Full anticoagulation may be required throughout pregnancy and puerperium in some patients with a personal or family history of thromboembolism (see Chapter 43).

Disorders of Maternofetal Alloimmune Relationships

No alloimmune theory has been substantiated, and no immunologic tests have been identified to predict pregnancy outcome. Further, immunotherapy is of no proven benefit and may actually cause harm. Immunotherapy should only be offered to women with recurrent miscarriage in the context of prospective controlled trials.

Unexplained Recurrent Miscarriage

Despite extensive testing, in approximately 50% of couples with recurrent miscarriage, no cause is identified.[7] Although the mechanism is unclear, several nonrandom-

ized studies[11,12] suggest the benefit of supportive care and attendance at a dedicated early pregnancy clinic. The prognosis for a successful future pregnancy in women with unexplained recurrent miscarriage who receive supportive care alone is approximately 75%; it is worse with increasing maternal age and increasing number of previous miscarriages. These data suggest that empirical treatment in women with unexplained recurrent miscarriage is unnecessary and should be avoided.

General advice about stopping smoking, avoiding excessive alcohol and caffeine intake, losing weight (in obese women), and dietary balance is important. Folic acid (400 µg/day) for at least 2 months before attempting conception is indicated to prevent neural tube defects.

Management during Subsequent Pregnancy, Delivery, and Puerperium

Strategies for management during subsequent pregnancy differ according to the underlying cause of miscarriage. The risk of repeated miscarriage increases with each successive pregnancy loss and with advanced maternal age. Even when the pregnancy progresses beyond 24 weeks' gestation, evidence suggests that women with recurrent miscarriage are at risk for late pregnancy complications (e.g., preeclampsia, intrauterine fetal growth restriction, preterm delivery, perinatal loss, and operative delivery[108,110,120]). Close antenatal surveillance and planned delivery in a unit with specialized obstetric and neonatal intensive care facilities are indicated.

First Trimester

Couples with recurrent miscarriage are understandably anxious and need support and reassurance throughout the first trimester. Ultrasound is important in the management of early pregnancy by confirming or predicting viability and, when fetal heart activity is detected, providing maternal reassurance. Transvaginal ultrasound shows a gestation sac at 5 weeks, a yolk sac at approximately 5.5 weeks, and fetal heart activity in embryos less than 4 to 5 mm at 6 weeks. Thereafter, a scan to show fetal heart activity may be obtained every week or every 2 weeks, until the end of the first trimester. These scans, together with the finding of normal fetal growth and activity, may be reassuring to some couples.

Women with APS should be offered aspirin and heparin treatment. Low-dose aspirin (75 mg/day) should be initiated as soon as the patient has a positive urinary pregnancy test result. Subcutaneous low-dose heparin therapy in the form of low-molecular-weight heparin (enoxaparin [Clexane] [Lovenox] 20 mg/day or dalteparin [Fragmin] [Fragmin] 2500 units/day) or unfractionated heparin ([Calciparine] 5000 IU twice daily) should be initiated when intrauterine pregnancy is confirmed by ultrasound scan (the finding of a gestational sac and a yolk sac within the uterine cavity). Although unfractionated heparin and

low-molecular-weight heparin preparations are equally beneficial, low-molecular-weight heparin can be administered once daily because of its longer half-life and increased bioavailability. Women should have a weekly platelet count during the first 3 weeks of heparin treatment to detect heparin-induced thrombocytopenia, which is rare.

Despite significant improvement in live birth rates, pregnant women who have aPLs and are treated with aspirin plus heparin until 34 completed weeks of gestation are at risk for late complications. These complications include pre-eclampsia, intrauterine growth restriction, placental abruption, and preterm delivery.[110] Whether continuation of treatment until delivery effectively reduces the risk of these late pregnancy complications is the subject of current research.

Second Trimester

When cervical incompetence is suspected in pregnancy, transvaginal ultrasonic assessment of the cervix is a noninvasive and objective means of assessing cervical length and shape and predicted preterm birth in high-risk populations.[121–123] The three ultrasound signs that suggest cervical incompetence are shortening of the endocervical canal, funneling of the internal os, and sacculation or prolapse of the membranes into the cervix, either spontaneously or as a result of fundal pressure (Fig. 5–3). A short cervix (<25 mm) is the best independent predictor of spontaneous preterm birth before 34 weeks' gestation.

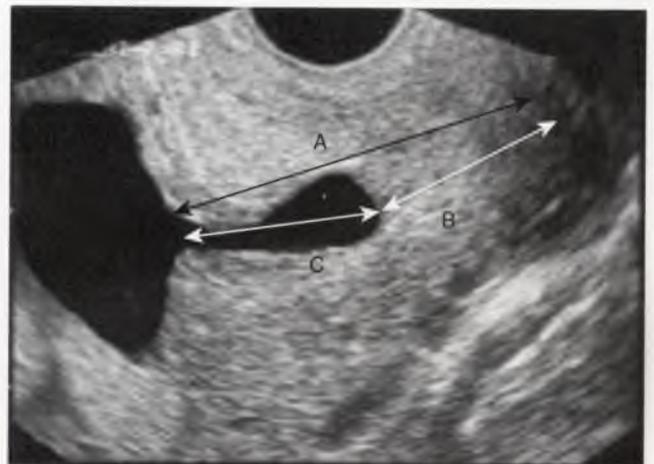
Cervical cerclage is a recognized treatment for cervical incompetence. However, a meta-analysis[124] of four randomized controlled trials found no conclusive evidence that prophylactic cervical cerclage reduces the risk of pregnancy loss and preterm delivery in women at risk for preterm birth or midtrimester loss because of


FIGURE 5–3
Transvaginal ultrasound scan of a cervix showing cervical shortening and funneling. A, Total cervical length; B, length of the distal cervical segment; C, depth of the cervical funnel.

cervical factors. Further, the procedure was associated with an increased risk of minor morbidity, but no serious morbidity. A small decrease in the number of deliveries before 33 weeks' gestation was noted in the largest trial.[125] The benefit was greatest in women with three or more second-trimester miscarriages or preterm births. There was no significant improvement in neonatal survival.

The same meta-analysis[124] assessed the role of therapeutic cerclage in women with a short cervix seen on ultrasound. The pooled results from two small randomized controlled trials[126,127] showed no reduction in midtrimester pregnancy loss and preterm delivery before 28 and 34 weeks in women assigned to undergo ultrasound-indicated cerclage. However, the numbers of women randomized were too small to allow firm conclusions to be drawn.

Based on the available evidence, it would seem reasonable to divide women with a history of midtrimester miscarriage that suggests cervical incompetence into two groups, with the therapeutic approach tailored accordingly. The first group includes women at increased risk for second-trimester miscarriage, including those with two or more second-trimester miscarriages without bleeding or clear signs of labor preceding the miscarriage. These women may benefit from prophylactic cervical cerclage at 13 to 16 weeks, with removal at 37 to 38 weeks. Several adjuvant short-term measures may be considered to minimize the risk of infection or other complications. These measures may include a short course of antibiotics and bed rest for 48 hours. Before prophylactic cerclage, these women should be offered ultrasound examination to assess fetal viability and exclude apparent fetal anomalies.

The second group, considered at medium risk, includes women with a history of one second-trimester miscarriage and those with evidence of other causes of preterm delivery (e.g., infection). These women can be offered serial transvaginal cervical ultrasound scanning beginning at 12 weeks and performed weekly or every 2 weeks until 23 weeks to measure cervical length and exclude funneling of the upper cervical canal. Therapeutic cervical cerclage may be offered to women with ultrasound signs of cervical shortening (<25 mm) or with progressive funneling in the absence of uterine activity or evidence of chorioamnionitis. Techniques for cervical cerclage are described in Chapter 6.

Uterine artery Doppler ultrasonography at 22 to 24 weeks may be useful in predicting preeclampsia and intrauterine growth restriction in women with APS and circulating lupus anticoagulant who are at increased risk for these complications.[128]

A glucose tolerance test at 28 weeks may be prudent for women with PCOS because of the increased risk of gestational diabetes. However, no evidence shows that the current management of gestational diabetes leads to improved outcomes for the mother and fetus.[129]

Third Trimester

During the third trimester, serial fetal growth scans and umbilical artery Doppler recordings are advisable. The risk of intrauterine growth restriction is increased in women with a history of recurrent miscarriage, particularly those with APS or inherited thrombophilia (see Chapters 42, 43, and 44).

Delivery and Puerperium

If pregnancy is progressing well, a history of recurrent miscarriage is not an indication for increased intervention. However, many women with a history of recurrent miscarriage request delivery by elective cesarean section. The obstetrician may consider that this approach or elective induction of labor at term is appropriate for psychological reasons.

In women receiving heparin, it is important to plan regional anesthesia to minimize the risk of epidural hematoma, and coordination with the anesthetist is required. Current guidelines[130,131] recommend that regional techniques should not be used until at least 12 hours after the previous prophylactic dose of low-molecular-weight heparin and 6 hours after a dose of unfractionated heparin. Heparin should not be given for at least 4 hours after the epidural catheter is removed.

There are no prospective data on the risk of systemic thrombosis to determine the optimal management of asymptomatic women with inherited thrombophilia. Current guidelines based on expert opinion recommend that postnatal thromboprophylaxis may be indicated in some women with known inherited thrombophilias, depending on the specific type of thrombophilia and the presence of other thrombotic risk factors.[130] Similarly, in women with APS and no symptoms other than recurrent miscarriage, there is no evidence to justify routine postnatal thromboprophylaxis. In women with APS without additional thrombotic risk factors, postnatal thromboprophylaxis is not recommended.

SUMMARY

The management of recurrent miscarriage requires a combination of sensitivity and a systematic approach to care. The goal is to identify a cause and implement appropriate treatment whenever possible. Of the many risk factors, parental karyotype abnormalities, APS, activated protein C resistance, and cervical incompetence are the only established causes of recurrent miscarriage. Of the many treatment options for couples with recurrent miscarriage, only aspirin plus heparin

treatment in women with APS has proven benefit. Despite detailed studies, in approximately 50% of couples with recurrent miscarriage, no cause is found. However, even without pharmacologic treatment, the prognosis is good and supportive care appears to play an important role. Empirical treatments for women with recurrent miscarriage should be avoided, and new treatments should be introduced only after their benefit has been assured through properly designed prospective controlled trials.

CONCLUSIONS

- Recurrent miscarriage, defined as the loss of three or more consecutive pregnancies, is a distressing problem that affects 1% of couples.
- Systematic screening of couples with three consecutive miscarriages identifies a probable cause in 50% of cases. The remaining 50% of cases may result from recurrent, but sporadic, chromosomal abnormalities that occur by chance.
- The chance of successful pregnancy outcome after three consecutive miscarriages is high, depending on maternal age, reproductive history, and the underlying cause of miscarriage.
- Parental karyotype abnormalities, cervical incompetence, antiphospholipid syndrome, and activated protein C resistance are established causes of recurrent miscarriage.
- In couples with chromosomal translocations, options include natural conception with or without prenatal diagnosis tests, gamete donation, and preimplantation genetic diagnosis with in vitro fertilization.
- Elective cervical cerclage may confer benefits in women with two or more midtrimester losses as a result of cervical incompetence. Cervical ultrasound screening during pregnancy may be useful in reducing the rate of cervical cerclage when the history is equivocal.
- Low-dose aspirin and heparin treatment is the first-line therapy in women with antiphospholipid syndrome because it results in a live birth rate of 70%.
- Low-dose heparin may confer benefits in women with recurrent miscarriage associated with activated protein C resistance and evidence of placental thrombosis.
- Supportive care in couples with unexplained recurrent miscarriage is associated with an excellent prognosis; empirical treatments should be avoided.

SUMMARY OF MANAGEMENT OPTIONS
Recurrent Miscarriage—Prepregnancy Assessment

Management Options	Quality of Evidence	Strength of Recommendation	References
AT THE TIME OF THE THIRD MISCARRIAGE			
Document the pattern and trimester of the pregnancy loss and whether a live embryo or fetus was present.	–	GPP	–
Carefully document a suspected uterine abnormality at surgical evacuation.	–	GPP	–
Send the products of conception for histologic testing or autopsy and karyotype with consent of the patient, as appropriate (see Table 5–1).	–	GPP	–
A general approach is important (e.g., see the couple together, express sympathy, show sensitivity).	–	GPP	–
Offer follow-up assessment and counseling.	IV	C	6

SUMMARY OF MANAGEMENT OPTIONS
Recurrent Miscarriage—Prepregnancy Assessment *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
PREPREGNANCY ASSESSMENT AND COUNSELING AFTER THE THIRD MISCARRIAGE			
History and Examination for Causative and Associated Factors			
Obtain an obstetric history to confirm the diagnosis of "recurrent miscarriage" (e.g., pattern of losses, gestations of former losses, previous confirmation of pregnancy: biochemical, ultrasonographic or histologic).	–	GPP	–
Obtain a general medical history	–	GPP	–
• Features associated with autoimmune disease (e.g., joint pain, rash)			
• Features related to antiphospholipid syndrome (e.g., migraine, epilepsy, vascular thrombosis)			
• Thrombophilia-related features (e.g., personal or family history of vascular thrombosis)			
• Exposure to environmental toxins or drugs			
Obtain a surgical history (cervix, uterus, ovary).	–	GPP	–
Obtain a family history (recurrent miscarriage, polycystic ovarian syndrome, genetic disease, hereditary thrombophilia)	–	GPP	–
Perform a physical examination: to identify signs of endocrine or gynecologic disease, including opportunistic screening (blood pressure, cervical cytology, breast palpation) and checking special risk factors identified by the history.	–	GPP	–
Routine Tests in All Patients (see Table 5–2)			
Karyotype			
• Both partners	III	B	18,19
• Miscarried tissue (with consent, as appropriate)	III	B	14,15,17
Pelvic ultrasound	III	B	97–99
Anticardiolipin antibodies (IgG and IgM)	III	B	58
Lupus anticoagulant	III	B	58
Early follicular phase luteinizing hormone, follicle-stimulating hormone, and testosterone	III	B	53,54
Thrombophilia screening:	IIa	B	68
• Activated protein C resistance and Factor V Leiden mutation testing is indicated in all cases. (Antithrombin III, factor XII, protein C, protein S, prothrombin gene mutation and MTHFR are reserved for patients with a high risk of thrombophilia.)	III	B	67
Prepregnancy opportunistic screening:	–	GPP	–
• Serology for rubella status			
• Blood group and Rhesus type			
Other tests are determined by positive findings on the history or examination (see Table 5–2).	–	GPP	–

Recurrent Miscarriage—Prepregnancy Assessment (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Counseling with the Following Key Principles and Guidelines			
See the couple together, preferably at a dedicated miscarriage clinic. Take a sympathetic approach.	–	GPP	–
The true rate of recurrent miscarriage is affected by a reproductive compensation effect.	IV	C	6
After three consecutive losses, intensive testing identifies a probable cause in approximately 50% of couples.	III	B	19
The remaining 50% probably result from repeated, but sporadic chromosome abnormalities that occur consecutively by chance.	III	B	14,15
Advanced maternal and paternal age and previous reproductive history are important risk factors for a further miscarriage.	III	B	2,8–10
Anatomic defects of the uterine fundus and cervix, parental chromosomal rearrangements, gene mutations, phospholipid antibodies, and activated protein C resistance also play a role.	III	B	18,19,25,26, 58,60,67,68, 121,122,123
Progesterone deficiency, hypersecretion of luteinizing hormone, infective agents, and immune rejection are not considered causes of recurrent miscarriage. Empirical treatment with progesterone, high luteinizing hormone suppression, or immunotherapy is of no proven benefit.	Ia	A	42–46,71,73
Subclinical thyroid disorders and diabetes mellitus are rare.	III	B	19,53,54
Psychological stress is probably not relevant.	IV	C	6
Even after three miscarriages, the chance of a successful pregnancy without treatment is approximately 60%, apart from women with antiphospholipid syndrome and those with activated protein C resistance. In these women, success rates are lower.	III IIa	B B	2,10 60,68

MTHFR, methylene tetrahydrofolate reductase.

Recurrent Miscarriage—Prepregnancy Treatment

Management Options	Quality of Evidence	Strength of Recommendation	References
Do not advocate unproven treatments.	–	GPP	–
Parental translocations			
• Genetic counseling for the couple and relatives	IV	C	18
• Proceeding to a further pregnancy, with or without prenatal diagnosis (amniocentesis or chorionic villus biopsy)	III	B	91–95
• Gamete donation	–	GPP	–
• Artificial insemination with donor sperm	–	GPP	–
• In vitro fertilization with a donor egg	–	GPP	–
• Preimplantation genetic diagnosis with in vitro fertilization	–	GPP	–
• Adoption	–	GPP	–

Recurrent Miscarriage—Prepregnancy Treatment *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Uterine abnormalities			
• Uterine septum	III	B	25,100,101
GnRH analog			
Hysteroscopic septal incision			
Temporary intrauterine device			
• Intrauterine adhesions	III	B	39
Hysteroscopic division and temporary intrauterine device			
Postoperative temporary cyclic estrogen and progesterone therapy			
• Fibroids (Significant submucous fibroid or intramural with a significant intracavity component)	III	B	34
Gonadotropin-releasing hormone analog			
Myomectomy			

SUMMARY OF MANAGEMENT OPTIONS
Management during Subsequent Pregnancy, Delivery, and Puerperium

Management Options	Quality of Evidence	Strength of Recommendation	References
Provide psychological support and reassurance.	III	B	11,12
Do not advocate unproven treatments.	–	GPP	–
There is no evidence that any immunologic therapy is of benefit.	Ia	A	71
Offer low-dose aspirin and heparin to women with antiphospholipid syndrome	Ib	A	3,11,109,114
Offer low-dose heparin to women with activated protein C resistance or other thrombophilia.	IIb	B	9,11,118
Maintain good metabolic control in patients with diabetes mellitus.	IIb	B	105
First trimester			
• Transvaginal ultrasound scan to confirm fetal viability	–	GPP	–
• Serial scans for reassurance	–	GPP	–
Second trimester			
• Suspected cervical incompetence options:			
Serial cervical ultrasonography with insertion of a cervical suture if there is evidence of shortening/funneling or	Ib	A	126
primary cervical cerclage	Ib	A	125
• Serial vaginal swabs for pathogens	–	GPP	–
• Uterine artery Doppler studies in selected patients	III	B	128
• Prophylactic maternal steroids at 28 weeks in selected patients	–	GPP	–
• Formal GTT at 28 weeks in selected patients	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS
Management during Subsequent Pregnancy, Delivery, and Puerperium (Continued)

Third trimester: Vigilance for fetal growth restriction, preeclampsia, and preterm labor in selected patients	III	B	102,108,110
Labor and delivery: Consider elective LSCS/IOL at term in some patients	III	B	110
Puerperium: Consider postnatal thromboprophylaxis in selected patients	–	GPP	–

GTT, glucose tolerance test; IOL, induction of labor; LSCS, lower segment cesarean section.

Midpregnancy Problems

Reynir Tómas Geirsson

INTRODUCTION

"Midpregnancy" is most accurately defined in theoretical terms as corresponding to the second trimester, from 12 to 28 weeks after the first day of the last menstrual period. However, in practical terms, it is usually considered to be the time between 15 to 16 weeks and 26 to 28 weeks, a period that encompasses the second phase of trophoblast invasion[1] and the most rapid phase of placental growth.[2] For most women, it is the easiest part of pregnancy, a time when the mother has passed the initial adaptive changes to the pregnant state and feels generally well. She experiences a slow increase in the physiologic and psychological changes associated with pregnancy, the growth and reactivity of the uterus as a living muscle compartment, and the awakening of new life within her. During this time, the development of the fetus is focused on organ maturation rather than physical growth.

Midpregnancy has an "air of healthiness" about it, and it is sometimes referred to as the "quiet stage" of pregnancy. Most mothers need little maternity care in midpregnancy, and antenatal care systems do not emphasize frequent visits during this time. Most problems and questions that arise are minor and require only understanding and adequate explanation based on physiologic knowledge. When a disorder or disease develops, in most cases, the mother becomes symptomatic. This should alert the physician or midwife, allowing diagnosis as well as appropriate and timely treatment.

In some cases, problems in midpregnancy are a considerable threat to the pregnancy, and sometimes a premature end to pregnancy cannot be averted. However, the experience may be used to prevent recurrence of the problem in a subsequent pregnancy. Some women belong to well-defined risk groups for problems in midpregnancy. In this case, advance planning and risk management is needed in asymptomatic women. In the absence of symptoms, both women and caregivers should not look for trouble where it is not expected. Testing is not needed if there are no symptoms. Within a modern screening environment, early data-gathering on maternal health, physical examination, and ultrasound and biochemical screening provide a basis for the completed planning of antenatal care by the early second trimester. Midpregnancy is typically quiet. In the third trimester, more adverse events may be anticipated and routine surveillance is increased.

PHYSIOLOGIC CHANGES OF MIDPREGNANCY

Knowledge of the maternal physiologic adaptations of midpregnancy is essential for the recognition of pathology during midpregnancy (Table 6–1). Fetal development comprises organ growth and maturation in a maternal environment dominated by physiologic adaptation favoring the needs of the fetus. Developments in the mother's body occur in advance of the main fetal growth spurt, reaching their maximum either early or late in midpregnancy. At this time, the maternal–placental supply line far exceeds immediate fetal needs. Changes in cardiac output and plasma volume approach their maximum velocity at approximately 20 weeks, and the red blood cell mass grows at a slower, steadier pace throughout midpregnancy. The result is a decrease in diastolic and systolic blood pressure and hemodilution. Increasing vascular permeability contributes to this as well as the developing low-resistance placental bed. Gastrointestinal motility and absorption, renal perfusion, and excretory changes in the mother begin even before the start of midpregnancy. Pelvic girdle distention and lumbar ligament softening gradually become more evident. Metabolic, hormonal, immunologic, and mental changes in the mother are less evident, but occur and are part of the adaptive process.

Uterine volume grows linearly during pregnancy, but the rate of placental growth is greatest between 20 and 30

TABLE 6–1

The Main Physiologic Adaptations in Normal Midpregnancy

General Changes

Increased cardiac stroke volume or output (inotropic, chronotropic)
Increased peripheral blood flow, decreased vascular resistance, venous dilation
Decreased midpregnancy blood pressure
Extracellular fluid accumulation, sodium retention
Blood and plasma volume expansion, hypervolemia, hemodilution
Increased erythrocyte production, count, increased plasma globulins and fibrinogen
Increased neutrophil count, reactivity, lymphocyte production
Increased platelet count, increased platelet adhesion, coagulation activation
Increased serum lipid level, metabolic and hormonal changes
Decreased pulmonary vascular resistance, increased tidal volume
Increased oxygen consumption, hyperventilation
Decreased gastrointestional motility, increased absorption
Increased renal blood flow, increased renal plasma filtration
Increased renin-angiotensin-aldosterone levels, angiotensin II resistance
Immunosuppression, altered B- and T-cell and complement function
Changes in connective and elastic tissue, change in thermoregulation

Uteroplacental Changes

Placental hormone production
Increased uterine size, contour and position changes
Increased uterine volume, amniotic fluid volume expansion
Increased intrauterine pressure
Increased myometrial mass and contractility
Increased energy production, action potential change, change in ion flow
Increased uterine blood flow
Second-phase invasion of spiral artery
Development of subplacental low-resistance flow compartment
Fastest placental growth rate
Cytotrophoblast shedding, aponecrotic change

weeks' gestation. Placental growth reaches its main velocity and bulk before fetal weight gain begins.[2] This basic physiologic adaptation ensures an adequate nutrition supply for the fetus and allows for third-trimester fetal volume growth. By the end of midpregnancy, the placenta can be thought of as "middle-aged" and well matured, whereas at term, it is reaching "old age." The physiologic adaptation process protects the mother from adverse events in pregnancy and contributes to fetal and maternal well-being.

MISCELLANEOUS SYMPTOMS AND PROBLEMS

Many problems in later pregnancy, including intrauterine growth disturbance, preeclampsia, and gestational diabetes may become evident in midpregnancy, but are discussed in the relevant chapters, as are the problems of multiple pregnancy, Rhesus isoimmunization, and other specific maternal and fetal diseases.

In midpregnancy, the signs and symptoms that indicate a risk of fetal death, late miscarriage, or early preterm delivery are abdominal pain and inappropriate uterine contractility (labor pains), vaginal bleeding and discharge, inappropriate uterine size, and infection. In addition, a vague feeling of "unwellness" should not be ignored.

Abdominal Pain (See Chapters 57 and 58)

Abdominal pain may originate from the pregnancy itself, the uterine muscle, or the ovaries. It may also stem from other intra-abdominal organs. Some pain is related to definite disease states, whereas other pain is functional. Most sources of pain do not pose a significant risk to the pregnancy, such as fibromyoma in the uterine muscle, ovarian cysts, urinary tract infections, pelvic girdle pain, irritable bowel syndrome, and pain caused by spontaneous uterine muscle contractility and tension from the round ligaments. Other sources of pain may have serious consequences because of the associated risk of reflex uterine contractility, intrauterine infection, and preterm labor. Potentially serious causes of abdominal pain include appendicitis, cholecystitis, severe pyelonephritis and urolithiasis, and twisted or ruptured hemorrhagic ovarian cysts. Any intra-abdominal organ may be responsible, and all must be considered in the differential diagnosis.

Appendicitis occurs in approximately 1 in 800 pregnancies.[3] By midpregnancy, the upward and lateral displacement of the ascending part of the large bowel by the growing uterus or the position of a pelvic appendix behind the uterus may mask the diagnosis. A moderate fever, an increased white blood cell count, and an increased C-reactive protein level occur with diffuse and uncharacteristic pain accompanied by nausea and sometimes vomiting. A low threshold of clinical suspicion must be maintained. When appendicitis occurs in midpregnancy, approximately 1 in 7 women deliver prematurely.[3] Early surgery with appendectomy is preferable, but with a ruptured appendix and appendiceal abscess, conservative treatment with appropriate antibiotics may be the first option. Some obstetricians prefer to treat appendicitis themselves, whereas others seek surgical assistance. The primary responsibility for care remains with the obstetric team, because maintenance of the pregnancy with tocolysis and prophylactic administration of steroids is an important goal of management (see Chapter 57).

The management of cholecystitis is conservative, and cholecystectomy is rarely needed. Complications of ovarian cysts are best treated with surgical removal, and pyelonephritis, renal calculi, and related problems are managed by appropriate measures to detect underlying pathology in consultation with a urology team (see Chapters 57 and 58).

Inappropriate Uterine Activity (See also Chapter 62)

Differentiating between normal uterine activity and the start of preterm labor in women with very different thresholds of pain is difficult in midpregnancy. Discomfort as a result of tension and muscle activity in the round ligaments and an increased perception of uterine contractility are common in midpregnancy, but usually harmless. Preterm labor entails both uterine contractions and cervical dilation. Not all women who have contractions are laboring; equally, women may approach delivery without a perception of uterine contractions.[4] Vague abdominal discomfort that is easily ascribed to another abdominal condition (e.g., gastroenteritis, irritable bowel syndrome) may be the only symptom of impending late miscarriage or very preterm delivery. Conversely, in a woman with a noncompliant, collagenous cervix, uterine contractions do not necessarily indicate labor or a risk of preterm delivery.

A thorough history and examination, patience, and careful observation are required. Emphasis must be placed on reaching a diagnosis by cervical assessment with a speculum (occasionally with careful digital palpation) and supplementing this examination with transvaginal ultrasound. Direct inspection of the cervix should be performed to detect dilation, fluid leakage, and cervical insufficiency as well as mucopurulent discharge indicative of intrauterine infection and chorioamnionitis. Endocervical bacterial culture is necessary unless the cervical mucus is clear. Tests for fibronectin, which indicates preterm premature rupture of the membranes, may be required.[5] Ultrasound is done to determine cervical length, identify cervical funneling, and assess amniotic fluid volume, fetal size, and viability in the early stages of midpregnancy. Before 24 weeks, external tocography has limited use, both for practical reasons and because viability is unlikely. To assess pain, the use of palpation and observation is better than attempting to record uterine contractility with an external monitor. Chorioamnionitis is not reflected in uterine tenderness or pain until it reaches an advanced stage, but uterine tenderness can be an early sign of placental abruption.

Treatment must be cause-oriented, but most options are not based on clear evidence. If delivery seems likely or inevitable, the viability of the infant and likelihood of survival without major disability must be considered. In a large study of infants delivered between 24 and 28 weeks' gestation, after adjustment for various confounding factors, no difference was seen between those delivered abdominally and those delivered vaginally.[6] The chance of survival improves with increasing gestational age, absence of maternal hypertension, singleton pregnancy, and antenatal steroid therapy. The rate of cerebral palsy in this study was 11.1%, but 63.1% of the infants were healthy at 2 years of age, regardless of the mode of delivery in these infants of borderline viability. Shennan and associates[7] found that of 383 liveborn infants between 26 and 30 weeks' gestation, before the advent of high-frequency ventilation techniques, 39, or approximately 1 in 10, did not survive. Further, 34, or another 1 in 10, had a significant disability at 1-year follow-up. When infants who died or were disabled were paired with gestational-age-matched infants from the total group, no difference was seen between the groups in the rates of prenatal complications, including prolonged rupture of the membranes and antepartum hemorrhage. However, their condition during labor or at birth was worse among infants who died or were disabled. Therefore, prelabor characteristics do not appear to have major prognostic significance for the pregnancy and are not a useful guide to management. Newer techniques for neonatal support have increased survival rates for infants born between 24 and 28 weeks' gestation, whereas disability rates remains the same, at approximately 14% to 17%.[8-11] However, the outlook for infants born before 25 to 26 weeks is still poor.

Vaginal Discharge (See Chapter 32)

Vaginal discharge can be physiologic or may be a sign of bacterial vaginosis, vaginitis caused by *Trichomonas* or *Candida albicans* infection, a foreign body reaction, or chlamydial or gonorrheal infection of the cervix. In midpregnancy, the risk associated with vaginal discharge is ascending intrauterine infection and chorioamnionitis, with resulting preterm labor and delivery.

Changes in Uterine Size (See Chapters 12 and 13)

Early growth restriction affects not only fetal growth but also placental and amniotic fluid volume. This possibility should be borne in mind when the fundal height is less than expected in midpregnancy. Measuring fundal height is not a sensitive way to detect growth restriction, but it is an inexpensive routine measure that detects approximately 30% of cases. A symphysis–fundus chart must be appropriately constructed and relevant to the population. The fundal height should be approximately equal in centimeters to the gestational age in weeks. After maternal size is considered, a difference of more than 3 cm is a reason for further ultrasound assessment.[12] Growth restriction in midpregnancy is usually caused by an underlying medical disease affecting the peripheral or renal blood vessels. It tends to be serious and affects the fetus and placenta in a symmetrical way. If poor growth is confirmed by ultrasound measurement, Doppler studies of flow in the uterine arteries and fetal umbilical artery, aorta, and cerebral arteries are indicated. Cytogenetic studies and a thorough repeat evaluation of the fetal anatomy may be necessary.

Uterine expansion caused by polyhydramnios may occur as a result of fetal infection (*Parvovirus* infection or

toxoplasmosis), congenital anomalies that affect the fetal gut, twin–twin transfusion syndrome, or poorly controlled diabetes.

General Malaise, Tiredness, and Fainting

Although these symptoms are common in normal pregnancy, they can be a clue to a new infectious or medical condition or the exacerbation of a preexisting problem. Many medical disorders are associated with an increased risk of loss in midpregnancy (e.g., cardiac or renal disease, ulcerative colitis, Crohn's disease, sarcoidosis, occult malignancy). Anemia caused by deficiency of iron, folic acid, and B_{12} as well as sickle cell anemia and thalassemia must be considered, along with toxoplasmosis and other zoonotic, bacterial, or viral infections.

PREVIOUS MIDPREGNANCY LOSS (See also Chapter 62)

Definition

Previous midpregnancy loss is any previous loss of a pregnancy between 12 and 28 weeks' gestation. A diagnosis of failed pregnancy, such as missed miscarriage or fetal death between 12 and 16 weeks, can be considered a prolongation of events originating in the first trimester. These occurrences are handled in a similar manner, usually by evacuation with suction or treatment with prostaglandins and mifepristone, when this drug is available. Problems that occur in the second trimester (e.g., fetal loss or very preterm delivery as a result of cervical insufficiency, intrauterine death as a result of fetal anomaly, ascending or systemic infection, or idiopathic or secondary placental insufficiency) have another cause and require different management.

Risks

Few women miscarry or deliver during midpregnancy. When this occurs, the cause may be fetal or maternal. Fetal causes are related to congenital and chromosomal anomalies as well as intrauterine growth restriction, and the usual outcome is intrauterine fetal death. Maternal causes may be related to uterocervical anomalies, vascular disorders, or infection, and the fetus is usually born alive.[13] The incidence of preterm labor varies from 4% in developed countries with high living standards to 12% to 20% in developing countries, depending on risk factors, such as maternal age, race, poverty, smoking, alcohol and drug use, low prepregnancy weight, poor maternal education, strenuous work, short interpregnancy interval, abnormal bacterial colonization in the vagina, multifetal pregnancy, and uterine malformations. The miscarriage rate of live fetuses between 14 to 22 weeks is approximately 1.3% of all deliveries,[13] but the rate of preterm delivery between 22 and 28 weeks is less than 0.5% of all deliveries and approximately 7% of preterm deliveries before 37 weeks[13–15] The same risk factors apply as a continuum for the period from 14 to 28 weeks.[13] A greater risk is seen with advanced maternal age, lower socioeconomic status, an adverse obstetric history, previous therapeutic termination of pregnancy, and heavy smoking. The spontaneous loss rate in twin pregnancies (3%–7% in the second trimester) is caused by the same factors, but at a higher rate than for singletons. In monozygotic twins, velamentous cord insertion and twin–twin transfusion are additional causes.[16] Although the World Health Organization recommends that birth be recorded from

22 weeks onward, viability is generally accepted from approximately 23 to 24 weeks' gestation.[17,18] The major risk factors for midpregnancy loss are previous loss in the second or early third trimester (up to five times more likely[13]), multiple pregnancy, and bleeding from the uterine cavity in the first trimester and early second trimester. Idiopathic preterm delivery and multiple pregnancy are discussed in Chapters 62 and 60, respectively. Pregnancy-specific conditions and preexisting medical conditions that are exacerbated by pregnancy are rarer causes that are not discussed here. The one remaining cause is increased and premature cervical compliance occurring with normal or increased myometrial activity, leading to early cervical opening (i.e., cervical insufficiency).

Cervical Insufficiency

Premature dilation of the uterine cervix is a major reason for loss or delivery in midpregnancy. Traditionally, the diagnosis of cervical insufficiency has been retrospective, based on a history of midpregnancy or early third-trimester loss associated with cervical dilation that occurs without a maternal sensation of uterine contractions.[19,20] The typical situation is "silent" or "painless" dilation in a patient with the finding of bulging fetal membranes extruding onto or through the external opening of the cervix. Slight vaginal bleeding and discharge, with perineal pressure and a varying sensation of pain, indicative of concomitant chorioamnionitis, often indicates early cervical dilation. This makes diagnosis and treatment difficult. Knowledge of the risks, pathophysiology, and treatment of cervical insufficiency is incomplete and is based on case reports, small observational or case–control studies of limited value, and inconclusive evidence from a few randomized studies.[21] However, transvaginal ultra-sound is improving the understanding of the antecedent pathophysiology of the condition and has increased the management possibilities.[22]

The varying incidence of preterm labor affects estimates of how often preterm delivery is caused by cervical insufficiency, particularly in midpregnancy. Older data suggest that, on average, clinicians performed cervical cerclage in 0.5% of women,[21,23] suggesting the approximate frequency of the condition and its diagnosis. If 10% of preterm deliveries occur before 28 weeks' gestation, approximately one in three deliveries between 22 and 28 weeks is because of cervical insufficiency. Among twins, the rate of cervical insufficiency is higher.[16]

Pathophyisology

The pathophysiology of cervical insufficiency is not well understood. Deficiency of collagen, elastin, or the interconnective glycosaminoglycan structures of collagen fibrils may affect the ability of the cervical sphincter mechanism to resist the steady expansion of the uterine cavity and gravitational pressure on the internal os.[14] The higher incidence in multiple pregnancies points to the importance of uterine cavity distention. Recent ultrasound studies showed that the cervix opens by funneling and herniation of the membranes into the cervical canal as it shortens and effaces (Fig. 6–1). The cervix is not a static organ, but living tissue that is constantly adapting to different pressures.[24] Compliance and molding may vary among women, possibly on a genetic basis and is in addition affected by events such as subclinical infection ascending through the cervix and bleeding from the decidua or placental edge.[21,24] Several factors are probably required to initiate the process of cervical softening and effacement. For this reason, it is difficult to treat developing cervical insufficiency. Optimal therapy is by

FIGURE 6–1
A, The transvaginal sagittal ultrasound appearance of a normal, undilated midpregnancy cervix. *B,* The cervix marked out; arrows point to the interal and external os.

preventive measures, either prophylactic, based on previous midpregnancy loss, or after a diagnosis is reached in an affected pregnancy. Several measures may be initiated, including cervical cerclage suture, antibacterial prophylaxis, tocolytic drugs, rest, and cessation of smoking, although none is adequately researched or proven.

Diagnosis

Diagnosis of cervical insufficiency is challenging. Typically, there is a history of midpregnancy painless dilation and effacement to 2 to 4 cm, accompanied by a feeling of pressure down onto the perineum and mucoid discharge. To this can be added a history of cervical lacerations from previous deliveries (although these often remain undiagnosed), cone biopsies, and excessive dilation (>9–12 mm) during earlier termination. After conization, only 2% to 3% of women deliver before 28 weeks' gestation, although the overall preterm delivery rate is increased two to five times.[25] However, the risk of early delivery varies with the type and extent of conization and may be higher than 3% after extensive or repeated procedures.

Routine digital examination of the cervix does not help and may be counterproductive. Digital examination increases prostaglandin production and may introduce infection. In a population at low risk for preterm delivery, repeated digital examination doubles the incidence of preterm delivery.[26] Attempts to produce risk scores lacked the necessary predictive value.[26,27] It is now necessary to add ultrasound evidence of funneling and prolapse of the membranes to a measured shortening of the cervical canal. The accepted median length of the normal cervical canal is 3.5 to 3.8 cm. The 10th percentile value is 2.5 cm.[24,28] With effacement, the internal os and cervical canal gradually change from a T to a Y shape and finally assume a V-shaped appearance (Fig. 6–2). This change is accompanied by progressive shortening of the cervical canal below the 2.5-cm mark. The predictive value of these changes for preterm delivery is high, and in the absence of major uterine myometrial activity, a diagnosis of cervical insufficiency is likely if the cervix is less than 2.5 cm long.[24,29-31] There is debate as to whether a lowest critical value exists, but a cervical length of 1.5 cm has been suggested.[32] This value may be realistic in view of a recent randomized trial that showed no benefit of cerclage at 2.5 cm.[33]

Although the risk of delivery increases with a shorter cervical length, there is no known value at which the prediction is absolute. Manual transfundal pressure may make the diagnosis clearer.[30,31] In a large prospective study assessing cervical length between 24 and 28 weeks in 2800 asymptomatic women, decreasing cervical length was positively associated with a risk of earlier delivery.[29] Incorporation of cervical assessment into the 18- to 20-week routine ultrasound examination may be useful because this is also the average time for an ultrasound diagnosis of cervical insufficiency, but this would need follow-up for at-risk women at approximately 24 weeks and awaits confirmation from randomized studies.[22,29,30] This approach may be acceptable to most women, even if it involves additional or repeated vaginal ultrasound.[28] Serial examinations of the cervix by transvaginal ultrasound do not appear to increase the risk of preterm delivery.[34] At an earlier gestational age (<14 weeks), however, there appears to be no appreciable difference in cervical length between women who deliver preterm and those who deliver at term.[22] This suggests that screening at 14 weeks or earlier has little value. This is to be expected because pressure on the internal cervical os does not increase until well into midpregnancy.

Management Options

PREPREGNANCY

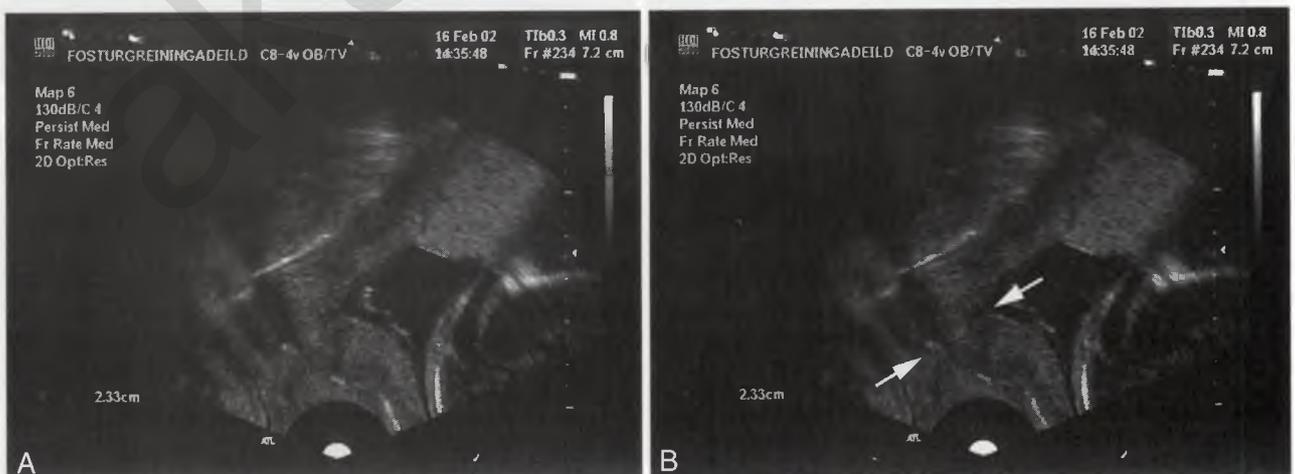
For women with a history of previous midpregnancy loss, management of suspected cervical insuffiency first


FIGURE 6–2
A, Funnelling of the cervical canal and widening of the interanl os with beginning chorioamnionic membrane herniation into the internal os of the cervical canal. B, The arrows mark out the shortened cervix (length 2.3 cm).

involves the repair of cervical lacerations that extend along the vaginal portion of the cervix and possibly above the cervical fornices. This repair should be done before pregnancy, with adequate time allowed for inflammation to resolve before the woman becomes pregnant again.

PRENATAL

Before or shortly after the woman becomes pregnant again, a decision must be made whether to insert a cervical purse-string (cerclage) suture. This procedure is usually done at 12 to 15 weeks' gestation, after fetal viability is established. Before cerclage is performed, screening at 11 to 13 weeks to ensure that the fetal anatomy is normal and that there is a low likelihood of chromosomal anomaly may be appropriate for most prospective parents. Although only one randomized trial has shown a benefit from prophylactic cerclage, and then only after at least two previous midpregnancy losses,[43] clinicians are under considerable pressure to take action.

Three options are currently available:

- Perform observation only, with or without clinical tests to detect and treat abnormal bacterial colonization in the vagina or inside the uterine cavity.
- Perform observation, with regular transvaginal ultrasound to detect cervical shortening and funneling. If necessary, perform a "rescue" cerclage suture procedure.
- Perform a prophylactic cerclage suture operation, either transvaginally or transabdominally. The transabdominal approach is indicated when the vaginal portion of the cervix (portio vaginalis) is very scarred, defective, short, or nonexistent, as may be the case after one or more conizations followed by one or more midpregnancy losses, or after an unsuccessful transvaginal cerclage procedure.

The technique for the abdominal approach was described by Mahran.[35] Series of these procedures have been reviewed, and the results in terms of a successful pregnancy outcome appear good.[36-38] These sutures have the advantage of being placed high on the cervix, near the internal os, in a bacteria-free environment. With a conventional or modified Shirodkar[39,40] or McDonald procedure,[41] the suture is placed transvaginally. Despite the potential for operative morbidity, the abdominal operative method is not difficult, but it requires laparotomy and subsequent cesarean section. Recently, laparoscopic suture insertion before pregnancy (interval suture) was described.[42] The suture may be left in place for a future pregnancy. Successful removal of the suture by culdotomy has been described with subsequent vaginal delivery but may not prove easy near term.

The transvaginal approach is a short, relatively simple procedure in which the suture is placed as high as possible on the vaginal portion of the cervix. Bladder dissection and upward displacement is no longer widely practiced, although the original Shirodkar procedure has a better success rate than a repeat McDonald suture when a previous suture did not prevent midtrimester loss. If the cervix is very deficient, bladder dissection and upward displacement may be unavoidable. Suture removal is usually performed at approximately 35 to 37 weeks or when labor starts and vaginal delivery is the goal. In addition to the mechanical compression effect of the suture, there may be more effective formation of a mucous barrier to bacterial invasion in the cervical canal.[26] Most clinicians prefer either Mersilene tape (two to three stitches required) or a braided double silk suture (five to seven stitches), inserted in a similar manner, with a knot in the anterior fornix.

There is still no consensus as to whether transvaginal cerclage suturing prolongs pregnancy and enhances neonatal survival.[21] Evidence seems to point to an overall benefit in prolonging pregnancy past 34 weeks' gestation for women with a cervix less than 2.5 cm long and for other high-risk groups.[31] The largest trial done for prophylactic historical reasons, before the advent of transvaginal ultrasound assessment,[43] showed a benefit with transvaginal cerclage after two preterm losses and no benefit after cervical conization. Although the complication rate after elective preventive cerclage suture is low (chorioamnionitis develops in 1%–7% of patients), an increased risk of infection after the procedure must be considered and discussed with the patient before a decision is made.

If the option of observing the cervix by transvaginal ultrasound is chosen, it is important for the clinician and the patient to understand that by the time funneling and effacement of the cervix are detected sonographically, a complicated pathophysiologic process may have begun and may be impossible to stop. Evidence is conflicting as to whether screening and placement of a rescue suture is effective. In a recent study of 2702 women evaluated at 23 weeks by transvaginal ultrasound, 43 (1.6%) had a cervical length of less than 1.5 cm. Half of the women were treated expectantly by their clinicians, and of those, 11 of 22 delivered before 32 weeks. The other half had a transvaginal cervical rescue suture inserted; only 1 of 21 delivered before 32 weeks. Although the two groups were comparable and a benefit of suturing was indicated, the study was not randomized.[44] Two small randomized studies and some observational studies suggested a benefit from serial transvaginal ultrasound and suture insertion when the cervical length is less than 2.5 cm,[30,31,45] although one randomized study showed no clear effect of cerclage suture.[33] Moreover, considerable morbidity occurred in the entire group studied and was attributed to prexisting subclinical infection, placental abruption, and preterm labor. The value of this approach and consequent late or emergency (rescue) cerclage is uncertain. Each case requires thorough evaluation of the options because there are no objective guidelines from well-constructed prospective studies.[21,31] When dilation and delivery in a

previous pregnancy was accompanied by bleeding and pain indicative of concomitant chorioamniotic infection, transvaginal ultrasound surveillance may be a better option than prophylactic transvaginal cerclage.

In twin or other multiple pregnancy, routine prophylactic cervical cerclage offers no benefit. Serial ultrasound cervical assessments with timely selective cerclage in women with evidence of cervical shortening and funneling may improve outcome, although this hypothesis is unproven.[16,21,31]

When very preterm delivery may be imminent because of advancing cervical shortening or dilation, rescue cerclage suture insertion can be considered. For this to meet with any degree of success, cervical dilation must not be more than approximately 2 cm and the membranes must not protrude out of the external cervical os. When the membranes are visible, the prognosis worsens appreciably.[32] It is then necessary to exclude infection by speculum examination and bacterial culture from the cervix

and to evaluate cervical length and appearance by transvaginal ultrasound. If the woman has no fever and a normal white blood cell count and serum C-reactive protein level, chorioamnionitis is less likely. A negative finding on cervicovaginal fibronectin assay (a marker of choriodecidual disruption) may also be useful.[5] Harger[21] suggested a management protocol to exclude infection and identify women who may benefit from late or emergency cervical cerclage suturing. Despite the risk associated with rescue suture, additional time is sometimes gained. Extra time is particularly useful from 24 to 26 weeks' gestation. Complication rates with rupture of the membranes and chorioamnionitis are high, between 20% and 50%. The value of prophylactic measures to maintain a normal vaginal bacterial environment (i.e., low pH, no bacterial vaginosis) is controversial,[46,47] although treatment of established bacterial vaginosis is likely to reduce the risk of preterm birth and is recommended.[47,48]

SUMMARY OF MANAGEMENT OPTIONS
Suspected Cervical Insufficiency

MIDTRIMESTER BLEEDING (See also Chapter 59)

Definition

Midtrimester bleeding is any bleeding that occurs during midpregnancy. It has the same causes as bleeding that occurs during the third trimester. It may originate from the vulva, the vagina and the vaginal portion of the cervix, from a low-lying placenta or placenta previa, and from marginal and (rarely) total placental separation.

Risks

Most midtrimester bleeding is not serious,[49] but is associated with a considerably increased risk of repeated bleeding and preterm delivery.[49,50] Repeated first-trimester bleeding, with or without evidence of hematoma on ultrasound, is common and is not associated with a poor prognosis if it resolves before 14 weeks. However, bleeding in the second trimester is likely to be related to abnormality of the placental site, and the risk of an adverse pregnancy outcome is increased twofold to fivefold.[51-53] Among women with painless bleeding in the second and early third trimesters, one third deliver preterm. In women with uterine contractility, two thirds deliver preterm and half of these do so within 1 week.[49] After bleeding in the second trimester, the relative risk of placental abruption increases between 5-fold and 30-fold.[51,53] This bleeding is related to intrauterine growth restriction and fetal distress.[53] Abruption is not common in midpregnancy, probably because of the normal decrease in blood pressure that occurs at this time, but if it occurs, the risk of fetal demise is doubled.[50] Placenta previa also leads to a considerable risk of bleeding in the second trimester.[54] An increased risk of bleeding is also associated with severe early-onset hypertensive disorder, rare cases of women who are carriers of a bleeding diathesis, and medication with anticoagulant drugs.

Management Options

Any bleeding, however slight, with or without pain or uterine contractions, must be investigated. The same considerations for diagnosis and treatment apply as in the third trimester. Cervical or postcoital bleeding may be related to vaginal or cervical infection, a frail ectropion or cervical polyps, the early stages of cervical insufficiency, or rarely, cancerous lesions. Domestic abuse must be kept in mind as well. Blood streaks in the cervical mucus indicate that the origin of the bleeding is the uterine cavity. The most likely source is a decidual blood vessel at the placental edge or a dilating cervix. Bleeding from a low-lying placenta (<2 cm from the internal os) or placenta previa or minor placental abruption (bleeding into the decidua and subplacental space) must be considered.

In 30% of pregnancies, ultrasound screening at approximately 18 to 20 weeks will show a low-lying placenta. A more definitive diagnosis may be made with color Doppler studies. Vaginal ultrasound shows whether funneling of the internal os and shortening of the cervical canal is taking place. A diagnosis at this time makes it possible to warn the mother and to take appropriate precautions.

Cervical polyps originate in the lower part of the cervical external os and arise in response to cervical infection, leading to a tissue reaction in the endocervical glandular tissue. This can produce a 0.5- to 3-cm inflamed protrusion from the cervix that bleeds easily, typically after exertion or intercourse. Diagnosis is made by speculum examination. Management consists of grasping the polyp with a sponge forceps and twisting it loose (taking care not to tear it away) to stop the blood supply and reduce bleeding. The woman should be reassured about the benign nature of the condition and its nonrecurrence, although histopathologic examination should be performed in all cases. Use of an appropriate self-administered antibacterial vaginal cream may be recommended for a few days.

After initial examination by speculum, the first rule is to await developments and not to examine the woman digitally by pushing a finger into or through the cervix. A new scan should not be necessary, unless the bleeding occurred before the 18- to 20-week scan, when it is more likely to be associated with fetal intrauterine death. Fetal viability can be shown easily with a portable handheld Doppler ultrasound fetal heart detector. Intrauterine hematoma can be recognized by an echolucent "stringy" area just above the internal os. The hematoma often lifts the membranes off the decidua or causes a separation of the placental edge. An older hematoma may be more echodense and difficult to detect.

Conservative management with bed rest is usually advised, although no studies show a benefit from this or from oral or parenteral tocolytic drugs or sedatives. It is important to allay the woman's anxiety as much as possible. Advising the woman to avoid strenuous work and to rest periodically throughout the day can be helpful because tiredness provokes uterine contractions that may lead to resumed bleeding. For the same reason and to prevent ascending infection, eradication of bacterial vaginosis or infection and abstaining from sexual intercourse may be helpful.[48] Occasionally, repeated bleeding may lead to anemia. Rarely, blood transfusion is necessary. The value of antifibrinolytic drugs, such as tranexamic acid, is debated.

MIDPREGNANCY MEMBRANE RUPTURE
(See Chapters 61 and 63)

Definition

Midpregnancy membrane rupture is leakage of amniotic fluid between 12 and 28 weeks. It is particularly significant after 20 weeks (very preterm prelabor rupture of membranes [PPROM]). The condition is serious because of the high likelihood of infection, placental abruption, fetal compromise, and early preterm birth, with its associated neonatal morbidity and mortality and the risks of maternal operative morbidity, infection, and thrombosis.

Risks

The antecedent risk factors are the same as for previous midpregnancy loss (i.e., previous midpregnancy loss or delivery, bacterial vaginosis, ascending bacterial infection with ensuing chorioamnionitis, cervical insufficiency and repeated bleeding from early in pregnancy, cervical conization). Other risk factors include low body mass, lung disease and smoking, strenuous working conditions, and perhaps genetic factors related to genes that regulate tissue breakdown and remodeling (matrix metalloproteinases).[25,48,51,53,55,56] These factors may predict which patients will have the condition, although none is easily recognized in an individual patient, except for cervical insufficiency seen developing on transvaginal ultrasound.

The fetal prognosis is affected by the gestational age at which the membranes rupture, the interval until delivery, the degree of oligohydramnios (which is not always complete), and the degree to which subclinical and overt infection develop. The sequence of events is likely to be initiated when proteolytic bacteria enter the cervical canal (made easier when bleeding from the placental site tracks down behind the membranes and through the cervix) and reach the chorionic membrane, where enzymatic breakdown is accelerated rapidly by proinflammatory mediators.[55,56] Infection affects both membranes and the amniotic fluid compartment, eventually reaching the fetus through the umbilical cord and lungs. Approximately 50% of infants are delivered by 1 week, 70% to 75% are delivered by 2 weeks, and 80% to 85% are delivered by 4 weeks.[56] Earlier rupture usually means a longer latent time until delivery. When very PPROM occurs before 24 to 26 weeks, serious complications related to arrest of lung development, (e.g., intrauterine pneumonia, bronchopulmonary hypoplasia [in approximately 16% of cases], pulmonary hypertension [if the neonate survives]) are major factors that affect survival.[55–57] Another risk factor is skeletal deformity caused by oligohydramnios and severe fetal distress, including that caused by cord entanglement or prolapse. If the membranes have been ruptured for more than 1 week, the risk of pulmonary hypoplasia and limb deformity increases, particularly before 26 weeks' gestation and if the duration of rupture is longer than 5 weeks.[58] With PPROM before 20 weeks, at least half of fetuses have bronchopulmonary hypoplasia, but this rate decreases as gestation advances and the latent time to birth becomes shorter. PPROM occurs in 5% to 7% of all pregnancies, but the interval to delivery is longer than 1 week in only 10% of these pregnancies. Diagnosis is made by clinical observation, ultrasound,[58] and positive signs of infection. The use of proinflammatory factors (interleukins) in amniotic fluid or cervical secretions to identify patients with PPROM is experimental.

Management Options

Treatment is conservative from early in the midtrimester until 28 weeks' gestation. If leakage occurs early in midpregnancy (i.e., before 18–20 weeks), the prognosis for fetal survival is so grave that termination must be discussed with the parents. Most women (but not all) miscarry spontaneously before 20 weeks. If pockets of amniotic fluid remain, the chance of a successful outcome improves. If fetomaternal infection occurs before viability is achieved at 20 weeks, it may be necessary to stimulate uterine activity with vaginal or oral prostaglandins or oxytocin infusion, depending on the degree of cervical dilation. Infection parameters, primarily maternal temperature, white blood cell count, and C-reactive protein level, must be monitored. Antibiotics that cover anaerobic bacteria (clindamycin or metronidazole) should be administered before and during evacuation of the uterus.

An elevated or increasing white cell blood count may be helpful in determining the onset of chorioamnionitic infection necessitating delivery, but its specificity and

positive predictive value are low. Measurement of the C-reactive protein level may be more reliable, but only if the value is clearly greater than the upper normal distribution level (two standard deviations). The C-reactive protein level does not increase to a diagnostic level until approximately 12 hours before the infection becomes clinically obvious.[59]

If the pregnancy is continued, the main option after 20 to 22 weeks' gestation, depending on local legislation, is expectant management, usually with initial hospitalization. After initial assessment, discharge home with monitoring for fetal viability and infection is feasible and does not worsen the prognosis.[56] A meta-analysis of the studies of prophylactic antibiotic treatment, dominated by one randomized study (the ORACLE trial), showed improved outcome after 24 weeks, defined as delaying preterm birth for 1 week (relative risk, 0.88; 95% confidence interval, 0.84–0.92), reducing the incidence of chorioamnionitis (relative risk, 0.62; 95% confidence interval, 0.51–0.72), and reducing the incidence of maternal infection (relative risk, 0.85; 95% confidence interval, 0.76–0.96).[56,60] The incidence of neonatal infectious disease, the requirement for oxygen, and the number of abnormal cerebral ultrasound findings were also significantly reduced. The antibiotics of choice are metronidazole and erythromycin. Corticosteroid administration is safe. The need for booster courses is questionable, but tocolysis can be used as indicated (particularly to allow in utero transfer to a tertiary neonatal unit). Amnioinfusion and sealing of the leak site are currently experimental approaches.[56] If PPROM occurs in a patient who has a transvaginal cerclage suture, the suture is usually removed if signs of infection occur. After 24 weeks, it may be possible to maintain the suture with antibiotic treatment.

INCARCERATED UTERUS

Definition

When the pregnant uterus is in a retroverted and retroflexed position and cannot rise out of the pelvic cavity, it is incarcerated. The fixed retroverted position pulls the cervix and vagina forward and cephalad, stretching and pressing on the urethra. Acute urinary retention, the usual symptom, is often preceded for a few days by frequency as a sign of overflow incontinence. Forward bulging may be noted behind the posterior vaginal wall.

Risks

A previously retroverted and retroflexed uterus is the usual antecedent. This uterine position is found in 1 in 5 to 1 in 10 women,[61-63] although the uterus rises out of the pelvis spontaneously after 12 to 15 weeks' gestation in almost all cases. The incidence of incarceration is reported to be only 1 in 3000 pregnancies. Predisposing factors are not known. Uterine wall fibroids or posterior wall adhesions may be implicated in some cases. Potential complications include neuromuscular damage to the bladder, ureteric obstruction and hydronephrosis with renal infection and damage, pressure necrosis of adjoining organs, and uterine rupture. In rare cases, sacculation persists into the third trimester, resulting in abnormal fetal presentation.[62,63]

Management Options

The bladder must be emptied by catheter. The catheter is left on free drainage for 24 to 48 hours. Subsequent ultrasound monitoring of bladder emptying to ensure a residual of no more than 150 to 200 mL is advisable. If the residual is greater, an indwelling catheter is inserted. Recurrent episodes of retention are common until the condition gradually resolves. Ultrasound examination is a necessary adjunct to diagnosis to exclude the alternative diagnosis of ovarian cyst incarceration in the pelvis.[63] Manual repositioning of the uterus may be considered and may need to be done under general anesthesia. Occasionally, ureteric stents or catheters are required to alleviate hydroureter and hydronephrosis.[64] Antibiotic treatment is not required unless there is evidence of infection.

SUMMARY OF MANAGEMENT OPTIONS
Incarcerated Uterus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Encourage bed rest in the prone position.	IV	C	62,63
Encourage regular emptying of the bladder, with ultrasound confirmation that it remains empty (<200 mL).	IV	C	62,63
Consider catheterization for 48 hr if the patient cannot keep the bladder empty by voiding.	IV	C	62,63

CONCLUSIONS

- Midpregnancy is a time of intense physiologic evolution that is relatively undisturbed by intercurrent problems.
- Vague symptoms consistent with maternal adaptation to the growing fetus and ongoing pregnancy must not be confused with developing disease.
- Most serious problems that occur during midpregnancy involve a risk of very early delivery or fetal loss, particularly in patients with repeated previous midpregnancy loss, cervical insufficiency and repeated early bleeding from the placenta implantation site, or very preterm prelabor rupture of the membranes.
- Some potential remedies are designed to delay delivery and counteract infectious morbidity, including cervical cerclage, with or without transvaginal ultrasound follow-up, and antibiotic, tocolytic, and corticosteroid treatment, when indicated.
- Most of these measures have been inconclusively researched, and their value is debated.
- More evidence-based guidelines are needed. Meanwhile, clinicians should be prepared to make therapeutic recommendations based on individual needs and the best available evidence.

First-Trimester Screening for Fetal Abnormalities

Romaine Robyr / Yves Ville

INTRODUCTION

The first-trimester diagnosis of fetal abnormalities is characterized by the confidentiality surrounding parental decisions. Early termination of pregnancy has considerable medical and psychological benefits for women compared with the effects of late termination. The early first-trimester ultrasound examination is also an opportunity to identify a family history of genetic syndromes or anomalies that warrant more frequent or detailed ultrasound assessments during the pregnancy (see also Chapter 8).

The most common indications for routine ultrasound examination at 11 to 14 weeks are the following:

- Assessment of viability
- Determination of gestational age
- Identification and typing of multiple pregnancies
- Screening for fetal aneuploidy based on the measurement of nuchal translucency (NT) thickness. A combination of ultrasonography and laboratory testing at 11 to 14 weeks' gestation is the best available method for screening for fetal aneuploidy.[1,2]
- Assessment of gross fetal anatomy. Technologic improvements, in particular, high-frequency transvaginal ultrasound probes, allow detection of the most severe fetal structural abnormalities before 14 weeks' gestation.[3,4]

Screening requires standardization and quality control. An ultrasound examination at 11 to 14 weeks includes at least the following three core views of the fetus:

- A strict midsagittal plane is used to allow measurement of the crown–rump length (CRL) and examination of the abdominal wall as well as both cranial and caudal fetal extremities. NT measurement is also performed in this plane.

- An axial view of the skull is used to identify the cranial contour, the midline of the brain, and the posterior fossa.
- A cross-section of the abdomen is used to identify the cord insertion site on the abdomen and the intra-abdominal position of the stomach. The presence of four limbs with three segments is also verified.

The 11- to 14-week window of gestational age is the best compromise to assess gestational age, measure NT thickness, and obtain a potentially detailed anatomic survey (Table 7–1). A more thorough examination of the fetal anatomy is performed when mandated by the patient's history or abnormal findings on a screening examination.

TABLE 7–1

Ultrasound Examination of the Fetal Anatomy at 11 to 14 Weeks' Gestation

Sagittal View to Assess
Crown–rump length
Integrity of the cranial vault
Insertion of the umbilical cord on the abdominal wall
Thickness of the nuchal translucency

Cross-Section Planes Showing
Normal position of the heart in the thorax
Four limbs with three segments, with normal mobility and alignment
Stomach bubble in the abdomen
Bladder

Axial View of the Brain Showing
Midline and falx cerebri
Lateral ventricles filled with choroids plexi
No cystic images

ULTRASOUND EXAMINATION AT 11 TO 14 WEEKS

Identifying a Viable Pregnancy

Ultrasound examination at 11 to 14 weeks is often the first opportunity to diagnose early pregnancy failure (Fig. 7–1). The prevalence of early pregnancy failure in one screening study of 17,870 women at 10 to 13 weeks was 2.8% (501 cases), including 313 (62.5%) missed abortions and 188 (37.5%) anembryonic pregnancies.[5] The diagnosis of a nonviable pregnancy is important because elective evacuation of the retained products of conception is likely more cost-effective and potentially safer than emergency surgery for miscarriage.[5]

The likelihood of pregnancy loss after the successful development of embryonic anatomic landmarks identified on endovaginal ultrasound has been evaluated.[6] Two hundred thirty-two women with positive urinary pregnancy test results and no history of vaginal bleeding underwent endovaginal sonography at their initial visit and then at subsequent visits, as clinically indicated. The presence of anatomic and embryonic structures (gestation sac, yolk sac, embryo) as well as cardiac activity was recorded. Twenty-seven losses were documented in the embryonic period, with 4 losses in the fetal period and 201 live births reported. When a gestation sac was seen, the total subsequent loss rate was 11.5% during the embryonic period; the rate was 8.5% with a yolk sac only, 7.2% with an embryo up to 5 mm, 3.3% with an embryo 6 to 10 mm, and 0.5% with an embryo larger than 10 mm. No pregnancies were lost between 8.5 and 14 weeks. The fetal loss rate after 14 weeks was 2.0%.[6]

Dating the Pregnancy

Dating a pregnancy by menstrual history is often unreliable. Up to 40% of women are uncertain of their menstrual dates, and even when they are certain, gestational age is often overestimated compared with ultrasound findings.[7] Overestimation of true gestational age by menstrual history increases the prevalence of postdated pregnancies.[8] Estimates of the duration of gestation based on the last menstrual period are subject to both random error and a systematic tendency to overstate the duration of gestation, most likely because of delayed ovulation.[9] In a recent study, the prevalence of post-term births was 12.1% based on menstrual history, but only 3.4% based on ultrasound findings. The effect on the cost of delivering obstetric health care is real, considering that more than 8% of pregnant women have unnecessary antenatal surveillance.

Before 6 weeks, dating is done by description and measurement of the gestation sac.[10] The size of the sac can be correlated to gestational age.[11] The gestation sac is always visible by 4 weeks. In 95% of cases, the yolk sac is present by 5 weeks, and in all cases, it is present by 6 weeks. The fetal heart is seen beating in 86% of cases by 6 weeks, and always by 7 weeks.

Of all of the available measurements, the maximum embryo length between 6 and 10 weeks and the CRL up to 14 weeks are the most accurate for determining gestational age. The random error is 4 to 8 days at the 95th percentile.[12–15] The largest study that used a strict method is that of Wisser and Dirscheld,[15] who highlighted potential pitfalls of earlier studies and reported a predictive interval of 4.7 days (standard deviation) in 160 patients who underwent in vitro fertilization, including 21 with multiple pregnancies.[15]

The maximum embryo or fetal length is usually measured excluding the inferior limbs and without correction of the body's flexion. All charts are concordant before 60 mm (predictive interval, 3 days [standard deviation]), but differ significantly thereafter.

The gestational age should not be altered if the discrepancy between the last menstrual period and the CRL measurement is less than 7 days. A discrepancy of more than 1 week suggests inaccurate menstrual dates. However, there is no advantage in considering the last menstrual period when an ultrasound has been performed, even when the date is described as "certain," because the outcome of pregnancy is more closely related to gestational age as determined by ultrasound.[16]

When the CRL is greater than 60 mm, other biometric parameters are more useful for dating the pregnancy up to 20 weeks.[17] These parameters include biparietal diameter, head circumference, femur length, and abdominal circumference. Some authors indicate that long bone measurements can aid in the detection of skeletal dysplasia, although the low prevalence of these abnormalities, together with technical difficulties involved in measurement, leads to a poor positive predictive value when applied to the general population.[18]

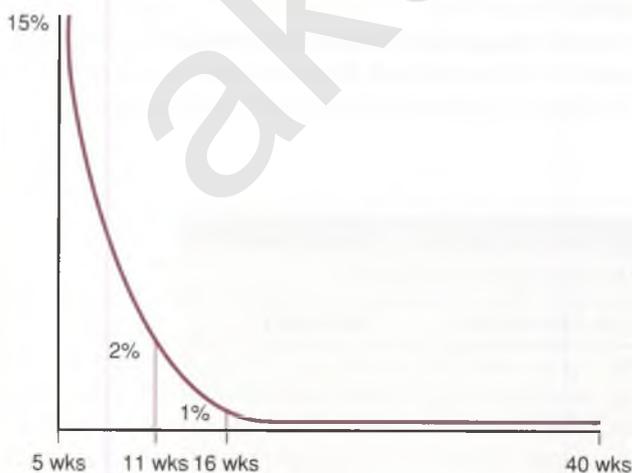
First-trimester fetal biometry is underused to diagnose or characterize abnormal fetal development. Fetal growth during the first trimester was previously considered relatively uniform, but increasing evidence shows that


FIGURE 7–1
Risk of spontaneous miscarriage.

anthropometric differences and other growth abnormalities may be expressed in the first trimester. In one series of transvaginal measurements, Kustermann and colleagues[19] observed that fetal biparietal diameter, head circumference, and abdominal circumference correlated better with the CRL than they did with gestational age. Further, direct assessment of early fetal measurements once established on the basis of the CRL may provide more relevant information than the two-step process using biometry based on gestational age. Salomon and associates[16] also found that fetal biometry is better estimated in relation to the CRL than to gestational age. Finally, reliable charts of biparietal diameter, head circumference, and abdominal circumference provide an opportunity to assess the quality of transverse views of the fetal head and abdomen at 11 to 14 weeks' gestation.

Detecting Multiple Pregnancies and Determining Chorionicity (See Chapters 24 and 60)

Two percent of all pregnancies are twin pregnancies (Table 7–2). Two-thirds of these are dizygotic (genetically different, or nonidentical), and one-third are monozygotic (genetically identical). An important task of the first-trimester scan is to diagnose twin pregnancy and determine chorionicity. For obstetricians, chorionicity is far more important than zygosity because the management of multiple pregnancies relies mainly on chorionicity. Zygosity is relevant only to specific genetic issues. The relationship between chorionicity and zygosity can be kept simple. Two-thirds of dichorionic pregnancies (two placentas) are dizygotic, but one-third of them are monozygotic. The only way to determine zygosity is through invasive testing, with chorionic villus sampling, amniocentesis, or cordocentesis to analyze the fetal DNA. In 2% of cases, monozygotic twins share organs (Siamese, or conjoined, twins).

The first trimester is the best time to determine chorionicity. Dichorionic twins have two placentas, but in most cases, the placentas are adjacent, making the diagnosis of chorionicity difficult. An ultrasound clue to chorionicity in the first trimester is the lambda sign (Fig. 7–2).[20] This sign

FIGURE 7–2
Dichorionic diamniotic twin pregnancy and the lambda sign.

is a triangular tissue projection at the base of the intertwin membrane. It is an extension of the two chorion layers within the intertwin membrane that is present only in dichorionic pregnancy. In monochorionic pregnancies, there is no layer of chorion between the two layers of amnion, and the lambda sign is absent. This sign can be seen from 9 weeks onward, and its identification at any stage of pregnancy is proof of dichorionicity. However, the chorion disappears with advancing gestation, and the lambda sign becomes progressively more difficult to identify. At 16 weeks and 20 weeks, respectively, the lambda sign, or twin peak sign, is present in only 98% and 87% of cases.[21]

Identifying Normal Sonographic Features in the First Trimester

Ultrasound examination of the fetal anatomy in the first trimester focuses on embryologic development. Most fetal structures can be visualized at approximately 12 to 13 weeks with either vaginal or abdominal ultrasound (Table 7–3).[3,22–24]

Some sonographic features are similar to those described in the second and third trimesters (see also Chapter 8). Others are characteristic of the first trimester. Normal

TABLE 7–2			
Types of Monozygotic Twins and Time of Division after Fertilization			
CHORION	**AMNION**	**TIME OF DIVISION (DAY)**	**FREQUENCY**
Dichorionic	Diamniotic	0–3	33%
Monochorionic	Diamniotic	4–8	65%
Monochorionic	Monoamniotic	>8	2%
Monochorionic	Monoamniotic (Siamese)	>13	Rare

*Gestational age at which organs may be visualized in >70% of fetuses.
(From Chitty L, Pandya P: Ultrasound screening for fetal abnormalities in the first trimester. Prenat Diagn 1997; 17: 1269–1281.)

sonographic characteristics at 11 to 14 weeks include the following features.

External Features

Ossification begins at approximately 11 weeks with the occipital bone. The skull appears regular and hyperechogenic compared with the underlying tissues.[25]

Central Nervous System

From 9 weeks onward, the outline of the lateral ventricles, the echogenic choroid plexus, and the midline echo are visible. At 10 to 11 weeks, the third and fourth ventricles become visible, and from 14 weeks onward, the cerebellum and thalami are seen. The ventricles occupy most of the cerebral hemispheres. The diagnosis of hydrocephaly is difficult to establish in the first trimester. The choroids plexus should fill the lateral ventricles completely. Choroid plexus cysts are more common in the first trimester than in the second (incidence, 5.7% vs. 1.4%)[26,27] and are not known to be associated with fetal abnormalities at this early gestation.

Heart

The position, axis, four-chamber view, and symmetry of the heart can be seen in the first trimester. Huggon and associates[28] examined the fetal heart before 14 weeks' gestation. A highly trained cardiologist performed the examinations, and informative images were obtained transabdominally in 84% of cases. With less specialized operators, the four-chamber view was imaged successfully in 76% and 95% of cases transabdominally and transvaginally, respectively at 12 to 13 weeks' gestation.[3] Whitlow and Economides[29] reported that the four-chamber cardiac view was seen in 83% at 11 weeks and in

98% from 13 weeks onward. Women with an increased NT measurement are at risk for cardiac abnormalities (discussed later).[30]

Stomach

The stomach bubble is seen by 8 weeks in 31% of fetuses,[31] and in all cases by 12 to 13 weeks, as a small, sonolucent cystic structure in the upper left quadrant of the abdomen, below the heart. The relationship of this structure to the diaphragm should be noted. Fetal swallowing movements can be seen from 11 weeks onward[31]; fluid production from the intestinal epithelium is the most likely explanation for visualization of a stomach earlier.[32]

Abdominal Wall

The physiologic hernia of the midgut into the umbilical cord is a normal feature of embryonic intestinal development.[31] It is a large, hyperechogenic mass that retracts into the abdominal cavity between 10 weeks and 4 days and 11 weeks and 5 days. Fetuses older than 11 weeks and 5 days should not show herniation.[31] At that point, a differential diagnosis of omphalocele and gastroschisis should be considered.

Bladder and Kidneys

The fetal kidneys are seen in most cases at 12 to 13 weeks and appear more echogenic than the rest of the intraabdominal contents. Renal echogenicity decreases as excretory function develops.[29] As a result, the fetal bladder is visualized in 80% of fetuses[33] by 11 weeks and in more than 90% by 13 weeks. The sagittal long axis of the bladder is less than 6 mm in the first trimester. In a study of 300 pregnancies at 10 to 14 weeks' gestation, the fetal bladder was always visualized when the CRL was greater than 67 mm. The fetal bladder was visualized in 90% of fetuses with a CRL of 38 to 67 mm.[34]

Skeleton

All three parts of the long bones are consistently seen from 11 weeks onward, although measurement of the long bones before 14 weeks seems clinically irrelevant. Body and limb movements are seen from 9 and 11 weeks onward, respectively. All long bones are similar in size at 11 to 14 weeks, ranging from approximately 6 mm at 11 weeks to 13 mm at 14 weeks.[35]

Nuchal Translucency

Definition

NT is the ultrasound definition of the physiologic collection of fluid under the skin behind the fetal neck at 11 to 14 weeks. NT thickness normally increases with

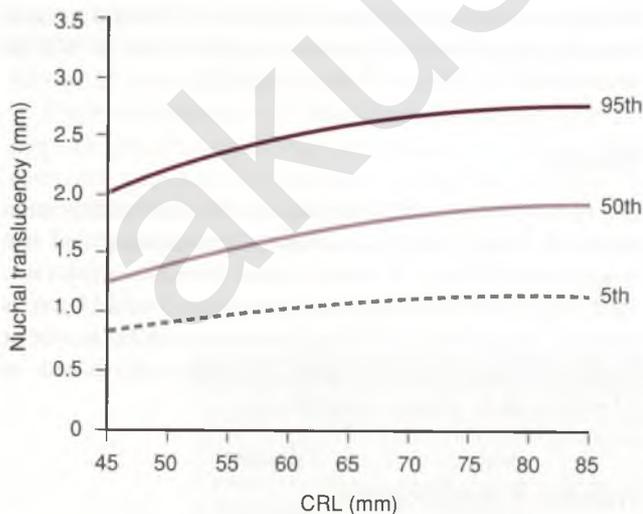
CRL.[36-38] It is important, therefore, to consider gestational age when deciding whether NT thickness is increased. The 50th percentile value for NT thickness is 1.2 mm and 1.9 mm for a CRL of 45 mm (11 weeks) and 85 mm (13 weeks and 6 days), respectively, and the 95th percentile value is 2 mm and 2.8 mm, respectively. Gestational age can therefore influence the risk calculation significantly (Fig. 7–3).

Because of the need to standardize measurement of the NT, initial attempts to differentiate the NT from cystic hygroma have been abandoned. However, cystic hygroma can be clearly differentiated from an increased simple NT, and further attempts to assess the prognosis of these fetuses are needed. When NT thickness is greater than 3.5 mm, thin septations are seen. The typical ultrasonographic appearance of cystic hygroma is two dilated jugular lymphatic sacs seen on a transverse scan at the level of the neck and separated from the NT (Fig. 7–4).

Measurement

Standardization and quality control in NT measurement is best served by the Fetal Medicine Foundation (FMF) initiative. This initiative established a process for certification in the 11- to 14-week scan to ensure that those performing the examination are adequately trained and maintain an appropriate level of performance through continuing education and audit (*www.fetalmedicine.com*).

To obtain a reliable measurement of fetal NT, the following steps are needed (Fig. 7–5):

- All sonographers who perform fetal scans must be appropriately trained. The ability to measure NT reproducibly improves with training; good results are


typically achieved after approximately 100 scans. Intraobserver and interobserver differences in measurements are less than 0.5 mm in 95% of examinations.[39-40]

- The ultrasound equipment must be of good quality, with a video-loop function. The calipers should be able to provide measurements to a tenth of a millimeter.
- NT can be measured successfully by transabdominal ultrasound in approximately 95% of cases; in the rest, transvaginal sonography is required.
- Because the optimal gestational age for the measurement of NT is 11 weeks to 13 weeks and 6 days, the minimum fetal CRL should be 45 mm and the maximum, 84 mm.
- Because fetal NT thickness increases with CRL, gestation must be taken into account when determining whether a given NT increases risk.
- To measure the CRL, a good sagittal section, with the fetus in the neutral position, is needed for accurate measurement of NT.
- The magnification should be such that each increment in distance between calipers is 0.1 mm.
- Care must be taken to distinguish between fetal skin and the amnion. Both structures appear as thin membranes at this gestation. This distinction is made by waiting for spontaneous fetal movement away from the amniotic membrane or by "bouncing" the fetus off of the amnion by having the mother cough or by tapping the maternal abdomen.
- During the scan, more than one measurement is taken, and the maximum technically acceptable measurement is recorded.
- The nuchal umbilical cord is present in approximately 8% of scans, and this finding may falsely increase the NT measurement.[41] In these cases, the measurements of NT above and below the umbilical cord are different. In the calculation of risk, it is more appropriate to use first- or second-trimester laboratory screening results (Fig. 7–6).

Screening for Fetal Aneuploidies

FETAL NUCHAL TRANSLUCENCY AND TRISOMY 21

Down syndrome is the most common chromosomal abnormality, and every woman is at risk for having an affected fetus. This pervasive risk justifies the screening programs that have been established worldwide. A woman's risk of having a fetus with Down syndrome depends on her age, the gestational age, and the woman's history of chromosomal defects. These factors establish the background risk. A 33-year-old woman at 10 weeks' gestation has a 1 in 352 risk of having a fetus with trisomy 21. Because the risk decreases with gestation as a result of the spontaneous death of fetuses with chromosomal abnormalities, the risk is 1 in 547 at 40 weeks.

NT measurement at 11 to 14 weeks, combined with maternal age, provides an effective method of screening

FIGURE 7–3
Changes in nuchal translucency with gestational age, as expressed by crown–rump length (CRL). (Adapted from Pandya PP, Snijders RJM, Johnson SJ, et al: Screening for fetal trisomies by maternal age and fetal nuchal translucency thickness at 10 to 14 weeks of gestation. BJOG 1995;102:957–962.)

for trisomy 21. An association between increased NT thickness and chromosomal defects has been seen since the early 1990s.[36,42–54]

The average detection rate with NT measurement is 77%, for a false-positive rate of 4.7%. The false-positive rate is the percentage of karyotypes potentially performed because of a positive screening test result. This detection rate represents the combined results of 14 prospective studies on NT measurement for chromosomal abnormalities involving 174,473 patients, including 728 with trisomy 21 (Table 7–4).[36,42–54] For comparison, screening by maternal age only, with a cutoff age of 37 years, has a detection rate of 30%, for a false-positive rate of 5%. With second-trimester maternal

FIGURE 7–9
Nuchal translucency measurements in 326 fetuses with trisomy 21 plotted against the normal range for crown–rump length (95th and 5th percentiles) (From Snijders RJM, Noble P, Sebire N, et al: UK multicentre project on assessment of risk of trisomy 21 by maternal age and fetal nuchal translucency thickness at 10–14 weeks of gestation. Lancet 1998;351:343–346.)

serum markers, the detection rate is approximately 60%, for the same false-positive rate.[55]

Whenever a screening test is performed, the background risk is multiplied by the test factor to calculate a new risk. Therefore, in a fetus with a given CRL, each NT measurement is a likelihood ratio that is multiplied by the background risk to provide a new risk (Fig. 7–7).[36,56] A woman's risk of having a fetus with trisomy 21 is higher if the NT measurement is large and lower if it is small (Figs. 7–8 and 7–9).[36,56]

The median NT thickness is approximately 2.0 mm in fetuses with trisomy 21. However, because NT thickness increases with gestation, the use of a cutoff value rather than a continuous assessment with CRL and maternal age leads to a 5% loss in sensitivity.[57]

FIGURE 7–8
Distribution of fetal nuchal translucency thickness expressed as deviation from the expected normal value for crown–rump length in chromosomally normal fetuses (*open bars*) and 326 fetuses with trisomy 21 (*solid bars*) (From Snijders RJM, Noble P, Sebire N, et al: UK multicentre project on assessment of risk of trisomy 21 by maternal age and fetal nuchal translucency thickness at 10–14 weeks of gestation. Lancet 1998;351:343–346.)

NUCHAL TRANSLUCENCY AND CHROMOSOMAL DEFECTS OTHER THAN TRISOMY 21

Chromosomal abnormalities that are much less prevalent than trisomy 21 are associated with increased NT thickness. In these fetuses, other characteristic sonographic findings are associated with increased NT measurements.

In trisomy 18, early-onset intrauterine growth restriction (IUGR) often occurs and may cause an error in dating the pregnancy. In approximately 30% of these cases, other anomalies, such as exomphalos, are seen after 11 weeks.[58]

Trisomy 13 may also cause early-onset IUGR and severe brain anomalies, mainly holoprosencephaly, in up to 30% of cases at 11 to 14 weeks.[59]

Turner syndrome is characterized by fetal tachycardia in approximately 50% of cases. These fetuses often have large cystic hygromas.[60]

In triploidy, there is early-onset, but asymmetrical IUGR, with an almost normal-sized head. Other severe anomalies are present in approximately 40% of cases, and molar changes in the placenta are seen in approximately one third of cases.[61]

INCREASED NUCHAL TRANSLUCENCY AND NORMAL KARYOTYPE

By definition, 5% of fetuses screened at 11 to 14 weeks have an NT measurement greater than the 95th percentile. Most of these fetuses are chromosomally and anatomically normal antenatally and at birth.[36,62] Fetuses with increased NT thickness but a normal karyotype are at increased risk for major cardiac defects as well as other structural anomalies, rare genetic syndromes, and other unfavorable outcomes (Table 7–5).[63–67]

Souka and colleagues[63] looked at pregnancy outcome in 1320 chromosomally normal fetuses with NT thick-

ness greater than 3.5 mm in the first trimester. In chromosomally normal fetuses, the chance of a live birth and no structural defects was 86% when the NT thickness was 3.5 to 4.4 mm, 77% when the NT thickness was 4.5 to 5.4 mm, 67% when the NT thickness was 5.5 to 6.4 mm, and 31% when the NT thickness was greater than 6.5 mm. Thus, parents should be counseled that even if the NT thickness exceeds 6.5 mm, there is a one in three chance that the pregnancy will end with the live birth of an infant with no major defects.[63]

CARDIAC DEFECTS

An abnormal NT measurement in a fetus with a normal karyotype is also associated with major abnormalities of the heart and great arteries. The prevalence of major cardiac defects increases with increasing NT thickness.[64] Fetal echocardiography can be performed at 16 weeks, and if the results are normal, the parents can be reassured.[30] However, many recommend a second echocardiogram at 18 to 22 weeks if the first results were normal. One explanation for the association of congenital heart defects and increased NT thickness is aortic arch abnormalities or heart failure. However, this finding is rarely confirmed either later in pregnancy or in the neonatal period.

DIAPHRAGMATIC HERNIA

In a study of 19 fetuses with diaphragmatic hernia, NT thickness was increased in 37%, including 83% of those who died in the neonatal period as a result of pulmonary hypoplasia. Only 22% of the survivors had an increased NT measurement. Increased NT thickness may reflect venous congestion in the head and neck as a result of mediastinal shift or compression and impaired venous return.[68]

EXOMPHALOS

The prevalence of exomphalos is approximately 10 times higher in fetuses with a normal karyotype and an increased NT measurement compared with the general population.[69,70] Other structural defects are associated with increased NT thickness and a normal karyotype.[70]

Increased Nuchal Translucency Measurement and Twin–Twin Transfusion Syndrome

In a study of 132 monochorionic twin pregnancies, an increased NT measurement (above the 95th percentile for CRL) at 11 to 14 weeks was associated with a fourfold increase in the risk of severe twin–twin transfusion syndrome.[71] Although the positive predictive value of this screening test is low, it is important to follow these pregnancies closely for the early diagnosis of twin–twin transfusion syndrome (see also Chapters 24 and 60).

Miscellaneous Associations

The association between increased NT thickness and a wide range of structural abnormalities and genetic syndromes is an indication of the need for long-term follow-up of these children, even when they appear normal at birth. Hiippala and colleagues[72] followed 50 chromosomally normal children 2.4 to 7.1 years of age who had NT thickness greater than 3 mm at 13 to 15 weeks' gestation. Their growth was within normal limits, but 1 in 12 had a previously unrecognized cardiac defect. One child had Noonan syndrome, one had cleidocranial dysplasia, and a third had developmental delays and an undefined syndrome. Webbing was seen in the neck region of two children who were otherwise free of associated pathology.

An increased NT measurement (>3.5 mm) with a normal karyotype is an indication for detailed follow-up ultrasound examinations. An anomaly scan should be performed at 14 to 16 weeks to determine the evolution of the NT to nuchal edema and to diagnose or exclude most fetal defects.[63] Nuchal edema is diagnosed when subcutaneous edema is noted in the midaxial plane of the neck and tremors occur if the uterine wall is tapped, or if the edema measures more than 6 mm.[73] If no obvious abnormalities are seen during the 14- to 16-week scan, echocardiogram should be performed at 20 to 22 weeks, when further genetic testing may be indicated (Fig. 7–10).[63]

An adverse outcome occurred in 18% of fetuses with persistent, unexplained nuchal edema at 20 to 22 weeks,[63] including progression to hydrops, genetic syndromes detected at birth, and cardiac defects (one third) that could have been detected, but were missed antenatally. The prevalence of neurodevelopmental delays in the group with normal findings on follow-up scans was 0.4%, but it was 1.2% in those with persistent nuchal edema. Other studies reported a 3.2% to 5.6% prevalence of residual neurodevelopmental delays in fetuses with increased NT thickness.[74,75] Methodologic issues

make it difficult to compare the prevalence of mental retardation in infants with increased NT measurements with the prevalence in the general population, which ranges from 0.5% to 2%.[76] Etiologies include chromosomal abnormalities in 25% of cases and genetic syndromes in 7% to 10% of cases. Mental retardation is unexplained in 30% to 50% of cases,[76] or less than 1% of the population. Children with an isolated NT measurement in utero of greater than 3.5 mm should be followed jointly by pediatricians and geneticists to allow enhanced prenatal counseling (Table 7–6).[62,63,74,75,77,78] Elucidation and integration of these data are essential if the counseling is to be balanced. Otherwise, counseling may resemble this confusing statement: "The good news is that the karyotype is normal, and the bad news is the karyotype is normal."[77,78] This type of uncertainty is potentially lethal, particularly when announced in the first trimester, especially in countries where social termination is an option at 14 weeks, but is challenged or forbidden at a later gestational age.

Fetal Nasal Bones

Recent studies indicate that the nasal bones are not visible on ultrasound between 11 and 14 weeks in more than 3% of chromosomally normal fetuses and in 60% of fetuses with trisomy 21.[79–82] This finding was first shown in high risk pregnancies and more recently was confirmed in unselected pregnancies. The actual value of screening for absent nasal bones on ultrasound at 11 to 14 weeks in the general population remains to be established. Methodologic problems surrounding that part of the first-trimester scan can generate a high false-positive rate, together with significant interoperator and intraoperator variability.[83]

Ultrasound Diagnosis of Fetal Abnormalities at 11 to 14 Weeks

Reports of detection rates of fetal structural defects in the first trimester other than those associated with increased NT thickness are mostly confined to high-risk groups or selected populations (Table 7–7).[84–87] However, increasing evidence shows that early detailed ultrasonography is technically feasible as a screening test for fetal structural defects in lowrisk pregnancies.[87] Most fetal structures can be visualized at 12 to 13 weeks, and this gestational age offers the earliest opportunity for screening for fetal abnormalities.

In 2853 pregnant women who underwent a routine ultrasound scan at 11 to 14 weeks by operators with different levels of experience,[88] 22.3% of fetal anomalies were detected in the first trimester ($n = 130$). Operator experience is important. More than half of major fetal abnormalities (1.5%) were identified during first-trimester screening in 20,465 unselected pregnant women who were screened at 13 to 14 weeks.[87] Sensitivity was lowest in the first year (22%) and highest (79%) in the

last (sixth) year. Adequate sensitivity in screening for major malformations during first-trimester ultrasonography can be achieved after 3 to 4 years of experience.[87]

The most frequently detected anomalies reported are central nervous system defects, such as anencephaly, encephalocele, and holoprosencephaly. The diagnosis of spina bifida is a challenge because the indirect sonographic signs that are characteristic later in gestation are usually missing before 14 weeks.[89] Exomphalos, gastroschisis, and megacystis are also commonly diagnosed in the first trimester. There are also several case reports of first-trimester diagnosis of a wide range of severe skeletal defects (see Fig. 7–4).

Acrania, Exencephaly, and Anencephaly

Anencephaly can be diagnosed reliably on routine 11- to 14-week ultrasound examination. Acrania is the main feature of anencephaly in the first trimester. Fetuses with acrania may have a normal brain or one that shows varying degrees of disruption.[90,91] In a large, multicenter

TABLE 7–7

Most Common Structural Defects Diagnosed Prenatally during Screening at 11 to 14 Weeks

Atrioventricular septal defects and hypoplastic left heart syndrome
Acrania and alobar holoprosencephaly
Omphalocele and gastroschisis
Megacystis
Lethal skeletal defects

study, screening for fetal abnormalities was performed in 53,435 singleton and 901 twin pregnancies. In this study, 8 of the 47 fetuses with anencephaly were missed during the early scan.[91] The sonographers were then instructed to look specifically for the cranial vault and at brain organization. All subsequent cases of anencephaly were identified at the 11- to 14-week scan.

Encephalocele

Encephalocele appears as a bony defect in the skull, with brain tissue protruding. It is associated with Meckel-Gruber syndrome.[92,93] In most cases, the lesion arises midline in the occipital area. The main alternative diagnosis is cystic hygroma. Once the diagnosis is suspected, the prognosis usually cannot be ascertained before the late second trimester.

Holoprosencephaly

Holoprosencephaly results from incomplete cleavage of the forebrain. The most severe forms, alobar and semilobar, are amenable to first-trimester ultrasound diagnosis. They are characterized by a monoventricular cavity and fusion of the thalami. These forms are often associated with facial abnormalities.[94,95] The most common related chromosome abnormality is trisomy 13.

Spina Bifida

Sonographic diagnosis of spina bifida aperta is difficult before 14 weeks. At this early gestation, the lemon (frontal bone scalloping) and banana signs (abnormal curvature of

the cerebellar hemispheres) are usually absent.[89,96] Other signs, such as a flattened occiput, parallel peduncles, a straight metencephalon, and the acorn sign (frontal bone narrowing) are not consistently present.[89,96] Blaas and colleagues[97] studied high risk pregnancies prospectively and identified three first-trimester fetuses with lumbosacral myelomeningocele characterized by an irregularity in the caudal part of the spine before 10 weeks. Three-dimensional ultrasound examination may be helpful, but is not necessary to make the diagnosis.

Heart Defects

Heart defects were largely covered in the earlier discussion of NT thickness of greater than 3.5 mm. The prevalence of major cardiac defects increases with NT thickness, from 5.4 per 1000 with an NT measurement of 2.5 to 3.4 mm to 233 per 1000 with an NT measurement of greater than 5.5 mm. The sensitivity of NT is 15% to 56% for the diagnosis of major cardiac defects.[57,64–66] Early fetal echocardiography is recommended and can be performed reliably by trained operators from 14 weeks onward.[28–30] Care should be taken in extrapolating the results of these studies to a population in which the initial index of suspicion is not high.

Exomphalos

Reduction of the physiologic midgut hernia ends by 11 weeks and 5 days.[98] An abdominal defect, especially exomphalos, should be suspected if herniation continues after 12 weeks. This defect is sporadic, with a prevalence at birth of approximately 1 in 4000. There are many reports of first-trimester ultrasound diagnosis of omphalocele.[99,100]

Megacystis

Fetal megacystis is defined as a bladder with a longitudinal diameter of 7 mm or more at 10 to 14 weeks' gestation. It is found in approximately 1 in 1500 pregnancies.[34] In a recent study of 145 fetuses with megacystis of 7 to 15 mm, 25% had a chromosomal abnormality, mainly trisomies 13 and 18.[101] In 75% of fetuses with chromosomal abnormalities, NT thickness was also increased, possibly as a result of thoracic compression. Ninety percent of chromosomally normal fetuses had spontaneous resolution, with no obvious adverse effects on the development of the urinary system. The risk of a chromosomal abnormality is lower, approximately 10%, when the longitudinal diameter is more than 15 mm. However, in these fetuses, a strong association with progressive obstructive uropathy is seen.[101] Favre and colleagues[102] also reported a high incidence of chromosomal abnormalities in fetuses with megacystis with a longitudinal diameter of 9 to 15 mm. Parents usually can be reassured when the fetus has megacystis of 7 to 15 mm with a normal karyotype because 90% of cases resolve and renal function is nor-

mal. Moreover, vesicoamniotic shunting in midgestation was ineffective treating these fetuses. There is no experience with first-trimester decompression.[103]

Renal Anomalies

Bilateral renal agenesis, hydronephrosis, and multicystic dysplastic kidney have been diagnosed with ultrasound in early pregnancy.[104–106]

Skeletal Defects

Skeletal dysplasias complicate approximately 1 in 4000 births. Twenty-five percent of affected fetuses are stillborn, and 30% die in the neonatal period. Growth impairment is not apparent until later in gestation in some skeletal dysplasias. However, first-trimester diagnosis of isolated cases is reported, mainly because severe skeletal defects in the first trimester are typically associated with increased NT thickness.[107–108]

Three-Dimensional Ultrasound

Three-dimensional ultrasound is used increasingly in obstetric practice. The method seems to offer several advantages in the first trimester because it allows visualization of planes that are otherwise difficult to obtain with two-dimensional scanning. It could potentially minimize actual scanning time and provides an excellent way to store scanned data for later study. However, no randomized controlled trials of three-dimensional versus two-dimensional ultrasound have been published, and the benefits of three-dimensional scanning are speculative. If the two-dimensional images are of poor quality, the resulting three-dimensional images are of little clinical use. As shown by Michailidis and associates,[109] two-dimensional ultrasound seems to be the best way to examine the fetal anatomy in the first trimester. In 93.7% of cases, a complete anatomic survey was achieved with two-dimensional ultrasound. However, it was achieved in only 80.5% of cases with three-dimensional volume acquisition ($P <0.001$).

There are several reports of the feasibility of obtaining an NT measurement with three-dimensional ultrasound.[110–113] Theoretically, NT measurement could be performed, regardless of the fetal position, significantly shortening examination time. Moreover, tomographic examination of the three-orthogonal sectional images would make it easy to distinguish fetal skin from the amnion. Paul and colleagues[110] studied the feasibility and repeatability of three-dimensional ultrasound for NT measurement. They concluded that reslicing of stored three-dimensional volumes could be used to replicate NT measurements only if the nuchal skin was also clearly seen on two-dimensional ultrasound. When the fetus was lying in a position that precluded clear visualization of the nuchal fold, three-dimensional ultrasound was unlikely to help.[110]

MATERNAL SERUM MARKERS AT 11 TO 14 WEEKS

Median serum concentrations of (α–fetoprotein, estriol, and βhCG (total and free) are independent of maternal age and can be combined in the second trimester to refine the risk of trisomy 21. This testing allows identification of approximately 60% of fetuses with trisomy 21 (compared with 30% based on maternal age alone) with a 5% invasive testing rate.[55,114]

Free βhCG is more discriminant in the first trimester (11–14 weeks), and when combined with pregnancy-associated plasma protein A (PAPP-A) and maternal age, it provides an estimated detection rate of 60%, with a 5% invasive testing rate.[1]

Free β-hCG

The maternal serum concentration of free βhCG is higher in fetuses with trisomy 21 than in chromosomally normal fetuses. The median multiple of the median (MoM) in pregnacies affected with trisomy 21 is approximately 2. First-trimester measurement of free βhCG alone allows for the detection of 35% of fetuses with trisomy 21, with a 5% invasive testing rate. The detection rate is increased to 45% if the findings are integrated with maternal age.[1] The maternal serum free βhCG level is decreased in trisomies 13 and 18.[115,116] It is usually normal in women whose fetus has a sex chromosomal abnormality.[117]

In a recent study, a free βhCG level at or above the 95th percentile (3.85 MoM) was associated with fetal loss only beyond 24 weeks. Levels lower than the 5th percentile (0.36 MoM) were not significantly associated with obstetric complications.[118,138]

PAPP-A

The PAPP-A level normally increases with gestation and is lower in pregnancies in which the fetus is affected with trisomy 21 than in those in which the fetus is chromosomally normal. The median value in trisomy 21 is approximately 0.5 MoM. When used alone in the first trimester, PAPP-A allows for the detection of 40% of fetuses with trisomy 21, with a 5% invasive testing rate. The detection rate increases to 50% when the findings are integrated with maternal age.[1] The maternal serum PAPP-A level is also decreased when the fetus has trisomies 13 and 18 or sex chromosomal abnormalities.[115–117]

In a recent study that excluded fetuses with chromosomal abnormalities, low levels of PAPP-A were associated with pregnancy complications in 11.3% (184 of 1622).[118] Patients with PAPP-A levels of 0.25 MoM or less had higher rates of IUGR (relative risk [RR] = 3.12), preeclampsia (RR = 6.09), and spontaneous abortion (RR = 8.76). Women with PAPP-A levels of 0.50 MoM or less also had higher rates of IUGR (RR = 3.30) and spontaneous abortion (RR = 3.78). A multicenter study was done to determine the frequency and clinical consequences of an extremely high maternal serum PAPP-A level. Among 46,776 tested pregnancies, in 79 pregnancies, PAPP-A levels were greater than 5.0 MoM (0.2%).[119] The authors concluded that the outcome of pregnancies with a high PAPP-A level is similar to the outcome of those with normal marker levels. The issue is controversial, and a recent study confirmed previous reports of increased PAPP-A levels in women who subsequently have preeclampsia.[120]

Free βhCG and PAPP-A

When maternal age is combined with first-trimester maternal serum PAPP-A levels and free βhCG levels, the estimated detection rate for trisomy 21 approximates 60%, with a 5% invasive testing rate.[1,121,122] These rates are similar to those obtained in the second trimester. Screening with a combination of fetal NT measurement and maternal levels of serum PAPP-A and free βhCG allows the detection of approximately 90% of these chromosomal abnormalities, with a 5% invasive testing rate (Table 7–8).[1,123–131]

Logistic and Organizational Issues

There is no significant association between fetal NT measurement and maternal serum free βhCG or PAPP-A

TABLE 7–8

Detection and False-Positive Rates of Screening Tests for Trisomy 21

SCREENING TEST	DETECTION RATE	FALSE-POSITIVE RATE
Maternal age (MA)	30% (or 50%)	5% (or 15%)
MA + serum βhCG + PAPP-A at 11–14 wk	60%	5%
MA + fetal nuchal translucency (NT) at 11–14 wk	75% (or 70%)	5% (or 2%)
MA + fetal NT + nasal bone (NB) at 11–14 wk	90%	5%
MA + fetal NT + serum βhCG + PAPP-A at 11–14 wk	90% (or 80%)	5% (or 2%)
MA + fetal NT + NB + serum βhCG + PAPP-A at 11–14 wk	97% (or 95%)	5% (or 2%)
MA + serum biochemistry at 15–18 wk	60%–70%	5%
Ultrasound for fetal defects and markers at 16–23 wk	75%	10%–15%

PAPP-A, pregnancy-associated plasma protein A.

levels in pregnancies affected by trisomy 21 or chromosomally normal pregnancies. Therefore, ultrasonographic and biochemical markers can be combined in the first trimester to provide more effective screening than either method individually. The same is true for NT measurement and second-trimester biochemical markers.[132] Many European countries have adopted first-trimester screening for chromosomal abnormalities with a combination of ultrasound NT measurement and maternal serum testing.[135–136] In 1997, the 32nd Study Group of the Royal College of Obstetricians and Gynaecologists concluded that the evidence in favor of first-trimester screening for trisomy 21 by NT measurement or biochemical testing was sufficiently well developed to justify moving out of the research phase and into routine practice. They also concluded that ultrasound in early pregnancy would be superior to biochemical screening in the second trimester. Several large studies support these conclusions.[133–140] Spencer and colleagues[2] studied 12,339 women with singleton pregnancies at 10 to 14 weeks' gestation who were screened by measurement of NT and maternal serum markers at 11 to 14 weeks in a one-stop clinic for assessment of risk (OSCAR).[2] The results of a prospective trial in the United States reached a similar conclusion.[139] It is time to shift screening for trisomy 21 from the second to the first trimester.[2]

Fetal Nuchal Translucency Measurement and Maternal Serum Free βhCG and PAPP-A (Combined Screening Test)

Spencer and associates[131] reviewed the findings in 12,339 pregnancies in which first-trimester screening was performed with measurement of NT, serum free βhCG, and PAPP-A. The detection rate for trisomy 21 was 92% (23 of 25). The invasive testing rate was 5.2%. The detection rate was far better than that achieved with second-trimester serum screening. This combined method also identified 94% of all other major chromosomal defects, such as trisomies 13 and 18, triploidy, and Turner syndrome, and 60% of other chromosomal defects, such as deletions, partial trisomies, unbalanced translocations, and sex chromosomal aneuploidy other than Turner syndrome.[133] Wapner and associates[137] found similar results in a prospective study of 8514 patients. With a false-positive rate of 5%, the detection rate was 78.7% (Table 7–9).

Fetal Nuchal Translucency Measurement and Maternal Serum Markers at 14 to 17 Weeks

Sonographic and biochemical screening methods evolved independently. As a result, many women undergo sequential two-stage screening, even when the NT screen result is negative. Each method is designed to generate a 5% invasive testing rate, and a two-stage screening paradigm has a cumulative rate. Thus, the proportion of patients undergoing invasive prenatal diagnostic testing can be as high as 10%, or even higher in countries that offer invasive prenatal diagnosis to women older than 35 years of age, regardless of the screening result. This approach increases both the iatrogenic loss rate of normal pregnancies and all related costs. The rate of invasive testing for fetal karyotyping is an important public health issue that must be controlled. When the combined first-trimester test is not available, one approach is to combine NT measurement and second-trimester maternal serum screening results into a single risk assessment and not to consider the results independently (integrated screening) (Table 7–10).[132]

In women undergoing second-trimester biochemical testing after first-trimester NT screening (with or without maternal serum testing), the background risk must be adjusted to take into account the first-trimester screening results. For example, in a 41-year-old woman whose age-related background risk of having a fetus with trisomy 21 is 1 in 50, the risk decreases if the NT is thin on the first-trimester scan (e.g., 1 in 200). If the risk after second-trimester screening with serum markers is 1 in 100, this woman has an integrated risk of 1 in 400 because the NT measurement allowed a fourfold reduction of the background risk and maternal serum testing has done so by

TABLE 7–9

Major Prospective and Retrospective Studies that Used a Combination of Maternal Age, Fetal Nuchal Translucency, Maternal Serum Pregnancy-Associated Plasma Protein A, and Free βhCG to Detect Down Syndrome

STUDY	N	PREVALENCE OF T21	GESTATION (WK)	FALSE-POSITIVE RATE	DETECTION RATE FOR TRISOMY 21
Orlandi et al., 1997[123]	744	0.9%	9–13.4	5%	87%

TABLE 7-10

Definitions

TERM	DEFINITION
Combined screening	Nuchal translucency measurement + first-trimester serum markers
Fully integrated screening	Nuchal translucency measurement + first-trimester serum markers + second-trimester serum markers
Serum integrated screening	Pregnancy-Associated Plasma Protein A + second-trimester serum markers
Sequential screening	Successive independent risk assessments, leading to cumulative false-positive rates

twofold. Both tests have therefore divided the background risk by 8. Because first-trimester combined screening can identify almost 90% of pregnancies affected by trisomy 21, second-trimester serum testing identifies, at best, 6% of affected pregnancies (60% of the residual 10%), although it doubles the overall invasive testing rate from 5% to 10%. It is theoretically possible to use various statistical techniques to combine NT measurement with different components of first- and second-trimester serum testing.[133] One hypothetical model combined first-trimester NT measurement and PAPP-A testing with second-trimester free βhCG, estriol, and inhibin A testing (fully integrated test), claiming a potential sensitivity of 90%, for a 5% false-positive rate.[138]

In one multicenter interventional study,[132] NT was measured at 12 to 14 weeks' gestation in 9444 women. Maternal serum markers were measured between 14 weeks and 1 day and 17 weeks' gestation. Karyotyping was delayed until after maternal blood was obtained. A combined risk for NT measurement and maternal serum markers was estimated retrospectively. The invasive testing rate generated by sequential two-stage screening was 8.6%, which means that 8.6% of patients underwent amniocentesis because of an increased risk generated by any of these tests. Twenty-one fetuses (0.22%) had trisomy 21. Adjusting for a 5% invasive testing rate, the detection rates would have been 55% and 80% for NT measurement alone and NT measurement combined with second-trimester serum marker testing, respectively. The results of the study suggest a 25% increase in the detection rate with a combination of NT measurement at 12 to 14 weeks and serum marker studies between 14 weeks and 1 day and 17 weeks, with a 5% invasive testing rate and a modest increase in cost. Four other studies reported screening with a combination of fetal NT measurement in the first trimester and maternal serum marker testing in the second trimester, with similar results.[132,134-136]

Sequential (but not integrated) screening programs also increase the invasive procedure-related pregnancy loss rate. This increased rate is an important issue in populations in which the prevalence of Down syndrome is less than 1 in 1000 births. In these populations, an invasive testing rate of 8.6% might be considered unacceptably high in women who are at relatively low risk,[132] compared with the 5% rate generated by a single-test screening program. A single risk assessment that integrates the results of NT measurement, free βhCG levels, and α-fetoprotein levels with maternal age is possible. With such an algorithm, it would be possible to keep the sensitivity as high as that obtained with combined screening while maintaining an invasive testing rate of as low as 5%. However, the cost is also significant because the 25% increase in the detection rate would delay risk calculation and invasive testing by 2 to 4 weeks. Such information should be included in genetic counseling, especially when termination for fetal abnormality is an issue. Further, screening strategies in the first trimester are cost-effective compared with the use of second-trimester biochemical markers.[132]

CONCLUSIONS

- The emphasis in screening for fetal abnormalities has moved to the first trimester.
- This is particularly true for fetal aneuploidies, using a combination of maternal age, gestational age, nuchal translucency, and maternal serum markers.
- The optimal gestational age range is 11 to 14 weeks.
- At this time, testing for viability, gestational age assessment, fetal number, and a fetal anatomic survey can be performed.
- If most pregnant women should be offered an ultrasound examination within this gestational window, there will be important implications for health care planners in terms of resources and teaching programs.
- All sonographers who perform fetal scans must be trained appropriately. The reproducibility of nuchal translucency measurements improves with training, and good results are typically achieved after approximately 100 scans.
- Combined first-trimester screening can be performed at multiple clinical sites.
- Adequate sensitivity in screening for major malformations during first-trimester ultrasonography seems to be achieved after a few years of experience.
- Nuchal translucency measurement combined with serum integrated screening for trisomy 21 has the highest detection rates.
- Chorionic villus sampling is the adjunctive diagnostic test; thus, screening at 11 to 14 weeks may lead to an increase in the demand for this testing.

SUMMARY OF MANAGEMENT OPTIONS
First-Trimester Screening for Fetal Abnormalities

Management Options	Quality of Evidence	Strength of Recommendation	References
General Approach			
Prerequisites: • Details of the history, examination, and routine tests completed and known relevant risk factors identified • Prescan interview, discussions, and counseling	See Chapter 9		
Screening is performed ideally between 11 and 14 weeks	III	B	2
Ultrasound is considered safe in both the short and long terms.	Ib	A	141
First-Trimester Screening—Benefits			
Confirm viability.	III	B	5,6
Dating the pregnancy by crown–rump length before 14 weeks is the most accurate method and decreases the risk of post-term pregnancy.	III	B	8–16
Screening for fetal aneuploidy:			
• Nuchal translucency (NT) measurement, combined with maternal age and maternal serum markers for trisomy 21, has a detection rate of 80% to 90%, for a 5% false-positive rate.	IIa	B	131,132
• Other chromosomal abnormalities are also more likely with increased NT thickness.	III	B	58–61
Detection of structural abnormalities:			
• Some major structural anomalies are detectable as early as 12 weeks. These include anencephaly, holoprosencephaly, abdominal wall defects, and major limb defects.	IIb	B	22–24,63,67
• Detection rates are dependent on sonographer experience.	III	B	87
Multiple pregnancy:			
• Chorionicity is optimally determined by either visualization or absence of the lambda sign.	III	B	20,21
• Twin–twin transfusion syndrome is more likely in monochorionic pregnancies with increased NT thickness.	III	B	71
Examine the uterus and adnexal structures.	IV	C	18

Second-Trimester Screening for Fetal Abnormalities

Lami Yeo / Anthony M. Vintzileos

INTRODUCTION

Every pregnant woman desires a healthy child who is free of anomalies. In the general population, the overall risk of having a child with a major malformation is 3% to 5%. The ability conferred by the increasing sophistication of ultrasonography and biochemical testing to screen for fetal abnormalities is of growing importance to obstetricians and their patients as a greater proportion of women delay childbirth. The shortened reproductive window has increased the pressure on all for a successful outcome. We found that genetic sonography is a patient-driven service. This chapter focuses on noninvasive modalities of screening for fetal abnormalities in the second trimester and reviews the likely continued shift to the use of screening earlier in gestation (see Chapter 7).

In the early 1970s, the only method available to screen for fetal Down syndrome was based on maternal age; amniocentesis was offered to all women 35 years or older. However, maternal age proved a very inefficient screening tool; fewer than one third of fetuses with trisomy 21 were identified. In the 1980s, a new screening method incorporated second-trimester maternal serum biochemical markers in addition to maternal age. In the 1990s, screening for Down syndrome by combining maternal age and fetal nuchal translucency (NT) thickness in the first trimester was introduced. Subsequently, maternal serum biochemical markers of value in the first trimester were identified. Most recently, three-dimensional sonography entered the arena of screening.

Invasive tests, such as amniocentesis, chorionic villus sampling, and cordocentesis, are diagnostic tools and not screening tests. They allow for essentially 100% accuracy in the diagnosis of fetal aneuploidy but carry a real risk of pregnancy loss. Thus, many women choose biochemical and ultrasound screening modalities for aneuploidy detection because the test efficiency (percentage of abnormal fetuses identified) is so much higher than that based on maternal age alone, even though they have a relatively high invasive testing rate (false-positive rate), typically set at 5%. Then, based on the result of the selected screening test, a decision is made as to whether an invasive test for diagnosis is necessary. The combination of screening and diagnostic tests allows the maximum number of patients to gain accurate information about their individual risk status.

FIRST-TRIMESTER SERUM SCREENING (See also Chapter 7)

Maternal serum testing in the second trimester is the standard of care in many countries, including the United States, for screening women at low risk for fetal aneuploidy, neural tube defects, and other fetal anomalies. However, first-trimester screening offers several advantages, including shortening of the diagnostic paradigm by several weeks, which provides either earlier reassurance or the option for termination of an affected fetus.

Many serum analytes have been investigated as first-trimester markers for trisomy 21. The two markers with the greatest discriminatory values are βhCG (human chorionic gonadotropin) and pregnancy-associated plasma protein A (PAPP-A).[1,2] In affected pregnancies, the median free βhCG level is approximately 1.8 multiples of the median (MoM), and the median PAPP-A level is approximately 0.4 MoM. The combination of the two, in addition to maternal age, yields trisomy 21 detection and screen-positive rates similar to those of second-trimester serum screening (63% and 5.5%, respectively).[3] Several caveats are noteworthy. First, free βhCG may not be increased in pregnancies affected by trisomy 21 until 12 weeks. Second, PAPP-A loses its discriminatory value after 13 weeks. Careful timing of the test is

essential, and accurate assignment of gestational age is an absolute requirement for the test to be useful.

There is no significant relationship between fetal NT and maternal serum free βhCG or PAPP-A levels in either trisomy 21 or nonaneuploid pregnancies. Thus, sonographic and biochemical markers may be combined and detection rates enhanced. A body of research shows that the combination of maternal age, first-trimester maternal serum screening, and NT allows for 85% to 90% sensitivity, with a 5% screen-positive rate for the detection of trisomy 21 (Table 8–1) [see also Chapter 7].[4] Even a modest increase in NT may be clinically significant when combined with biochemistry findings and maternal age.

Other types of aneuploidy affect first-trimester maternal biochemical markers. For example, PAPP-A and free βhCG levels are lower in women with a trisomy 18 fetus, and it is estimated that 77% of trisomy 18 fetuses could be detected with a 0.5% screen-positive rate.[4] Trisomy 13, too, is associated with lower multiples of the median of free βhCG and PAPP-A. In contrast, PAPP-A levels are lower, but free βhCG is unchanged in pregnancies with fetal Turner syndrome.[4] Combining NT and biochemical screening also increases the sensitivity for other types of aneuploidy. Low levels of free βhCG (0.28 MoM) and PAPP-A (0.18 MoM) plus an increased NT (3.3 MoM) increase the detection rate for trisomy 18 to 89%, with a 1% screen-positive rate.[4]

NORMAL FIRST-TRIMESTER ULTRASOUND

First-trimester scanning requires familiarity with the normal development of the embryo or fetus. The presence or absence of certain sonographic structures may be normal or abnormal, depending on gestational age. Transvaginal sonography improves first-trimester embryo imaging. Embryologists use the term "embryo" to describe the conceptus during the first 9 weeks of pregnancy. The gestational sac is visible at 4.5 weeks menstrual age. The yolk sac is visible at 5 weeks in 95% of cases and in nearly all cases by 6 weeks. A fetal pole should be seen next to the yolk sac by 6 weeks.[5] Fetal heart motion is seen in 86% of cases by 6 weeks, and always by 7 weeks. The fetal heart rate increases steadily from 110 beats/min to 171 to 178 beats/min, with crown–rump lengths of 3 to 4 mm and 15 to 32 cm, respectively. Heart rates outside these ranges are associated with pregnancy failure, and these patients should be monitored closely.[5]

Between 6 and 7 weeks, the first anatomic structure that is sonographically apparent is the primitive neural tube that runs throughout the embryonal length. By week 7, the head is discernible from the rest of the fetal body (Fig. 8–1), and the primitive ventricular system is visible, appearing as a single round sonolucent cavity that almost completely fills the head.[5] At 8 weeks, the primitive brain contains sonolucencies, and the hindbrain, or rhombencephalon, is visualized. With transvaginal imaging, the limbs can be imaged by 8 weeks. The cerebral falx, choroid plexus, thalami, long bones, and fingers appear at 9 weeks' gestation. After 9 weeks, previously developed organs and structures become easier to visualize as a result of rapid fetal growth (Fig. 8–2).[5] The cerebellum is seen by 10 to 11 weeks, when the face, palate, feet, and toes can also be seen. Ossification of the fetal cranium begins and accelerates after 9 weeks (important for ruling out acrania). Active fetal movements can be observed from 10 weeks onward. Midgut herniation into the umbilical cord is an important physiologic phenome-

TABLE 8–1

Various Sensitivities for Fetal Down Syndrome (False-Positive Rate of 5%) with Various Screening Tests in Combination

SCREENING TEST	SENSITIVITY FOR FETAL DOWN SYNDROME
Age	30%
Age, first-trimester biochemistry results	63%
Age, NT	75%
Age, first-trimester biochemistry results, NT	85%–90%
NT, nasal bone	90%
Age, first-trimester biochemistry results, NT, nasal bone	97%
Age, second-trimester triple-screen results	60%–70%
Age, second-trimester quadruple-screen results	67%–75%

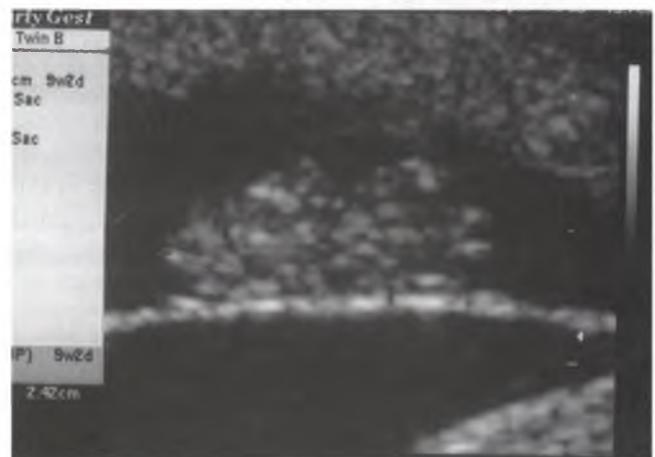
NT, nuchal translucency.


FIGURE 8–1

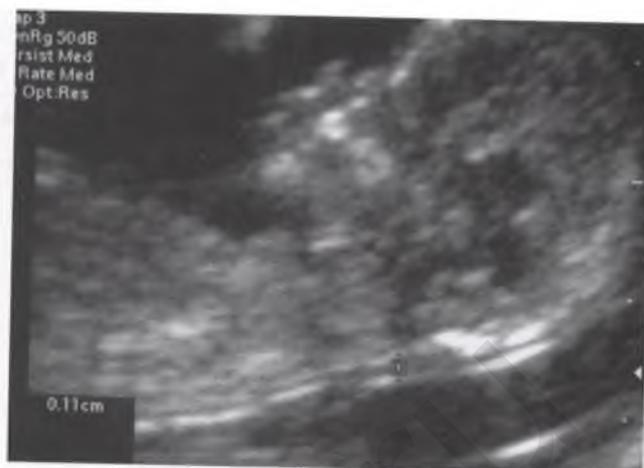
FIGURE 8–2
Crown-rump length of a 12- to 13-week fetus. Anatomic structures are easier to see than in Figure 8–1.


FIGURE 8–3
Normal nuchal translucency (0.11 cm) in a longitudinal section of the fetus, showing the fetal head, neck, and upper thorax.

non that occurs normally between 8 and 10 weeks; the gut returns to the abdomen by 12 weeks.[6] Failure to recognize this normal process may lead to an erroneous diagnosis of omphalocele.

Although the four-chamber view of the heart is seen as early as 11 weeks, it is not readily imaged until 14 weeks, when the four-chamber view and the great vessels should be visible. Although the fetal kidneys can be imaged consistently from 12 to 13 weeks with transvaginal sonography, the bladder is visible in only 50% of cases at 12 weeks, and it is not imaged consistently until 13 weeks. Fetal urine enters the amniotic cavity beginning at approximately 8 to 11 weeks; however, urine does not contribute significantly to the amniotic fluid volume before 15 weeks. Most (but not all) fetal structures can be seen well by 15 weeks with a high-frequency transvaginal probe.[5]

NUCHAL TRANSLUCENCY SCREENING
(See also Chapter 7)

In 1866, Langdon Down observed that the skin of individuals with trisomy 21 appeared to be too large for their body. It was observed initially in the 1980s that cystic hygromas in the first trimester appear different (non-septated vs. septated) from those seen in the second trimester, and they also differed in their association with aneuploidy.[7] Further, cystic hygromas visualized in the first trimester could evolve into increased nuchal thickening or become normal in nuchal thickness but still be associated with aneuploidy. Simultaneously, second-trimester nuchal fold thickening was associated with an increased risk of fetal trisomy 21.[8]

In 1992, Nicolaides and associates[9] coined the term "nuchal translucency" to describe the sonographic anechoic area under the skin at the back of the fetal neck during the first trimester (Fig. 8–3). The concept of measuring NT in all fetuses became the basis for first-

trimester ultrasound screening. By 1995, several large studies of NT were published.[10] Increased NT was clearly associated with an increased incidence of trisomy 21. In addition, increased NT was associated with other types of aneuploidy (trisomy 13, trisomy 18, Turner syndrome), congenital heart disease, and a wide range of miscellaneous congenital anomalies. The prevalence of aneuploidy varied from 30% to 86% in fetuses with increased NT.[11] The etiology of increased NT is unclear. Suggested causes include accumulation of lymphatic fluid as a result of delayed or abnormal lymphatic duct development. However, the specific pathophysiologic etiology of increased NT may vary with the underlying condition. For example, the increased "fluid" may be the result of decreased circulation and cardiac function because increased NT is associated with major fetal cardiac abnormalities.[12] Further, differences in skin composition, such as increased collagen and hyaluronan, are associated with increased NT.[13,14] Collagen composition may vary in the various trisomies because of a gene dosage effect that reflects the extra chromosome 13 or 21.[14] Increased amounts of hyaluronan would also lead to excessive hydration of the extracellular matrix.[13] In some cases, these abnormalities of collagen and hyaluronan may explain the known association between increased NT and skeletal dysplasias.

There is wide variation in the reported sensitivities for Down syndrome when NT screening is used (29%–100%), with screen-positive rates of 0.4% to 8.0% (Table 8–2).[15–32] This variation is attributed to differences in the techniques used to measure NT, along with differing criteria and cutoffs for abnormality. Other factors that no doubt contributed to the variable detection rates include inconsistencies in the study populations and variability in training quality, mean values, success in measuring NT, and follow-up (both pregnancy and neonatal). Many initial studies used a specific cutoff value (2.5 or 3 mm). Subsequent studies used gestational age-specific

TABLE 8–2

Reported Sensitivities and False-Positive Rates of Fetal Down Syndrome with Nuchal Translucency Screening

AUTHOR AND YEAR	N	GESTATIONAL AGE (WK)	CUTOFF	SENSITIVITY FOR TRISOMY 21	FALSE-POSITIVE RATE

*The risk of Down syndrome was calculated with maternal age and gestational-dependent multiples of the median or delta value.

thresholds combined with maternal age to generate an individual risk estimate, or used a cutoff of greater than the 95th percentile. Further, there is no universal consensus as to what constitutes an increased measurement. The original studies included high-risk women (35 years or older) undergoing first-trimester prenatal diagnosis in referral centers for indications such as advanced maternal age or family history of aneuploidy. Subsequent studies of low-risk women in routine clinical practice settings produced conflicting results.[19,33,34] This variability may be attributable to interobserver and intraobserver variations in NT measurements. More recent reports show sensitivities for the detection of fetal trisomy 21 approaching 70% to 80%, with a 5% screen-positive rate.[4] In 1998, an impressive study from the Fetal Medicine Foundation prospectively screened more than 100,000 women at 22 centers in the United Kingdom (see Table 8–2).[26] Clinicians at all centers were trained in a standardized approach, and quality control measures were in place. The study found 82% sensitivity for trisomy 21, for an 8.3% screen-positive rate. Further, 80% of fetuses with trisomy 13 and trisomy 18 were detected.

The Fetal Medicine Foundation, based in London, England, developed strict criteria and auditing practices to certify practitioners to perform NT screening. The system ensures that the screening test is performed uniformly to maximize efficiency. Consistent, accurate measurements of NT require high-quality sonography, experienced and well-trained sonographers, and continuous quality assessment.

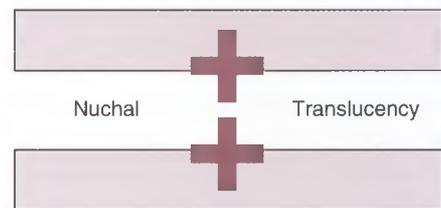
Current criteria for measuring NT include the following[35]: the use of high-quality sonographic equipment with video-loop function and the capability to magnify the image sufficiently to measure to 0.1 mm; screening between 11.3 and 13.6 weeks' gestation (crown–rump length, 45 to 84 mm); placement of the fetus in a sagittal plane in the midline filling more than 50% of the frame; placement of the fetal head in a neutral (straight) position, with the head in line with the spine; care taken to distinguish fetal skin from amnion (both appear as thin membranes); and correct placement of the calipers on the skin and underlying tissue interfaces (Figs. 8–3 and 8–4). The examiner may either wait for spontaneous movement away from the amniotic membrane or bounce the fetus off the amnion by asking the mother to cough or by tapping the maternal abdomen. It is important to measure the maximum thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine. More than one measurement should be taken during the scan, and the largest measurement that is technically correct is recorded. Only the fetal head, neck, and upper thorax are required to be in the image (see Fig. 8–3). Although NT is usually measured transabdominally, a transvaginal approach may be required in 5% of cases.[36] In one study that compared transabdom-


FIGURE 8–4

Nuchal translucency, showing correct placement of the calipers for measurement. Nuchal translucency measurements should be taken with the horizontal lines of the calipers placed on the lines that define the nuchal translucency thickness (not in the line and not in the nuchal fluid).

inal and transvaginal approaches, the authors found that NT could be measured in 92% of pregnancies by transabdominal scanning, in 90% by transvaginal scanning, and in 100% if both approaches were used when necessary.[37] Transabdominal measurements are slightly but significantly larger than those obtained with transvaginal scanning.

The accuracy of NT measurement is highly dependent on technical factors. For example, the position of the fetal neck affects the measurements. Extension of the fetal neck is associated with a mean NT increase of 0.6 mm, whereas neck flexion reduces the measurement by 0.4 mm (compared with the neutral position).[38] NT measurement is most reproducible in the neutral position, where 95% of measurements are within 0.48 mm of each other.

The ability to measure NT reproducibly improves with training. Good results are achieved after 80 and 100 scans for the transabdominal and transvaginal approaches, respectively.[36] Pandya and colleagues[39] reported that intraobserver and interobserver variabilities were 0.54 mm and 0.62 mm, respectively, in 95% of cases. NT can also be used in twins and higher-order multiple gestations. Increased and discordant NT in a monochorionic gestation may indicate an increased risk of subsequent twin–twin transfusion syndrome.[40]

The normal NT measurement is dependent on the crown–rump length, and gestational age must be considered when determining whether NT is increased.[36] Pandya and associates[41] found that median NT increased from 1.3 mm (crown–rump length, 38 mm) to 1.9 mm (crown–rump length, 84 mm). They also observed that the 95th percentile increased from 2.2 mm (crown–rump length, 38 mm) to 2.8 mm (crown–rump length, 84 mm).

The definition of abnormal NT has evolved since the initial descriptions. Initially, a categorical cutoff of 2.5 or 3 mm was used. However, because NT increases with gestational age and the risk varies with the measurement,[28] NT measurements are now expressed relative to either gestational age or crown–rump length as a delta value or multiple of the median.[26] A patient-specific risk is calculated from either the multiple of the median or derived likelihood ratios. This approach also permits the integration of risks based on NT, biochemical markers, and maternal age to generate a combined risk.

Fetuses with increased NT but a normal karyotype are at increased risk for other adverse pregnancy outcomes, such as major cardiac defects, a wide range of structural defects, and rare genetic conditions. Hyett and associates[42] observed that the prevalence of major cardiac abnormalities rose in chromosomally normal fetuses in direct relation to the magnitude of the increase in NT. The prevalence of major cardiac defects rose from 0.8 in 1000 when NT was below the 95th percentile for gestational age to 63.5 in 1000 when NT was greater than the 99th percentile.[12] For fetuses with NT greater than 5.5 mm, the prevalence of major cardiac defects was nearly 20% (195.1 in 1000), more than 100 times the overall

FIGURE 8–5
First-trimester scan showing increased nuchal translucency thickness of 5.8 mm. The karyotype proved to be trisomy 21.

prevalence (1.7 in 1000). In total, 55% of nonaneuploid fetuses with a major cardiac defect had NT greater than the 95th percentile. In contrast, Schwarzler and colleagues[29] prospectively studied 4523 women at low risk and found that only 1 of 9 (11%) major cardiac defects were associated with NT of greater than 2.5 mm. Thus, the sensitivity of increased NT as a screening test for major cardiac defects remains uncertain.

Increased NT (Fig. 8–5) is associated with other anomalies, including diaphragmatic hernia, omphalocele, neural tube defects, and body stalk anomalies. NT is reportedly increased in a number of rare genetic syndromes and skeletal dysplasias, such as Smith-Lemli-Opitz syndrome, Noonan syndrome, arthrogryposis, Pena-Shokeir syndrome, multiple pterygium syndrome, spinal muscular atrophy, Jarcho-Levin syndrome, thanatophoric dysplasia, and thalassemia.[4] Superior mediastinal compression, as might occur with diaphragmatic hernia or with the narrow thorax seen in some skeletal dysplasias, may cause venous congestion in the head and neck. Another possible mechanism for increased NT is failure of lymphatic drainage as a result of impaired fetal movements with fetal neuromuscular disorders, such as the fetal akinesia deformation sequence. In summary, the finding of increased NT during the first trimester mandates a detailed investigation in a fetal ultrasound laboratory to complement the indicated karyotype. This detailed examination may be performed by vaginal sonography at 14 to 16 weeks or by abdominal sonography at 18 to 20 weeks.

FIRST-TRIMESTER DUCTUS VENOSUS DOPPLER VELOCIMETRY

Ductus venosus Doppler sonography may further discriminate between chromosomally normal and abnormal fetuses in the first trimester.[43] In one study, the authors

examined 486 fetuses between 10 and 14 weeks' gestation.[43] Of these fetuses, 68 had aneuploidy; in 90.5% of the aneuploid fetuses, flow was either reversed or absent during atrial contraction. Abnormal ductal flow was present in only 3.1% of nonaneuploid fetuses. Interestingly, ductus venosus Doppler imaging may also help to determine which nonaneuploid fetuses with increased NT are at increased risk for cardiac defects. Matias and colleagues[44] studied 142 first-trimester chromosomally normal fetuses with increased NT measurement. Eleven fetuses had reversed or absent flow during atrial contraction; of these, 7 (64%) had major cardiac defects seen on fetal echocardiography. No major cardiac defects were identified in the remaining 131 fetuses with increased NT and normal findings on ductus venosus Doppler studies.

SONGRAPHIC ABNORMALITIES UP TO 15 WEEKS' GESTATION

The progressive improvement in sonographic resolution, coupled with growing expertise, has made the detection of many structural abnormalities during the first trimester a reality.[45] Transvaginal scanning has had a tremendous effect on the ability to detail fetal structures, and targeted ultrasound for fetal anomalies can be performed as early as 14 to 15 weeks.[5] However, not all anomalies are apparent by this time, and expertise in early transvaginal sonography is not widespread. Thus, in most cases, a targeted scan later in gestation is warranted.

Whitlow and colleagues[46] used transabdominal or transvaginal scanning, as necessary, from 11 to 14 weeks. They detected 59% of fetuses with structural abnormalities. Structural abnormalities were seen in 35% of aneuploid fetuses, excluding three fetuses with XXY. However, structural anomalies during the first 14 weeks are more likely to be associated with trisomy 13 and trisomy 18 than with trisomy 21. Only 9% of fetuses with trisomy 21 (2 of 23) had visible structural abnormalities. In another first-trimester study of trisomy 21, the detectable structural abnormality rate was 12.5%.[28] In contrast, holoprosencephaly was diagnosed in 24% and omphalocele in 10% of 46 fetuses with trisomy 13.[47]

Malformations of the fetal head, neck, and spine that are detectable by transvaginal sonography before 15 weeks include acrania (absence of the entire cranium or a major portion of the cranium in the presence of a brain), anencephaly (absence of the cranium above the orbits, with variable amounts of remnant brain tissue), cephaloceles (cranial defects, with herniation of the brain or meninges), holoprosencephaly (failure of the forebrain to differentiate into cerebral hemispheres and lateral ventricles), ventriculomegaly or hydrocephalus, Dandy-Walker malformation (cystic dilation of the fourth ventricle),

neural tube defects, and iniencephaly (see Chapter 18). Iniencephaly is a lethal anomaly that includes an occipital defect, retroflexion of the spine, and open spinal defects. The diagnosis of ventriculomegaly in the first trimester or early second trimester may be especially difficult because the lateral ventricles are normally prominent at this stage (Fig. 8–6). In the first trimester, cranial findings associated with neural tube defects (NTDs), such as the lemon or banana signs and hydrocephalus, may be very subtle or absent. Therefore, a follow-up scan in the second trimester is warranted for at-risk fetuses.

Cystic hygromas may also be seen in the first trimester. It is important to differentiate a cystic hygroma from increased NT. Cystic hygromas appear as bilateral, posterior cystic structures that contain characteristic thick septations. They are often associated with hydrops, effusions, or ascites and adverse outcomes. Bronshtein and colleagues[48] reported 125 fetuses with cystic hygroma in the early second trimester and observed that, compared with "nonseptated" cystic spaces (NT), septated cystic hygromas were more likely to persist (56% vs. 2%) and to be associated with aneuploidy (72% vs. 5.6%), hydrops (40% vs. 1.7%), other anomalies (52% vs. 15%), and pregnancy loss (88% vs. 6%). In another series of 56 fetuses with hygromas diagnosed between 9 and 14 weeks, chromosomal abnormalities were found in 29%: 38% had trisomy 18, 31% had trisomy 21, 25% had Turner syndrome, and 6% had 47 XXX. The prevalence of an adverse outcome in fetuses with cystic hygromas and normal chromosomes was 30%.[49]

Facial anomalies that are diagnosable in the first trimester include cleft lip or palate, ocular anomalies (hypertelorism or hypotelorism, anophthalmia, microphthalmia), and fetal cataracts. Cardiac malformations are also diagnosable before 15 weeks. Bronshtein and associates[50] identified 47 fetuses with congenital heart disease among 12,793 fetuses scanned transvaginally at 12 to 16 weeks. Ectopia cordis is reported as early as 12 to 14

FIGURE 8–6
Axial view of a fetal head at 13.5 weeks, showing prominent lateral ventricles filled with the choroid plexus (*arrows*).

weeks, and pentalogy of Cantrell is noted as early as 11 weeks.[5] Body stalk anomalies are also reported in the first trimester. Umbilical cord cysts and the presence of a single umbilical artery are reported within the first 14 weeks. Although transient umbilical cord cysts do not appear to be associated with either aneuploidy or structural anomalies, persistent cysts detected after the first trimester may be associated with other fetal malformations.

The normal protrusion of the midgut into the umbilical cord between 8 and 10 weeks can easily be confused with omphalocele, which is associated with aneuploidy, especially for trisomy 13 or trisomy 18. The bowel normally returns to the abdominal cavity by 12 weeks.[6] Persistence of this normal gut migration can produce small, bowel-containing omphaloceles. Omphaloceles that include liver have a lower association with aneuploidy, especially if no other fetal anomalies are present. Snijders and associates[51] reported that of omphaloceles detected in the first trimester, aneuploidy (trisomy 13, trisomy 18, or triploidy) was present in 61%. The risk is significantly higher than that observed when omphalocele is first diagnosed in the second or third trimester. Omphalocele is found during the first trimester in 9% of fetuses with trisomy 13, 23% with trisomy 18, and 13% with triploidy.[51] Gastroschisis also can be diagnosed before 15 weeks, although there is no association between gastroschisis and fetal aneuploidy.

Several malformations of the urinary system are visible before 15 weeks, including hydronephrosis, bilateral renal agenesis, multicystic dysplastic and infantile polycystic kidneys, and obstructive uropathy. Before 15 weeks, fetuses with bilateral renal agenesis may have normal fluid volume and a visible bladder. The same is true for severe multicystic or polycystic kidney disease.[5] Osteogenesis imperfecta, sirenomelia (complete or nearly complete fusion of the lower extremities), and various skeletal abnormalities have been diagnosed sonographically before 15 weeks.

Nonstructural sonographic markers of fetal aneuploidy are also sought in the first trimester. Whitlow and colleagues[52] reported the prevalence of three such markers (choroid plexus cyst, renal pyelectasis, and echogenic intracardiac foci) in 5383 women who underwent scanning between 10 and 14 weeks. The prevalence of these markers was 2.2%, 0.9%, and 0.6%, respectively, in normal fetuses. Pyelectasis (likelihood ratio, 8.0) and echogenic intracardiac foci (likelihood ratio, 10.3) were significantly associated with fetal aneuploidy, but choroid plexus cysts were not.[52]

COST-EFFECTIVENESS OF FIRST-TRIMESTER SCREENING

Although routine first-trimester ultrasound offers certain benefits, such as accurate dating, NT measurement, the potential to detect structural abnormalities, and determi-

nation of chorionicity in multiple gestations, it has not replaced the second-trimester anatomic survey and creates additional costs. We addressed this issue in a cost–benefit analysis comparing two approaches: the "British" approach of first-trimester NT screening followed by chorionic villus sampling in screen-positive patients and the "American" approach of second-trimester maternal serum screening followed by amniocentesis in screen-positive patients.[53] The costs of first-trimester screening are comparable to those of second-trimester screening if the screening has a sensitivity of at least 80% and a screen-positive rate of no more than 5% for detecting fetal trisomy 21.[53]

SUMMARY OF FIRST-TRIMESTER SCREENING (See also Chapter 7)

Screening for aneuploidy in the first trimester rather than second trimester has the obvious advantage of providing earlier prenatal diagnosis and the ability to terminate the pregnancy with less morbidity. NT screening requires only one measurement but must be preceded by basic training. It also requires ongoing quality control. The risks of fetal aneuploidy and adverse outcome increase progressively with increasing NT. NT is a marker for aneuploidies other than trisomy 21 as well as for other anomalies. The combination of maternal age, first-trimester serum screening, and NT allows 90% sensitivity for the detection of trisomy 21, with a 5% screen-positive rate. Sonographers who perform NT screening must be familiar with normal and abnormal first-trimester fetal anatomy so that they can detect anomalies accurately.

SECOND-TRIMESTER BIOCHEMICAL SERUM MARKER SCREENING

Screening for trisomy 21 in low-risk patients (women younger than 35 years) was initiated in the mid-1980s with the observation that the mean maternal serum concentration of α-fetoprotein was 0.7 MoM in affected pregnancies.[54–56] Subsequently, it was recognized that hCG levels were higher (2.04 MoM) and unconjugated estriol levels were lower (0.79 MoM) in pregnancies with trisomy 21.[57–60] By using the relative risks derived from maternal serum levels, the maternal age-related risk can be modified and a "triple-screen" risk derived for each woman.

Triple-marker screening is used extensively and is the preferred screening modality in some locales for the detection of fetal trisomy 21 in women younger than 35 years.[60–63] In this group, the triple-marker screen identifies approximately 60% of pregnancies affected by trisomy 21 as being at risk, with a 5% screen-positive rate

(see Table 8–1). In the population of women 35 years and older, the triple-marker screen identifies 75% or more of pregnancies affected by trisomy 21 and some other aneuploidies.[64] Because the maternal age-related risk of trisomy 21 is the basis of the serum screening protocol, both the trisomy 21 detection rate and the screen-positive rate increase with maternal age.[65] Different laboratories use different screen-positive cutoffs. For example, some use the midtrimester risk of trisomy 21 in a 35-year-old woman (1 in 270). Others apply a screen-positive cutoff that provides an acceptable balance between the detection rate and the screen-positive rate (usually 1 in 190 or 1 in 200).

Maternal serum screening is performed between 15 and 20 weeks but is most accurate between 16 and 18 weeks. Like first-trimester screening, the pregnancy must be dated accurately because errors will affect the assigned risk, causing false-negative and false-positive results. It is important to recalculate the results if the dates are found to be in error, or to have a new sample drawn if the original sample was obtained before 15 weeks.

Serum screening is used primarily to detect trisomy 21, and it does not efficiently detect other fetal aneuploidies, except possibly trisomy 18. Thus, serum screening will miss both lethal (e.g., trisomy 13) and sex chromosomal abnormalities that are not associated with severe physical or developmental limitations or profound mental retardation.

Some investigators believe that, as a marker, the free beta subunit of hCG (βhCG) is superior to the intact hCG molecule, but this has not been proven in the second trimester. Recently, several new analytes of interest have emerged. Dimeric inhibin A is the most promising and is used by many commercial laboratories in combination with the three traditional analytes. This four-analyte combination ("quad screen") detects 67% to 76% cases of fetal trisomy 21 in women younger than 35 years, with a screen-positive rate of 5% or less.[66,67]

Diagnostic options are limited for screening multiple gestations. With twins, the risk of trisomy 21 is calculated by considering the maternal age-related risk and the probability that one or both fetuses will be affected. In a twin gestation in a 33-year-old woman, the midtrimester risk of trisomy 21 in at least one fetus approximates the risk in a singleton pregnancy in a 35-year-old woman, justifying an offer of invasive testing.[68]

FETAL ANATOMIC SURVEY ON SECOND-TRIMESTER SONOGRAPHY

The introduction of two-dimensional static scanning in the early 1970s allowed physicians to view the fetus for the first time. In the late 1970s and early 1980s, real-time B-mode imaging emerged as a widespread clinical tool. Because sonography images with sound waves and not ionizing radiation, it quickly became the most commonly used method during pregnancy. The major advantage of ultrasound is its lack of a demonstrable adverse fetal effect.[69] Despite the apparent safety of this method, some believe that fetal sonography should be used only when there is a clear indication. However, most complicated pregnancies are unexpected, and ultrasound examinations are routinely performed throughout pregnancy in many European countries. Ultrasound resolution has improved dramatically, and a detailed examination of the fetus for both structural anomalies and markers of aneuploidy is possible. The diagnosis and management of specific congenital fetal abnormalities are discussed in other chapters. We focus here on the elements of a complete sonographic fetal anatomic survey.

We believe that all pregnant women should have access to expert obstetric sonography. The examination should be systematic and thorough. Normal findings provide reassurance to patients, and the examination should detect most fetal malformations, along with abnormalities in fetal growth, the placenta, amniotic fluid, and the cervix. We examined the value, from a patient's perspective, of a targeted ultrasound examination performed after an abnormal karyotype was discovered.[70] All women valued the scan because it helped them to visualize the anomalies and accept the diagnosis of aneuploidy, and this in turn affected their plans for pregnancy management. All patients considered the effect of the ultrasound greater than that of the chromosomal diagnosis alone, and all believed that ultrasound should be used for patients in similar clinical situations.

The American Institute of Ultrasound in Medicine first published standards for the performance of obstetric ultrasound in 1994.[71] Minimum requirements in the first trimester include evaluation of the uterus, adnexa, cul-de-sac, gestational sac, crown–rump length, fetal number, and presence of cardiac activity. Minimum requirements in the second and third trimesters include verifying fetal life, number, presentation, and activity (multiple gestations require additional documentation); measuring amniotic fluid volume; determining the placental location, appearance, and relationship to the internal os; visualizing the umbilical cord; measuring the fetal biparietal diameter or head circumference; measuring the limbs; estimating fetal weight (requires the abdominal diameter or circumference); evaluating the cerebral ventricles; evaluating the posterior fossa; obtaining a four-chamber view of the heart and determining its position; and evaluating the spine, stomach, kidneys, bladder, abdominal cord insertion site, uterus, cervix, and adnexa.

The current state of the art requires a more detailed examination than that described by the American Institute of Ultrasound in Medicine for optimal diagnostic accuracy of fetal abnormalities (Table 8–3). Further, sonographer training must be targeted to ensure that these detailed examinations are done appropriately. The sonographer must be familiar with normal fetal anatomy,

fluid volume, and placental location. Accurate determination of the right and left sides of the fetus is crucial. Factors that may limit visualization (Table 8–4) include equipment quality, fluid abnormalities, maternal body habitus or tissue density, and other scanning characteristics. Techniques to improve visualization include changing the maternal position (to effectively change the fetal position) and using different scanning probes (including transvaginal). The timing of the second-trimester ultrasound varies with the center and physician preference. Repeating the examination later may aid the resolution of anatomic detail of some structures (e.g., heart) but hinder visualization of others (e.g., extremities). This is not to infer that scanning, even late in pregnancy, cannot provide important information and be highly sensitive for fetal anomalies whose diagnosis will alter pregnancy management. We recommend that the fetal anatomy survey be performed at 18 to 20 weeks to optimize the assessment of anatomy while leaving an adequate window for invasive testing, if necessary. Scans performed at 18 to 20 weeks are less likely than earlier scans to end incompletely and trigger the need for a repeat examination. In addition to evaluating the fetal anatomy, the number and position of fetuses should be determined. The placental appearance, thickness, echogenicity, and location are important to document, along with amniotic fluid volume. Amniotic fluid abnormalities may indicate an anomalous (e.g., anhydramnios is associated with renal agenesis and polyhydramnios with esophageal atresia) or infected fetus. The fetal echocardiogram is best performed between 22 and 24 weeks, when the cardiac structures are larger.

Content of the Fetal Anatomic Survey

The examination begins with the fetal head and proceeds caudally. Imaging the fetal intracranial anatomy is extremely important because central nervous system anomalies can have a devastating effect on perinatal morbidity and mortality. The calvarium can be identified from the late first trimester onward. It should be well

mineralized (hypomineralization may indicate skeletal dysplasia) and elliptical. Brachycephaly (anteroposterior shortening) suggests fetal trisomy 21 or 18 ("strawberry" head). A lemon-shaped head suggests a neural tube defect. Tangential imaging shows cranial sutures (hypo-echoic spaces between bones) that are best visualized early in gestation. Premature closure of the sutures occurs in many syndromes (e.g., craniosynostosis) and with several skeletal dysplasias.

The transthalamic view is an axial view through the brain at the level of the thalami (Fig. 8–7). It is here that the biparietal diameter and head circumference are obtained. Biparietal diameter is measured from the outer margin of the near calvarium to the inner margin of the far calvarium (with cranial bones perpendicular to the ultrasound beam). The head circumference is measured circumferentially at the outer margin of the calvarium (see Fig. 8–7). Other structures that are visualized in the transthalamic view include the cavum septum pellucidum (a fluid-filled midline structure anterior to the thalami), midline falx, third ventricle (between the thalami), and frontal horns of the lateral ventricles. A normal cavum suggests proper midline brain formation; its absence may signal abnormalities, such as holoprosencephaly or agenesis of the corpus callosum. The transventricular view is just superior to the transthalamic view and includes the lateral ventricles that contain sonolucent cerebrospinal fluid. Within lies the echogenic choroid plexus that normally fills the atrium and may contain cysts (a potential marker for trisomy 18) [Figs. 8–8 and 8–9]. The cerebral ventricle is measured through the atrium in an axial plane and is normally less than 10 mm. The transcerebellar view contains the cerebellum and vermis, cisterna magna (between the dorsum of the cerebellar hemispheres and inner calvarium), and nuchal fold (Fig. 8–10). Visualization of this area is important to exclude spina

FIGURE 8–9

bifida; obliteration of the cisterna magna and a banana-shaped cerebellum typically occur with this disorder. This view is also used to exclude Dandy-Walker malformation or variant, occipital encephalocele, and cerebellar agenesis or hypoplasia. The nuchal fold should be less than 6 mm, although breech presentations may create false-positive thickening. The transcerebellar diameter provides a useful estimate of gestational age because it is relatively spared by growth restriction. Sometimes the head is low in the pelvis, blocking access to the intracranial structures; in this case, transvaginal scanning may be useful.

The facial structures are especially important for the diagnosis of genetic disorders or syndromes, and they should be examined routinely. This is accomplished with coronal (Fig. 8–11), sagittal (profile) [Fig. 8–12], and axial views. Often, a combination of these planes is optimal. Structures important to image include the chin (for micrognathia), nasal bone (absent or shortened)

[Fig. 8–13], nose, lips, anterior palate (to exclude cleft lip or palate), orbits (and diameters, if necessary, to exclude hypertelorism or hypotelorism), and ear (which may be short in aneuploid and nonaneuploid fetuses) [Fig. 8–14].

Next, the fetal spine is imaged in sagittal (Fig. 8–15), transverse, and coronal views, when possible. The overlying skin should be intact to exclude open spina bifida and masses or tumors. Each normal vertebral segment consists of three echogenic ossification centers (two located posteriorly, and one located anteriorly that is the vertebral body) lying in a symmetrical, triangular configuration. In the transverse plane, the posterior processes appear angled in the same way as the roof of a house; if they are splayed, a neural tube defect should be sought (Fig. 8–16). Sagittal and coronal views are useful to observe how well the ossification centers align to exclude hemivertebrae that cause disorganization or absence of ossification centers. The sacrum should curve gently upward.

FIGURE 8–13

FIGURE 8–14

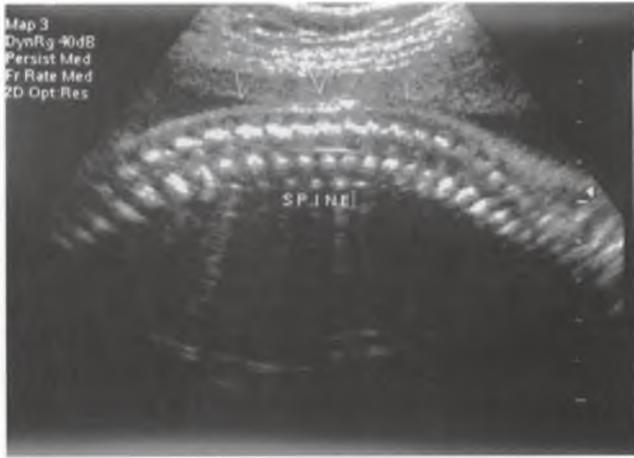

FIGURE 8–15
Normal sagittal view of the fetal spine. The overlying skin (*arrows*) is intact, and the features of the spinal centers are parallel.

The ribs, clavicles, and scapulae are examined next. A normal appearance excludes some types of skeletal dysplasia. Abnormal lung tissue or echogenicity (e.g., cystic adenomatoid malformation) or pleural effusions may be seen. The thoracic circumference is measured to exclude pulmonary hypoplasia, and the diaphragm is examined for evidence of a hernia.

A detailed fetal cardiac examination is perhaps the most challenging task performed by a sonographer. The cardiac rate and rhythm (normally 120–160 beats/min and regular), size (one-third of the fetal thorax), axis and position (apex points to the left at an angle of 45 ± 20 degrees relative to the midline), and situs should be established (liver on the right, stomach on the left). Alterations in position, axis, or both suggest malposition or an intrathoracic mass deviating the mediastinum. Multiple planes and views are used in real time to exclude cardiac defects. Routine imaging of the outflow tracts increases detection sensitivity and should be part of the standard fetal cardiac examination. When screening for cardiac defects, the examination should include, minimally, the four-chamber apical (Fig. 8–17) and subcostal views, outflow tracts, longitudinal parasternal arches (aortic and ductal), inferior and superior vena cava, valves, and atria and ventricular septa. The chambers are roughly equal in size. The pulmonary veins should enter the left atrium; the two atrioventricular valves and septa should be visualized in their entirety and the rate and rhythm documented as well as the axis, position, and size of the heart. The great vessels should cross each other, and there should be no dependent pericardial fluid. Some recommend routine color, M-mode, or pulsed Doppler sonography to assist in the visualization of the heart and great vessels and to exclude significant valvular stenosis or regurgitation (see Chapter 17 for a discussion of specific cardiac abnormalities). An echogenic focus is commonly seen, typically in the left ventricle. It is caused by specular reflection from the papillary muscles and chordae tendineae (Fig. 8–18).[72]

Intra-abdominal organs that are identifiable on ultrasound include the liver (occupying most of the upper abdomen), spleen (solid organ posterior to the stomach), gallbladder (teardrop-shaped organ in the right upper quadrant, at the inferior edge of the liver), stomach, bowel, umbilical vein, and umbilical cord insertion site. Abdominal circumference is the most sensitive fetal growth parameter. It is measured at the transverse level, where the umbilical vein joins the right portal venous system (Fig. 8–19), which should "curve" away from the stomach. If the curve is toward the stomach, persistence of the right umbilical vein is suspected. The stomach and spine should be imaged in this axial plane; the stomach should always be located below the diaphragm. An absent or small stomach despite prolonged scanning to allow for filling suggests esophageal atresia, with or without tracheoesophageal fistula, or a diaphragmatic hernia (stomach located within the chest). Most of the abdomen is

FIGURE 8–16

bowel-filled, and the appearance varies with gestational age. In the second trimester, the bowel appears as midlevel to increased echogenicity filling the abdomen. Hyperechoic bowel is associated with aneuploidy, infection, and bowel abnormalities. In the third trimester, prominent hypoechoic loops of colon may be seen. More dilated loops of bowel may reflect atresia or another cause of obstruction. The umbilical cord insertion and the adjacent ventral abdominal wall should be visualized to exclude ventral wall defects (e.g., omphalocele, gastroschisis). There should be no fetal ascites.

Next visualized is the genitourinary tract, which is a common site for fetal anomalies. The kidneys are bilateral, hypoechoic, paraspinal structures that include the urine-containing renal pelvis. Abnormal findings include dilation of the renal pelvis, calix, or ureter; renal masses; cysts within the parenchyma; hyperechogenicity; and enlargement or absence of the kidneys. Color or power

Doppler imaging is useful to identify the renal arteries, especially when the kidneys cannot be seen in their usual location. It is important to distinguish between pyelectasis (dilated renal pelvis) and hydronephrosis (pyelectasis plus upper tract dilation). The bladder is a urine-filled structure located midline, anterior, and low in the fetal pelvis. Absence of the fetal bladder (bladder exstrophy) or a very enlarged bladder (lower obstructive uropathy) should be excluded. The sonographer should confirm that the two umbilical arteries course around the fetal bladder. This image all but excludes a two-vessel cord. Gender is assigned by imaging the genitalia, and not by the lack of an image. Ambiguous genitalia should be excluded. The fetus is male if both the penis and scrotum are seen. The testicles are echogenic and usually descend into the scrotum during month seven. The labia appear as several parallel linear echoes.

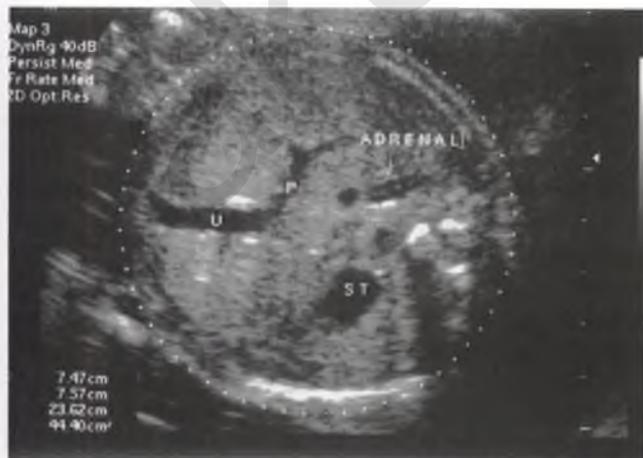
Documentation of all fetal extremities is not included in the guidelines for routine obstetric ultrasound examination. However, a survey of all extremities (including hands and feet) may provide important diagnostic information. The five fingers should extend fully (Fig. 8–20). Movement and tone should be normal, and the middle phalanx of the fifth digit should be visualized. Persistently clenched hands with overlapping digits are a highly sensitive (95%) sonographic feature for trisomy 18.[73] The long bones (femur, humerus, radius and ulna, tibia and fibula) should be well mineralized and of normal length. Absence, fractures, contractures, or bowing of these bones is abnormal. The ulna extends farther into the elbow than the radius, and the tibia extends farther into the patella than the fibula. The length of each long bone is measured. Images are obtained with the diaphysis located horizontally in the image (Fig. 8–21) because vertical measurements can falsely "shorten" the length. Multiple images are measured, and the longest technically adequate image is the optimal measurement. The


FIGURE 8–19

lower extremities should not be clubbed, nor should the plantar surface appear "rocker-bottom." There should be five toes (Fig. 8–22), and they should not appear dysplastic. The foot length can also be measured.

Finally, the umbilical cord is examined. There should be two arteries and one vein. Once the umbilical vein enters the fetal abdomen, it should turn superiorly, enter the liver, and communicate with the portal vein. The umbilical vein continues into the ductus venosus and then into the inferior vena cava and right atrium.

Second-Trimester Ultrasound Screening for Structural Abnormalities

There are many accepted indications for ultrasound examination during pregnancy, and 60% to 70% of all pregnant women in the United States undergo an examination at some stage during pregnancy.[74] The rate is much higher in other industrialized countries. One of the first studies to quantify the diagnostic accuracy of ultra-

FIGURE 8–22
Third-trimester fetal foot, showing five toes.

sound in high risk pregnancies was performed in the United Kingdom in the late 1970s and early 1980s; 95% of malformations were correctly diagnosed.[75] Subsequently, many studies examined the efficacy of routine screening ultrasound. Published sensitivities range from 13.3% to 82.4%,[76] with the collaborative world experience approximating 50%.[77] We believe that much of the variation in results reflects differences in the quality of training. In light of these wide variations in detection rates, it is understandable why the reliability and utility of sonographic screening for fetal malformations have been challenged. Even among those who recommend routine ultrasound screening, the number and timing of scans are debated. Because 75% of patients with abnormal fetuses are considered low risk, it is important to review the literature to assess the effect of routine sonography.[76]

The antenatal diagnosis of a fetal abnormality has many advantages. It may trigger additional testing to refine the diagnosis or prognosis, alter pregnancy management (e.g., termination, intrauterine therapy, early delivery, delivery in a tertiary care center), prepare the parents for an adverse pregnancy outcome, and alert the clinician to the possibility of other malformations. For many patients, the benefits of sparing social and psychological costs are also very important. However, there is one fact that no one contests. Sonographic screening performed by inexperienced individuals increases the costs of health care and generates high false-negative and false-positive rates, with serious consequences, such as termination of an actually normal fetus.

Many biases and problems may explain much of the variation in sensitivity.[76] Reasons for the variation include technical issues (e.g., fetal positioning, obesity), lesions that resolve over time, and the undetectability of certain anomalies by ultrasound. However, these factors are unlikely explanations for differences in large studies. Selection bias may play an important role, depending on whether the patient source is a hospital or an office practice. The most important bias is the variation in sonographic skills, capability, and experience of individuals performing the ultrasound examination. In the Helsinki study, which incorporated patient populations from two hospitals, the sonographic sensitivity for detecting anomalies was twofold higher in the university hospital than in the city hospital (77% vs. 36%).[78] A systematic and almost compulsive approach to each examination is necessary, with attention paid to all structures. Each center has different criteria as to what constitutes a detailed ultrasound examination. The less detailed the examination, the lower the sensitivity. The selection of pregnant women is also important. Screening high risk women is likely to be more effective because sonographers become more focused because they expect to find an anomaly. One group noted an average sensitivity of 55% in a low risk population and 92% in a high risk population.[76]

Gestational age at screening also affects sensitivity because various anomalies may appear at different gesta-

tional weeks. Some are seen only later in gestation (e.g., duodenal atresia). The more scans a patient undergoes, the greater the anomaly detection rate. Levi[76] reported that the average sensitivity of studies that included only scans performed once before 20 weeks was 45%. The sensitivity increased to 60% if the scanning was performed several times during the pregnancy.

The prevalence of specific malformations within a population can significantly affect the sensitivity of ultrasound screening. Studies that exclude certain anomalies because they are considered either minor or undetectable can dramatically alter the sensitivity compared with a calculation that includes all anomalies. A 1996 study found that the sensitivity of ultrasound for diagnosing both minor and major anomalies was only 8.7%; however, if only major anomalies detectable by ultrasound were included, the sensitivity rose to 75%.[77]

Finally, other factors may affect the reported fetal anomaly detection rates, such as a lack of autopsies (the "gold standard"), suboptimal neonatal evaluation at birth, and inadequate length of neonatal follow-up (some anomalies may not express themselves immediately after birth).[76]

The Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial was the first randomized clinical trial of second-trimester ultrasound in the United States.[79] It compared pregnant patients who underwent routine scanning with those who had ultrasound when indicated. An additional scan was performed in the study group early in the third trimester. The goal of the trial was to determine the benefits, if any, of routine ultrasound among pregnant women at low risk. Although the identification rate of anomalies in this study was three times better with routine vs. indicated ultrasound (35% vs. 11%, respectively), the sensitivity of 17% for anomalies detected between 15 and 22 weeks was extremely low.

The findings of the trial underwent intense scrutiny. One potential source of bias was that practice-based patients were used, which may have created an inadvertent selection bias (vs. a community- or hospital-based population). Others criticized the relative simplicity of the scans performed. The investigators reported a relative detection rate of 2.7 (95% confidence interval, 1.3–5.8) for tertiary compared with nontertiary ultrasound units.[79] The detection rate of anomalous fetuses was 35% versus 13% in nontertiary centers. Sonographic screening did not significantly affect the management or outcome of pregnancies complicated by congenital malformations. This was to be expected because there was no standardized response to the sonographic findings. Diagnostic ultrasound is not a therapeutic instrument.

In 1998, Van Dorsten and associates[80] reported that the sensitivity of ultrasound for anomaly detection at a tertiary care center (in women at risk for anomalies) was 89.7%. Although the sensitivity was decreased (47.6%) in the lower-risk population (screening group), it was sufficient to ensure cost-effectiveness for the patients.[80] In 1999, the Eurofetus group reported the results of a study designed to evaluate the sensitivity of routine ultrasound screening for fetal malformations.[81] Nearly 200,000 pregnant women (the largest group among screening studies) were enrolled and evaluated in 60 hospital laboratories in 14 countries. The sensitivity rate was 64% (2363 of 3685), a rate much higher than that in the RADIUS study. However, the two trials may not be comparable. Women in the RADIUS trial were at very low risk because strict exclusion criteria were applied before patient recruitment occurred. Further, the criteria used to designate major fetal anomalies (gold standard) were very liberal. Both of these factors could have lowered sensitivity. In contrast, all women in the Eurofetus trial were studied, regardless of risk status, and only "truly" major abnormalities were considered as endpoints; this classification may have artificially raised the sensitivity of the ultrasound screening.

Women in the Helsinki trial underwent one screening examination in the second trimester; 40% of major fetal anomalies were detected, including most anomalies of the central nervous system or genitourinary system and cases with multiple anomalies. In this trial, screening was less effective in detecting cardiac and gastrointestinal tract anomalies.[82] This finding is logical because many bowel abnormalities are sonographically "silent." In addition, cardiac morphology changes in response to malformations and may not be seen when first imaged unless flow abnormalities are sought. In the 1991 Belgian Multicentric Study,[83] 154 of 381 structurally abnormal fetuses were correctly detected by ultrasound (sensitivity, 40%). The specificity, positive, and negative predictive values were 99.9%, 95%, and 98.6%, respectively.

We examined the efficacy of a complete sonographic survey (as described in this chapter) for the detection of fetal abnormalities and correlated the findings with perinatal autopsy results.[84] Of 88 abnormal autopsy findings, 85 fetuses had one or more abnormal structural sonographic findings, giving a sensitivity of 97% for anomalous fetuses. The low sensitivities reported in the past may be in great part the result of failure to look for specific abnormalities. There were 372 separate abnormalities found on autopsy. Antenatal sonography detected 75% and 18%, respectively, of the 299 major and 73 minor abnormalities. Thus, the sensitivity for minor abnormalities is poor, even when a complete sonographic survey is performed. In 65% of cases, there was either complete agreement or only minor differences between sonographic and autopsy findings.[84]

Because sensitivity for the antenatal sonographic detection of fetal anomalies is highly dependent on the clinical setting and the expertise of the sonographer, there is insufficient evidence to list a single estimate of the sensitivity of routine ultrasound as a screening tool for fetal anomalies. However, the specificity of a fetal anatomic survey exceeds 99% in many studies.[79,85–87] Therefore, in low-risk patients, ultrasound is helpful in excluding anomalies and detecting normal features, but

may not be equally reliable in detecting anomalies. The sensitivity of screening programs may continue to improve because of technologic advances (e.g., three-dimensional sonography) and uniform and detailed training of practitioners.[76]

Antenatal detection of an anomalous fetus, especially one with a life-threatening defect, allows the delivery of these infants in a tertiary care center that can provide immediate and appropriate care, maximizing survival. Is this statement supported by evidence in the literature? In the 1994 RADIUS study,[79] screening did not affect the detection, management, or outcome of fetuses with anomalies. However, of the infants with life-threatening anomalies, 75% (21 of 28) survived in the routinely screened group compared with 52% (11 of 21) in the non-screened group.[79] The study may have been inadequately powered to address this specific question, and although many fetal medicine practitioners are convinced, additional studies are required.

Another important question is whether routine ultrasound improves overall perinatal morbidity and mortality rates. For example, routine sonography increases the accurate detection of multiple gestations, gestational age, and placental abnormalities. Table 8–5 summarizes three trials[74,78,88] that investigated the perinatal morbidity and mortality rates of pregnancies in which routine ultrasonography was performed. The perinatal mortality rates were similar in the routine sonography and control groups in both the RADIUS and Stockholm trials.[74,88] However, the perinatal mortality rate in the Helsinki trial was significantly lower in the routine ultrasound group (4.6 of 1000 vs. 9.0 of 1000). This difference was attributable mainly to improved early detection of major malformations, leading to pregnancy termination.[78] There were no differences in perinatal morbidity rates between the study and control groups in these three trials (see Table 8–5).[74,78,88] Although two trials had a similar distribution of birth weights between study groups,[74,78] the

third trial had fewer births less than 2500 g in the routine ultrasound group.[88] The mean birth weight was also higher in the routine ultrasound group in women who smoked, and the authors speculate that this difference may be attributable to healthier maternal behaviors after these women saw their fetuses on ultrasound.[88] Although the authors of the RADIUS trial concluded that the adoption of sonographic screening in the United States would increase health care costs without improving perinatal outcome or providing measurable benefit from early detection of fetal anomalies, another study concluded that routine screening for anomalies improves perinatal outcome by leading to termination of pregnancy for certain anomalies and delivery at tertiary care centers for life-threatening malformations.[80] The prospective trials also showed that twin gestations are diagnosed earlier with routine sonography. In the Helsinki trial, 100% of twins were detected before 21 weeks in the routine ultrasound group, compared with 76% in the control group.[78] Further, the perinatal mortality rate was reduced (27.8 of 1000 vs. 65.8 of 1000).

A subgroup analysis was also performed in the RADIUS study for infants who were small for gestational age and neonates born at 42 weeks or later.[74] There was no improvement in overall outcome for these conditions when routine ultrasound was performed. The available evidence indicates that routine sonography will, at a minimum, reduce perinatal outcome in low-risk pregnancies by decreasing perinatal mortality rates because of induced abortions after the detection of fetal abnormalities.

Sonographic screening for anomalies may also provide value to both patients and physicians that is not quantifiable in terms of psychological reassurance, antepartum management, referral, genetic counseling, or preparation of families and health care providers. The benefits discussed earlier may outweigh the "risks" of ultrasound (e.g., false-positive diagnosis). Most patients will choose

TABLE 8–5

Three Trials Comparing Perinatal Morbidity and Mortality Rates in Patients Undergoing Routine Ultrasonography (vs. Control Groups)

TRIAL	PERINATAL MORBIDITY	PERINATAL MORTALITY	P	MEAN BIRTH WEIGHT AND NO. OF INFANTS WITH LOW BIRTH WEIGHT (<2500 G)	P
Ewigman et al., 1993[74] (RADIUS)	*Similar	Similar	NS	Similar birth weight	NS

				Nonsmokers: higher mean birth weight	NS

*Moderate morbidity defined as neonatal sepsis, grade I or II intraventricular hemorrhage, or stay of >5 days in neonatal unit; severe morbidity defined as ventilation >48 hours or stay of >30 days in neonatal unit.
†Defined as admission to neonatal unit.
‡Attributable to early detection of malformations, leading to termination of anomalous fetuses.
NS, not significant.

anomaly screening if given a choice and counseled on the current diagnostic capability of sonography. Pregnant women usually do not perceive ultrasound as a "test," but rather as a tool to evaluate the fetus as a patient. We agree with this philosophy and argue that examination of the fetus as a patient should be a routine practice, as it is in all aspects of adult medicine.

The last issue to address is the cost–benefit analysis of routine second-trimester sonography. We performed a cost–benefit analysis based on the RADIUS trial, comparing routine second-trimester sonography in low-risk pregnant women with a policy of not offering screening. Routine second-trimester sonographic screening is associated with net benefits only if the sonogram is performed at a tertiary care center.[89] Another study showed that a one-stage second-trimester screening ultrasound was both cost-effective and associated with fewer perinatal deaths.[90] Finally, Van Dorsten[80] and colleagues assessed the cost-effectiveness of anomaly screening in their patient population and concluded that routine screening was cost-effective. There seems to be little doubt that the cost-effectiveness of routine sonographic screening for fetal anomalies rests not on the tool but on the caliber of the sonographer.

Sonographic Aneuploidy Markers and Genetic Sonography

The most common autosomal trisomy in liveborn infants is Down syndrome, or trisomy 21, which was first described by John Langdon Down in 1866. Autosomal trisomies are primarily the result of meiotic nondisjunction, the risk of which increases with maternal age. The first screening method for fetal trisomy 21 was introduced in the early 1970s and was based on maternal age. Amniocentesis was offered to women 35 years or older, based on the findings of an early study that stated that the risk of a procedure-related loss approximated the likelihood that a midtrimester fetus of a 35-year-old woman would have trisomy 21 (1 in 270). There has been a fundamental shift in birth trends over the last three decades, with more births occurring in women older than 35 years.[91] In 1974, women 35 to 49 years old accounted for 4.7% of live births compared with 12.6% in 1997.[91] As a result, the prevalence of fetal trisomy 21 during the second trimester has increased from 1 in 740 in 1974 to 1 in 504 in 1997. However, the fact remains that most infants with trisomy 21 are born to women younger than 35 years. Fetuses with aneuploidy account for 6% to 11% of stillbirths and neonatal deaths,[92] whereas chromosomal defects that are compatible with life, but associated with significant morbidity, occur in 0.65% of newborns.[93]

A large body of literature attests to the specific use of second-trimester genetic ultrasonography for antenatal detection of trisomy 21 by seeking aneuploidy markers. We offer genetic sonography as an option to all (and only) high risk patients (i.e., advanced maternal age at

the time of delivery, abnormal serum marker screen results, or both). The information derived from this sonogram is used to generate an adjusted risk of Down syndrome to guide a woman's decision about genetic amniocentesis. When the findings on genetic sonogram are normal in high risk patients, the amniocentesis rate is only 3%.[94] The amniocentesis rate increases in direct proportion to the number of abnormal sonographic markers identified, with almost 100% of women selecting invasive testing when four or more markers are seen. Since the initiation of our genetic sonography service 10 years ago, 4951 women have avoided amniocentesis based on normal findings on genetic sonogram. If the fetal loss rate related directly to amniocentesis is between 1 in 100 and 1 in 300, then between 17 and 50 fetal lives were saved, attesting to the power of genetic sonography.

Screening based on maternal age identifies at most 47% of fetuses with trisomy 21, with a false-positive rate of 13% to 14% (a rate that has increased in recent years).[91] Based on advanced maternal age, 140 amniocentesis procedures are required to detect one fetus with trisomy 21,[95] implying that one healthy fetus will be lost for every two affected fetuses identified. Although the combination of maternal age and triple-screen results increases the detection rate to 60% to 65%,[65] 60 to 70 amniocentesis procedures are required to detect one fetus with trisomy 21.[95] Thus, one healthy fetus will be lost for every three to four fetuses in which trisomy 21 is detected. As a result, some challenged the practice of offering invasive testing to all high risk pregnant women (based on age or triple-screen results).[65] Reducing the screen-positive rate is beneficial, regardless of an individual's personal opinion on testing. Genetic sonography reduces the invasive testing rate by refining the selection of candidates for invasive testing without significantly decreasing detection rates.

Ideally, genetic sonography is performed between 18 and 20 weeks. It is a targeted examination for fetal aneuploidy (predominantly, trisomy 21) during which the sonographer searches for abnormal fetal biometry, fetal structural anomalies, and other markers of aneuploidy.[94] Because only 25% of fetuses with trisomy 21 have a sonographically detectable major anomaly in the second trimester,[95] the examination must include other markers to increase sensitivity (Table 8–6). Markers of aneuploidy that are detectable on ultrasound include shortened long bones, increased nuchal fold thickness (Fig. 8–23), pyelectasis (Fig. 8–24), choroid plexus cysts (see Fig. 8–9), short ear length, wide iliac wing angle, hyperechoic bowel, echogenic intracardiac focus (see Fig. 8–18), sandal gap toes (Fig. 8–25), hypoplastic midphalanx of the fifth digit, clinodactyly, and absent nasal bone (see Fig. 8–13). The risk of fetal trisomy 21 increases with the number of markers present. Each marker alone has low to moderate sensitivity for trisomy 21 and does not necessarily increase the risk of

TABLE 8–6

Aneuploidy Markers of the Genetic Sonogram at Robert Wood Johnson Medical School

ANEUPLOIDY MARKER

Structural anomalies, including cardiac (four-chamber and outflow tracts)
Short femur (observed to expected <10th percentile)
Short humerus (observed to expected <10th percentile)
Pyelectasis (anteroposterior diameter of renal pelvis ≥ 4 mm)
Nuchal fold thickening (≥ 6 mm)
Echogenic bowel (similar to echogenicity of iliac bones)
Choroid plexus cysts (>10 mm)
Hypoplastic middle phalanx of the fifth digit
Wide space between the first and second toes (sandal gap)
Two-vessel umbilical cord
Echogenic intracardiac focus, short tibia, short fibula, short ear (since October 1997)
Absent nasal bone (since 2003)

FIGURE 8–24
Bilateral pyelectasis in a second-trimester fetus.

aneuploidy when found in isolation in low risk patients. However, the risk of fetal aneuploidy may increase when multiple sonographic abnormalities or markers are detected in low-risk patients or when isolated markers are seen in high-risk patients.

A thickened nuchal fold (sensitivity, 40%; false-positive rate, 0.1%)[96] is the single most sensitive and specific marker for Down syndrome, although absent nasal bone has also been shown to have 41% sensitivity and 100% specificity for fetal trisomy 21.[97] A short femur length (measurement-to-expected length ≤ 0.91) is found in 24%,[98] and a short humerus (measurement-to-expected length < 0.90) in 50% of affected fetuses, with a false-positive rate of 6.25%.[99] There is a large overlap in bone measurements between affected and normal fetuses. The sensitivity of pyelectasis (anteroposterior diameter of the renal pelvis ≥ 4 mm in the second trimester) for trisomy 21 is 25%.[99] Echogenic bowel has a reported sensitivity of 7% to 12.5%, whereas an echogenic intracardiac focus

(see Fig. 8–18) has a reported sensitivity of 18%.[99] We examined the sensitivity of a short sonographic ear length for trisomy 21.[100] Forty-one percent (21 of 51) had an ear length at or below the 10th percentile. However, a short ear length was not as sensitive a marker for trisomy 21 as it was for trisomy 13 (100%) or trisomy 18 (96%). The association between trisomy 21 and choroid plexus cyst is controversial.

Several studies reported the accuracy of genetic sonography in detecting trisomy 21 in high risk populations.[94] When "abnormal" is defined as the finding of at least one marker on ultrasound, the overall sensitivity was 77% (range, 50%–93%) and the false-postive rate was 13% (range, 7%–17%).[94] In 1998, an 11-center collaborative study examined the sensitivity of sonography for the detection of trisomy 21.[101] Eighty-five percent of fetuses with trisomy 21 (*n* = 241) had at least one abnormal finding on ultrasound. In 2003, an eight-center study evaluated the utility of second-trimester genetic sonography in

FIGURE 8–23
Thickened nuchal fold (0.86 cm) in a fetus with Down syndrome.

FIGURE 8–25
Sandal gap (wide space between the first and second toes) in a fetus with Down syndrome.

high risk women, including 176 fetuses with trisomy 21.[102] The sensitivity for the detection of trisomy 21 was 72% (center range, 64%–80%). Approximately half (47%) of the fetuses with trisomy 21 had a thickened nuchal fold of 5 mm or more.

In 1996, we published findings on the use of second-trimester genetic sonography to guide clinical management in women at high risk for pregnancy affected by trisomy 21.[103] After analyzing the data through 1999, we began to counsel women that the likelihood of trisomy 21 in the absence of abnormalities or markers was reduced by at least 80% from the a priori risk (triple-screen results or, if unavailable, maternal age).[94] Our experience was reassuring. Since November 1992, we evaluated 5299 fetuses with genetic sonography. The findings were normal in 85% (no markers seen); 12% had one marker, and 3% had two or more markers. When at least one marker was present, the sensitivity, specificity, and positive and negative predictive values for trisomy 21 were 87% (52 of 60), 91% (4395 of 4831), 11% (52 of 488), and 99.8% (4395 of 4403), respectively. Approximately two thirds of fetuses with trisomy 21 had two or more abnormal sonographic markers.

Over the years, we found that more and more high-risk women prefer genetic sonography as their first option rather than amniocentesis (Table 8–7). Since 1998, more than 70% of women chose to begin with genetic sonography. Accordingly, the number of amniocenteses performed has decreased. The total amniocentesis rate (the sum of amniocentesis procedures as the first option plus amniocentesis procedures performed after genetic sonography) decreased from 99.6% in 1993 to 32% in 2002. Recently, we examined the accuracy of genetic sonography for the detection of fetal trisomy 21 according to the indication for testing (advanced maternal age, abnormal triple-screen results, abnormal triple-screen results in women younger than 35 years, and abnormal triple-screen results in women 35 years and older). We also examined the risk of trisomy 21 after normal findings on genetic sonography.[104] The magnitude of the risk adjustment after normal findings on genetic scan is independent of the testing indication, and there are no significant indication-specific variations in the accuracy of genetic sonography.

Although some advocate second-trimester genetic sonography for screening of the general population, we believe that it should be reserved for the high-risk population. First, a high degree of expertise is required to exclude sonographic fetal malformations (especially subtle cardiac defects), and this expertise is not widely available in many countries. Second, the application of genetic sonography to low risk women may be inappropriate and perhaps dangerous, in light of the high screen false-positive rate (12%–15% in the high risk population), which is likely even higher in a low risk population. In low risk women, the a priori risk of trisomy 21 may be so low that the presence of one aneuploidy marker (e.g., pyelectasis) would not elevate the risk enough to justify amniocentesis. Therefore, with this approach, the positive predictive value and perhaps even the sensitivity of genetic ultrasound for fetal trisomy 21 are likely to be decreased in low risk patients. Third, the accuracy of second-trimester aneuploidy markers has been studied mainly in high risk populations. Extrapolation of such accuracy to low risk women may not be appropriate. Some concluded that an isolated marker (other than increased nuchal fold thickness or structural anomalies) should not be used as an indication for amniocentesis testing in the low risk population.[94] Others argue that if it is applied to the low risk population, any risk adjustment must reflect both the a priori risk of trisomy 21 and the sensitivity of the specific marker identified.

Figure 8–26 shows the algorithm we apply to both high and low risk patients. Clinicians should not recommend amniocentesis to low risk patients who have an isolated marker identified because the sensitivity is low (with the possible exception of increased nuchal fold thickness).[105] The incidental finding of an organ or structural anomaly (with few exceptions), nuchal thickening, or two or more aneuploidy markers in a low risk patient should trigger counseling and informed consent with the patient. The patient should be informed that if the accuracy of genetic ultrasound is extrapolated from high risk to low risk women, then the risk of trisomy 21 is likely high enough to justify offering genetic amniocentesis. In these patients, the risk of trisomy 21 is higher than the risk of amniocentesis-related fetal loss, regardless of maternal age or triple-screen results (unless the a priori risk is less than 1 in 10,000). Certain isolated sonographic fetal abnormalities (e.g., gastroschisis) are

not usually associated with aneuploidy and do not require further invasive testing.

In high risk patients, we use genetic sonography as an adjunct to maternal age and serum screening (triple or quadruple, whichever is available) to adjust the risk of fetal trisomy 21 for each patient, based on our accuracy (see Table 8–8). The a priori risk is based on serum screening results. If serum screening results are not available or if testing was not performed, the risk is based on maternal age. We then multiply the a priori risk with var-

TABLE 8–8

Ultrasound-adjusted Risk for Fetal Down Syndrome (Maximum Risk 1:2) in Genetic Sonography and Clinical Examples

ULTRASOUND FINDINGS	LIKELIHOOD RATIO	CLINICAL EXAMPLES
Normal scan	0.20	35-year-old woman with no serum screen done 2VC seen 1:274 ÷ 1.00 = 1:274

One marker structural anomalies, including cardiac, short femur length, short humerus length, pyelectasis, nuchal fold thickening, echogenic bowel, HELV, short tibia length, short fibula, short ear length, absent nasal bone	1.35	44-year-old woman with triple-screen risk 1:798
		  Only pyelectasis seen 1:798 ÷ 1.35 = 1:591
		
		22-year-old woman with quadruple-screen risk 1:200
		  Increased nuchal fold seen 1:200 ÷ 1.35 = 1:148

One marker choroid plexus cyst >10 mm, hypoplastic middle phalanx of the fifth digit, sandal gap, 2VC	1.00	38-year-old woman with triple-screen risk 1:5000
		  No markers seen 1:5000 ÷ 0.20 = 1:25,000
		
		16-year-old girl with quadruple-screen risk 1:240
		  Sandal gap and HELV seen 1:240 ÷ 37.03 = 1:6

HELV, hyperechoic focus in the left ventricle; 2VC, two-vessel cord.

ious likelihood ratios (LR), depending on the presence or absence of aneuploidy markers. For example, if the a priori risk of fetal trisomy 21 is 1 in 274 and the results of genetic scanning are normal, the adjusted risk of fetal trisomy 21 is (1 in 274 × 0.20), or 1 in 1370, a reduction of at least 80%. The revised risk is discussed with the patient. The patient should be told that the genetic scan can never reduce her risk to 0%. In our experience, the presence of only one of the following markers increases the risk of trisomy 21 by 1.35-fold: structural anomalies, including cardiac; short femur length; short humerus length; pyelectasis; nuchal fold thickening; echogenic bowel; hyperechoic focus in the left ventricle; short tibia length; short fibula length; short ear length; and absent nasal bone. Thus, the adjusted risk of fetal trisomy 21 is (1 in 274 ÷ 1.35), or 1 in 203, which is "abnormal." In our experience, this group of markers in isolation (choroid plexus cyst greater than 10 mm, a hypoplastic middle phalanx of the fifth digit, a sandal gap toe, or a two-vessel cord) is not associated with an increased risk of trisomy 21. Thus, the risk of fetal trisomy 21 remains the same (1 in 274). Once two or more markers are visualized, the a priori risk (in this case, 1 in 274) is modified by an LR of 37.03, and the adjusted risk becomes 1 in 7 (1 in 274 ÷ 37.03). The maximum adjusted risk for Down syndrome reaches 1:2. Other clinical examples are shown in Table 8–9. An adjusted risk of trisomy 21, based on the genetic sonogram, is given, even for high risk patients. For example, based on age alone, a 44-year-old patient is at high risk for fetal trisomy 21. However, if triple-screen results are 1 in 798 (a priori risk) and the findings on genetic sonogram are normal, the adjusted risk for trisomy 21 is 1 in 3990. If the same patient has one marker, the adjusted risk for Down syndrome is 1 in 591 (LR, 1.35) or remains the same at 1 in 798 (LR, 1.00), depending on the marker found.

Although it would intuitively seem that certain markers (e.g., nuchal fold thickening, cardiac defects) in isolation are very "strong" and would increase the risk for trisomy 21 (above an LR of 1.35), we have found these markers most frequently in combination with other markers. Therefore, for any marker in isolation (except the four described above, where the LR is 1.00), we use an LR of 1.35. Either a triple or a quadruple screen risk is acceptable as an a priori risk because most of our findings are based on high risk patients who underwent serum testing.

We and other investigators believe that risk adjustment for trisomy 21 is institution-specific and that the published experience from one center does not necessarily apply to another.[106] Each center performing genetic sonography must monitor their sensitivity for the detection of trisomy 21 to provide patients accurate, detailed, and updated counseling about their degree of risk reduction when scan findings are normal. Considering the range of expertise available in many countries, it is reasonable to suggest limiting genetic sonography to specialized centers.[64]

We analyzed the cost of universal amniocentesis and genetic sonography and concluded that genetic sonography was cost-effective when the sensitivity for the detection of trisomy 21 was greater than 74%.[107] We observed that genetic sonography saved the health care system 9% and reduced the loss rate of normal fetuses as a result of amniocentesis by 87%.[107] Genetic sonography is also cost-effective in women younger than 35 years who are at moderate risk for Down syndrome based on their triple-screen results as well as in patients with advanced maternal age who decline amniocentesis after second-trimester genetic counseling.[108] Offering genetic sonography to these patients is associated with cost savings for most acceptable genetic ultrasound accuracies. Finally, a recent study indicated that the combination of second-trimester genetic sonography with traditional serum markers may further improve diagnostic accuracy.[109] Various integrated algorithms combining serum analytes and sonographic markers have been reported (e.g., nuchal thickness, humerus length, serum α-fetoprotein, hCG) but have not been validated prospectively.

Nasal Bone

Nasal hypoplasia is part of the trisomy 21 phenotype. Cicero and associates[110] reported in 2001 that the nasal bone was sonographically absent in 73% of first-trimester fetuses with trisomy 21, with a false-positive rate of 0.5%. Shortly after that, Sonek and Nicolaides[111] reported a small series of second-trimester scans and noted that two of the three fetuses with trisomy 21 had a sonographically absent nasal bone; the third had a nasal bone length of less than 2.5% for gestational age.

Several studies (Table 8–9) examined the sensitivities and screen false-positive rates for trisomy 21 of a sonographically absent or short fetal nasal bone during the first or second trimester.[97,110–118] First-trimester sensitivity ranged from 60% to 73% (false-positive rate, 0.25%–0.6%), whereas second-trimester sensitivity ranged from 37% to 66% (false-positive rate, 0%–20%).

A recent study suggested that obtaining a fetal profile in the first trimester for the presence or absence of the nasal bone can improve the sensitivity for fetal trisomy 21 to greater than 95% (with a 5% false-positive rate) when combined with maternal age, NT, and the results of first-trimester biochemical serum screening (see Table 8–1).[114] We studied the usefulness of the finding of a sonographically absent nasal bone in a matched case–control study of 40 second-trimester fetuses with trisomy 21.[97] The facial profile was adequate in 29 (72.5%). Of these, 12 had an absent nasal bone, yielding a sensitivity of 41% and a specificity of 100%. Importantly, when absent nasal bone was added to the other sonographic markers of aneuploidy, the sensitivity of genetic sonography increased from 83% (24 of 29) to 90% (26 of 29).[97] Absence of the nasal bone was noted in two fetuses with trisomy 21 with no other ultrasound

markers for aneuploidy. Thus, we added this marker to the list of aneuploidy markers evaluated in a genetic scan.

Ossification of the nasal bone in fetuses affected with a trisomy may increase with advancing gestational age, explaining the lower sensitivity in the second trimester compared with the first trimester. Additional studies show absent nasal bone in first-trimester fetuses with trisomy 18 (50%–55%).[110,112] Lee and colleagues[116] reported at least 58 genetic syndromes that may be associated with a sonographically absent nasal bone.

THREE-DIMENSIONAL SONOGRAPHY

Three-dimensional ultrasound was first introduced in the late 1980s. Two-dimensional ultrasound acquires a single plane of image information with traditional transducers. Three-dimensional ultrasound acquires volume data with one of several techniques. The resulting data can be viewed as single or multiple planes, or in combination with a rendered image that conveys the information from the entire volume (the "classic" three-dimensional appearance).[119] The initial machines were somewhat slow, but display times decreased dramatically with the evolution of computer processors. The image quality is directly related to the image quality of the two-dimensional scan used to acquire volumes. In some cases, multiplanar imaging in a standard orientation allows the sonographer to be more confident of a finding compared with conventional two-dimensional imaging.

This technology has the potential to provide both the physician and the patient with more accurate and additional information about the fetus (e.g., extent or size of anomalies) than is possible with traditional two-dimensional sonography. Other advantages of three-dimensional sonography include rapid acquisition of volume data, use of new orientations and planes (not obtainable with two-dimensional scanning), maternal–fetal bonding,

and improved comprehension of the fetal anatomy by the patient and family.[119] The study of fetal behavior is facilitated by the rapid acquisition of data, which can be up to 16 frames/sec.[119] Technical problems occur with three-dimensional ultrasound because these scans are at least semimanual (the operator must remain still) and thus are in part limited by the operator's skill. Three-dimensional images are easier to generate with computed tomography because the scanning system is automatic and provides sequential slices.

Three-dimensional imaging can be more useful than conventional two-dimensional scanning for the evaluation of fetal malformations. Merz and colleagues[120] studied 204 anomalous fetuses and found that compared with two-dimensional ultrasound, three-dimensional ultrasound was advantageous in 62%, equivalent in 36%, and disadvantageous in 2%. In a similar study of 63 fetuses with 103 anomalies, three-dimensional sonography was advantageous in 51%, equivalent in 45%, and disadvantageous in 4%.[121] Several anomalies, such as cleft lip and abnormal facies, were seen only with three-dimensional ultrasound. Most anomalies were better visualized with three-dimensional than with two-dimensional imaging.[120,121] Although patient management was altered in only 5% of patients, the improved visualization derived from multiplanar and rendered images can help the physician and family to understand the anomalies.

First Trimester (See also Chapter 7)

Three-dimensional sonography is an excellent tool in the first trimester, allowing extensive and detailed evaluation of the embryo or fetus. Volume data are acquired with transvaginal transducers, and the resulting image is manipulated to identify the desired structures. One group reported that more anatomic structures were identifiable with three-dimensional compared with two-dimensional imaging.[122] As a result, the anatomic survey was more complete, and the detection of anomalies was

improved. Obtainable images include the stomach, bladder, umbilical cord insertion, NT, and limbs. Some investigators believe that three-dimensional ultrasonography will allow even greater accuracy and reproducibility of NT compared with two-dimensional sonography.[123] One advantage of three-dimensional imaging is that the embryo can be rotated into a sagittal plane, regardless of the acquisition plane, theoretically allowing NT to be measured in all cases. Hull and associates[122] observed that the actual scanning time for the patient was significantly less with three-dimensional ultrasound (2.7 minutes vs. 14.7 minutes).

Blaas and colleagues[124] studied the brain cavities of human embryos with three-dimensional ultrasound. Visualization was possible as early as 7 weeks. The brain cavities grow and develop with time, and their volumes can be measured accurately with three-dimensional ultrasound. Because the planes examined from transvaginal acquisitions cannot be acquired with two-dimensional ultrasound, the detection of congenital abnormalities should be improved. The detection of conjoined twins and ectopia cordis is reported with three-dimensional sonography.[119] In addition, the volume of the gestational sac can be measured in the first trimester; this measurement is more predictive of a successful pregnancy outcome than maternal hormone levels.[125]

Second- and Third-Trimesters

Three-dimensional imaging is useful in the second and third trimesters to image anomalies of the skull, brain, face, heart, spine, limbs, urinary tract, umbilical cord, and placenta.[119] Other applications being studied include evaluations of the placenta, umbilical cord, cervix, fetal weight, and uterine anomalies (e.g., bicornuate, septate).

One of the most valuable features of three-dimensional sonography is the ability to rotate the face so that it can be viewed directly and in an upright position. Surface-rendered displays are obtained successfully in 70% of patients.[119] Several studies noted that three-dimensional imaging is beneficial for the detection of facial anomalies, such as cleft lip or palate, midface hypoplasia, asymmetric facies, micrognathia, facial masses, hypotelorism or hypertelorism, facial dysmorphia (sloping forehead, flat facies, flat nose), holoprosencephaly, and deformed ears.[119] Three-dimensional imaging is particularly valuable in examining the face for cleft lip or palate, especially the primary, or hard, palate. Some anomalies that were detected on three-dimensional ultrasound were missed on two-dimensional ultrasound. These include cleft lip or palate, micrognathia, flat facies, unilateral orbital hypoplasia, and cranial ossification defect.[119] In one series, two-dimensional ultrasound identified only 45% of fetuses with cleft palate, whereas three-dimensional imaging identified 86%.[126] Artifacts produced from three-dimensional volumes can imitate "clefting" of lips that are actually normal. These artifacts include

shadowing from the umbilical cord adjacent to the face, motion during image acquisition, nasal bone shadowing, and identifying a nostril as a cleft.[119]

It is almost always possible to obtain a fetal profile. In addition, rotation of the volume allows consistent and accurate depiction of the midsagittal plane. Three-dimensional imaging of the face may be difficult early in gestation, if there is oligohydramnios, if limbs obscure the face, and when the face is very close to the uterine wall or placenta.[119]

Three-dimensional imaging is valuable in examining fetal skull defects, intracranial pathology and symmetry, and abnormal sutures or fontanelles of the skull. A new view has been suggested ("three-horn view") to examine the lateral ventricles, in which the anterior, inferior, and posterior horns are visualized together.[127] Fluid in the inferior horn is abnormal and is an early sign of ventriculomegaly. By placing the "marker dot" in the volume, the sonographer can "navigate" through ventricles, parenchyma, and cystic structures, and along vascular structures.[119] This knowledge can be important for consulting pediatric neurologists and neurosurgeons. The fetal spine is often imaged more clearly with three-dimensional sonography. Image quality is improved with rendering techniques that optimize the appearance of bone for the diagnosis of scoliosis, hemivertebrae, and neural tube defects. Studies suggest that three-dimensional evaluation of neural tube defects allows more accurate identification of the level, because the transverse and coronal images are viewed simultaneously with the rendered image.[128]

Three-dimensional sonography of the heart is difficult because of its rapid motion. Most current three-dimensional machines acquire only static, nongated volume images.[119] Cardiac abnormalities have been missed or misidentified with nongated acquisitions.[120] However, the great vessels can often be seen well. Cardiac gating is usually necessary to obtain an adequate cardiac image.[119] With gated volume data, the reviewer can slow the heart and evaluate its anatomy from various orientations in multiple planes throughout the cardiac cycle.[119] Sklansky and colleagues[129] found that fetal cardiac anatomy was more consistently shown and less dependent on the orientation (compared with two-dimensional ultrasound) of the volume acquisition when using gated data. Volume-rendered images of the ventricles, atria, great vessels, and valves were useful to assess the anatomy. In the future, volume measurements of the chambers may be helpful to evaluate cardiac function.

Abnormalities of the fetal abdomen and pelvis (and in some cases, their volume) can be imaged with three-dimensional ultrasonography (e.g., gastroschisis, omphalocele, bowel obstruction, hydronephrosis, multicystic dysplastic kidney). However, it is not clear whether additional information is obtained compared with two-dimensional sonography. Abnormalities of the genitalia may also be assessed with three-dimensional imaging.

The fetal extremities can usually be imaged with three-dimensional sonography because of the rapid acquisition. If the limb moves during an acquisition, the volume should be discarded and another one acquired. With conventional two-dimensional ultrasound, motion often obscures limb anatomy or makes assessment difficult. However, once a three-dimensional volume is obtained, the structure can be studied carefully without motion, and the limb can be "rotated" to various orientations for full evaluation. Rendered images can be used to evaluate surface and bony features and the number and position of digits. In evaluating the lower extremities for clubfeet, it is often difficult to determine whether this is a "transient" (false-positive) or "fixed" (true-positive) event. Three-dimensional imaging may help in some cases.

Three-dimensional ultrasound offers several advantages over conventional two-dimensional imaging in fetuses with skeletal dysplasia. Abnormal bone shapes, shortened ribs, and abnormal facies are more accurately identified with volume acquisition.[119] One author reported that three-dimensional ultrasound allowed identification of abnormalities that were not seen on two-dimensional ultrasound in 43% of fetuses (3 of 7) with skeletal dysplasias.[130] Specific bones may be imaged with three-dimensional sonography to narrow the normally wide differential diagnosis of skeletal dysplasias (see Chapter 21).

Three-dimensional sonography has been used to estimate fetal weight. Fetal weight has been estimated with volume data of the abdomen and extremities because it is impossible to obtain an entire fetal volume.[119] Preliminary studies suggest that three-dimensional ultrasound may be more accurate than two-dimensional ultrasound.[131] Fetal liver and lung volumes are also reported.[132,133] Chang and associates[132] found that two-dimensional ultrasound underestimated fetal liver volume.

Another area under investigation is the maternal cervix. Cervical funneling can be imaged with three-dimensional sonography, along with the entire cerclage, if present. Vascular structures and their distribution and extent (e.g., umbilical cord, vasa previa, placenta accreta, velamentous insertions, aneurysm of the vein of Galen) can be evaluated with three-dimensional ultrasound.[119] However, image acquisition may be difficult and time-consuming because of motion, flash artifacts, and the longer time needed to acquire volume with color and power Doppler techniques. Interventional procedures are also being performed with three-dimensional imaging, including oocyte aspiration, embryo transfer, treatment of ectopic pregnancy, and laser surgery.[119]

Perhaps one of the greatest advantages of three-dimensional sonography is improved bonding with the fetus. Among patients who undergo three-dimensional sonography for reassurance, women with a history of fetal or neonatal demise, those with a history of a fetus with congenital anomalies, those carrying fetuses with lethal anomalies, those treated for infertility, and couples who have a surrogate carry their pregnancy seemed to derive the most benefit.[119]

In summary, the world is three-dimensional, and three-dimensional ultrasonography provides anatomic images that are more easily understood by both physicians and patients. It offers women and their care team an improved understanding of the anomalies found on two-dimensional ultrasound, clarifies the extent of the anomaly, and provides visual confirmation of the reality of the abnormality. It also facilitates bonding with the fetus.

SCREENING FOR TRISOMY 18 AND OTHER ANEUPLOIDIES

Trisomy 18 is the second most common autosomal trisomy and has a uniformly poor prognosis. In the multicenter NT trial conducted by the Fetal Medicine Foundation, 325 first-trimester pregnancies were complicated by chromosomal abnormalities other than trisomy 21.[26] Fetal NT was greater than the 95th percentile for crown–rump length in 71%. In addition to increased NT, sonographic findings showed abnormality in many of these fetuses. Trisomy 18 was associated with early-onset intrauterine growth restriction, relative bradycardia, and in 30%, exomphalos.[36] Trisomy 13 was characterized by fetal tachycardia in 66% and by holoprosencephaly or exomphalos in 30%.[36] Approximately 40% of triploid fetuses show early-onset, asymmetrical intrauterine growth restriction, relative bradycardia, holoprosencephaly, exomphalos, or a posterior fossa cyst. Molar placental changes are seen in approximately one third.[36]

First-trimester serum biochemistry results may be abnormal in fetuses with aneuploidies other than trisomy 21.[36] In trisomies 13 and 18, serum free βhCG and PAPP-A levels are decreased. In sex chromosomal abnormalities, the maternal serum free βhCG level is normal, but the PAPP-A level is low. These analytes may also be abnormal in fetal triploidies, depending on the source of the third chromosome set. With paternal origin (diandric triploidy), a partial molar placenta is usually seen. The free βhCG level is greatly increased, and the PAPP-A level is mildly decreased. If the extra set is of maternal origin (digynic triploidy), the normal-appearing placenta is small; the fetus is severely, asymmetrically growth-restricted; and the free βhCG and PAPP-A levels are markedly decreased. Screening with a combination of fetal NT and serum free βhCG and PAPP-A allows identification of approximately 90% of these chromosomal abnormalities, with a screen-positive rate of 1%.[36]

Second-trimester serum triple-marker screening can identify 60% to 75% of fetuses with trisomy 18 when a separate analysis is performed that seeks low levels of all three analytes, with or without consideration of maternal age.[134,135]

Sonography has variable but high sensitivity for detecting trisomy 18 (64%–100%), particularly when the

examination is part of a thorough anatomic survey.[73] In a recent study, we found that all fetuses with trisomy 18 had four or more sonographic anomalies (one fetus had 19 separate detectable anomalies). Short ear length was present in 96%, bilateral clenched or closed hands or overlapping digits in 95%, and central nervous abnormalities in 87%. In another study, we observed shortened ear length (at or below the 10th percentile) in 100% of fetuses with trisomy 13, 96% of fetuses with trisomy 18, 75% of those with Turner syndrome, and 91% of those with other various aneuploidies.[100] Many investigators confirmed that abnormal hands are seen in most fetuses with trisomy 18.[73] Other sonographic abnormalities that are common in trisomy 18 include growth restriction, abnormal feet, choroid plexus cysts, and structural cardiac defects. We found intrauterine growth restriction in 63% of fetuses with trisomy 18.[73] Early-onset growth restriction is common in trisomy 13 and triploidy. In particular, triploidy is associated with a characteristic small body relative to the head.

Choroid plexus cysts are visualized in 1% (range, 0.3%–3.6%) of normal fetuses in the second trimester (see Fig. 8–9). These cysts may be associated with trisomy 18,[136] and in the past, genetic amniocentesis was considered even if they were isolated. However, a cyst can be considered "isolated" only after a detailed fetal survey shows no other structural abnormalities or markers. In our study, half of the fetuses with trisomy 18 had a choroid plexus cyst, but they were always associated with multiple other sonographic abnormalities (i.e., never isolated).[73] In another study, none of 98 fetuses with an isolated choroid plexus cyst had aneuploidy, whereas 100% of the 13 fetuses with a choroid plexus cyst and major anatomic abnormalities had trisomy 18.[137] In our experience, the risk of aneuploidy is very low and does not justify amniocentesis if no other anomalies are found (especially if the hands are open and the ear length is normal). Many investigators concur that if the choroid plexus cyst is isolated and the patient is at low risk for fetal aneuploidy, the presence of these cysts should not affect management. Like genetic sonography for screening for fetal trisomy 21, normal findings on a complete anatomic survey in experienced hands should "decrease" a patient's risk of trisomy 18 (regardless of the presence of choroid plexus cysts or abnormal triple-screen results) to a low level sufficient to avoid genetic amniocentesis after appropriate patient counseling.[73]

CRITICAL REVIEW OF THE EVIDENCE ON FIRST- AND SECOND-TRIMESTER SCREENING FOR FETAL ABNORMALITY

Both physicians and patients often ask whether first-trimester screening is more effective than second-trimester screening. Studies show that 85% to 90% of cases of trisomy 21 can be detected (with a 5% screen false-positive rate) in the first trimester (11–14 weeks) with a combination of maternal age, NT thickness, and serum biochemical screening (PAPP-A and free βhCG). This level of sensitivity seems significantly higher than that of second-trimester biochemical screening plus maternal age, which has a 60% detection rate (with a 5% screen false-positive rate). However, it does not account for the increased in utero lethality of trisomy 21 between the first and second trimesters. More than 10% of fetuses with trisomy 21 that are alive at 11 to 13 weeks are lost spontaneously by 16 to 18 weeks.[4] In addition, fetuses with trisomy 21 and increased NT thickness are more likely to be lost spontaneously.[4] These facts raise an important issue. Although first-trimester screening has the definite advantage of early diagnosis, we believe that the intrauterine lethality requires higher sensitivity rates compared with second-trimester screening for equivalent efficiency.

There is no uniform population-based screening for trisomy 21 in the United States. There are even variations in the specific second-trimester serum markers used, depending on the laboratory. Although some centers use integrated first-trimester screening, others use second-trimester serum marker screening, and some couple serum screening with an ultrasound for sonographic markers to derive individual risks for fetal trisomy 21. Although new developments in both first- and second-trimester screening offer women a variety of options for trisomy 21 screening, they increase the complexity of choices. The addition of more screening tests (especially when additive or sequential) can increase false-positive rates, patient anxiety, invasive testing rates, and procedure-related pregnancy loss. However, if sequential tests are interpreted in light of the results of earlier tests, it may be possible to decrease the invasive testing rates while maintaining high sensitivity.[4] Another variable to consider is that if 80% to 90% of fetuses with trisomy 21 are detected by first-trimester screening, the predictive values of second-trimester screening (ultrasonography and biochemical screening) are dramatically reduced.[4] In theory, second-trimester biochemistry will probably identify at best only 6% (60% of the residual 10%) of affected pregnancies while doubling the overall invasive testing rate (from 5% to 10%).

There is also no uniformity in screening for fetal malformations. Table 8–10 lists several approaches that may be used clinically. Examples of approaches are: A and D or E, B and D or E, C only, D only, E only, and F only. We prefer A and B and then D or E. We follow the protocol shown in Figure 8–27 and use the Fetal Medicine Foundation software to calculate a first-trimester risk (using NT and maternal age) for all patients, while noting the absence or presence of nasal bone. We anticipate incorporating first-trimester biochemical testing into the calculated risks once we validate first-trimester risk adjustments clinically. Although very good data support the efficacy of NT screening, we do not use the first-trimester

calculated risk as an a priori risk for genetic sonography for several reasons. First, not all examiners or centers performing NT screening do so accurately and with high quality. Second, there are no data on the accuracy of second-trimester genetic sonography when a priori risks are established by NT screening. Third, there are no data to suggest how to combine the findings of second-trimester sonographic markers and NT. Until there is clear evidence, we believe that it is premature to incorporate NT-generated risks as a priori risks in second-trimester genetic sonography.

How to use information obtained from first-trimester calculated risks when performing level II scans is also not clear. There is also a lack of data on the relationship between first- and second-trimester biochemistry results.[36] Therefore, regardless of the first-trimester risk adjustment (whether abnormal or normal), we recommend second-trimester serum screening because it offers additional benefits. For example, elevation of maternal serum α-fetoprotein and hCG can suggest placental disease, future development of intrauterine growth restriction, hypertension, or other abnormalities. A fetal anatomy survey or genetic sonogram is also performed, depending on maternal age and serum screening results (Table 8–10 and Fig. 8–28). Some patients may elect invasive testing (chorionic villus sampling or amniocentesis) as a first choice if they have advanced maternal age or abnormal serum screening results. In summary, although we recommend first-trimester risk calculation for all patients (and counsel accordingly at that time), we do not use these results to alter risk adjustment in the second trimester because of a lack of data.

The best method for patients is unclear. A reasonable approach might be to integrate all available markers into a single reported risk, with the goals of optimizing sensitivity and minimizing screen false-positive results. One group proposed an "integrated test," combining first-trimester NT and PAPP-A levels with the second-trimester quadruple serum screen.[138] Mathematical calculations were performed but not validated clinically. It was estimated that an 85% sensitivity rate for trisomy 21, with a very low 1% invasive testing rate, could be achieved with this approach.[138] For women 35 years and older, the predicted detection rate is 92%, with a screen false-positive rate of 3.3%. However, even if an integrated type of screening gains physician acceptance, its ultimate success will depend on patients' willingness to wait until 16 weeks to receive the combined results. Whether a patient chooses first-trimester screening or waits for an "integrated screen" will most likely vary, and the choice will depend on personal preferences, the types of invasive tests that are available, the risks that are present, the patient's plans for termination, and the patient's previous experiences. This concept may be more complex than it seems. A prospective multicenter trial funded by the National Institute of Health is being performed to address both first- and second-trimester screening (FASTER trial). The findings of this trial should shed important light on these questions and may affect the implementation of screening in the United States.

Two studies specifically examined the effect of first-trimester NT screening on second-trimester biochemical testing.[23,139] In the first study, the positive predictive value of second-trimester screening was initially 1 in 40. However, after the introduction of NT screening, when 83% of fetuses with trisomy 21 were identified in the first trimester, the positive predictive value of biochemical screening decreased to 1 in 200.[139] In the second study, first-trimester NT screening identified 71% of fetuses with trisomy 21, for a screen-positive rate of 2%. The

TABLE 8–10

Various Approaches Used Clinically in Screening for Fetal Malformations

APPROACH	DESCRIPTION	NOTES
A	First-trimester risk adjustment (nuchal translucency, biochemistry results, age), with or without nasal bone	Use FMF software (follow protocol in Fig. 8–27)
B	Second-trimester serum screening (triple or quadruple)	Quadruple screening has higher sensitivity
C	Invasive testing (chorionic villus sampling amnio) offered automatically to patients with advanced maternal age or abnormal serum screen results	Discuss risks and benefits of invasive testing Genetic sonogram not performed
D	Level II anatomy scan; offer amnio, depending on results	Not advanced maternal age or has normal serum screen results No calculated adjusted risk for aneuploidy given
E	Genetic sonogram (only high-risk patients); offer amnio if risk adjustment is abnormal	A priori risk: second-trimester serum screening (first) or maternal age Based on absence or presence of aneuploidy markers or structural anomalies on ultrasound, adjusted risk for Down syndrome given
F	No testing performed	
Ours	Both A and B, then D or E (based on age or results of second-trimester serum screening)	Although we incorporate both schemes (A and B), we do not use first-trimester risk as an a priori risk for genetic sonography If patients want only invasive testing, this is done

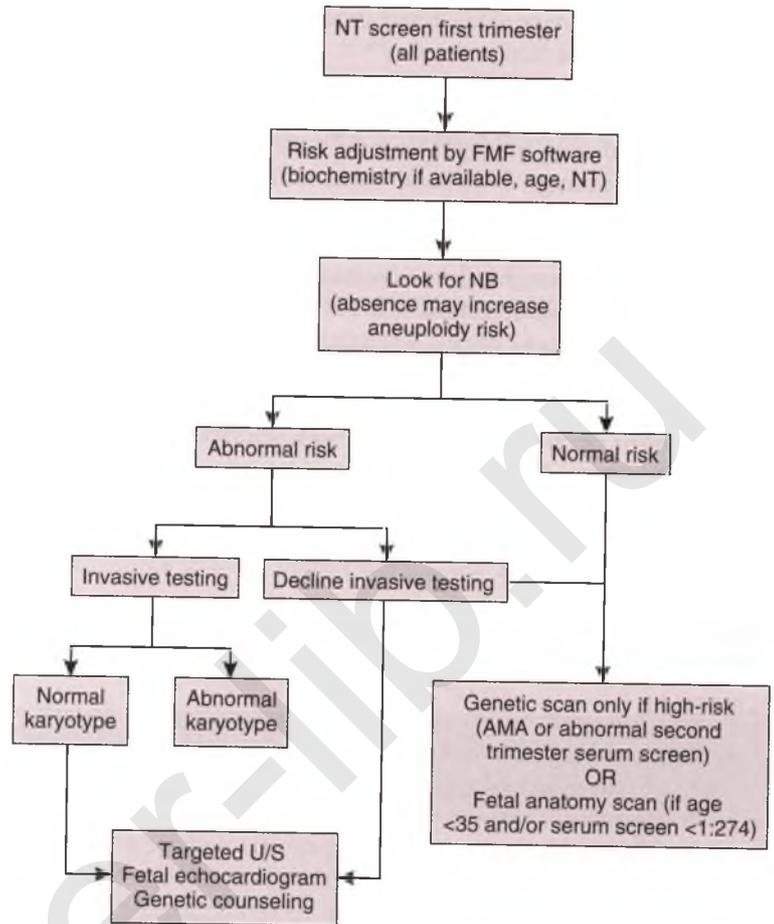
Amnio, amniocentesis; FMF, Fetal Medicine Foundation.


FIGURE 8–27

positive predictive value of second-trimester screening (via quadruple test) was only 1 in 150.[23] These studies suggest that the gain of an integrated approach may not offset the delay in results.

Several studies examined screening with a combination of fetal NT and serum biochemistry in the second trimester. Schuchter and colleagues[140] examined 9342 pregnancies and classified as screen-positive those with NT of 2.5 mm or greater as well as those with an estimated risk from biochemical testing of 1 in 250 or greater. The screen-positive rate was 7.2%, and the sensitivity for trisomy 21 was 95% (18 of 19 cases). Audibert and colleagues[141] examined 4130 pregnancies and classified as screen-positive those with NT of 3 mm or greater those with an estimated risk from biochemical testing of 1 in 250 or greater. The screen-positive rate was 5%, and the sensitivity for trisomy 21 was 90% (9 of 10 cases).

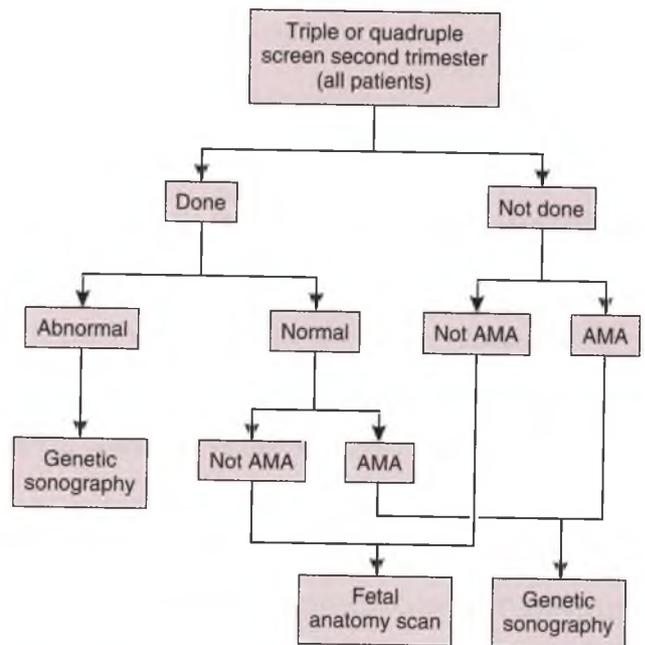
As previously discussed, there are no data on the interrelationship between second-trimester sonographic markers and NT or first- and second-trimester biochemistry findings.[36] It may be reasonable to assume that these factors are independent.[36] However, there may also be exceptions because the concept of sequential screening assumes independence between the findings of different screening results. For instance, the finding of nuchal edema or a cardiac defect during the second-trimester


FIGURE 8–28
Algorithm for second-trimester screening used at our institution. AMA, advanced maternal age. Genetic sonography is used only in high-risk patients (advanced maternal age at the time of delivery, abnormal serum screen, or both). For genetic sonography, we use serum screening (first) or maternal age (if the results of serum screening are not available or if the test is not performed) as the basis for the a priori risk.

examination cannot be considered independent of NT measurement in the first trimester.[36]

Potential changes will likely involve using both first- and second-trimester screening in some form. As future studies are published, first-trimester risk assessment (age, biochemistry findings, NT, nasal bone) will likely gain increasing and prominent importance, and may even become the standard of care, because this screening is noninvasive and offers the clear advantages of high sensitivity (97%) and early detection of fetal Down syndrome. Thus, second-trimester serum screening may fall out of clinical favor, with first-trimester calculated risks becoming the a priori risk. However, this screening will never be abandoned because many patients seek prenatal care after the first trimester.

We anticipate that first-trimester calculated risks will eventually be incorporated into second-trimester ultrasonography. Ultrasonography in some form will probably never fall out of favor because it offers many distinct benefits, both clinically and psychologically, for patients and physicians alike. We anticipate that, with growing expertise, more genetic sonograms will be offered as a first choice to high risk patients and will become the standard of care in this group, with targeted fetal scans reserved for the low risk patient. Some patients may prefer first- or second-trimester screening, just as some may prefer chorionic villus sampling to second-trimester amniocentesis. High sensitivity is important for high risk women, whereas low false-positive rates are most desirable among low risk women.

CONCLUSIONS

GENERAL

- Prenatal Diagnosis and Screening for Fetal Abnormalities Performed for Various Reasons
  - To provide reassurance to patients (and obstetricians)
  - To provide information and knowledge to patients
  - To provide opportunities for prenatal invasive testing
  - To provide counseling about the prognosis and modify management
- Some patients specifically request screening for the purposes of pregnancy termination. Other patients may not choose this as an option but wish to be prepared ahead of time, with the ability to have counseling with pediatric surgeons, geneticists, and other specialists well before the actual delivery date.
- Information about specific abnormalities or aneuploidies can optimize management of the pregnancy as well as labor and delivery, including resuscitative measures.
- Knowledge of abnormalities or aneuploidy can affect future pregnancies and alter counseling about prognosis and genetics.
- In practice, patients have many screening options available to them in both the first and second trimesters.
- Each test has advantages and disadvantages as well as varied sensitivities in detecting fetal Down syndrome or other forms of aneuploidy.

FIRST-TRIMESTER BIOCHEMICAL SERUM SCREENING

- Combined with maternal age, the sensitivity and false-positive rates for trisomy 21 are 63% and 5.5%, respectively.
- The two most discriminatory analytes are βhCG and pregnancy-associated plasma protein A.
- The results may also be altered in other types of aneuploidy.

FIRST-TRIMESTER SONOGRAPHY

- Transvaginal scanning should be performed to improve and optimize image quality when transabdominal scanning is suboptimal.
- The sonographer must be familiar with normal anatomic structures to recognize abnormalities.
- Ductus venosus Doppler velocimetry can discriminate between chromosomally normal and abnormal fetuses.

NUCHAL TRANSLUCENCY SCREENING

- Testing is performed only between 11 weeks, 3 days and 13 weeks, 6 days
- Testing is associated with aneuploidy, congenital heart disease, congenital anomalies, and genetic syndromes.
- Sensitivity varies from 29% to 100%, with screen-positive rates of 0.4% to 8%.
- Strict criteria for performance must be followed, and sonographers should be trained appropriately.
- Normal nuchal translucency values depend on the crown–rump length.

SECOND-TRIMESTER SERUM SCREENING

- Accurate dating of the pregnancy is essential.
- Triple-screen sensitivity for Down syndrome in women younger than 35 years is 60%, with a 5% false-positive rate.
- Quadruple-screen sensitivity for Down syndrome in women younger than 35 years is 67% to 76%, with a 5% false-positive rate.

SECOND-TRIMESTER SONOGRAPHY

- The RADIUS trial had low sensitivity for the detection of fetal anomalies; routine ultrasound did not affect the detection, management, or outcome of fetuses with anomalies and did not improve perinatal outcome.
- Much has changed since the RADIUS trial.
- A complete, targeted, and thorough examination should be performed,
- Sensitivity for fetal abnormalities varies widely, depending on the center and other issues.
- Testing is cost-effective in centers with reasonable accuracy for detecting fetal abnormalities.
- Genetic sonography should be offered only to high-risk patients and has sensitivities ranging from 50% to 93% (overall, 77%), with a screen false-positive rate of 13%.
- More patients prefer genetic sonography as their first option compared with invasive testing.
- Absence or shortening of the nasal bone is a sensitive sonographic marker for trisomy 21 in the first and second trimesters.
- Three-dimensional sonography has many advantages in the first and second trimesters.

SUMMARY OF MANAGEMENT OPTIONS
First- and Second-Trimester Screening for Fetal Abnormality

Management Options	Quality of Evidence	Strength of Recommendation	References
General			
Prerequisites:	See Chapter 9	–	–
• Details of the history, examination, and routine studies completed; known relevant risk factors identified			
• Prescan interview, discussions, and counseling			
Discuss the screening options in the first and second trimesters and decide on an individual pregnancy management plan (e.g., serum testing, ultrasound, invasive testing)	–	GPP	–
First-Trimester Serum Screening			
Use analytes βhCG and pregnancy-associated plasma protein A	IIa	B	1,2
	IIb	B	
May combine with maternal age, nuchal translucency, nasal bone	IIa	B	114
Use for other types of aneuploidy	IIa	B	4
First-Trimester Sonography			
Improved by the transvaginal method	IV	C	5
Screen all patients with this test	–	GPP	–
Nuchal Translucency Screening			
Screen all patients with this test	–	GPP	–
Express measurements relative to gestational age or crown–rump length as a delta value or multiple of the median. Use multiple of the median and derived likelihood ratios to generate patient-specific risks	IIa	B	26

Continued

First- and Second-Trimester Screening for Fetal Abnormality *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Nuchal Translucency Screening			
Offer karyotype testing if the results are abnormal; if the karyotype is normal, examine for structural defects (especially cardiac) and various syndromes	IIa IV	B C	4 11
Combine with nasal bone imaging	IIa	B	114
Use ductus venosus Doppler velocimetry to determine which nonaneuploid fetuses with increased nuchal translucency thickness are at risk for cardiac defects	III	B	44
Second-Trimester Serum Screening			
Use quadruple screen testing for greater sensitivity	IIa	B	66, 67
Combine with detailed sonography to screen for aneuploidy	III	B	94
	IIa	B	104
Second-Trimester Sonography			
Perform a detailed survey to increase sensitivity, and screen all patients with this test	–	GPP	–
Genetic sonography should be offered only to high risk patients and performed by experienced laboratories	III	B	94
Use three-dimensional ultrasound to add more information to two-dimensional scanning, if available	IV III	C B	119 120, 121
Authors' Practice			
For all patients, perform first-trimester screening (nuchal translucency, age) and look for nasal bone (biochemical screening in the future)	IIa	B	114
For all patients, perform second-trimester serum screening (quadruple preferred)	IIa	B	66, 67
For all patients, perform level II or genetic sonography (both detailed examinations for aneuploidy markers and structural anomalies), depending on maternal age or serum screening results.	III IIa	B B	94 104
Invasive testing also discussed as an option, when applicable	–	GPP	–
Perform three-dimensional ultrasound, if necessary	IV III	C B	119 120, 121

Counseling and Management of an Abnormal Result on a Screening or Diagnostic Test for Fetal Abnormality

Lauren Kerzin-Storrar / Sarah Vause / Michael Maresh

INTRODUCTION

Although medicine benefits from many technologic advances, too often the communication of information about these advances to our patients lags behind. The individuality of patients and their feelings and values must be considered when imparting information.

The goal of current medical practice is to provide a quality service, and we must ensure that our patients are as satisfied as possible. Thus, there is little benefit in providing a scientifically excellent antenatal screening program if our patients are unhappy with the way that the information is presented. Too often, communication issues are considered unexciting and are the subject of very little research in contrast to the vast sums spent developing and evaluating new screening methods. No new screening test should be introduced into routine practice without comprehensive education for those who are in contact with patients, backed up by information leaflets that have been developed in conjunction with patients' groups.

Concept and Perception of Risk

One area that both health professionals and the public have difficulty with is the concept of risk. What is the real meaning to an individual of being told that her unborn baby has a risk of 1% of having a certain condition? To a woman who has a 1 in 4 (25%) risk of having the condition, 1% may seem very low, whereas to another who has a lower background risk (e.g., 1 in 1000), it may seem very high. In addition, the interpretation of the terms "low" and "high" may vary between professionals and parents.

In pregnancy, for historic reasons, a cutoff of 1 in 200 or 250 has developed as differentiating between high and low risk (possibly from the perceived risk of miscarriage from amniocentesis). In other areas of medicine and life, other cutoffs may be used. Yet, can a woman compare the risks encountered in other walks of life, such as the risk of having an accident on a certain stretch of road, with the risk of her baby having a major abnormality?

Attributes of a Screening Test

Before the introduction of a screening test, ideally, the test has been shown to have the following attributes:

- **Relevance.** The condition must be a relevant and important medical condition. For example, prenatal screening for a major cardiac abnormality is clearly relevant, but screening for cleft palate is more debatable.
- **Effect on management.** Alternative management options must be available. For example, with a suspected diaphragmatic hernia, management options include planning for delivery in a tertiary care center.
- **Sensitivity.** The screening test must detect the vast majority of cases. For example, serum screening for Down syndrome using only two serum markers is not considered sufficiently sensitive (approximately 60% sensitive for a 5% false-positive rate).
- **Specificity.** The screening test must exclude the vast majority of patients who do not have the condition.
- **Predictive value.** More relevant than specificity and sensitivity in practical counseling is the predictive value of a test. If a woman has a positive result on a screening test for Down syndrome, she wants to know

the likelihood that her baby will have this condition so that she can balance this knowledge with the risks of an invasive diagnostic test, such as amniocentesis.

- **Reproducibility.** When repeated, the test must produce the same results in the same patient. Laboratories that perform serum screening for Down syndrome participate in quality control programs. Routine use of nuchal translucency screening requires appropriate and regularly checked equipment. In addition, the operator must be appropriately trained and involved in the evaluation of data quality.
- **Affordability and availability of resources.** Before the introduction of a test, the resources must be identified for both equipment and personnel. Too often, a suboptimal service is introduced because no time is allowed for counseling.
- **Equity of availability.** If a screening service is being introduced within the context of a national program, then it must be available in all areas (rural and urban) and to all relevant populations, including minority groups.

Ethical Issues

The following ethical issues must be considered as well:

- The ability of caregivers to separate their own moral and ethical viewpoints from the decision-making process.
- Societal and cultural attitudes about disability, not only in general terms, but also regarding the degree of disability. These attitudes may vary enormously in multi-ethnic environments, such as may be found in parts of Europe or North America. In addition, in some societies, screening is equated with eugenics, whereas in others, it is regarded as a natural right.
- The validity of assessing the costs and benefits of screening by comparing the costs of screening with the costs incurred in life by a person with a disability. Is it possible to put a value on life in this way?

Legal Issues

Some relevant legal issues are discussed briefly here and more fully later. There have been recent reviews of the law in the United Kingdom and the United States.[1,2]

- **Provision of a comprehensive service.** In the United Kingdom, the National Health Service has a statutory responsibility to provide a comprehensive service. Recent recommendations have been made with regard to screening for Down syndrome.[3] If the service is not available as described by a certain date, the hospital or local authority may be liable.
- **Informed consent.** Before a management decision is made, the patient must be counseled and provided with the necessary information to allow her to make an informed decision. For example, if a clinician does not

make it clear and document that termination of pregnancy is an option, the clinician may be liable after childbirth if the woman decides in retrospect that she would have preferred to have the pregnancy terminated.

- **Operator skill.** All clinicians must be competent in the areas in which they work. Those involved in invasive procedures must demonstrate that they are performing sufficient numbers of procedures to remain skilled. If a woman miscarries after an amniocentesis and it is clear that the clinician is performing significantly fewer procedures than published guidelines recommend,[4] the court might find the clinician liable.
- **Termination of pregnancy.** English law is complex and involves several separate acts; however, clear summaries are available.[1] There is no gestational age limit for termination of pregnancy for fetal handicap. What is required is that two physicians believe in good faith that there is a substantial risk that the child would suffer from such physical or mental abnormalities as to be seriously handicapped. The imprecise terms "substantial" and "seriously" tend to allow consensus medical opinion to determine the working of the law[5]. In the United States, although laws on the availability of abortion vary from state to state, the judgment in specific cases of fetal abnormality is usually left to health care rather than legal professionals.[2]

Thus, the management of an abnormal screening test result involves many challenges and pitfalls for the health professional. In addition, it puts the staff involved under frequent pressure, and the welfare of the staff involved in this difficult work should not be forgotten. This chapter describes strategies to help women who have an abnormal result on a screening test. The evidence base is regrettably limited, and this is a challenge for the future.

PRETEST COUNSELING

Before a prenatal screening test is performed, counseling is essential to ensure that the woman (and her partner, when relevant) can make an informed choice about whether to have the test and also to prepare her for the possible outcome of an abnormal screening or diagnostic result.[6] Biochemical and ultrasound screening for abnormality is now available to all pregnant women in many centers, regardless of previous risk, and providing quality counseling to large numbers of women has become a challenge in contemporary maternity care. Some express the view that because most screening tests provide reassurance, it is wrong to raise unnecessary anxiety through detailed discussion before a screening test is performed, and that from a resource perspective, more time should be spent counseling women with positive screening or diagnostic test results. However, if the aim of informed consent is to be fulfilled, full and accurate information must be available before a woman decides whether to opt for screening.

Informed Consent: Opting in or Opting Out?

Because screening tests have been incorporated into standard prenatal care, the issue of consent has focused on women who choose to opt out of a process seen as routine, rather than on ensuring that women who do consent have made a positive decision to opt in to a genuinely optional screening program.[7] One approach to promoting choice is to provide pretest information and counseling on a separate day from the screening procedure, so that women who want testing make the positive choice to return to the clinic on another day.[8] Although this approach may inconvenience women who find an additional prenatal visit impractical for socioeconomic reasons, it is important to avoid the presumption that most women want screening tests and that those who do want them must justify their decision.

Needs of Different Patient Groups

Although basic general principles for providing information and counseling apply to all women offered tests in pregnancy, the needs of women may vary according to their previous obstetric and family history as well as their cultural background. Most women who undergo screening tests have a low previous risk of abnormality, and many perceive screening as an opportunity to gain reassurance about the normality of their baby. It has been argued that this perception presents a greater challenge for professionals to ensure informed consent.[9,10] In contrast, some women at high genetic risk may approach testing with a heightened expectation that the baby will be affected. Their needs are therefore focused on receiving access to up-to-date, relevant testing as early as possible. Awareness of these potential differences can improve communication and understanding between clinicians and patients.

Women at High Genetic Risk

Women at increased genetic risk are likely to have the following characteristics:

- History of poor pregnancy outcome
- Anxiety
- Well-informed
- Tentative attitude toward the pregnancy
- Desire to delay routine prenatal care until after testing is complete
- Need for prenatal diagnosis in future pregnancies

Women who Perceive they Are at Increased Risk

Women may believe that they are at increased risk because they have one or more of the following characteristics:

- A previous affected child (although the risk of recurrence may be low)
- A positive screening result in one or more previous pregnancies
- Advanced age

With changes in society, increasing numbers of women are having children in their later reproductive years. These women are at increased risk of having a baby with Down syndrome. Some of these women and also those who have had a previous baby with an abnormality may believe that the uncertainty associated with screening methods is unacceptable and may wish to move straight to a diagnostic test, with its small but definite risk of miscarriage.

A particularly difficult scenario that is becoming increasingly common is that of a woman in her late 30s who, after years of trying to conceive, has done so with the aid of assisted reproduction techniques and has a multiple pregnancy. This is likely to be her only pregnancy, she is at increased risk of having a child with Down syndrome and other congenital anomalies, amniocentesis carries a risk to both pregnancies, and feticide has a significant risk of losing both pregnancies. In addition, there may be the added problem of triplets. This situation raises the further difficult issue of selective reduction. It is incumbent on the assisted reproduction service to ensure that all of these issues have been discussed in advance. In the future, the use of embryo aneuploidy screening may reduce the complexity of the management, although it has its own potential problems. Often it appears to those providing pregnancy care that with the enormous desire of the woman to achieve a pregnancy and the goal of the assisted reproduction service to obtain good results, these issues have not been discussed in depth. As a result, the early part of pregnancy is a time of anxiety while the patient undergoes multiple counseling sessions to determine the best way to proceed.

Women at Population Risk

Women with increased population risk are likely to have the following characteristics:

- Less likely to be well informed
- Unlikely to have personal experience with the conditions that testing may detect
- Usually expect a normal finding

Cultural Issues

Within a multicultural society, specific issues that need to be addressed may include the following:

- Religious beliefs, particularly in relation to pregnancy termination
- Attitudes of the community toward a congenital abnormality or disability
- Role of the partner and extended family in pregnancy decisions
- Language barriers (where English is not the first language)

Assumptions are often made about the views of members of certain racial, cultural, or religious groups on the acceptability of termination of pregnancy. These assumptions may affect the discussion of test results, follow-up diagnostic tests, and the option of termination of the pregnancy.

Clinicians may also, consciously or unconsciously, alter or delay clinic appointments if they do not believe that women from certain ethnic or cultural backgrounds will consent to antenatal tests. Physicians and midwives should be aware of this possibility and take steps to ensure equity and avoid discrimination. Although some evidence shows that women from specific ethnic minority groups, including Pakistani and Bangladeshi Muslims (in the United Kingdom) and Mexican Americans (in the United States), are less likely to accept prenatal screening tests, attitudes among women within the same ethnic group may vary considerably.[9,11–13] Therefore, it is important to avoid generalizations while recognizing potential culturally sensitive issues.

Information Content

There are clear recommendations (Table 9–1) about what information should be made available to women before screening tests are performed.[14,15]

Providing an accurate description of the condition being tested for is essential, and obstetricians and midwives must stay up-to-date on the long-term outlook for affected individuals.[16,17] Although serum screening programs for Down syndrome are often emphasized, opinion varies as to whether information should be provided on other, less common chromosomal conditions that may be identified through screening. Women should be informed that less common conditions can be identified, but detailed descriptions of these conditions are not needed at this point.

In the case of ultrasound screening for abnormality, providing such detailed information would be impossible. Many potential abnormalities could be identified, and much of the information may not be available. In 1997, the Royal College of Obstetricians and Gynaecologists suggested a practical approach to providing information before ultrasound screening (Table 9–2).[14]

Women must be made aware from the outset that an offer of termination of pregnancy is a potential outcome of screening. Some women may decline screening on this basis alone. However, they should also be made aware that screening may detect conditions that can benefit from prompt treatment in the neonatal period and that testing may allow the care of their baby to be optimized.

Providing Information

The provision of information is a process that ideally begins preconception, particularly for those at genetic risk, and continues until after delivery when an abnormality is identified. This emphasis on process is important, and the amount and nature of information needed at each stage vary. The information provided at each stage should address the key decisions currently facing the woman and her partner. These are summarized in Table 9–3.

Many approaches to information provision are used, including written leaflets, touch screens, videos, group discussion, and one-to-one counseling. There is no evidence that a particular method improves understanding or affects participation in screening,[18,19] but several studies reported that the quality (measured in terms of comprehensiveness, accuracy, presentation, and accessibility of language) of both written and spoken information varies considerably.[15,20,21] Peer-reviewed written information leaflets are now available, and these may also be used as a template for individual institutions to produce

TABLE 9–1

Prescreening Information Content[14,15]

Description of the condition
  Prognosis
  Available management (e.g., medical, social)
  Variability
Chance that the baby with have the condition
Procedures and risks to the pregnancy
Accuracy of the test, including the meaning of a screen-positive (increased risk) result and a screen-negative (decreased risk) result
Potential problematic outcomes of the screening process:
  Affected pregnancy and offer of termination
  Positive screening test result in an unaffected pregnancy
  Possibility of identifying an unexpected condition

Adapted from RCOG: Ultrasound screening for fetal abnormalities: Report of the RCOG Working Party. London, Royal College of Obstetricians and Gynaecologists, 1997, and Murray J, Cuckle H, Sehmi I, et al: Quality of written information used in Down syndrome screening. Prenat Diagn 2001;21:138-142.

TABLE 9–2

Prescreening Information Content: Ultrasound Screening for Abnormality[14]

The scan may:
  confirm normality
  identify a fatal condition
  identify significant conditions that are untreatable, but compatible with survival
  identify treatable conditions
  detect abnormalities with uncertain significance
  detect "minor" features or abnormalities
The scan findings may lead to:
  the offer of invasive tests, such as amniocentesis
  the offer of termination of pregnancy

Adapted from RCOG: Ultrasound screening for fetal abnormalities: Report of the RCOG Working Party. London, Royal College of Obstetricians and Gynaecologists, 1997.

TABLE 9–3

Key Decisions at Different Stages of the Counseling Process

STAGE	DECISIONS
Preconception (particularly for those at increased genetic risk)	Should I have a child? Which reproductive options available are acceptable to me (e.g., prenatal diagnosis, assisted conception)
At the offer of a screening test	Do I want this test? What would I do with a screen-positive result?
After a screen-positive result	Do I want to have further invasive tests? What will I do when I receive the result?
After an abnormal diagnostic result After delivery or termination of a baby with an abnormality	Should I continue with the pregnancy? Did I make the right decision? (Was the prenatal diagnosis correct?) Should I have another child?

locally appropriate patient literature, including translated versions for non-English-speaking patients.[22,23]

Who Should Provide Counseling?

A multidisciplinary approach to maternity care means that a wide range of health professionals will be involved in the delivery of screening and diagnostic tests. Primary care physicians, obstetricians, midwives, and nurses may play a role in presenting screening tests and facilitating informed choice; however, this is likely to represent a small proportion of their overall workload. On the other hand, specialists such as those working in fetal medicine units and genetic services may be involved in disclosing abnormal prenatal diagnostic test results and managing the sequelae on a daily basis. Both the "generalists" and the "specialists" play an important role in prenatal screening, and both groups require training in counseling issues.

Important points to consider include the following:

- Knowledge of the test and condition
- Personal attitudes toward screening, termination, and the patient's choices
- Communication skills, including explaining risk and facilitating decision-making

In the United Kingdom, the National Screening Committee commissioned the establishment of a national network of training workshops for midwives, ultrasonographers, obstetricians, and general practitioners, and the Royal College of Obstetricians and Gynaecologists and the Royal College of Radiologists jointly offer courses that include counseling issues.

Communicating Results

An important issue for women is knowing how, when, and by whom they will be informed about the results of screening tests. When possible, women should be given the choice of how they want the results to be given. Some women prefer a face-to-face discussion, whereas others might wish to hear the news by telephone or letter in the privacy of their own home, before coming in for a discussion of a positive result. For women who are at high risk for abnormality, it may be helpful to have a prearranged appointment to discuss the results, given the increased level of anxiety and the expectation of an abnormal result. This also allows the woman's partner to be present when the results are communicated and allows the woman and her partner to prepare emotionally and practically. For all women, the agreed arrangements should be written in the case notes, for reference when the results are available. Arrangements for giving results are also relevant to the vast majority of women who receive screen-negative results. The importance of communicating screen-negative results promptly should not be underestimated.

Communicating results is a more complicated issue in the context of ultrasound screening for abnormality because "results" may emerge during the procedure. This can be stressful for the person performing the scan as well as for the woman and her partner, if present. Although different units have different protocols, the important principle, again, is clarity. Sonographers are governed not only by their own professional body's guidelines, but also by the protocols in their own departments.[24] The sonographer should explain at the start of the scan how concerns will be discussed, whether during the scan, at the end of the scan, after consultation with colleagues within the scan unit, after a report is issued to the obstetrician, or after a further ultrasound scan.

As with other professional groups, appropriate training in communication skills, an awareness of personal limitations, and clear guidelines for working in multidisciplinary teams enable sonographers to provide appropriate care in a difficult situation.[25,26]

COUNSELING FOR SCREEN-POSITIVE RESULTS

General Issues

Every hospital or unit should have a policy for communicating abnormal screening results. These issues should be decided, in conjunction with the woman, before testing. Midwives and sonographers, as front-line professionals, often must break the news of a screen-positive result.

Presenting screen-positive results in a way that allows the woman and her partner to interpret the findings and make a decision about invasive testing is a challenge. Helpful guidelines include the following:

- Use the word "chance" or "likelihood" because "risk" implies an assumption that an affected child would be viewed negatively.
- Give the numeric risk in two forms, such as a percentage and a ratio.
  "There is a 1 in 100, or 1%, chance that the baby will have Down syndrome."
- Reverse the risk to explain the chance that the baby will be unaffected.
  "In other words, there is a 99 in 100, or 99%, chance that the baby will not have Down syndrome."
- Compare the screen-positive figure with the risk before testing or the population risk.
  "Before your screening test, your chance of having a baby with Down syndrome at this age was 1 in 300. Now, with this test result, the risk has increased to 1 in 100."
- Use descriptive analogies if the woman has difficulty understanding the concept of probability.
  "If we had 100 women in the clinic, all of whom had the same screening result as you, we know that one of the women would be carrying a baby with Down syndrome, but the other 99 would be unaffected."
- Avoid the use of descriptive terms that are subjective, such as "low" or "high," other than in response to the woman's interpretation.
  "I understand that you are concerned and that you feel that this is a high risk. It is certainly considered high enough to offer you an amniocentesis, but it is important to remember that there is a 99% chance that the baby does not have Down syndrome."

Although the risk of an invasive test, such as amniocentesis, should also be presented, it should not be considered a direct comparison with the risk of having an affected child. For some women, a miscarriage may be the worst possible outcome, whereas for others, the highest priority is to avoid the birth of an affected child.

Decision to Have Invasive Test

One aim of informed consent before screening is to encourage women to think about what they might do if they receive a screen-positive result or if a possible abnormality is identified on a scan. However, many women do not consider their options until they are faced with the decision of whether to proceed to an invasive test, such as amniocentesis.

There have been few published studies of the number of women who consent to amniocentesis after a screen-positive result for Down syndrome, and this is likely to vary from center to center because of cultural and socioeconomic differences. However, from our own experience and from the limited evidence available, a substantial proportion of women who consent to screening choose not to proceed to invasive testing, given a screen-positive result.[27]

Of women who choose to proceed, not all do so with the intention to terminate. They may choose an invasive test for any of the following reasons:

- To allow them to prepare psychologically and practically in advance of the birth of an affected child
- To influence obstetric management. For example, if ultrasound found severe early-onset growth retardation, a woman might choose to have amniocentesis even though she would not consider termination. If she knew the fetus had trisomy 13, trisomy 18, or triploidy, she might choose not to have further scans, not to be monitored in labor, or not to have a cesarean section.
- To make the decision to terminate an affected child

Specific Screening Problems

Even if women have had adequate pretest counseling, most are poorly prepared for a positive result from a screening test.[28] Although women may be well informed about the practical aspects of the test, they are less well informed about aspects of the test that could inform their decisions about whether to undergo diagnostic testing and prepare themselves for an adverse outcome.[29]

The following specific problems may be encountered in patients who have positive screening test results:

- Ongoing anxiety after false-positive results
- Soft markers
- Inability to provide a specific diagnosis antenatally
- Variations in options for diagnostic testing based on gestation
- Lack of specificity
- Issues associated with multiple pregnancy

False-Positive Results

All screening tests give false-positive and false-negative results, and handling these results presents a significant challenge. Although recently introduced screening tests for Down syndrome have lower false-positive rates than older tests, it is inevitable that they will occur.

False-positive screening test results may lead to ongoing anxiety. Women who receive negative results from a

diagnostic test after a false-positive screening test result may have enormous relief initially, but worries often re-emerge later.[30] If the baby doesn't have Down syndrome, what does it have? Women frequently search for explanations of false-positive results. Even after the birth of an unaffected child, these worries can persist.[31]

Younger women with false-positive results often have very high levels of anxiety, even after normal karyotype results. Research shows that women who are classified as high risk on the basis of a blood test have higher levels of anxiety than those with the identical numeric risk based on age alone.[32] Professionals should be aware of these issues and address them in their counseling.

Soft Markers

The concept of soft markers is difficult to explain and can lead to ongoing anxiety about the function of the respective organ. For example, the detection of an echogenic focus in the heart may lead a woman to be concerned about congenital heart abnormalities or cardiac function. Choroid plexus cysts are poorly understood by obstetricians who provide a range of counseling, often advocating unnecessary follow-up. This may lead to ongoing anxiety in women or their partners regarding the "cysts in the brain" and requests for follow-up scans that are at times agreed to.[33] Visual imagery is powerful, and anomalies detected on ultrasound may exaggerate the psychological costs (e.g., nuchal thickening, choroid plexus cysts).[34] Clinicians may alleviate this by taking care to choose appropriate language and to avoid reinforcing the ongoing anxiety by arranging further testing that may or may not show resolution of the marker.

Inability to Provide a Specific Diagnosis or Prognosis

Discussing isolated structural abnormalities is often relatively straightforward. It is far more difficult to counsel a patient when multiple abnormalities are detected or when there is an inability to provide a specific diagnosis. When multiple abnormalities are detected, it is important to convey the concept that each abnormality cannot be taken in isolation and that a combination of abnormalities may indicate an underlying syndrome or genetic disorder. The inability to provide a specific diagnosis or cases in which there may be a variable prognosis may result in ongoing uncertainty for both the woman and staff. For example, isolated ascites with negative test results for viruses, antibodies, and a normal karyotype have an extremely variable prognosis, ranging from a normal baby to a one with a lethal genetic condition. Isolated ventriculomegaly is another such finding in which the neurodevelopmental outcome can vary from normal to significant disability. Such uncertainties in the prognosis should be acknowledged and explained, and referral to a clinical geneticist may be helpful.

Gestation

The point in gestation at which the result of a screening test is available can affect which diagnostic test is offered. A woman who obtains a high risk result after first-trimester screening has the option of undergoing chorionic villus biopsy or waiting until the second trimester for an amniocentesis with a lower risk of miscarriage.

A two-stage integrated test for Down syndrome screening has been proposed. This includes first-trimester screening, with the second part of the test performed in the second trimester. Women must choose whether they wish the results to be revealed in a staged way, and if high risk, after the first stage of testing; whether to have diagnostic testing in the first trimester; or whether to wait until the results of the second-trimester test are integrated. Waiting until after the second-trimester component is obtained reduces the false-positive rate. Counseling, both before and during the testing process, would be extremely difficult.

Lack of Specificity

In addition to being a marker for Down syndrome, an increased nuchal translucency measurement is associated with cardiac abnormalities,[35] other structural abnormalities, and poor pregnancy outcome.[36] If a thickened nuchal translucency is detected but the karyotype is normal, a detailed second-trimester scan and fetal echocardiogram should be considered. Ongoing testing engenders ongoing anxiety. Even if no anomalies are detected on ultrasound, it is difficult to provide complete reassurance because some anomalies may be undetected or are undetectable on ultrasound.[37]

A further example is an increased level of α-fetoprotein, which is associated with structural abnormalities and later growth retardation, preeclampsia, preterm delivery, abruption, and fetal death. Ongoing follow-up should be offered and complete reassurance cannot be given, even if abnormality is excluded.

Multiple Pregnancy (See also Chapters 24 and 60)

In a multiple pregnancy, determination of chorionicity is important and is best done in the first trimester. The incidence of abnormality is higher in multiple pregnancy. Before screening tests are performed, it is important to discuss the options available for diagnostic testing and subsequent termination, if necessary.

If diagnostic testing, such as amniocentesis, is performed in a multiple pregnancy, it is extremely important to document precisely and rigorously which sample comes from which fetus. Features such as the position of the fetus in the uterus, placental site, and fetal sex can be used to identify each fetus. The importance of this documentation becomes apparent when there is one normal result and one abnormal result.

A woman with a twin pregnancy should be made aware of the option of selective reduction. This discussion should include the risk of miscarriage of the healthy twin. The woman should be informed that the terminated fetus remains within the uterus until delivery and that it must be registered as a stillbirth if delivery (not termination) occurs after 24 weeks' gestation. Selective feticide with potassium chloride injection cannot be performed if the twins are monochorionic because the potassium may cross through the placenta into the normal twin. Selective reduction by cord occlusion is possible in monochorionic twins. Potassium chloride feticide can be used for selective reduction in dichorionic twins.

Although structural abnormalities may be diagnosed in a twin around the time of the "20-week" anomaly scan, it may be more appropriate to wait for viability of the other fetus in the early third trimester before performing the selective termination. The advantages of delaying the termination should be explained, and the woman's views on the timing of the termination should be taken into account.

Problems with Diagnostic Tests

Diagnostic tests may produce any of the following:

- Unexpected results (e.g., sex chromosome trisomies, structural rearrangements, mosaicism)
- False reassurance
- Findings that show nonpaternity
- The need for an unexpected and sometimes ethically challenging decision

Unexpected Results

Although prenatal diagnostic testing is often performed because of concerns about trisomy 21, other chromosomal abnormalities may also be detected. In some cases, such as when trisomy 18 or trisomy 13 is detected, the outcome for the infant if the pregnancy continued is predictable. For these conditions, clear information can be given to a couple to enable them to make an informed choice as to whether to continue with the pregnancy or terminate.

In other situations, for example, when a sex chromosome abnormality, a balanced structural rearrangement of the chromosomes, or mosaicism is detected, then predicting the likely outcome for the infant is much more difficult. Involvement of a clinical geneticist is frequently required.

SEX CHROMOSOME ABNORMALITIES (TURNER SYNDROME XO, KLINEFELTER SYNDROME XXY, TRIPLE X SYNDROME XXX, EXTRA Y XYY)

When a sex chromosome abnormality is diagnosed antenatally, the parents should be offered expert counseling by clinical genetics professionals.[38] The obstetrician or other professional who initially discloses the diagnosis must avoid giving inaccurate or out-of-date information on the implications of the chromosomal abnormality. A recent study emphasized the effect of this first information on parents' decisions and on their perception of the more expert information given to them later in the genetics clinic.[19] As more information about the long-term outcome becomes available from prospective studies, more parents opt to continue the pregnancy.[4,39–41] The main issues for parents faced with the decision of whether to continue with a pregnancy in which the fetus has been found to have a sex chromosome abnormality appear to be worries about congenital abnormalities, the risk of mental retardation, behavioral problems, and the prospects for establishing sexual identity, future sexual relationships, and a successful family life.[42]

STRUCTURAL REARRANGEMENTS

If the rearrangement appears balanced, there should be no harmful effects. However, if it occurs de novo and is not found in either parent, it could cause congenital abnormalities or mental retardation. Because the phenotypic effects of a de novo translocation are unpredictable, it is difficult to provide parents with information to use when making decisions about whether to continue with a pregnancy or terminate. Input from clinical geneticists may be useful. Detailed tertiary-level scanning may have a role. If an abnormality is seen on a scan, it would support the assertion that the rearrangement is exerting a phenotypic effect. However, a normal ultrasound provides limited reassurance because it may detect only approximately one third of abnormalities.

MOSAICISM

Chromosomal mosaicism is the mixture of two or more cell lines with different chromosome constitutions. Mosaicism causes difficulty in interpretation and adds uncertainty to counseling. The difficult is in determining whether this represents the pattern in the fetus, reflects confined placental or membrane mosaicism, or is an in vitro artefact. Chromosomal mosaicism confined to placental tissue, with a normal fetal karyotype, is relatively common (1%). This possibility should be mentioned during counseling, before chorionic villus biopsy is performed. Sampling other tissues, such as amniotic fluid or fetal blood, may provide more information, but does not remove the original abnormal result.

False Reassurance

False reassurance may be provided by a rapid fluorescent in situ hybridization (FISH) test for aneuploidy, when karyotype on cultured cells subsequently show a problem. For example, a FISH test may miss a balanced translocation and therefore give false reassurance initially. Women should be made aware of the limitations of the diagnostic test being offered.

Nonpaternity

Nonpaternity may be discovered when investigating Rhesus disease and finding that the fetus is Rhesus-

negative and the putative father is homozygous for the Rhesus-positive gene. Such cases should be handled with tact and respect for confidentiality.[43]

Unexpected Decisions

At times, women make unexpected decisions when the results of tests are available. This can create ethical dilemmas for the team of professionals caring for the woman. For example, amniocentesis may be requested and performed because of maternal age, but on learning the sex of the baby, the woman may then request a termination. This creates a difficult situation for the clinicians. If the pregnancy is clearly of less than 24 weeks' duration (in practice, usually no more than 22 weeks), then in England, it would be feasible and legal to perform a termination if two physicians considered that continuation of the pregnancy would cause more risk to the physical or mental health of the woman (or her existing children) than termination. Most physicians are uncomfortable with termination under these circumstances. However, if they decline the request for termination, it is expected that they would at least try to find other physicians who would be prepared to consider the request or to offer other forms of psychosocial support.

Timing of Diagnostic Procedures

Sometimes a scan performed as part of ongoing obstetric management may show an unexpected abnormality that may be associated with karyotypic abnormality. Diagnostic tests must be discussed in relation to the gestation of the pregnancy. For example, if a "double bubble" suggestive of duodenal atresia is noted on a 32-week scan, amniocentesis may be offered. However, the woman should be aware that although she has the option of termination of pregnancy if trisomy 21 is detected, potassium chloride feticide is necessary before the induction of labor. Many women find it extremely difficult to contemplate a termination in the third trimester, find the need for feticide extremely distressing, and are upset at the prospect of induction, labor, and vaginal delivery. Some women therefore decide not to have karyotyping performed later in pregnancy.

When formulating departmental policies on the appropriate gestation for routine scanning, it is important to bear in mind that in the United Kingdom potassium chloride feticide is advised for most terminations from 22 weeks' gestation. The only exceptions are cases in which the abnormality would be lethal in the early neonatal period. In some hospitals, there is a tendency to perform routine scanning after 20 weeks' gestation to maximize visualization of the heart, but if an abnormality is detected and subsequent testing is needed, then it is easy to exceed the 22-week limit before a definitive diagnosis is made and a termination decided on.

COUNSELING AFTER THE DIAGNOSIS

Emotional Effect

The diagnosis of abnormality has a profound emotional effect on the woman and her partner. These parents now face the following prospects:

- Loss of the anticipated normal pregnancy and child
- Possible end to a wanted pregnancy
- Responsibility for deciding whether to continue or terminate the pregnancy
- Guilt over either decision

After the diagnosis of abnormality in a fetus or child, parents experience a bereavement reaction, as they mourn the "perfect" wished-for baby while incorporating the diagnosis into an altered relationship with the affected baby.[44,45] Responses associated with bereavement reactions, including shock, anger, sadness, and helplessness, are common. When the diagnosis is made prenatally, the parents have the additional burden of deciding whether to continue with the pregnancy within a limited time.

Breaking Bad News

The emotional response to hearing that their baby has an abnormality is so strong that the parents are likely to remember the circumstances of being told for the rest of their lives. For this reason, the importance of the way in which bad news is given cannot be overstated. Basic principles include the following:

- Results should be given in the way discussed before testing, according to the woman's wishes.
  "You asked us to arrange an appointment for you and your partner when the results of your amniocentesis were available. We expect these tomorrow, so can you come in tomorrow afternoon?"
- Arrange to give the results in a room that affords adequate privacy and is located away from women who are receiving routine antenatal care.
  "I will see you in my office, which is down the corridor from the clinic."
- When giving the result, lead in with a short "warning shot."
  "I know that you are anxious to hear the result of your amniocentesis. I do have the result here. I'm afraid it's not what we were hoping for."
- Give the result clearly.
  "The baby's chromosome pattern is abnormal. The baby has a serious condition called *Edwards syndrome*, or *trisomy 18*."
- Acknowledge the effect of the news. Show empathy.
  "I am so sorry to have to give you this news. This must be a terrible shock for both of you."
  "Women in this situation often blame themselves; it is important for you to know that there was nothing you did, or didn't do, that caused this to happen."

- Offer further information about the diagnosis.

  "I can give you more information about Edwards syndrome today, but you may find it difficult to concentrate now, so I have this leaflet that you can take with you."

- State the options clearly.

  "You may decide to terminate the pregnancy or to continue. I will be able to make the arrangements if you decide to terminate. If you decide to continue, I will continue to look after your care through the pregnancy."

- Offer counseling to facilitate decision-making.

  "You may find it helpful to see a genetic counselor while you are deciding whether you want to continue with the pregnancy."

  "There is a support group run by other parents who have been in a similar position. Here are the details."

- Emphasize that there is time to decide (within the constraints of the stage of pregnancy).

  "You don't need to decide today. You have time to consider this carefully over the next few days."

- Make clear what happens next.

  "I will ask the genetic counselor to telephone you tomorrow. I will see you again on Monday."

Decision-Making

For most women and their partners, deciding whether to continue with the pregnancy is the most difficult decision they have had to face in their lives. Although analytic decision models do not appear to account for the way in which women arrive at these decisions, broadly, the process involves the following features:

- An objective assessment of the facts
- A subjective interpretation based on personal values, beliefs, experiences, and circumstances

It is not surprising that women with the same diagnostic result will make different decisions. This individuality has been borne out in a number of large quantitative studies that attempted to identify primary factors in the decision-making process; these studies have yielded varied findings.[46–48] It is important to be aware of factors that may affect the decision-making process for a specific patient, including the following:

- Severity of the condition
- Perceived "burden" of the condition (its likely effect on the child, parents, and other family members)
- Gestational age
- Beliefs and values (religious, cultural, or moral)
- Family size
- Experience with the condition, whether personal or indirect
- Practical and social considerations

Most women are able to come to a decision once they have been given full information, opportunity for discussion, and time. In the longer term, few women regret their decisions, although most experience periods of doubt.[49] However, the burden of responsibility weighs heavily, and women may still seek reassurance that they have made the "right" decision. It is possible to offer this reassurance while upholding the ethos of noncoercion, which is sacrosanct:

"I can tell you have thought carefully about this before coming to your decision. There is no such thing as a 'right' decision, but the important thing is that when you look back, you will be able to say that you made the best decision you could at the time."

Some parents may seek more than reassurance and may ask directly for advice about what to do. The need to maintain neutrality does not eliminate the responsibility for facilitating decision-making. Some parents reported feeling abandoned by their clinicians and felt that they were left to make a decision without support.[50] If the patient asks an awkward question, such as "What would you do in our situation?" a supportive response might be as follows:

"It sounds as if you are unsure about what to do. Some ("most" or "a few") of my patients in your situation have decided to terminate the pregnancy, whereas others ("many" or "a few") have continued. What can I do to help you with your decision?"

For women who are struggling to make a decision, it is important to offer help in facilitating this process. To help them gain a sense of control and the confidence to make a decision, it may be helpful to encourage them to reflect on how they have coped with previous difficult decisions. A useful counseling strategy is to explore the various potential outcomes that may result from the diagnosis by imagining them as scenarios. This approach enables the woman and her partner to imagine which outcome would be least difficult for them personally.

A smaller group of women have sustained difficulty in reaching a decision. This is more likely to occur if any of the following factors is present:

- Disagreement between the woman and her partner
- Uncertainty about the diagnosis or prognosis
- Religious, cultural, or moral conflict
- Vulnerability because of age or cognitive impairment

For these women, other sources of counseling and support should be considered, including genetic counselors, specialists (e.g., neonatologists, surgeons), lay support groups, trusted professionals (e.g., general practitioner), and religious advisors.

POST-DECISION CARE

Whatever decision women make, they experience feelings of guilt. Many report an expectation that they will be judged by health professionals as well as by family and friends. It is crucial that they receive understanding and nonjudgmental support at this vulnerable time.

Continuing Pregnancy

In the early years of prenatal diagnosis and screening, the presumption was that these services were only for women who intended to terminate an affected pregnancy.[51] In more recent years, there has been an increase in the number of women choosing to continue with their pregnancy after a diagnosis of abnormality, although maternity staff are less familiar with how to care for these women.[52] This group includes women who make an informed choice at the outset that although they would not terminate an affected pregnancy, they would prefer to be warned about a problem in the baby before delivery; others who have tests with the intention of terminating, but who change their mind when faced directly with the decision; and others who entered screening programs unaware that a possible outcome would be the offer of termination.

The choice to continue the pregnancy has been made for a range of abnormalities, including known lethal conditions in which parents would prefer to "allow nature to take its course," structural abnormalities with a reasonable prospect for surgical intervention, and chromosomal conditions with and without an associated mental handicap (e.g., Down syndrome, Turner syndrome).

A different approach to ongoing prenatal care is required for women continuing with a pregnancy affected with a serious abnormality.[52,53] These women understandably feel different from other pregnant women, and these feelings fluctuate through the rest of the pregnancy. Anxiety is usually greatest around the time of diagnosis and again near the expected date of delivery. Many aspects of care for these women should be addressed, including the following:

- The importance of a nonjudgmental approach by health professionals
- The realization that the woman may change her mind and request termination later
- The need for access to detailed information on the likely outcome for the baby at delivery and beyond, which may include input from lay support groups, pediatricians, and pediatric surgeons
- The option to attend prenatal appointments outside routine prenatal clinic sessions, if desired
- Continuity of care with senior staff and careful communication with primary care practitioners
- Avoidance of further ultrasound scans unless strictly indicated or desired by the woman
- The choice of a private room in the hospital, with the recognition that the woman may prefer to be with other women
- Preparation of both parents and staff for delivery of a baby who may die in the neonatal period or require immediate intervention
- Confirmation of the abnormality after delivery and the offer of genetic counseling, when appropriate

Termination of pregnancy (See also Chapter 68)

Before Viability

After the decision to terminate is made, the woman and her partner need to know what will happen next. If the decision to terminate the pregnancy is made before 14 weeks' gestation, either medical or surgical termination may be performed. After 14 weeks' gestation, there may not be a local gynecologist experienced in late surgical termination, so the only option may be medical termination. A thorough explanation of the processes is required. Some obstetricians and midwives find it difficult to discuss these matters frankly, but women who have had terminations have emphasized the importance of this information at the time. Patient support group literature may also be helpful.[54,55]

When there is a choice of methods, the surgical method may appear attractive initially because the woman is spared the pain of contractions and the often lengthy induction process. Instead, the woman wakes from her anesthetic and the termination is complete. However, disadvantages include the following:

- The experience of giving birth may help in the grieving process.[56]
- There is no opportunity to see the fetus.
- Confirmation of a structural anomaly is unlikely, although chromosomal abnormalities can be confirmed.
- If the surgical procedure is incomplete, the woman may pass recognizable fetal parts.

In contrast, the major disadvantages associated with medical methods are the following:

- A delay of approximately 48 hours between the administration of mifepristone and prostaglandin induction is advised.
- The induction process is often long.
- The woman needs adequate pain relief.
- There is a slight risk of an incomplete procedure, and a subsequent surgical procedure may be needed.

Before undergoing a termination, the woman and her partner must also be informed of a number of decisions that they must make shortly after the procedure is complete.

- Whether to see or hold their baby after a medical induction and delivery
- Whether to have photographs taken
- Whether to agree to have a postmortem examination, either full or limited
- Whether they wish to arrange a funeral, cremation, or other type of remembrance

All of these decisions may be very difficult. Good practice emphasizes the importance of offering parents the opportunity to see their baby. Whether they accept this

offer is an intensely personal choice for them and should be respected. Seeing the baby can help the parents to acknowledge the reality of their loss and can also provide precious memories. Even externally severe abnormalities can appear less frightening than imagined. For babies without obvious external abnormalities, parents must be prepared that this does not imply that the diagnosis was incorrect. If parents decide not to see their baby, photographs can be taken for access at a later date if they choose.

The issue of postmortem examinations is important in the United Kingdom because of the retention of material for subsequent research.[57] This practice appears to be resulting in a further decrease in the number of postmortem examinations. Attempting to confirm an abnormality that is not externally apparent, but has been diagnosed on ultrasound scan, is important for the woman as well as for quality control for the prenatal diagnostic service. In addition, the necropsy may change the diagnosis from that presumed before delivery. For those who dislike the idea of such an examination, the concept of limited examinations, biopsies, and detailed imaging (possibly including magnetic resonance imaging) must be explored. In addition, a detailed external examination by a clinical geneticist may show subtle external signs of the underlying problem. Such investigations may lead to a specific diagnosis and a more accurate recurrence risk.

Usually, these patients are cared for in the gynecology department when the pregnancy has not advanced beyond fetal viability. However, the nursing staff may not be accustomed to caring for a woman who has terminated a wanted pregnancy and may have difficulty providing optimum care. Midwives may also have difficulty caring for these women in a delivery unit. Each hospital must recognize the important aspects of care and must provide care in the best possible setting, where the woman is most likely to receive the following[58]:

- Care by staff with experience with terminations for abnormality
- Access to adequate pain relief
- Privacy, including privacy from women delivering healthy babies

In addition, staff should avoid making clinical comments about the fetus because often mistakes are made, such as comments that the baby appears normal or mistaking female fetuses for male fetuses.

After Viability (See also Chapters 24 and 68)

Decisions to terminate a pregnancy are sometimes made around the time of fetal viability for a variety of reasons, including the following:

- Most hospitals perform routine anomaly scans around 20 weeks' gestation. However, some hospitals perform these scans at 21 or 22 weeks' gestation. It is likely that if an abnormality is detected and a termination requested, it would be performed around the time of viability.
- At times, further confirmatory scans are needed or other tests, such as amniocentesis, are indicated. The pregnancy may proceed to 22 weeks' gestation before the woman is in a position to make a decision about termination. Similar delays may occur when thalassemia trait in pregnancy is diagnosed.
- At times, women seek care late in pregnancy and anomalies are detected at this point.
- Sometimes the disease occurs late in the pregnancy (e.g., intraventricular hemorrhage).
- Sometimes an anomaly progresses during the pregnancy, with a worsening prognosis. For example, a couple may choose to continue a pregnancy with isolated mild ventriculomegaly, but if this condition progresses during the pregnancy to severe ventriculomegaly, they may reconsider their decision and request late termination.

Although in some countries, including the United Kingdom, terminations can be performed after viability if it is likely that the child will be seriously handicapped, either physically or mentally, induction of labor may result in the baby being born alive. In this case, unless the attending pediatrician believes that the external appearance of the baby is such that it is incompatible with life, resuscitation of the baby must be undertaken, regardless of parental wishes. In the United Kingdom, feticide is necessary from 22 weeks' gestation unless the baby would die in the immediate neonatal period as a result of its abnormality.[5] The woman and her partner need to have been counseled about this possibility. Injecting potassium chloride into the fetus under ultrasound guidance is clearly very traumatic for the woman and her partner. The woman may feel considerable fetal activity just before fetal demise. She must actively cooperate in the feticide procedure by lying still on the ultrasound table and allowing the operator to inject the potassium chloride. She knows exactly when and where her baby died.

In addition, it is very traumatic for all of the staff present, particularly the person giving the lethal injection and watching fetal demise on the ultrasound screen; the staff will need the support of the entire team and sometimes independent counselors.

Occasionally, a woman feels unable to have a feticide procedure. In this case, she must be fully counseled about the steps that the team must take; unless the baby appears to have a condition that is incompatible with life, at least initially, they must provide full resuscitation and neonatal care.

As in early pregnancy, women may request surgical rather than medical termination, so in later pregnancy, women may ask for a cesarean delivery. Although this procedure offers some benefits, such as a speedier process, cesarean section has several disadvantages, including the following:

- The opportunity to deliver normally may help in the grieving process.
- The maternal morbidity rate is greater.
- The hospital stay is longer.
- Subsequent deliveries may be affected.
- The abdominal scar may act as a constant reminder of the baby.

Postdelivery care

How long a woman wishes to stay in the hospital varies depending on many factors, including family support, cultural concerns, and the type of facility. It is often assumed that women want to go home immediately, but some women who stay in the hospital for medical reasons find the continued support from staff helpful. Women must be warned that they may produce milk; if they do, they should be offered suppression of lactation. They also must be advised how long they may bleed. Most units have detailed checklists to be completed before discharge. These include routine postdelivery issues, such as checking Rhesus status, direct notification of primary care practitioners, and arrangements for follow-up.

At follow-up visits, the following issues should be addressed:

- Emotional adjustment
- Test results
- Appointments with other experts (e.g., geneticists)
- Future pregnancies

The woman may not be able to cope with all of these issues in one session, and further appointments may be advised. Unless the woman specifically requests it, these appointments should not take place in prenatal clinics.

Psychological Sequelae

Parents experience grief after termination for abnormality akin to that after the death of a child, as reported by many authors.[45,48,49,59–61] While still in the hospital, many parents describe relief that the termination procedure is behind them. However, this relief is quickly followed by emotions associated with bereavement, including sadness, emptiness, anger, isolation, and guilt. Almost all women experience grief in the first 2 months after the termination. The intensity of psychological distress decreases over time, with most women reaching a sense of resolution within 6 to 24 months. Studies of factors that may predict which women will have a complicated or prolonged grief response are not conclusive, but those who are very young, are not well supported by their partners, have a psychiatric history, or have had other recent stressful life events may be at greater risk. There is no objective evidence that women grieve less after a first-trimester rather than a second-trimester termination.

In addition to coping with their loss, women almost universally experience guilt and shame that can affect their self-esteem. They may feel that they were in some way responsible for the occurrence of the abnormality (even in the presence of a medical explanation to the contrary), and they feel responsible for deciding to end the pregnancy. Even parents who believe that they made the right decision experience periods of doubt. Some women have nightmares in which the baby or other family members chastise them, or where the diagnosis turned out to be wrong. The sense of shame over having a termination may be particularly acute in women with conflicting religious or cultural values, and most women are concerned about how other people would react to their decision to terminate.

After the initial acute grieving period of 4 to 8 weeks, looking ahead to another pregnancy can play an important part in moving forward, and it may be helpful to initiate discussions about a further pregnancy, including options for prenatal diagnosis. One study in the United Kingdom found that 75% of women became pregnant again 14 months after termination for abnormality.[48]

It is important not to overgeneralize the psychological effects of termination for abnormality, and professionals must avoid prescriptive advice and support. Parents must find their own way to grieve, which may include rituals, such as spending time with the baby and having a funeral. Parents must be offered choices, and relevant patient support group literature should be made available.[54,55] Anticipatory guidance about possible psychological sequelae can help to prepare parents for the following reactions:

- They may experience initial feelings of relief after the termination.
- They are likely to experience grief for a period of months.
- The emotions associated with grief become less intense with time.
- The woman and her partner may grieve in different ways. Understanding and supporting each other is very important.
- It may be helpful to prepare what they will tell other people about the loss. The explanation may be different for their other children, extended family, friends, or colleagues.
- The woman may find it difficult to be around other women who are pregnant, particularly family members or close friends. Making a plan for how to deal with this possibility can be helpful.
- Parents may experience guilt and doubt over their decision. Many parents who say that they know they made the right decision still have doubt at some point. Some women experience nightmares in the first few months after the termination.
- Many women feel psychologically ready to consider a further pregnancy within a year after the termination.

Fathers

The psychological needs of fathers are often overlooked, and the partners of women undergoing termination may

feel marginalized. The limited data from studies of fathers' experience of termination for abnormality confirm that fathers also experience profound psychological sequelae, although they may manifest in different ways.[62,63] Fathers often take a supportive role toward their partners, and although both they and their partners can benefit from this approach, it may interfere with or delay their own grief response. However, men and women may not express grief in the same way. If the man shows less overt distress, this may be misinterpreted by others as a lack of grief or failure to grieve. Health professionals can respond more effectively to fathers by following these guidelines:

- Acknowledge that he, like his partner, has lost a wanted child.
- Recognize his role as the supportive partner.
- Recognize that he may feel marginalized because he cannot share the physical burden with his partner.
- Reassure him that men may not express emotion openly and that this does not reflect a lack of feeling.
- Show empathy to a father who cries.
- Suggest opportunities for follow-up support, including lay groups and access to published accounts by fathers.[63]

STAFF SUPPORT

It is stressful for any staff members who are involved in the care of a woman with a suspected major fetal abnormality.[64] For some, this is an unusual event (e.g., a midwife working on a delivery unit who is caring for the first time for a woman who is having a very late termination for a fetal abnormality). For others (e.g., fetal medicine specialists in regional centers), counseling women about these decisions and following through with them is almost an everyday occurrence. However, both groups face common issues, such as the following:

- Moral conflicts
- The need to maintain neutrality
- Reaction to patient choices

These can take an emotional toll on the staff, and further training and support may be needed.

Support for Those Involved in General Maternity Care

A midwife working on the delivery unit usually can decide whether to become involved in the care of such women after they leave the hospital. Her colleagues and the unit manager should discuss the issues in a nonjudgmental way, allow her to make her own decision, and allow her to discuss her final decision with them so that if she does not want to become involved in the future she does not feel alienated. The United Kingdom has a statutory midwifery supervision process, and this process must

support the decisions of midwives. Midwives in tertiary care units, many of whom work with women who undergo termination for abnormality, should have the opportunity to attend a fetal anomaly ultrasound scanning session. There, they can begin to understand what women and their partners experience, and they can also see the type of work that their clinical colleagues perform every day. This experience is likely to make the decision-making process easier; ideally, midwives should be able to do this before they are faced with an actual patient. Midwives in smaller units (in which termination for abnormality is much less common) should have the opportunity to join a tertiary care fetal medicine unit for a day to see how they work. This experience can supplement their training in related areas, such as care of the bereaved, to allow them to provide good care. These cases must be discussed at routine general clinical meetings, such as perinatal mortality and morbidity meetings, or at adverse event meetings or clinical case presentation sessions, and not just brushed aside as another case of abnormality. This type of discussion allows those who are not involved to begin to understand some of the moral and ethical dilemmas that can face the staff who are directly involved.

Support for Staff Working in Specialized Fetal Medicine Units

For staff working in a fetal medicine unit, caring for women where a major fetal anomaly being diagnosed is almost a daily occurrence, and for those performing feticide with potassium chloride injections, this is also a fairly regular event. Those deciding to enter this field, whether physicians, midwives, or sonographers, must realize that this aspect of care will become part of their routine work. Several strategies are needed to support the members of the team.

- Sharing the workload. The members of the team must try to share the workload as equally as is feasible. In addition, they should be trained to recognize a colleague who appears to be going through a difficult period and should try to lighten this person's workload.
- Weekly clinical meetings. Meeting frequently to discuss recent cases allows the other members of the team to show support for their colleagues who have had difficult cases.
- Support for the patient's decision. It is important to focus on the fact that the woman made a positive informed choice to terminate a pregnancy based on the belief that she was preventing her unborn child from suffering and that this was the best option for her and her family.
- Away days. Scheduling time away from the clinic allows more relaxed discussions about policy, workload, and future developments. This time should make it easier for team members to discuss work-related anxiety.

- Social events. Occasional social gatherings may increase support for the team and allow team members to discuss work-related problems.
- External support. Sometimes additional counseling is needed, and these services must be made available.

Some team members may feel shame if they need this support. To minimize negative feelings, team members should be told about these counseling services when they join the team, and the team should be reminded about their availability from time to time.

CONCLUSIONS

- Almost every woman who has antenatal care undergoes some form of screening; therefore, all health care professionals involved must be equipped to counsel and manage patients who have abnormal results.
- Health care professionals should focus on the principle that the aim of offering a screening test is to allow women and their partners to make informed choices about their pregnancy. This choice may include termination, but that is not a prerequisite for testing.
- Health care professionals should provide clinical, psychological, and social support to women throughout pregnancy, especially with respect to screening for fetal abnormality.
- Screening should be offered within a professional ethos of supporting the choices and decisions made by the woman and her family.
- Reflective practice should include consideration of the counseling process.

SUMMARY OF MANAGEMENT OPTIONS
Counseling and Management of an Abnormal Finding on a Screening or Diagnostic Test for Fetal Abnormality

Management Options	Quality of Evidence	Strength of Recommendation	References
Pretest Counseling			
Informed Consent			
Although a prenatal test can be presented as an opt-in or opt-out test, obtaining true informed consent fosters an ethos of opting in to testing.	IIb	B	8
Needs of Different Groups			
Counseling and diagnostic options should be offered according to the patient's clinical history, and access to services should not be restricted because of professional assumptions about the patient's cultural or ethnic background.	IIb	B	9,13
Content of Information			
Recommendations about information content should be followed (see Table 9–1).	IV	C	3,14
Affected individuals should be given access to information abut the long-term outlook.	IIb	B	16,17
Communication of Information			
Quality, peer-reviewed information, available in locally appropriate languages, should be used.	Ib IV	A C	15 24,25
Responsibility for Providing Patient Counseling			
Information may be given by a range of professionals, but a nondirective approach should be used.	III IV	B C	18 3

Counseling and Management of an Abnormal Finding on a Screening or Diagnostic Test for Fetal Abnormality *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Communication of Test Results			
Arrangements for communication of results should be discussed with the woman and clearly documented in the records.	IV	C	3
Counseling for Screen-Positive Results			
General Issues			
To promote the patient's understanding of the meaning of a screen-positive result, risk figures should be presented in different formats and in the context of the background risk.	III	B	20
Decision to Have an Invasive Test			
Not all women with a screen-positive result will choose to proceed with an invasive diagnostic test.	III	B	27
Specific Screening Problems			
Women should be made aware of the limitations of screening, including false-positive and inconclusive results.	III	B	10,20
Problems with Diagnostic Tests			
When an unexpected or ambiguous result, such as a sex chromosome abnormality, is identified, referral for expert genetic counseling should be offered.	IIb	B	17,39,40,41
Timing of Diagnostic Procedures			
The options that would be available should a diagnosis be confirmed must be considered before a procedure is performed later than the second trimester.	IV	C	1,2
Counseling after Diagnosis			
Emotional Effect			
Acknowledgement of the profound emotional effect of a diagnosis of abnormality contributes to psychological adjustment.	III	B	45,49,52,56
Breaking Bad News			
Results should be given clearly and empathetically.	IIb	B	17,49
Decision Making			
Women should be supported in making a decision that is consistent with their personal values and circumstances, free of coercion.	IIb III	B B	46,47 48,52
Postdecision Care			
Continuing Pregnancy			
Continuing with an affected pregnancy should be presented as a valid choice.	III	B	54,55
Specialized postdelivery care should be provided.			

SUMMARY OF MANAGEMENT OPTIONS

Counseling and Management of an Abnormal Finding on a Screening or Diagnostic Test for Fetal Abnormality (*Continued*)

Management Options	Quality of Evidence	Strength of Recommendation	References
Termination			
Individualized care plans should consider the most appropriate method and setting for the termination.	IIb	B	48,56,60
Anticipatory guidance about bereavement and common feelings of guilt and responsibility should be offered.	III IIb	B B	48,56,60 49
Fathers			
Acknowledging the father's loss can reduce potential feelings of marginalization.	III	B	63,64
Staff Support			
The emotional toll on staff involved in prenatal diagnosis should be acknowledged. Support should be made available.	–	GPP	–

Invasive Procedures for Antenatal Diagnosis

Alyson Hunter / Peter Soothill

INTRODUCTION

Ultrasound in pregnancy fostered the development of invasive techniques to assist in antenatal diagnosis. Methods such as chorionic villus sampling (CVS), amniocentesis, fetal blood sampling (FBS), and fetal tissue biopsy allow testing of fetal materials for chromosomal, genetic, and biochemical abnormalities. The type of procedure selected depends on many factors, including the indication, the gestational age, and how soon the result is needed. Possible applications are increasing rapidly with advances in human genetics and the evolution of molecular tools. All invasive in utero diagnostic techniques carry a risk of fetal injury or death. These risks must be properly explained to the parents so that informed consent can be obtained. Noninvasive approaches, such as measuring free fetal DNA in the mother's blood, show great promise, but are clinically used only in specific areas, such as fetal blood grouping.[1] This chapter summarizes the indications, methods, and complications of the most common invasive diagnostic methods.

ISSUES COMMON TO ALL INVASIVE DIAGNOSTIC TECHNIQUES

All of the techniques described in this chapter share certain features.

Guidelines for Training

The Royal College of Obstetricians and Gynaecologists published guidelines for training in antenatal invasive diagnostic methods, and these guidelines can serve as a global model.[2] Trainees in obstetrics and gynecology should perform at least 30 amniocenteses under supervision before they act independently. After they complete training, physicians who perform amniocentesis should perform at least 30 per year. The College also recommends that amniocentesis for multiple gestation be performed in a tertiary fetal medicine unit. Training in CVS and FBS is not part of general obstetric training and is usually limited to trainees who specialize in fetal and maternal medicine. Units that perform more complex fetal procedures should perform enough procedures each year to maintain skills. They should periodically audit the results and make these available to patients and colleagues. A reasonable minimum number of complex procedures is 12 per year.

Consent

The procedure, its goals, and likely or significant complications must be explained in language that is understandable to the patient so that written informed consent can be given. The specific considerations for each procedure are discussed later.

Sampling Site

Ultrasound is used to determine the best site to obtain the sample, considering the target size, needle length, needle path, and potential injury to structures in the path. The skin site for needle insertion is planned, but the position chosen reflects the ultrasound-guided technique used.

Ultrasound-Guided Needling Technique

Two approaches to ultrasound-guided needling are used: needle guide and freehand.

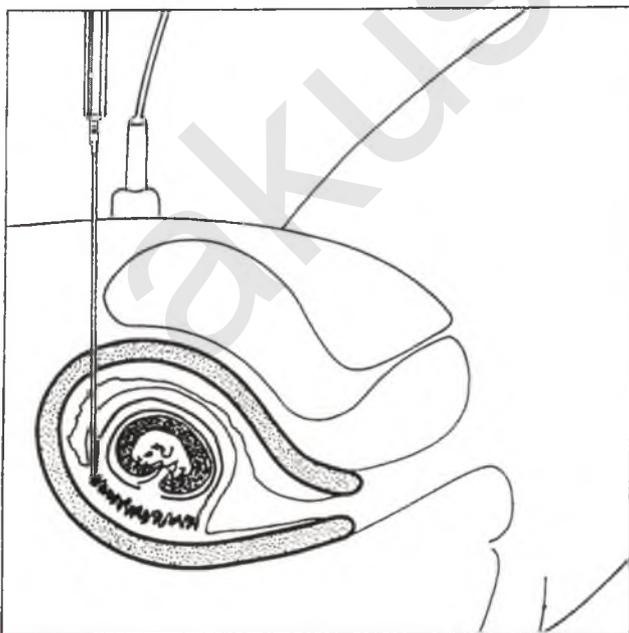
Needle Guide

The needle guide technique uses a sector or curvilinear ultrasound transducer with a guide that has an attached

needle channel. Lines on the ultrasound screen indicate the path of the needle when inserted down the guide. The transducer is moved until these lines cross the intended target. This approach allows the use of thinner needles (i.e., 22–26 gauge) than those needed for a freehand procedure (i.e., 20–22 gauge). Despite the use of a thinner needle and the fact that the entire length of the needle is not usually seen, the tip is visible as a bright dot (Fig. 10–1). Some suggest that because the needle is thin and its movement confined to a single plane, the complication rate may be lower than with the freehand technique.[3] The guide does not seem to increase the need to remove and reinsert the needle, nor is there a relationship between the complication rate and the number of insertions.

Freehand

The freehand technique uses a curvilinear or linear ultrasound transducer. The ultrasound transducer is moved until the intended sampling site is identified and appears on one side of the ultrasound screen, with the skin insertion point on the other. The intended needle path is nearly perpendicular to the ultrasound beam, allowing the entire length of the needle to be imaged (Fig. 10–2). The freehand technique allows the operator to image the entire length of the needle and compensate for a suboptimal insertion or adjust to changes during the procedure (e.g., contractions, interfering fetal movements). It also may facilitate rare procedures in which multiple sites are sampled.

Some operators prefer to have an assistant control the scanning transducer, but then the operator forfeits con-


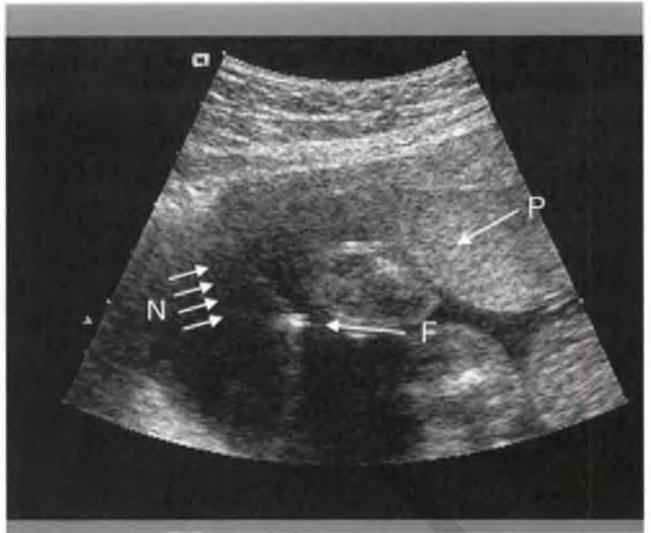


FIGURE 10–2
Ultrasound view of an amniocentesis needle (N) entering a pool of amniotic fluid. F, fluid; P, placenta.

trol of the intended needle path. Others prefer a single operator. With this approach, one hand holds the needle and the other holds the ultrasound transducer. An assistant is required to withdraw the needle stylet, fix a syringe, aspirate at the right time, and place the sample in appropriate containers without spillage, contamination, or mislabeling.

Preparation

The atmosphere should be informal, and any additional staff required should be present for the procedure and introduced to the patient. Anything that gives the patient an image of an "operation" (e.g., surgical masks, hats, drapes) should be minimized or replaced by a scrupulous "no-touch" technique. The length of the needle required depends on abdominal wall thickness, amniotic fluid volume, and fetal and placental positions. An 8- to 12-cm needle is usually sufficient, but if in doubt, the distance should be measured on the screen before the procedure. Detailed ultrasound examination of the fetus is performed before the procedure because the discovery of structural defects, impaired growth, or other problems may alter the physician's and patients' choice. New ultrasound findings may make the procedure unnecessary, or help subsequently, when there is an unusual chromosomal finding such as mosaicism.

Needle Path Selection

The target is visualized on screen, and the transducer is rotated through 180° until a path that avoids fetal parts and maternal vessels is identified. With the freehand technique, the best skin insertion point is determined by observing sonographically the effect of digital pressure on the maternal abdomen. The transducer is adjusted

FIGURE 10–1
Line drawing of chorionic villus sampling via the transabdominal route showing the needle.

until the sampling site and the skin insertion point are on opposite sides of the screen.

Antiseptic and Anesthetic

The skin insertion site is scrupulously cleaned with antiseptic solution (e.g., chlorhexidine). Procedures that require larger than a 22-gauge needle may be helped by local anesthetic, which is injected first into the skin and then into the abdominal and uterine peritoneum. Anesthetic injection can help to confirm the needle angle required to follow the intended path and may decrease the need to change the direction of the sampling needle during the procedure. Patients who underwent amniocentesis with a 22-gauge needle with and without anesthesia reported that the anesthetic injection is more painful than the procedure.

Postprocedure Considerations

The patient should be shown both the fetus and the motion of the fetal heart on the ultrasound monitor after the procedure. The sample is carefully labeled, and the details are confirmed by the woman before the sample is taken to the laboratory. The information submitted to the laboratory must be sufficient for testing to be done and diagnosis to be made. It should include information about consent, including permission to store DNA and maintain cells lines, if applicable.

Alloimmunization

An invasive procedure associated with placental bleeding doubles the risk of Rhesus sensitivity.[4–6] After an invasive intrauterine procedure, 500 IU rather than 250 IU anti-D immunoglobulin can be given intramuscularly to an at-risk Rhesus-negative woman.

Multiple Pregnancies

In women with multiple pregnancies, invasive procedures should be performed in a fetal medicine unit.[2] The chorionicity should be determined and the placental implantation site mapped in the first trimester.[7] In monochorionic pregnancies, a single amniotic fluid sample may be sufficient unless ultrasound shows discordant abnormalities. In dichorionic pregnancies, both sacs should be sampled separately, either with a single needle through the intertwin septum or with two separate maternal abdominal punctures.[8,9] The operator should be able and willing to perform a selective feticide if an abnormal result is discordant. In skilled hands, ultrasound guidance eliminates the need for indigo carmine. Potentially harmful dyes, such as methylene blue, should not be used.[10] Fetal zygosity can be determined from DNA when there is doubt or when the fetuses are at risk for inheritable syndromes.[11]

Complications

The loss rate after a diagnostic invasive procedure is a combination of the procedure-related loss rate and the background loss rate. The background loss rate is much higher if the fetus has an anomaly (e.g., chromosomal abnormality, intrauterine growth restriction, fetal hydrops).[12] The procedure-related loss rate is the product of many factors, including maternal age, operator experience, type of procedure, and difficulties experienced during the procedure.[3,13] The gestational age at the time of the procedure is also relevant. In one study, the rate of fetal loss in older women after transabdominal and transcervical CVS was 5.8% and 6.2%, respectively, if done before 12 weeks, but 2.4% thereafter.[14] Some portion of the excess loss early in gestation reflects losses destined to occur. Early CVS and diagnosis of aneuploidy may result in termination, with all of the physical and psychological implications for the parents, whereas delayed CVS or amniocentesis may, by virtue of the later gestation, allow time for spontaneous loss to precede the planned procedure. Several multicenter studies did not show consistent procedure-related differences with regard to the safety of CVS compared with other methods.[15,16]

The procedure-related loss rate for CVS, amniocentesis, and FBS is reported in many studies, including those listed in Table 10–1.[3,4,15,17–30] No standard criteria are used to determine background loss rates. Postprocedural loss rates were included up to 28 weeks and up to term in some studies.[4,28] Others suggest that most procedure-related losses occur within 2 weeks of the procedure (Table 10–2).[12] These procedures should be confined to centers with volumes large enough to calculate their own loss rates rather than to quote the rates of other units.

SPECIFIC PROCEDURES

Chorionic Villus Sampling

Introduction

CVS, or placental biopsy, is performed from 11 weeks onward and is used to diagnose many chromosomal and genetic conditions. CVS is usually performed by transabdominal needle aspiration, although some practitioners use a transcervical technique, with catheter aspiration or biopsy. Some suggest that the highest success rates are achieved when the clinician is comfortable using either approach.

Indications

Fetal trophoblast cells, especially the mesenchymal core of the villi, divide rapidly. The advantage of first-trimester CVS is rapid diagnosis in early gestation. If an abnormality is detected, surgical termination, rather than medical induction of labor, can be offered.

TABLE 10-1

Reported Outcomes after Invasive Prenatal Diagnostic Procedures[3,4,17-30]

SERIES	PROCEDURE	STUDY TYPE	REPORTING OF OUTCOMES
MRC, 1978	Amnio	Controlled	Reported outcome until the end of the neonatal period
Tabor et al., 1986	Amnio	RCT	Reported outcome as SA (<16 wk and >16 wk), induced abortion, SB (<36 wk >36 wk)
Canadian trial, 1989	Amnio, CVS	RCT	Reported outcome as induced abortion, loss ≤140 days, between 141–196 days postprocedure
Smidt-Jensen et al., 1992	Amnio, CVS	RCT	Reported outcome until the neonatal period; classified as spontaneous loss before the procedure, elective abortion, postprocedure, and unintentional loss
Johnson et al., 1996	Amnio	RCT	Reported outcome as postprocedure total fetal loss rate until term
Nicolaides et al., 1996	Amnio, CVS	Observational	Outcomes classified as total loss (spontaneous and induced) and spontaneous loss (IUD/NND)
Sundberg et al., 1997	Amnio, CVS	Observational	Reported outcome as total fetal loss rate and neonatal morbidity
Hanson et al., 1987	Amnio, CVS	Observational	Reported outcomes <2 wk, >2 wk, and 28 wk postprocedure
CEMAT, 1998	Amnio	RT	Reported loss as preprocedure abortion, postprocedure abortion (20 weeks), SB, LB, and NND
Rhoads et al., 1989	CVS	Observational	Reported outcome until the end of the neonatal period
MRC European Trial, 1991	CVS	RCT	Reported outcome as spontaneous fetal death <28 wk, termination, SB, and NND
Wapner et al., 1997	CVS	Observational	Reported outcomes until 28 wk
Maxwell et al., 1991	FBS	Observational	Reported losses in pregnancies with normal fetal anatomy, fetal abnormalities, fetal physiologic assessment, nonimmune hydrops; 2-wk cutoff for procedure-related loss
Anandkumar et al., 1993	FBS	Observational	Reported loss when FBS was done for fetal abnormality on scan, normal fetuses, nonimmune hydrops, advanced maternal age; 2-wk cutoff for procedure-related loss
Ghidini et al., 1993	FBS	Observational	Reported outcomes in low-risk groups as total fetal losses <28 wk and >28 wk
Wilson et al., 1994	FBS	Observational	Reported procedure-related loss in cases with normal fetal growth and anatomy, fetal abnormality, or IUGR; 1-wk cutoff for procedure-related loss
Weiner and Okumura, 1996	FBS	Observational	Reported outcomes until term; 2-wk cutoff for procedure-related loss

Amnio, amniocentesis; CVS, chorionic villus sampling; FBS, fetal blood sample; IUD, intrauterine death; IUGR, intrauterine growth restriction; NND, neonatal death; RCT, randomized controlled trial; RT, randomized trial; SA, spontaneous abortion; SB, stillbirth.

Early detection of chromosomal disorders is the most common indication. The introduction and growing availability of first-trimester screening for Down syndrome (e.g., nuchal translucency measurement) has increased the importance of this technique. Noninvasive approaches, such as measuring maternal plasma free fetal DNA, may make invasive testing for sexing unnecessary.[31] Because of the increasing number of diagnosable monogenic disorders, couples with a family history of a genetic disorder should be offered genetic counseling, either before conception or early in pregnancy. Many laboratories provide a rapid direct preparation of the fetal karyotype within 2 to 5 days or fluorescent in situ hybridization (FISH) of chromosomes 13, 18, 21, and Y, if requested. Fetal cells are also cultured for more detailed analysis.

CVS can be used at any time in gestation, and it is a very successful way to obtain a karyotype after delivery when the fetus has died. Although CVS is possible throughout gestation, the cytotrophoblast divides more slowly with advancing gestation, and other procedures, such as amniocentesis and FBS, may be more appropriate.

TABLE 10-2

Overview of Pregnancy Losses after Amniocentesis, Chorionic Villus Sampling, and Fetal Blood Sampling as Classified

TEST	TOTAL	MINUS	KNOWN LETHAL CONDITION	MINUS	> 2/52	= PROCEDURE-RELATED
Amniocentesis	10 (1.8%)		3		3	4 (0.7%)
Chorionic villus sampling	18 (4.1%)		14		3	1 (0.23%)
Fetal blood sampling	18 (10.7%)		16		0	2 (1.19%)

PROCEDURE

CHORIONIC VILLUS SAMPLING

Consent

The procedure should be described to the patient. Counseling must include the aims of the CVS (i.e., karyotype, DNA analysis) and the risk of a serious complication (often described as 1%), including abortion, either procedure-related or background, should be quoted. The risk of limb defects should also be mentioned. The risk is minimal after 10 weeks. The limitations of a karyotype and the risks of unrelated abnormalities that are not detected by a karyotype should be explained. Patients should also be informed of the small chance that testing will show confined placental mosaicism or sex chromosome abnormality and the possiblility of a further invasive technique to confirm a diagnosis such as amniocentesis or fetal blood sampling. Alternative diagnostic techniques may be discussed. Only after the counseling process is complete is the patient asked to provide written consent.

Sampling Site

The ideal target is a thick part of the placenta that can be sampled at an angle that allows a long needle path through the placenta and avoids a perpendicular path to the chorionic plate (see Fig. 10–1). Rarely, at approximately 11 weeks, transabdominal CVS is difficult if the uterus is retroverted, the placenta is posterior, and a lateral approach is not possible. Some operators switch to a transcervical approach, but we ask the patient to return in a week, when sampling may be easier.

Target Puncture

Transabdominal CVS can be done either freehand or with a needle guide. With the "double-needle" technique, after a local anesthetic has been administered, the first needle is advanced through the maternal skin, through the uterine wall, and into the placenta. The introducing stylet is removed, and a second needle is passed into the placenta and attached to a syringe that contains normal saline. The placental villi are then aspirated.[32,33] By drawing the finer needle into the outer needle during aspiration, the sharp bevel of the first needle seems to cut the villi, reducing the need for needle movement and presumably reducing placental trauma. A placental biopsy forceps may also be used through an outer guide needle. With the double-needle technique, if the tip is inserted correctly into the placenta, maternal contamination should not occur. If a single needle is used, the aspirated tissue should be dissected under the microscope to exclude maternal contamination. Whatever technique is selected, the sample is placed in a suitable CVS medium before it is transferred to the cytogenetics laboratory.

Maternal contamination of chorionic cell cultures may lead to a false-negative diagnosis, particularly when polymerase chain reaction amplification is used and in some biochemical examinations. Operator experience reduces the risk of maternal cell contamination.

Transcervical CVS

This approach is less common now because of an apparent increased risk of fetal loss.[16,34,35] Some practitioners consider this approach useful in high-risk patients who require early diagnosis. It is also helpful when the uterus is retroverted and the placenta is posterior or when an anterior wall leiomyoma makes an abdominal approach difficult. A bendable polyethylene catheter with a metal obturator is introduced through the cervix and advanced into the placenta under ultrasound guidance. A syringe that is partially filled with saline is attached to the hub and a vacuum created to aspirate 10 to 50 mg of tissue, which is then rinsed into a Petri dish. Some units prefer curved biopsy forceps.[36]

Complications

Canadian, Danish, and American multicenter trials found no significant difference in procedure-related loss rates between the first and second trimesters. A 1% fetal loss rate is usually quoted for amniocentesis and CVS.[1] A rate of 0.25% is reported for CVS and amniocentesis.[20]

Some reports[37,38] suggested that first-trimester CVS (including those performed as early as 6–7 weeks) may be associated with severe limb defects. These defects were not observed in CVS performed after 11 weeks' gestation. The World Health Organization (WHO) International Registry for Limb Defects after CVS found no difference in the prevalence of limb defects after CVS compared with the background population.[39] Therefore, during counseling, it is standard practice to indicate that there is no increased incidence of limb defects after 10 weeks.

PLACENTAL MOSAICISM

Confined placental mosaicism occurs in approximately 1% of samples.[40] Analyzing several cultures makes it easier to detect in vitro changes, because they are usually present in a single culture (pseudomosaicism). However, the same finding in several or all of the cultures increases the likelihood of true mosaicism, either confined to the placenta or present in both placenta and fetus. In this case, another fetal tissue, such as blood or amniotic fluid, should be tested. The finding of markers or a structural abnormality on ultrasound is very important and makes it much less likely that the results are caused by confined placental mosaicism.

LATE PLACENTAL BIOPSY

Several small series indicate that late placental biopsy is both safe and reliable for diagnosis. The loss rate is similar to that of first-trimester CVS.[41,42]

Conclusion

CVS provides a rich source of fetal cells or DNA for analysis of karyotypic and genetic disorders. It is usually performed after 11 weeks, typically by a transabdominal route.

One advantage of first-trimester CVS is that an abnormal result allows surgical termination, if desired. Karyotypic analysis can be accomplished by direct preparation and culture. Placental mosaicism complicates 1% of samples.

Amniocentesis

Introduction

Amniotic fluid contains amniocytes in addition to fetal cells from the skin, genitourinary system, and gut, along with biochemical products that may be removed for analysis. Amniocentesis is performed only under continuous ultrasound guidance.[2]

Indications

GENETIC

Amniocentesis is usually performed to determine a fetal karyotype. Indications for fetal karyotyping include an abnormal screening test result for trisomy 21, advanced maternal age, a sonographically detected structural abnormality, previous aneuploidy, and known chromosomal translocation in either partner.

The amniotic fluid is labeled, the information is examined by the patient for accuracy, and the sample is sent promptly to the cytogenetics laboratory for analysis. The amniocytes are studied during the metaphase stage of cell division. Although standard culture techniques require 2 to 3 weeks, newer methods, with the cells grown on a cover slip, allow a complete analysis in 7 to 10 days.[43] Approximately 0.5% of cultures are unsuccessful; less often, maternal contamination complicates the diagnosis.[44] Fewer than 0.4% of cultures show evidence of pseudomosaicism or true mosaicism.[45,46] FBS may be helpful, but a normal result does not guarantee that all is well.

Direct DNA probing of interphase chromosomes by FISH can be used to detect known deletions, such as 22q in at-risk pregnancies, in addition to rapid diagnosis of trisomy 13, 18, and 21.[47,48] Although a positive test result is reliable, detecting 90% or more of chromosomal abnormalities, a normal FISH result should be confirmed by culture. Polymerase chain reaction (PCR)-based primers are now used with DNA from amniotic fluid samples to determine almost all potentially relevant fetal RBC and platelet genotypes.[49,50] Studies of free fetal DNA in maternal blood may further reduce the need for amniocentesis. In some countries, it is already used to detect fetal D status as part of routine prenatal care.[31]

BIOCHEMISTRY

Amniocentesis to diagnose inborn errors of metabolism and cystic fibrosis by measuring the activity of fetal enzymes and their byproducts has been largely replaced by molecular DNA analysis. Likewise, amniocentesis to measure α-fetoprotein and acetylcholinesterase to diagnose a neural tube defect is rarely necessary because of the reliability of ultrasonography.[51]

FETAL INFECTION

Cytomegalovirus is excreted in fetal urine, and fetal infection is reliably detected by culture of amniotic fluid.[52,53] However, PCR technology is the method of choice for the antenatal diagnosis of fetal viral infection, because many viruses grow poorly in clinical laboratories (see Chapter 27). PCR has replaced the traditional mouse inoculation test for toxoplasmosis because it can be used earlier in pregnancy and has greater sensitivity (see Chapter 33).[54] As with traditional methods, a false-negative result may occur if there has been insufficient time since the maternal infection for transplacental passage to occur.

CHORIOAMNIONITIS

Up to 97% of women with preterm premature rupture of the membranes (PPROM)[55] can be successfully sampled and the specimen assessed by direct microscopy, Gram stain, and culture. It is unclear whether the information gained in women with PPROM changes the clinical outcome. No randomized trial supports the use of routine amniocentesis to diagnose chorioamnionitis in women with either preterm labor or PPROM. Amniocentesis may be useful when the woman is asymptomatic and fetal infection is suspected. Between 17% and 34% of asymptomatic women with PPROM have positive culture findings,[55] allowing for earlier diagnosis and treatment.[56] However, most women with positive culture findings deliver within 48 hours, and there is inadequate information to guide antibiotic selection.

FETAL LUNG MATURITY

Improved gestational dating, appropriate use of corticosteroids, and a growing understanding of the timing of iatrogenic premature delivery has nearly eliminated the need for amniotic fluid analysis to assess fetal lung maturity.[57]

EARLY AMNIOCENTESIS

Some hoped that early amniocentesis (before 15 weeks) would be an alternative to CVS.[22,58,59] However, the risks of early amniocentesis, including spontaneous abortion, stillbirth, and neonatal death, are greater than those of CVS.[21] The CEMAT group concluded that early amniocentesis should be performed only in special circumstances because of the higher fetal loss rate and incidence of talipes with early versus second-trimester amniocentesis.[25] The risk of membrane rupture is particularly high when performed before 13 completed weeks, possibly because, at this stage, the amnion is not adherent to the chorion and so is more likely to rupture. Several other studies found an increased risk of oligohydramnios and associated orthopedic abnormalities, including talipes equinovarus.[21,60] Tenting of the amniotic membrane and the smaller amount of fluid in the amniotic sac before 15 weeks increase the incidence of a "dry" tap caused by tenting of the membranes.[61] The sample is smaller and

there are fewer cells per milliliter, although a higher percentage of cells is dividing actively. Djalali and colleagues[62] reported that longer culture times were required after early amniocentesis.

AMNIOCENTESIS

Amniocentesis is performed under ultrasound guidance after 15 weeks' gestation. A typical karyotypic study requires the removal of 15 to 20 mL amniotic fluid.[2] Removal of larger volumes should be avoided unless necessary for specific tests.

Antiseptic and Anesthetic

Local anesthetic is not normally required for diagnostic amniocentesis.

Target Puncture

Under ultrasound guidance, the needle is advanced into the targeted pool of amniotic fluid, with care taken to avoid the fetus, placenta, and cord (see Fig. 10–2). If the freehand technique is used, the ultrasound beam is directed so that the length of the needle is visualized, allowing the operator to alter the course in response to fetal movements and contractions. When the tip of the needle reaches the targeted location, 1 to 2 mL amniotic fluid is aspirated and discarded to avoid maternal contamination. Approximately 15 to 20 mL fluid is aspirated and sent for analysis. To prevent maternal contamination, the syringe is removed from the hub before the needle is withdrawn from the patient.

Complications

Early studies, including CEMAT, reported a total loss rate of 3.2% after amniocentesis.[25,63] These losses are believed to reflect, at least in part, the large needles used (>19 gauge) as well as unsuccessful attempts. The British Working Party on Amniocentesis reported a 2.4% total fetal loss rate before 28 weeks (stillbirth rate of 1.2% vs. 0.8% in control subjects) and neonatal death (0.5% control subjects), but concluded that the loss rate attributed directly to amniocentesis was 1.5%.[4] A more randomized trial of low-risk women suggested a 1% risk of spontaneous abortion after amniocentesis.[1] Our study of fetal loss after amniocentesis (defined as the total loss rate minus known lethal condition minus losses beyond 2 weeks postprocedure) was 0.7%.[12] Perforating the placenta increases the relative risk of loss 2.6 times and increases the maternal serum α-fetoprotein level 8.3 times.[64] The transplacental route should be avoided unless no other option is available.

Although no randomized controlled trials assessed the procedure-related loss rate from amniocentesis in multiple

pregnancies, case–control studies suggest that the loss rate is only slightly higher than the background rate.[12,65]

OLIGOHYDRAMNIOS

A report by the Medical Research Council[4] noted that 2% of amniocenteses are associated with chronic leakage of amniotic fluid. There are variable reports of an increased prevalence of neonatal respiratory morbidity after amniocentesis; the small risk of oligohydramnios after amniocentesis may contribute to this complication.[1,4,66] Similarly, talipes equinovarus is rarely attributable to amniocentesis, and only when there is oligohydramnios.

FETAL TRAUMA

Inadvertent puncture of the fetus during amniocentesis has not been not reported in a large series when the procedure was performed under continuous ultrasound guidance by experienced operators.[17] Several case reports suggest an association between amniocentesis and skin dimpling, fistulae, cord hematoma, and corneal perforation.[67–69] Because intended fetal puncture rarely leaves a mark and similar findings occur in neonates who did not undergo amniocentesis, the association is dubious.

Conclusion

Amniocentesis after 15 weeks is the most widely performed antenatal diagnostic technique. It is relatively simple to perform, and although a fetal karyotype is the most common reason for amniocentesis, the procedure has many indications. The use of FISH and PCR has steadily reduced the amount of material needed for testing and the time needed to obtain a result.

Fetal Blood Sampling (FBS)

Introduction

Fetal blood was first obtained during labor from the capillary circulation of the presenting part.[70] FBS in a continuing pregnancy was first undertaken transabdominally by fetoscopy to diagnose severe inherited diseases, with termination considered if the fetus was affected. Cordocentesis was first reported two decades ago.[71] The development of medical approaches to fetal disease has made the role of fetal phlebotomy (typically by cordocentesis) comparable to that in postnatal medicine.

Indications

Indications for FBS may be grouped into diagnostic and therapeutic areas. FBS is indicated when the potential benefit of a change in management outweighs the procedure-related risks.

Diagnostic Uses

CHROMOSOMAL ABNORMALITIES

The rapid rate at which white blood cells divide allows a high-quality karyotype with good chromosome banding to be obtained within 48 to 72 hours. The most common indication for a rapid karyotype is fetal malformation or early-onset fetal growth restriction detected by ultrasonography. Other problems that can be resolved by a fetal blood cytogenetic analysis include possible mosaicism, culture failure after either amniocentesis or placental biopsy, fetal karyotyping in a woman who seeks care late in pregnancy, and antenatal diagnosis of fragile X syndrome. For some indications, the application of FISH to amniocytes has replaced FBS.

SINGLE-GENE DEFECTS

FBS can diagnose hemoglobinopathies, coagulopathies, severe combined immunodeficiency, chronic granulomatous disease, and some metabolic disorders.[72] FBS is performed less often for antenatal diagnosis of single-gene disorders because many can be diagnosed earlier in gestation by applying various DNA techniques to amniocytes. FBS is important for at-risk patients who seek care late in pregnancy and when DNA analysis is not possible.

ANEMIA

Although various indirect methods are used to assess fetal anemia (see Chapter 14), the definitive test before and after birth is measurement of the hemoglobin concentration. This may be required in maternal red cell alloimmunization[72] and some cases of nonimmune hydrops.[73] The development of middle cerebral artery Doppler peak velocity greatly enhanced the likelihood of detecting anemia.[7]

THROMBOCYTOPENIA

Severe fetal thrombocytopenia as a result of alloimmune thrombocytopenia may lead to cerebral hemorrhage before, during, or after birth and may cause mental handicap or death (see Chapter 15). The fetal platelet count can be measured to guide diagnosis and treatment.

HYPOXIA AND ACIDOSIS

Fetal acidemia may be excluded by Doppler studies of the fetal vasculature (see Chapters 11 and 12). Suspected fetal hypoxia or acidemia can be confirmed or refuted by fetal blood gas analysis.[74] Increasing evidence shows that chronic fetal acidemia is associated with impaired long-term neurodevelopment.[75] However, no convincing evidence shows that the benefits of fetal acid–base status outweigh the risks of FBS, and it is rarely indicated.

INFECTION

Appropriate fetal blood tests (e.g., infection-specific fetal immunoglobulin M or detection of specific genomic material by PCR) can determine whether maternal infection has led to fetal infection. However, the difference between being "infected" and "affected" (i.e., damaged) must not be forgotten. Fetal blood tests may be unnecessary if the results of an amniotic fluid sample (e.g., a positive PCR result) agree with ultrasound findings (e.g., hydrocephalus).

MONITORING OF TRANSPLACENTAL THERAPY

Some fetal diseases are treated by drugs that are given to the mother, cross the placenta, and achieve therapeutic concentrations in the fetus. Examples include antiarrhythmic agents to correct fetal tachyarrhythmias and γ-globulin to improve low fetal platelet counts. An accurate assessment of placental transfer and monitoring of the success of therapy may require FBS.[76,77]

Procedure

The operator chooses the intended sampling site and guide technique from several options.

SAMPLING SITE

Umbilical Cord Vessels (Cordocentesis). FBS was first performed under fetoscopic guidance,[78] but fetoscopy carried a 2% to 5% risk of serious complications.[79] In addition, the maternal sedation that was used to facilitate the procedure affected fetal blood gas measurements.[80] Ultrasound-guided needling is considered safer than fetoscopy and is the preferred technique.[71,81]

The placental origin of the umbilical cord is often the easiest site to puncture. Many prefer this site because of its fixed location, which prevents movement of the needle. Others accept free loop puncture, but use pancuronium to minimize subsequent fetal movement. The relevant consideration is not the location, but the ease of access. The fetal origin of the umbilical cord is problematic because there is no length to buffer the effect of fetal movement after puncture. In addition, the proximal few centimeters of the umbilicus are sympathetically innervated, theoretically increasing the risk of bradycardia. Although cordocentesis is usually done after 18 weeks, success is reported as early as 12 weeks, at the cost of an increased fetal loss rate.[82,83]

Fetal Intrahepatic Vessels. Blood can also be obtained from vessels within the substance of the liver (Fig. 10–3).[76,84] This procedure is rarely done now, and usually after fetal paralysis with intramuscular injection of pancuronium,[85] but good results have been reported. However, fetal hepatic necrosis within 24 hours of intrahepatic vein blood sampling has been reported.[86]

FIGURE 10–3
Fetal blood sampling by ultrasound-guided needling of the intrahepatic vein.

Intrahepatic blood sampling is an alternative when cordocentesis is difficult, but even then, many prefer to sample the heart.

Fetal Heart. The heart is larger than the umbilical cord, and puncture of the heart is relatively simple (Fig. 10–4). Despite fear of damage, cardiac puncture is relatively safe.[87] The heart can be used in the unusual event that the umbilical cord or hepatic vein cannot be punctured and fetal blood must be obtained. It can also be useful if an emergency blood transfusion is required (e.g., to treat procedure-related bleeding) or for feticide.

FIGURE 10–4
Fetal blood sampling by ultrasound-guided needling of the heart.

FIGURE 10–5
A, A typical needle guide used to perform cordocentesis. The small footprint allows the needle to enter the sonographic plane shortly after it penetrates the skin. *B,* The needle is seen as bright white echoes crossing the amniotic fluid diagonally. The predicted track of the needle is seen as a dotted line immediately adjacent to the needle.

Because the fetal heart contains blood from different circulatory origins, it may not be suitable for blood gas assessment.[88]

NEEDLING TECHNIQUE

A needle guide or freehand technique may be used (Figs. 10–5 and 10–6). The lowest loss rates for cordocentesis are reported with the use of a needle guide.[3]

PROCEDURE

FETAL BLOOD SAMPLING

The following elements are shared, regardless of whether FBS is performed freehand or with a needle guide. FBS should be performed only by physicians who have extensive experience with other obstetric, ultrasound-guided needle procedures (e.g., amniocentesis, transabdominal CVS). Units

FIGURE 10–6
Cordocentesis with the freehand technique.

that offer this service must perform enough cases to maintain expertise; 20 procedures per year is a reasonable minimum. This typically requires a center with many referrals.[89]

Preparation

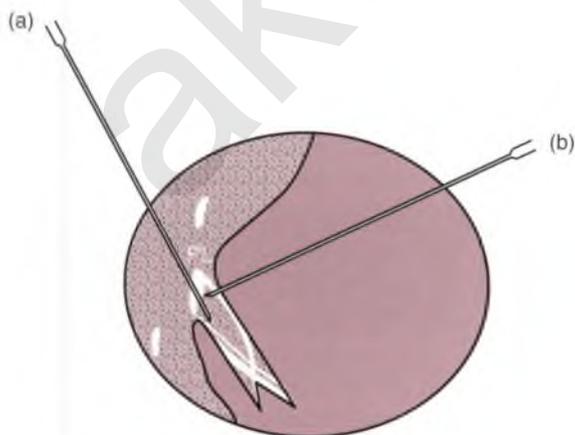
An urgent delivery may be required if the pregnancy is at a potentially viable gestation, and if the indication for the procedure does not indicate a conservative approach before the result is available (for example a major brain malformation). Therefore, the procedure must be performed at a site with easy and rapid access to an operative delivery room with an anesthetist immediately available. The mother should be positioned to avoid supine hypotension; hyperventilation and sedation should be avoided. A 12-cm needle is usually sufficient, but the distance should be measured on the ultrasound screen before starting.

Needle Path Selection

A transplacental approach usually provides the easiest route to the placental cord origin, unless the placenta is entirely posterior. However, in women with red cell alloimmunization, transplacental puncture boosts the maternal antibody titer as a result of fetal–maternal hemorrhage.[90] Therefore, it is best to avoid the placenta unless transfusion is anticipated in an alloimmunized woman (Fig. 10–7).

Target Puncture

Cordocentesis

Many operators prefer the placental origin of the umbilical cord, approximately 1 cm from the placenta, because the blood obtained from this site must be fetal. The needle is brought close to or even touching the umbilical vein, and then sharply advanced the remaining distance. A slow advance may push the tissues away, even at this relatively fixed site. After the needle tip is visualized within the lumen of the umbilical cord, the stylet is removed. If the needle is ideally sited, blood will fill the hub. A 1-mL syringe is applied tightly to the hub, and blood is withdrawn. After 20 weeks, 5 mL may be removed without concern. However, before 20 weeks, the volume removed should be the minimum necessary for the specific tests. Often, no blood is obtained initially and the operator must assess whether the needle tip has passed through the vessel lumen or perhaps is located in Wharton's jelly. The needle is sharply advanced or gently withdrawn, and the shaft is rotated 180° between the operator's finger and thumb while suction is maintained.


Occasionally, amniotic fluid is obtained when the needle tip appears intraluminal. With the freehand technique, the needle is moved side-to-side in search of cord movement. With a needle guide, an up-and-down movement of the needle produces the same result. Cord movement indicates that the needle has passed through the cord. It is withdrawn until no more amniotic fluid is aspirated, the syringe is changed (because even a small amount of amniotic fluid is a very powerful coagulant), and the procedure is continued. If the needle has passed through the side of the cord without entering a vessel lumen, it is withdrawn slightly and its path adjusted. If the tip is lateral to the umbilical cord, it is withdrawn and the needle used to touch the vein before the puncture attempt is repeated.

If blood gas results are to be interpretable, it is essential to identify the vessel that has been entered. If the puncture is performed at either the placental or the fetal origin of the umbilical cord, the vessel can usually be identified by the direction of turbulence after rapid injection of up to 1 mL normal saline.[81] If fetal paralysis is desired, intravascular administration of pancuronium (0.3 mg/kg estimated fetal weight) serves the same purpose as saline for identification.

Intrahepatic or Heart

If the intrahepatic vein or the heart is the intended sampling site, fetal paralysis with intramuscular pancuronium (0.2 mg/kg estimated fetal weight) may be used. The effect is rapid (within minutes) and lasts for 90 to 120 minutes. The techniques for needle path selection and guidance are similar to those described for the umbilical cord. However, the fetal chest or abdomen is entered first, the direction is checked, and the needle is advanced into the sampling site as a separate movement. The heart is best entered through the anterior chest, through the thick muscle of the ventricles, to reduce blood leakage and avoid damage to the valves or electrical conduction system.

A double-needle technique has also been described.[91] The first needle is used to puncture the fetal body cavity, and a second, finer needle is passed within the first to puncture the target. This technique offers no advantage and has several inherent weaknesses. The first needle is usually a larger gauge than otherwise required.

Postprocedure Monitoring

The puncture site is observed ultrasonically for bleeding after the needle is removed. Bleeding is common after transamniotic cordocentesis, but is usually brief and without clinical significance. After bleeding has stopped, the fetal heart rate is measured. Bradycardia is the most common complication of cordocentesis, but it is usually transient in the absence of fetal hypoxemia. If the fetus is previable, the woman should wait in

FIGURE 10–7
Transplacental (*A*) and transamniotic (*B*) fetal blood sampling from the placental insertion of the umbilical cord (cordocentesis). PL, placenta.

the hospital until she feels well, and then return home. There are no special precautions or restrictions. If a local anesthetic is used, she should be warned to expect a bruised sensation in a few hours. Acetaminophen (paracetamol) or another nonprescription analgesic can be used safely. If the fetus is viable, the heart rate pattern is assessed by cardiotocography for at least 30 minutes before discharge. Pancuronium causes a nonreactive tracing, with mild fetal tachycardia. The mother should be warned that perceptible movement might not return for several hours.

In the rare event that bleeding from the puncture site is prolonged and heavy, maternal blood may be collected into heparinized syringes for an emergency fetal transfusion. This is most likely with alloimmune thrombocytopenia when the fetus is profoundly thrombocytopenic.

Laboratory Testing

Several laboratory techniques are available to rapidly confirm that the blood sample is fetal and pure. However, they may be unnecessary if the technique described above is used. Further, they may be usable if the fetal blood has been replaced by transfusion with adult blood. It is prudent to send a small sample of blood for a hematology profile to confirm that the mean cell volume is increased and that the hemoglobin concentration, white blood cell count, and platelet count are normal.

Complications and Risks

FETAL

The principal complications of FBS that threaten fetal well-being are hemorrhage or an obstructing hematoma at the puncture site,[92] fetal bradycardia (probably as a result of smooth muscle spasm after inadvertent puncture of the umbilical artery), and intrauterine infection.[93] Chorioamnionitis is often caused by *Staphylococcus epidermidis*. It typically causes myalgia, arthralgia, and a low fever 4 to 10 days after the procedure. There is no evidence to support prophylactic antibiotic administration. A case report of an abruption shortly after cordocentesis was published.[94] Premature membrane rupture is rare, and the expected frequency is similar to that of amniocentesis. There is a theoretical risk of transmitting infection from the mother's blood (e.g., hepatitis, human immunodeficiency virus) to the fetus, although it does not appear to have been documented. Nevertheless, invasive procedures should be avoided when a mother has a life-threatening viral illness, unless the fetal indication warrants the additional risk.[95]

POSTPROCEDURE LOSS RATES

Several well-recognized factors affect postprocedure loss rates. Loss and complication rates are clearly related to the indication for sampling and the final fetal diagnosis.[3,24,27,29,30,96] The background risk of intrauterine death is high when there is a severe structural malformation or a major chromosomal abnormality. The risk of profound bradycardia is significantly increased by fetal hypoxemia and arterial puncture. Gestational age at sampling is also an important determinant because a viable fetus can be delivered if a complication arises. Emergency cesarean section may prevent fetal death, but by the time the problem is recognized and delivery is accomplished, the neonate may survive permanently damaged or die in the neonatal period. Performing the procedure near the delivery suite minimizes these risks, if delivery can be accomplished within 15 minutes. Complications may not be seen until delivery occurs.

The literature must be interpreted carefully because postprocedure loss rates are described after the application of qualifiers. It is essential to control for the indication or final diagnosis when comparing loss rates. It is only by doing so and by limiting the comparison to healthy fetuses that the risk of the technique is shown. Reports of procedures performed freehand show a total procedure loss rate of approximately 1% to 2%, depending on the mix of indications. In one study of 202 pregnancies, the loss rate was 1 of 76 (1.5%) fetuses sampled for antenatal diagnosis, 5 of 76 (7%) sampled for an anomaly, 4 of 29 (14%) sampled for fetal assessment, and 9 of 35 (25%) sampled for nonimmune hydrops.[29] In our unit, the procedure-related loss rate for FBS is approximately 1.2% with the freehand method described.[12] Transfusion carries a considerably higher procedure-related risk than FBS.

MATERNAL

The main maternal risk associated with FBS is red cell alloimmunization. The fetal blood type should be tested in at-risk women, and anti-D immunoglobulin should be given if the fetus is Rhesus-positive. Chorioamnionitis or emergency cesarean section can create secondary maternal risks. When FBS or transfusion is undertaken and the fetus is considered viable, maternal aspects of emergency delivery should be considered. Needle injury to the maternal intra-abdominal organs, such as intestines, or vessels may be more common than recognized, but significant morbidity has not been reported after FBS. Maternal intra-abdominal infection and bleeding would be expected to occur at the same rate as that for amniocentesis.

Conclusion

FBS is indicated when the potential benefits of a change outweigh the procedure-related risks. The risks and benefits to both the fetus and the mother should be considered. Most prefer FBS by ultrasound-guided needling of the umbilical cord (cordocentesis). The fetal heart and intrahepatic vein are alternative sampling sites. None of these techniques should be attempted unless the operator has considerable experience with related procedures. The most important determinant of the fetal loss rate is the indication for sampling.

SUMMARY OF MANAGEMENT OPTIONS

Fetal Tissue Biopsy

Although progress in molecular biology allows more diseases to be diagnosed from fetal DNA, some conditions are diagnosable by testing of fetal tissue, such as skin, liver, and muscle. These tests are rarely indicated because the diseases are rare. Only experienced fetal medicine specialists should perform them. Rapid advances in the field mandate close contact with a clinical geneticist to stay abreast of advances.

Skin Biopsy

INDICATION

Histologic examination of a fetal skin biopsy specimen is useful for the diagnosis of some bullous disorders (congenital bullous epidermolysis, epidermolysis bullosa dystrophica, epidermolysis bullosa lethalis[79,97,98]) and hyperkeratotic disorders (congenital ichthyosiform erythroderma, epidermolytic hyperkeratosis, Harlequin ichthyosis) [Figs. 10–8 and 10–9].[99–101] A molecular understanding of these diseases will make early diagnosis by CVS possible.

PROCEDURE

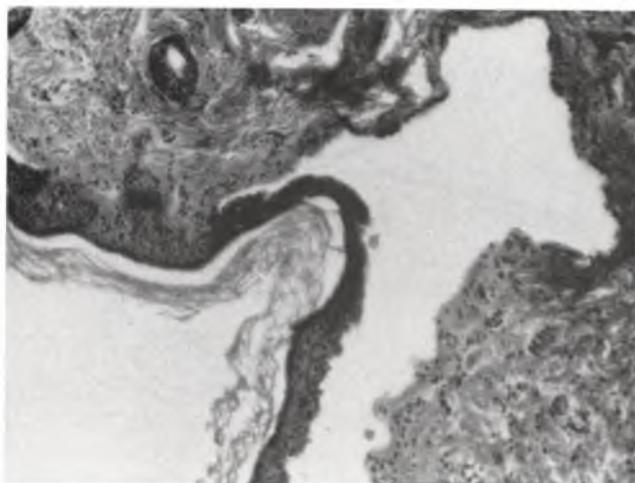
Fetoscopy is rarely performed diagnostically, but the development of new fiberoptic scopes has decreased the preg-nancy loss rate to less than the rate of 2% to 5% associated with classic fetoscopic methods.[97] These scopes are popular aids for some therapeutic fetal procedures (e.g., laser ablation). For skin sampling, this technique has been replaced by ultrasound-guided biopsy, commonly performed with a 20-gauge biopsy forceps introduced through a 16- to 18-gauge needle. Obtaining multiple small biopsy


FIGURE 10–8

FIGURE 10–9
An infant with harlequin ichthyosis.

FIGURE 10–11
A cutting needle with an aspiration trocar.

specimens of skin from the scalp over the occiput or from the buttocks is recommended.[102,103] The fetal skin heals well after biopsy.

LABORATORY TECHNIQUES

Histologic and biochemical tools are used to diagnose skin conditions. Several ichthyoses and genetic conditions associated with ichthyoses are diagnosable with fetal cells obtained from CVS, amniocentesis, or FBS.[101]

Fetal Liver Biopsy

Amniotic fluid cells and placental tissue may be used to diagnose most fetal metabolic diseases.[104] However, some inheritable inborn errors of metabolism show defects in enzyme activity confined to the liver, and require a fetal liver biopsy.

PROCEDURE

Fetoscopic[97] and ultrasound-guided[105] procedures are used (Fig. 10–10). Either a hollow needle or a Tru-Cut biopsy needle is inserted through the skin, over the right upper quadrant of the fetal abdomen, and into the liver. (Fig. 10–11) The biopsy specimen is sent to a laboratory. Normal overall activity of a number of enzymes but low activity of a specific enzyme is considered evidence of disease.

Fetal Muscle Biopsy

The most common inheritable major muscular dystrophy is Duchene muscular dystrophy, which is caused by a defect in the gene for dystrophin.[106] Although it is often diagnosable antenatally from fetal DNA obtained by CVS, with molecular analysis seeking either a deletion

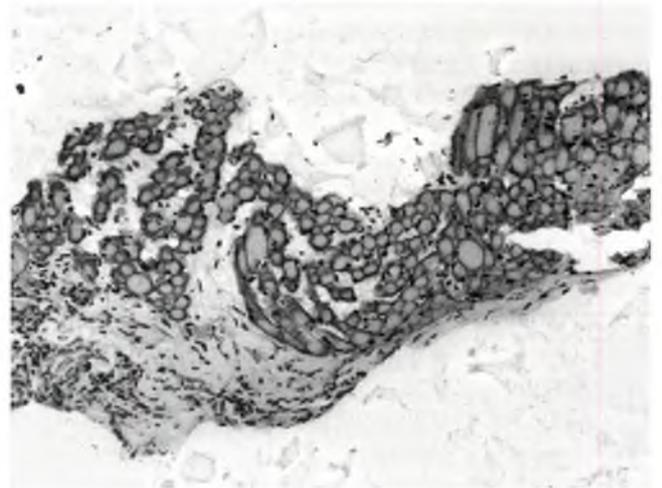
FIGURE 10–10
Fetal liver biopsy performed with a fetoscope.


FIGURE 10–12
A fetal muscle biopsy specimen obtained at 22 weeks' gestation. The immunofluorescence of dystrophin indicates that the fetus is normal; this finding was confirmed at birth. (Courtesy of Prof S. Love, Department of Neuro-pathology, Bristol.)

mutation or linkage analysis, the gene is large, with many possible defect sites.[107] In some cases, no deletion is found and biopsy is the only recourse.[108]

LABORATORY TECHNIQUES

A wide range of studies is possible. For Duchenne muscular dystrophy, the biopsy specimen is examined to confirm the presence of muscle and treated with an immunofluorescent antibody for dystrophin protein (Fig. 10–12).[109]

PROCEDURE

These uncommon procedures should be performed only by experienced fetal medicine specialists.[110] The maternal abdominal skin is anesthetized, and a small nick is made with a scalpel to facilitate the entry of a Tru-Cut biopsy gun (Fig. 10–13).[108] Under ultrasound guidance, the tip is advanced into the fetal buttock or thigh in a down-and-out direction. The coring guide is extended, and the trigger is pulled to cut the biopsy specimen. Risks of the procedure include fetal bleeding, nerve damage, and pregnancy loss. There are reports of maternal contamination,[111] but this can be prevented with a double-needle technique.

Other Organ Biopsy

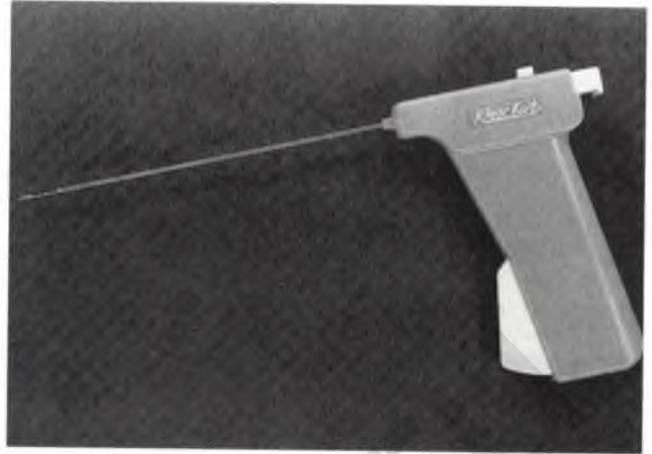
Histologic diagnosis of fetal tumors would be helpful in many cases, and there are reports of biopsy of fetal mediastinal and renal tumors.[112] However, biopsy of any tumor can cause uncontrollable bleeding, leading to severe fetal damage or death. In many cases, the histo-


FIGURE 10–13

logic features vary in different locations. As a result, biopsy of a fetal mass is rarely advised.

Conclusion

Most antenatal fetal diagnoses are based on fetal DNA obtained by CVS, amniocentesis, or FBS. However, fetal skin, liver, and muscle biopsy specimens are required for some lethal or severely disabling conditions. These are complex procedures, with significant risk to the pregnancy, and they should be performed only in tertiary fetal medicine centers by experienced clinicians.

CONCLUSIONS

- The need for invasive procedures has decreased as the sophistication of ultrasound diagnosis has improved. However, indications for these procedures will continue, and they must be performed by specialists in fetal medicine who regularly audit their postprocedure complication rates.
- Training in these procedures must be well supervised and limited.
- Performing fetal invasive diagnostic procedures is a steppingstone to performing more complex invasive therapeutic procedures.

SECTION THREE

Late Prenatal—Fetal

Critical Evaluation of Fetal Assessment Methods

Clare Gribbin / Jim Thornton

INTRODUCTION

Much of modern obstetric practice consists of fetal assessment to permit early delivery if it is considered safer than continued observation. However, little evidence supports much of this practice.

For the high risk fetus, in certain clear-cut cases, careful monitoring and timed delivery prevents fetal death. Some evidence from randomized controlled trials of fetal monitoring supports this belief. Whether timed delivery has an effect on fetal brain damage is not known.

For low risk pregnancies, there is little evidence that direct assessment of the fetus reduces adverse outcomes, and screening for fetal compromise may do more harm than good. In the few areas in which trials have been done, the results generally support this view. Conventional practice is to monitor the maternal condition by regular blood pressure screening and urine testing, and at most, to perform simple, indirect fetal assessment, such as reporting fetal movement and measuring fundal height. Other tests should be used only in the context of research trials.

Prenatal assessment of the fetal condition has the following two main phases:

- In the first half of pregnancy, assessment is done to exclude fetal abnormality and, in a limited way, fetal infection. These issues are discussed in Chapters 7, 8, and 27.
- In the second half of pregnancy, the priority is to monitor the condition of the presumed normal fetus, with a view to determining the optimum time for delivery.

Practical Problems

Much of our understanding of fetal compromise comes from animal studies in which the fetus was rendered chronically hypoxemic by narrowing of certain vessels. These models provide rough guidance for the management of the human fetus. However, even the best models do not mimic human diseases precisely, and obviously, there is no reliable animal model for human hypoxic brain damage. Policies for investigating and managing human pregnancy must be based on human research studies.

At least four problems arise in practice:

- Tests are rarely evaluated for the prediction of important endpoints, such as fetal death and brain damage. More often, an abnormal test result is related to another adverse outcome, such as fetal acidemia, a low Apgar score, or admission for neonatal care. Because the relation between these outcomes and fetal death or brain damage is weak, it is easy to be misled.
- To evaluate tests for the prediction of death or disability, the results should be concealed from the clinician to avoid treatment paradox. For example, if an abnormal test result correctly predicts fetal death but is revealed to the clinician, who administers an effective treatment (e.g., delivery), and the fetus survives, the test result will appear to have been false-positive. In contrast, if a false-positive result is revealed and the physician delivers the infant so early that the infant dies of complications of prematurity, the test will appear to have correctly predicted death. The only way to avoid this paradox is to conceal the results from the physicians who treat these patients. This has been done for the umbilical artery waveform,[1] but has rarely been done for other tests because of ethical concerns about concealing potentially important clinical information.
- The difficulty facing the physician who is attempting to interpret a specific test result, such as a biophysical score of 6, is that the meaning of the result for this patient depends on the population of pregnancies in which it is

being applied. In a woman who smokes, has had two previous stillbirths, and is hypertensive and bleeding, this result would predict a high risk of fetal death in the next week or so. However, in an asymptomatic, non-smoking, normotensive woman in her first pregnancy who had an ultrasound scan because of anxiety, the same test result would be associated with a much better prognosis. Among women with low risk pregnancies, there is a relatively greater chance of a false-positive result. Physicians often neglect the effect of different previous risks on test interpretation (discussed later).

- Finally, timed delivery is the only effective treatment for the preterm fetus that is failing to thrive. However, timed delivery may do harm as well as good, and until recently, it had never been evaluated by a randomized controlled trial. The lack of clear evidence that one testing regimen is better than another is reflected in the different practice across the Atlantic Ocean. In North America, a biophysical profile is the most popular test for deciding the timing of delivery, whereas in Europe, a combination of cardiotocography (CTG) and Doppler findings is more common.

Clinical Judgment

The lack of hard evidence from randomized trials is not an argument for a nihilistic approach to testing in high-risk pregnancy. Few tests have been shown to be useless, and most have not been properly evaluated. Even adequately powered trials of good tests may give negative results if participating physicians do not know how to interpret the results or act on them wisely. The Growth Restriction Intervention Trial (GRIT)[2] provides reassuring evidence that at least the specialists who participated in the trial know how to interpret the results of these tests properly. When the obstetrician was uncertain, participants were randomly allocated to "deliver now" or "delay." Although more stillbirths occurred in the "delay" group, these were balanced by other deaths in the "deliver now" group. It is likely that when specialists were certain that delivery was indicated, they were usually correct.

INDICATIONS FOR FETAL ASSESSMENT

Pregnancies with No Risk Factors for Fetal Compromise ("Low Risk")

As discussed earlier, the most common and conventional methods of fetal assessment in low risk pregnancies are the following:

- Maternal monitoring of fetal movement
- Measurement of symphysis–fundal height
- Auscultation of the fetal heart

No evidence supports the use of routine ultrasound to screen for fetal compromise in low risk pregnancies.[3–5]

Pregnancies with Risk Factors for Fetal Compromise ("High Risk")

Disease in the Fetus (See also Chapter 12)

Triploidy is associated with severe asymmetrical growth restriction and abdominal measurement that lags many weeks behind the head measurement. The diagnosis is easily made by recognizing this and identifying the multicystic appearance of the placenta. The diagnosis is confirmed by placental biopsy. These fetuses are nonviable. Other aneuploidies, such as trisomy 13, trisomy 18, and to a lesser extent, trisomy 21, are associated with lesser degrees of growth restriction. These can be diagnosed by identifying the typical anatomic features on ultrasound and by placental biopsy (see Chapters 8, 9, and 10).

Confined placental mosaicism explains some cases of growth restriction.[6] Most specific syndromes associated with uniparental disomy (UPD), such as Prader-Willi syndrome (maternal UPD15). Angelman syndrome (paternal UPD15), Silver-Russell syndrome (mUPD7), and Beckwith-Wiedemann syndrome (pUPD11), are also characterized by growth restriction. Uniparental disomy of other chromosomes has been described in growth-restricted patients without additional phenotypic abnormalities. However, with current searching techniques, few cases can be explained by uniparental disomy, usually for chromosome 16.[7]

Growth restriction is a feature of intrauterine infection with toxoplasmosis, cytomegalovirus, and rubella. However, this type of infection accounts for few cases of isolated growth restriction.[8] In areas and settings in which they are prevalent, malaria and HIV infection are also important causes.

Multiple pregnancies are associated with an increased risk of fetal compromise from either uteroplacental vascular disease or twin–twin transfusion syndrome (see Chapter 24).

Disease in the Mother

Two types of patients can be identified:

- Those with a specific pathology
- Those with no known pathology, but a risk of adverse fetal outcome

RISK WITH SPECIFIC PATHOLOGY

Essential hypertension and preeclampsia and renal and autoimmune diseases, especially systemic lupus erythematosus, are associated with an increased risk of growth restriction in association with uteroplacental vascular disease (see Chapters 36 and 44). Many types of thrombophilia, such as lupus anticoagulant and factor V Leiden homozygosity, are associated with growth restriction.[9–12]

Maternal diabetes typically causes fetal macrosomia and risk of fetal death (probably from a combination of

fetal hypoxia, acidemia, and hyperglycemia[13]), especially in women with microvascular complications (see Chapter 45).

Drugs and toxins can reduce fetal growth. Important examples include anticonvulsants, especially phenytoin; smoking; cocaine use; and excessive alcohol intake.

Other maternal factors associated with increased fetal risk are thyroid disease (transplacental transfer of thyroid-stimulating antibodies that cause fetal thyrotoxicosis), isoimmunization (fetal hemolytic anemia [see Chapter 14]), maternal cyanotic heart disease (see Chapter 37), and inadequate nutrition.

RISK WITH NO KNOWN PATHOLOGY

Risks with no known pathology include the following:

- Reduced fetal movements (discussed later)
- Vaginal bleeding (see Chapter 59)
- Prolonged pregnancy (see Chapter 66)
- Abdominal pain of uncertain cause
- Ruptured membranes (see Chapter 63)

In high-risk pregnancies, the following methods are often used to assess fetal health:

- Measurement of fetal growth
- Measurement of amniotic fluid volume
- Umbilical artery Doppler recordings
- Measurement of middle cerebral artery blood flow
- Measurement of ductus venosus blood flow
- Uterine artery Doppler recordings
- Fetal heart rate recordings
- Biophysical profile testing

The following methods, which are less commonly used, are also reviewed:

- Placental grading
- Biochemical testing

CRITICAL EVALUATION OF FETAL ASSESSMENT METHODS

Monitoring of Fetal Movements

Although it is easy for women to count fetal movements, obtaining a total daily count is time-consuming and unnecessary for most pregnancies in which movement is normal. A better method is for women to count 10 movements and to record how long it took for these movements to occur (the "count to 10" chart). Inability to count 10 movements in a 12-hour period is associated with an increased likelihood of fetal death, although randomized trials of this policy have not shown improvement in fetal outcome with this approach.

The authors of the largest randomized study suggested that the failure to reduce the death rate was mainly caused by false reassurances or inappropriate interpretation of subsequent studies, including fetal heart rate

monitoring (discussed later) (cardiotocography, CTG; and nonstress testing, NST).[14]

Symphysis–Fundal Height Measurement

Inspection and informal palpation of the abdomen alone detect only 30% of fetuses that are small for gestational age.[15] Formal measurement of symphysis–fundal height (the distance in centimeters from the top of the uterus to the pubic bone) is not more effective and did not improve the perinatal outcomes measured in the one controlled trial found during systematic review.[16]

A controlled trial of fundal height measurement plotted on customized antenatal growth charts compared this practice with fundal height assessment by abdominal palpation (the usual management). The study group had a significantly higher antenatal detection rate of infants who were small for gestational age (48% vs. 29%; odds ratio, 2.2; 95% confidence interval, 1.1–4.5). There were no differences in perinatal outcome.[17] The United Kingdom National Institute of Clinical Excellence (NICE) guidance on antenatal care stated that pregnant women should be offered estimation of fetal size at each antenatal appointment.

Auscultation of Fetal Heart Sounds

No studies have examined whether auscultation of fetal heart sounds identifies fetuses at risk or improves fetal outcome. Nevertheless, it is recommended as standard practice. In theory, fetal arrhythmia, such as congenital heart block or tachyarrhythmia, could be identified, although detection of such rare conditions would require routine and regular documentation of fetal heart rate, which is not performed in routine practice.

Ultrasound Assessment of Fetal Growth

A systematic review showed no evidence from randomized trials that the use of fetal growth assessment reduces important adverse outcomes in either high-risk or low-risk pregnancies.[4] In low-risk pregnancies, most trials were of isolated measurement of fetal size (usually abdominal circumference). Because single measurements of abdominal circumference are poor predictors of fetuses with pathologic growth, serial measurements may be better. The trial of McKenna and associates[18] supports this approach. In this study, scans were performed at 30 to 32 weeks and at 36 to 37 weeks. The rates of intervention in the study and control groups were 31.3% and 16.9%, respectively. The authors concluded that introduction of an ultrasound scan at 30 to 32 weeks and at 36 to 37 weeks may reduce the risk of the delivery of a growth-restricted infant, but increase antenatal interventions.

In theory, serial measurements can show a decline in growth as a fetal measurement crosses percentile lines.

This approach may be superior to waiting until the absolute measurement is below a particular cutoff value. Measurements of abdominal circumference are relatively inaccurate, and using two measurements doubles the chance of measurement error. If the first measurement is randomly high and the second measurement is randomly low, a normal fetus can easily be classified as having falling growth.

Ultrasound measurements are the best predictors of fetal weight.[19] Few experts would consider not performing at least some measure of fetal size when managing a high-risk pregnancy.

Amniotic Fluid Volume

In the second half of pregnancy, the fetal kidneys produce most of the amniotic fluid. If the fetus redistributes blood flow away from them (discussed later), urine production and amniotic fluid volume decrease. Amniotic fluid volume cannot be measured accurately in clinical practice. Ultrasound measurement of amniotic fluid volume is the best reproducible method. There are two ways in which this can be measured with ultrasound: the single maximum pool diameter and the amniotic fluid index (the sum of the maximum vertical pool in each of four uterine quadrants, excluding those containing fetal limbs or cord [see also Chapter 13]).

A systematic review with a meta-analysis of 18 studies involving more than 10,000 pregnancies showed that oligohydramnios (defined as an amniotic fluid index below the third percentile) was associated with an increased risk of a 5-minute Apgar score of less than 7 (relative risk, 5.2; 95% confidence interval, 2.4–11.3).[20] However, a low Apgar score is considered a fairly poor outcome endpoint. In that systematic review, only one study looked at the predictive value of the amniotic fluid index for neonatal acidosis, and this study reported a poor correlation between the two.

Chamberlain and associates[21] and Bastide and associates[22] showed that pregnancies with reduced liquor volume were associated with increased perinatal mortality compared with control subjects with normal liquor volume. However, the predictive value of a low volume of amniotic fluid is not clear when it occurs in isolation (e.g, in the absence of an abnormal umbilical artery Doppler recording or abnormal growth velocity). Further, no randomized controlled trials have shown the effect on fetal outcome of the use of amniotic fluid volume in the management of high-risk pregnancies.

Pathophysiology of Fetal Blood Flow

Much can be inferred from Doppler ultrasound recordings of blood flow velocity waveform signals from the fetal circulation in normal and pathologic pregnancies as well as from experimental models of acute hypoxia in animals. The umbilical artery is the most commonly studied vessel.

Umbilical Artery

In the first half of a normal pregnancy, the fetal side of the placental circulation is of relatively high resistance. There is little or no forward blood flow in the umbilical artery at the end of diastole. Even as late as 28 weeks, nearly 1% of normal pregnancies have absent end diastolic flow velocities. However, as gestation advances, placental resistance decreases, and in the normal fetus, considerable forward movement of blood occurs in the umbilical artery throughout the cardiac cycle. Therefore, the systolic-to-diastolic ratio is low. In normal pregnancy, the actual values for the S/D ratio decrease with increasing gestational age. In placental insufficiency, the S/D ratio increases until forward flow ceases at the end of diastole (absent end diastolic flow) and flow reverses later (reversed end diastolic flow).

Regional Changes in Blood Flow

Animal models show a consistent increase in blood flow to the heart, brain, and adrenal glands with experimental hypoxia and redistribution of umbilical venous return, with an increased proportion of highly oxygenated blood bypassing the liver through the ductus venosus. Initially, this causes increased heart rate and cardiac output. With increasingly adverse conditions, progressive impairment of cardiac function occurs, leading to decreased cardiac output. Normally, right-sided cardiac output is higher than left-sided output by a factor of approximately 1.3. With redistribution, the ratio changes as the left ventricle (which mainly sends blood to the brain) afterload decreases and the right ventricle afterload increases. If the right side of the heart begins to fail, then the increased right atrial pressure causes marked reduction in flow velocities during the atrial systole phase of the cycle in the vena cava, ductus venosus, and umbilical vein. Atrial systole is timed by the "A wave" of the venous cycle, and reduced flow velocities are seen as an increase in the size of this inverted A wave. These venous pulsations are analogous to the pulsatile waveforms seen in the jugular vein in adults with left-sided heart failure.

As the afterload in the right ventricle increases and end diastolic pressure increases in the right atrium, impairing forward flow, the reduction in forward flow progresses to absence and then reversal of venous blood flow with atrial contractions. This reversal is initially restricted to the inferior vena cava, but as fetal compromise progresses, it is seen across the ductus venosus and umbilical vein. This distal progression reflects deterioration in myocardial function.

In humans, the flow velocity waveforms in fetal cerebral arteries show the development of low resistance patterns under hypoxic situations. This suggests that, as in animals, the human fetus is redistributing blood flow and giving preferential supply to the brain ("brain-sparing phenomenon" or "centralization" of flow). There is some evidence that, as in animals, redistribution of the umbilical venous return occurs, with an increased proportion of

highly oxygenated blood bypassing the liver through the ductus venosus, although this has not been shown directly in humans.

Studies comparing Doppler circulatory changes with cord blood gas levels at cordocentesis suggest that fetal arterial and ductus venosus pulsatility provides a good estimate of the degree of fetal hypoxemia and acidemia.[23] Vasodilatation in the cerebral vasculature occurs during mild to moderate hypoxemia. With severe hypoxemia (2–4 standard deviations below the mean for gestation) and acidemia, the reduction in middle cerebral artery pulsatility index (PI) reaches a limit that may represent maximum vessel dilation. At this point, vital organs receive so much of the available cardiac output that the oxygen supply for nonessential organs is inadequate and leads to metabolic acidosis, myocardial hypoxia, and cardiac failure.

Fetal Umbilical Artery Doppler Recordings

Perinatal mortality and morbidity rates increase with the degree of abnormality of umbilical artery Doppler recording.[24–26] Karsdorp and associates[24] estimated that the odds ratios for perinatal mortality in pregnancies complicated by absent and reversed end diastolic flow were 4 and 11, respectively. Although most studies were susceptible to treatment paradox, these waveforms have been measured in studies in which the results were concealed. Those results confirm that the umbilical artery waveform is a good test for the prediction of fetal death.[1]

Fetal umbilical artery Doppler blood flow waveform is the only test that has been evaluated in randomized trials that included a reasonable number of pregnancies. These studies support the conclusion that its use in high risk pregnancies reduces the rates of perinatal morbidity (defined as admission to antenatal units and induction of labor) and mortality.[27] No data are available to guide clinicians about the optimum frequency of use.

However, studies of its use in low risk pregnancies showed more deaths in the groups allocated to Doppler.[5,28] The numbers were small, and the results are equally compatible with an important beneficial effect and an important adverse effect. It is unlikely that umbilical artery waveforms behave differently in low risk women. More likely, the clinicians did not recognize that the predictive value of a positive test result in a low risk population was lower than the predictive value of the same result in a high risk group. This would have resulted in an excessively high rate of unwise early delivery. Whatever the mechanism, Doppler cannot be recommended as a general screening tool in low risk populations.

Regional Blood Flow: Cerebral Artery

Measurement of Redistribution

The middle cerebral artery is the easiest fetal cerebral vessel to visualize. It is the main branch of the circle of Willis and the direct intracranial continuation of the internal carotid artery. It carries approximately 80% of blood to the ipsilateral hemisphere and is divided into the following four segments.

- M1, which extends from the origin by the internal carotid to the anterolateral side of the sphenoid bone, where the anterior temporal artery originates
- M2, which extends from this point to the origin of the frontal arteries (anterior and ascending)
- M3, the posterior temporal artery
- M4, the cortical segments

Because the PI in M2 is always higher than that in M1, measurement must be made in the same portion of the vessel to allow reliable comparisons. Conventionally, PI is measured in the most proximal segment of M1, at the origin by the internal carotid.

Definition of Arterial Redistribution

Redistribution is indicated by a low middle cerebral artery PI (or resistance index, RI). Usually, a cutoff value of less than 2 standard deviations from the mean for gestational age is used. However, cerebral redistribution of fetal blood flow during hypoxia is probably associated with peripheral vasoconstriction. Therefore, the ratio between cerebral arterial PI or RI and, say, umbilical artery PI may be a more sensitive indicator of redistribution. The ratio between blood flow velocity of the umbilical artery and that of the middle cerebral artery does not appear to depend on gestational age. A cerebroplacental ratio of less than 1 indicates redistribution.

Clinical Value

Several comparative studies examined high risk pregnancies with redistribution and correlated this finding with perinatal outcome. As with umbilical artery Doppler assessment, the fetus with small for gestational age (SGA) and middle cerebral artery PI in the normal range is at lower risk perinatally than the fetus with abnormal middle cerebral artery PI.[23,29,30]

Studies reporting longer-term outcome found no difference in neurodevelopmental assessment in infants up to 2 years of age.[31] However, by 5 years of age, some neurologic differences were detectable.[32] The inclusion of fetal cerebral artery velocimetry in the management of complicated pregnancies may improve the outcome.

No randomized controlled trials have tested the effect of including measurement of fetal cerebral artery velocimetry or venous waveforms (discussed later) in the management of even high risk pregnancies.

Fetal Anemia (See also Chapter 14)

The fetal middle cerebral artery has been the subject of research that has directly affected the clinical management of conditions that cause fetal anemia. Doppler peak

velocity recording appears to correlate with fetal hemoglobin more precisely than the maternal antibody titer. Moderate and severe anemia can be detected noninvasively by Doppler ultrasonography on the basis of an increase in the peak velocity of systolic blood flow in the middle cerebral artery.[33,34] This should decrease the need for invasive procedures (e.g., amniocentesis, fetal blood sampling) and their associated complications. Reference ranges for middle cerebral artery peak systolic velocity and intervention zones have been developed to guide clinical practice.[35]

Regional Blood Flow: Venous Waveforms

The development of abnormal waveforms in the umbilical vain, inferior vena cava, and ductus venosus point to a late stage of progressive deterioration of the fetal condition and severe fetal compromise.[23,29,30] However, venous Doppler waveforms can be difficult to obtain, and in some series, evaluable waveforms were achieved in only approximately 75% of cases.

Uterine Artery Doppler Waveforms

The uterine artery waveform is used more often to predict disease in late pregnancy than to assess the fetal condition directly. An abnormal waveform at 11 to 14 weeks[36] or at 23 weeks[37,38] identifies a high proportion of cases of severe preeclampsia or fetal growth restriction. This may provide the basis for preventive therapy with either low-dose aspirin or vitamin supplements. After 34 weeks, abnormal uterine artery Doppler waveforms at diagnosis are associated with a fourfold increased risk of adverse neonatal outcome.[39]

Biophysical Measures of Fetal Assessment

Fetal Heart Rate Patterns*

The normal fetal heart rate varies continuously as the vagal and sympathetic tone constantly adjust cardiac output to meet the demands of fetal activity. Regular acceleratory periods occur in response to movement and are superimposed on a lower level of baseline variability. As the fetus becomes hypoxic, both the baseline variability and the accelerations in response to movement decrease. At a late stage of hypoxemia, the fetus has intermittent periods of bradycardia in response to temporarily worsening hypoxia related to Braxton Hicks contractions.

The fetal heart rate pattern is easily measured noninvasively with an external Doppler device. These devices calculate the fetal heart rate every three to five beats and plot the rate on paper. Uterine contractions can be measured simultaneously with an external tocometer, and fetal movements may be recorded by the mother with a marker device. The normal fetal heart rate pattern varies

with gestational age. Beyond 30 weeks, the normal baseline is between 120 and 160 beats/min, the baseline variability is more than 5 beats/min, and there is a 20- to 30-minute cycle of sleep activity. During the active phase of the cycle, the fetal heart rate accelerates in response to uterine contractions and fetal movement.

Computerized Analysis of Fetal Heart Rate

Short-term variation derived from fetal heart rate monitoring is a widely used indicator of fetal compromise. It correlates well with the development of metabolic acidemia and intrauterine death.[40] Dawes and associates[41] developed a computer program to assess variations in fetal heart rate. Short-term variation is best correlated with hypoxemia and increases with gestational age. The 2.5 percentile value is 4.4 msec at 26 weeks, 5 msec at 28 weeks, 5.4 msec at 30 weeks, 5.9 msec at 32 weeks, and 6 msec at 34 weeks and beyond. Acidemia is rare when the short-term variation is 4 msec or more. Administration of steroids causes a transient decrease in short-term variability.

Clinical Studies of the Value of CTG/NST

In a systematic review of four randomized controlled trials (involving fewer than 2000 pregnancies), the use of CTG/NST did not improve fetal outcome. There was a trend toward increased mortality in the group receiving CTG/NST compared with those who did not.[42] However, the trials did not have sufficient power to detect a significant effect on perinatal mortality rates. Computer analysis of CTG/NST had greater accuracy than clinical experts in predicting fetal acidosis and low Apgar scores.[43,44]

Biophysical Profile Score

The biophysical profile score predicts both acute and chronic outcome (the former more than the latter) and has very high negative predictive value.[45–47] In a systematic review, Alfirevic and Neilson[48] concluded that there were insufficient data to determine the value of the biophysical profile score in the management of high-risk pregnancies. However, only four poor-quality studies, with fewer than 3000 patients, were available for review.

Order of Changes

Four studies[29,30,49,50] attempted to describe the order in which these changes occur. This is difficult in humans because not all fetuses follow the same pattern, the results depend on how abnormality is defined, and because it is unethical to withhold delivery from sick human fetuses, whichever test is used to time delivery will appear to be the last result to change. Nevertheless, abnormalities in the umbilical artery waveform tend to appear first, followed by cerebral redistribution, early venous changes, and decreased breathing movements. Amniotic fluid volume starts to decrease, and then short-term variability in the fetal heart rate decreases.

*Cardiotocography (CTG) or non-stress testing (NST)

Abnormal umbilical venous pulsation, reversed umbilical artery pulsation, abnormal fetal movements and tone, and fetal bradycardia are late events.

Test Combinations

There is no accepted standard of practice for the surveillance and management of high risk fetuses. Many centers use a combination of fetal growth, umbilical artery Doppler recordings together with CTG, biophysical profile, and other Doppler studies[49,51,52] and give the mother steroids, if preterm delivery is considered. The optimum timing of delivery is unknown, although most would not continue the pregnancy beyond 34 weeks if Doppler recordings show persistent abnormality of the umbilical artery.[49]

Placental Grading

As the normal placenta ages, its ultrasound appearance changes. It becomes calcified, and the cotyledons become more clearly demarcated. These changes can be graded from I to IV. There has been only one randomized controlled trial of routine placental grading as a screening tool in a low risk population.[53] This trial showed improved perinatal outcome in the scanned group compared with those who were not scanned. However, several important points should be noted. The numbers in the study were smaller than would normally be expected to show a significant difference in fetal outcome measures. The group that did not have placental grading had a higher incidence of adverse fetal outcome than would normally be expected for a low risk population, and the improvement in outcome did not occur exclusively in those with abnormal placental grading. Further research on placental grading in low risk and high risk pregnancies is needed. Placental grading is not widely used in clinical practice.

Biochemical Tests

The most recent Cochrane review[54] found that the use of biochemical tests of placental function led to no obvious differences in perinatal mortality rates (relative risk, 0.88; 95% confidence interval, 0.36–2.13). Available trial data do not support the use of estriol estimation in high risk pregnancies. This review included only one eligible trial of poor quality. The only argument in favor of using a biochemical test in fetal assessment is the use of midtrimester elevated maternal serum α-fetoprotein levels as a predictor of later intrauterine growth restriction or preeclampsia.[55] There is no information about the ideal frequency of subsequent surveillance, nor is there evidence that this surveillance is associated with improved outcome.

CONCLUSIONS

- Maternal monitoring of fetal movements is useful for identifying fetuses at increased risk for fetal death.
- Further study is needed to determine the best method for subsequent fetal monitoring when women report reduced fetal movements.
- Symphysis–fundal height measurement has considerable limitations when used as the sole screening test for pathologic fetal growth. It has low sensitivity, a high false-positive rate, and significant intraobserver and interobserver variation. Customized serial measurements give a better clinical prediction.
- Auscultation of the fetal heart gives information only about fetal viability. There is no evidence that it identifies at-risk fetuses or improves fetal outcome.
- Routine recording of the fetal heart rate helps to identify fetal arrhythmias.
- Ultrasound assessment of fetal growth and size in a high risk pregnancy predicts fetal outcome, but there is no evidence that this strategy alters outcome.
- Amniotic fluid volume less than the third percentile is associated with an increased risk of poor perinatal outcome. It is not clear whether this association is valid if it is an isolated finding.
- Umbilical artery Doppler recordings in high risk pregnancies are a useful screening tool and reduce perinatal morbidity and possibly mortality rates. There is no agreement about the optimum frequency of use of this modality.
- No evidence supports the use of umbilical artery Doppler recordings in screening low risk pregnancies.
- There is no evidence that the use of regional blood flow recordings in patients with chronic hypoxia and anemia improves pregnancy outcome, although these recordings indicate the degree of fetal compromise.
- Uterine artery Doppler recordings obtained before 24 weeks can identify an increased risk of intrauterine growth restriction and preeclampsia. There is evidence that their use improves pregnancy outcome, although the degree of improvement needs further research.

CONCLUSIONS *(Continued)*

- A biophysical profile score is not recommended for routine screening in low risk pregnancies. However, it is a useful adjunct to umbilical artery Doppler recordings in high risk pregnancies, particularly because of its high negative predictive value.
- A biophysical profile score is predominantly an acute measure of fetal well-being, giving short-term information and reassurance. In high risk cases, an abnormal biophysical profile score usually predicts imminent fetal death.
- Cardiotocography analysis, especially by computer, predicts outcome. However, like the biophysical profile score, in most cases, cardiotocography provides information about the acute status of the fetus. The findings become grossly abnormal late in the process of fetal deterioration. Arguably, it should be used only in combination with tests of chronic fetal health (e.g., measurement of fetal growth, umbilical artery Doppler).
- The use of cardiotocography has not been shown to improve fetal outcome, but large enough studies have not been performed and none relate to computer analysis.
- Further randomized controlled trials with appropriate power should be conducted to determine whether placental grading is a valuable screening tool in low risk pregnancies.
- Biochemical testing has no place in fetal assessment, with the exception of midtrimester maternal serum α-fetoprotein levels, which may indicate an increased risk of intrauterine growth restriction and preeclampsia later in the pregnancy.

SUMMARY OF MANAGEMENT OPTIONS
Assessing Fetal Health

Management Options	Quality of Evidence	Strength of Recommendation	References
Indications			
Low risk patients: Implement a surveillance program to identify when the risk ceases to be low; this might include:	–	GPP	–
• Ultrasound in the first half of pregnancy: Insufficient evidence to show the value of routine ultrasound screening in pregnancy	Ia	A	3–5
• Fetal movement counting: Evidence suggests that this identifies fetuses at risk but does not improve outcome	Ib	A	14
• Fundal height measurement: Poor at identifying pathologically grown fetuses although measurements are better if they are serial and customized; insufficient evidence of value in improving fetal outcome	III IIa Ib	B B A	15 17 16
• Auscultation of fetal heart sounds: Recommended in practice, but no evidence of value; recording the rate may identify fetal arrythmias	–	GPP	–
High risk patients, where there is a risk of chronic hypoxemia:	III	B	9–13
• Maternal: cyanotic heart disease, diabetes, autoimmune disease, renal disease, hypertension, inadequate nutrition, smoking (often synergistic with other factors), alcohol and other drug abuse			
• Placental: idiopathic growth restriction, recurrent abruption, preeclampsia			
• Fetal: congenital anomalies (monitoring not likely to be implemented), acquired abnormalities (infection, anemia, hydrops, metabolic)			
• Combined: serum α-fetoprotein	III	B	55

Fetal Growth Disorders

Ahmet Alexander Baschat

INTRODUCTION

Disturbance of normal fetal growth can result in abnormal weight, body mass, or body proportion at birth. The two principal fetal growth disorders are intrauterine growth restriction (IUGR) and macrosomia, both of which are associated with increased perinatal mortality rates and short- and long-term morbidity rates. Perinatal detection of fetal growth disorders has evolved dramatically over the last four decades. Before antenatal ultrasound assessment of fetal growth was clinically available, absolute birth weight was classified as either macrosomia (>4000g) or low birth weight, very low birth weight, or extremely low birth weight (<2500g, <1500g, and <1000g respectively). Growth is a dynamic process, and only the comparison of absolute measurements with gestational age reference ranges allows the detection of discrepancies between expected and actual growth. The landmark observations of Lubchenco and colleagues[1] in 1963 showed that the classification of neonates by birth weight percentile has a significant prognostic advantage because it improves the detection of neonates with IUGR who are at increased risk for adverse health events throughout life.[2-4] Neonates are now classified as very small for gestational age (below the third percentile), small for gestational age (below the 10th percentile), appropriate for gestational age (10th–90th percentile), or large for gestational age (above the 90th percentile).[5] The detection of a fetal growth disorder is further enhanced if the reference ranges for fetal biometric data and birth weight account for maternal height and race and fetal birth order and sex[6] (growth potential). A neonate may be of normal weight but still significantly lighter than its growth potential. Growth potential percentiles are superior to conventional reference ranges for the prediction of adverse perinatal outcome.[7,8]

The detection of abnormal body mass or proportions is based on anthropometric measurements and ratios that are relatively independent of sex, race, and to a certain extent, gestational age. The ponderal index [(birth weight (g)/crown–heel length^3) × 100][9] is one tool that has high accuracy for the identification of IUGR[10] and macrosomia,[11] independent of the birth weight percentile.[12] In one study, 40% of neonates with a birth weight below the 10th percentile did not have growth restriction based on the ponderal index.[10] From a clinical perspective, the ponderal index correlates more closely with perinatal morbidity and mortality than traditional birth weight percentiles, but may miss proportionally small and lean neonates with growth restriction.[13,14] Inappropriate fetal growth is also suggested by abnormal symmetry between head and abdominal measurements. Again, a different subset of neonates is identified with this descriptive approach.[15]

A gold standard for birth weight criteria that distinguishes between abnormal and physiologic growth patterns is highly desirable for any study of the relationship between neonatal size and outcome. Although the immediate effect of disturbed fetal growth is an abnormal expression of the growth potential, the effect on outcome and fetal programming is determined predominantly by the underlying condition.

REGULATION OF FETAL GROWTH

Fetal growth is regulated at multiple levels, and successful placentation is required for the coordination of key components within the maternal, placental, and fetal compartments. In the first trimester, placental adherence and implantation are prerequisites for placental vascular development, which is necessary for the delivery of nutrients and oxygen to the growing trophoblast beyond simple diffusion. Successful adherence permits differentiation of placental transport mechanisms and paracrine and endocrine signaling pathways between the mother,

placenta, and fetus by the second trimester. These are essential for efficient and coordinated nutrient transfer and waste and gas exchange. These milestones promote exponential fetal growth and differentiation in the third trimester.

After fertilization, the cytotrophoblast migrates to form anchoring villi between the decidua and uterus through controlled breakdown of the extracellular matrix by metalloproteinases and localized expression of adhesion molecules, including integrins and collagen IV. Simultaneously, hypoxia-stimulated angiogenesis initiates vascular connections between the maternal circulation and the intervillous space. Once the maternal blood supply to the intervillous space is established, increasing quantities of placental secretory products appear in the maternal circulation. Concurrently, extravillous cytotrophoblasts infiltrate the maternal spiral arteries, progressively remodeling the vessel walls so that the musculoelastic media is lost[16,17] In parallel, continuous villous vascular branching and thinning of the cytotrophoblast occurs in the fetal compartment.[18] These processes result in low-resistance, high-capacitance vascular beds that allow increasing and matched perfusion of the maternal and fetal placental compartments. Intervillous blood flow is regulated mainly through paracrine factors, such as nitric oxide, endothelin, adenosine, released cyclic guanosine monophosphate, and fetal atrial natriuretic peptide.[18] After successful placentation, approximately 600 mL/min maternal cardiac output[19,20] is matched to 400 mL/kg/min fetal flow distributed over a term placental exchange area of 12 m.[2,21]

The design of the fetal circulation allows preferential streaming of nutrients that enter the circulation through the umbilical vein. Modulated by shunting in the ductus venosus, 70% to 80% of the returning blood continues on to the liver; the rest is distributed to the heart.[22] In the right atrium, the directionality of incoming bloodstreams ensures that nutrient-rich blood is distributed to the myocardium and brain, whereas venous return from the body is distributed to the descending aorta and ultimately to the placenta for reoxygenation and nutrient and waste exchange.[23,24] In addition, because of the preferential distribution of left- and right-sided cardiac output, several organs can modify local flow by autoregulation to meet oxygen and nutrient demands.[25]

Once the blood supply to the trophoblast and fetal circulation is established, placental transport capacity is the major determinant of maternal–fetal nutrient transport. All substances that traverse between the maternal and fetal circulation must pass through the villous trophoblast, a syncytial bilayer 4 μm thick that consists of a maternal microvillus and a fetal basal layer.[26] Its capacity for transport is enhanced by a growing membrane surface area and increased density and affinity of carrier proteins for glucose, amino acids (mainly), and fatty acids.[24,27–29] The sodium/hydrogen (Na/H$^+$) family of transport proteins maintains syncytiotrophoblast intracellular pH and cell volume homeostasis, ensuring proper function of the transplacental substrate carrier proteins.[30] By the second trimester, these placental activities consume 40% of the O_2 and 70% of the glucose entering the uterus, leaving the rest for fetal use.[31–33] This proportion decreases progressively until term.

With the establishment of placental transport systems, endocrine signaling between maternal, placental, and fetal compartments helps to coordinate placental and fetal growth. Maternal metabolic changes include postprandial hyperglycemia, lipolysis, and increased fasting levels of free fatty acids, triglycerides, and cholesterol. All of these enhance substrate availability to the placenta and fetus and are at least partly mediated by increases in placental levels of lactogen and leptin. Similarly, maternal intravascular volume expansion and its relative refractoriness to vasoactive agents promote steady nutrient delivery to the placenta.[34]

Placental and fetal growth is regulated by the combination of substrate availability and endocrine or paracrine signaling. Glucose and amino acids stimulate insulin release from the fetal pancreas, and the subsequent release of insulin-like growth factors I and II provides the major stimulus for fetal growth and differentiation.[35] Leptin stimulates fetal pancreatic growth and transplacental amino acid transport and affects fatty acid transport. Therefore, it may be an important modulator of fetal body fat content and body proportions.[36,37]

Normal placental and fetal growth across pregnancy is characterized by sequential cellular hyperplasia, hyperplasia plus hypertrophy, and finally, hypertrophy alone.[38] Placental growth follows a sigmoid curve, with a plateau occurring earlier in gestation than the fetal curve. Between 16 weeks and term, human fetal weight increases 20-fold.[27] The fetal growth curve is exponential. Maximal growth occurs in the third trimester, when significant body mass and particularly adipose tissue are accumulated.

FETAL GROWTH RESTRICTION

Etiology and Risk Factors

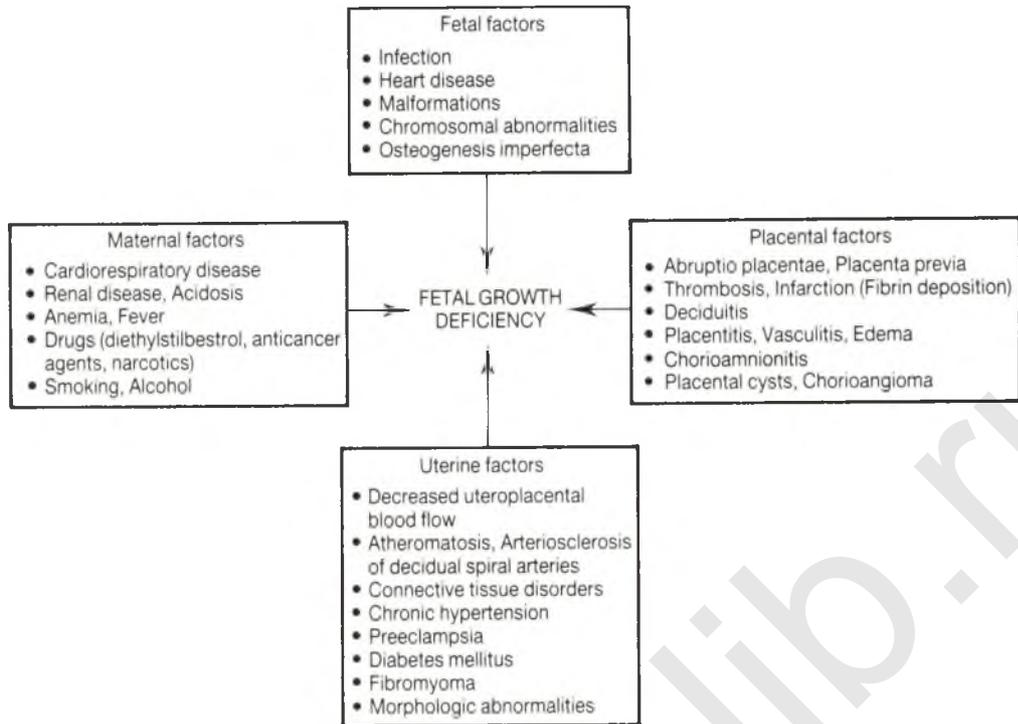
Several conditions may interfere with normal placentation and culminate in either pregnancy loss or IUGR. Broadly categorized into maternal, uterine, placental, and fetal disorders, these conditions affect either nutrient and oxygen delivery to the placenta, nutrient and oxygen transfer across the placenta, fetal uptake, or regulation of growth processes. When they are sufficiently abnormal, they produce growth restriction characterized by a reduction in fetal cell size, and when they are early and severe enough, cell number is also affected (Fig. 12–1). In clinical practice, considerable overlap occurs between conditions that determine the manifestation, progression, and outcome of growth restriction. Fetal


FIGURE 12–1
Causes of growth restriction by compartment.

abnormalities (both chromosomal and anatomic) and abnormal placental vascular development account for the vast majority of cases of IUGR in singleton pregnancies.[39–43] Usually, the earlier the onset of the disease process, the more likely the fetus is to be symmetrically small, with a reduced cell number, and the more likely the etiology is to be either a severe maternal vascular disorder, fetal infection, or a chromosome disorder.[44]

Maternal causes of growth restriction include chronic renal disease, collagen vascular disease, hypertension, and some thrombophilias. Aggravating circumstances include smoking, malnutrition, and drug use. Many risk factors can act synergistically. For example, the adverse effect of smoking is doubled in thin, white women and further potentiated by poor maternal weight gain.[45] Similarly, the possible benefits of low-dose aspirin therapy and the detrimental effects of excessive blood pressure reduction are also more apparent in this group of women.[46,47]

Pathophysiology

Our knowledge of the pathophysiology of IUGR was initially derived from animal experiments but has been greatly expanded by human studies with sophisticated epidemiologic analyses and by advanced ultrasound technology to elucidate the relationships between fetoplacental hemodynamic characteristics, fetal behavior, amniotic fluid production, and regulation of fetal heart rate.

Interference with the placental nutrient supply can affect all aspects of placental function. The gestational age at onset, the magnitude of injury, and the success of adaptive mechanisms determine the ultimate severity. Mild placental disease is more likely to affect organ function and maturation at the cellular level, with little perceivable growth delay perinatally, but may affect adult health by fetal programming. With more severe placental disease, fetal growth delay and adaptive organ responses become evident in utero. Exhaustion of the placental and fetal adaptive potential leads to decompensation, with variable progression and manifestations in the fetal organ systems. Adaptive responses that are intended to enhance fetal survival in a hypoxic environment may become destructive under conditions such as acute ischemia-reperfusion. Much of the long-term effect of growth restriction is unclear, as are the effects of obstetric intervention. As a result, severe disturbances of fetal growth pose a challenge to even the most experienced multidisciplinary team.

Mechanisms of Placental Dysfunction

Early interference with placentation affects all levels of placental and fetal development and culminates in the most severe clinical picture. Diffusion may be adequate to meet embryonic nutrient needs, but it compromises fetal survival and growth potential. Typically, the trophoblastic invasion is confined to the decidual portion of the

myometrium, and the spiral and radial arteries do not transform into low-resistance vessels.[16,48,49] Altered expression of vasoactive substances increases vascular reactivity, and if hypoxia-stimulated angiogenesis is inadequate, placental autoregulation becomes deficient. Maternal placental floor infarcts and fetal villous obliteration and fibrosis increase placental blood flow resistance, producing a maternal–fetal placental perfusion mismatch that decreases the effective exchange area.[18,24,50,51] With progressive vascular occlusion, fetoplacental flow resistance is increased throughout the vascular bed, which is the metabolically active placental mass, and nutrient exchange decreases or is outgrown.

The severity of placental vascular dysfunction is clinically assessed in the fetal and maternal compartments with Doppler ultrasound. An early diastolic notch in the uterine arteries at 12 to 14 weeks (Fig. 12–2) suggests delayed trophoblast invasion,[52] whereas persistence of "notching" beyond 24 weeks provides confirmatory evidence.[16,51,53] A reduction of umbilical venous blood flow volume may be the earliest Doppler sign of subtle decreases in fetal villous perfusion.[54] Umbilical artery waveforms correlate with both the tertiary villous architecture and blood flow resistance. If villous damage is minimal, elevated blood flow resistance may be seen only with sophisticated Doppler techniques.[55] At least 30% of the fetal villous vasculature is abnormal when the umbilical artery end-diastolic velocities are low and Doppler resistance indices are elevated.[56] Absence or reversal of umbilical artery end-diastolic velocity suggests that 60% to 70% of the villous vascular tree is damaged (Fig. 12–3).[56,57] Abnormal flow patterns in the uterine

FIGURE 12–3
The normal umbilical artery flow velocity waveform has marked positive end-diastolic velocity that increases in proportion to systole toward term (*A*). Moderate abnormalities in the villous vascular structure increase blood flow resistance and are associated with a decrease in end-diastolic velocity (*B*). When a significant proportion of the villous vascular tree is abnormal, end-diastolic velocities may be absent (*C*) or even reversed (*D*).

arteries are consistent with abnormal implantation and indicate an increased risk of preeclampsia, placental abruption, and IUGR.[58] Abnormal umbilical flow patterns indicate an increased risk of hypoxemia and acidemia proportional to the severity of Doppler abnormality.[18,59–61]

Metabolic and Cellular Effects of Placental Dysfunction

Oxygen and glucose consumption by the placenta is unaffected when nutrient delivery to the uterus is only mildly restricted and fetal demands can be met by increased fractional extraction. Fetal hypoglycemia occurs when uterine oxygen delivery (and likely substrate delivery) is less than a critical value (0.6 mmol/min/kg fetal body weight in sheep) and fetal oxygen uptake is reduced.[31,33,62] Insulin is an important fetal growth factor. Fetal pancreatic insulin responses are blunted by mild hypoglycemia, allowing gluconeogenesis from hepatic glycogen stores.[63–66] At this stage, fetal glucose

FIGURE 12–2
Flow velocity waveforms obtained from the uterine artery beyond 24 weeks' gestation. (*A*) High-volume diastolic flow is established, indicating successful trophoblast invasion. (*B*) Impaired trophoblast invasion of the spiral arteries is associated with elevated placental vascular resistance and persistence of an early diastolic notch in the uterine artery flow velocity waveform.

stores and lactate are preferentially diverted to the placenta to maintain placental metabolic, endocrine, and nutrient transfer function.[24,29,31]

As the nutrient supply worsens, fetal hypoglycemia intensifies and secondary energy sources are required. Proteins are catabolized to gluconeogenic amino acids. However, limitations in placental amino acid transfer eventually result in hypoaminoacidemia.[27] Decreased transfer leads to relative deficiencies of circulating long-chain polyunsaturated fatty acids, whereas metabolic limitation leads to hypertriglyceridemia and the inability to estabish essential adipose stores. Even if provided adequate substrate, inadequate oxygen is available to maintain oxidative metabolism. Hypoglycemia, hyperlactic acidemia, and a growing base deficit correlate with the degree of fetal hypoxemia and protein energy malnutrition.[24,67–71] Down-regulation of several cellular transporters and the Na/H^+ pump affects placental cellular function and aggravates the condition further.[27,28,30,37] In this setting, the fetal brain and heart switch primary nutrients from glucose to lactate and ketones.[72] Cardiac metabolism may consume as much as 80% of the circulating lactate.[73,74]

Simultaneously, the principal endocrine growth axis (insulin and insulin-like growth factors I and II) as well as leptin-coordinated fat deposition is down-regulated.[75] As a result, the placenta and fetus do not reach their size potential. The combination of fetal starvation, a modified endocrine milieu, and deficient tissue stores limits fetal growth and affects cellular and functional differentiation in many target organs.

Fetal Response in Major Organ Systems

Vascular and metabolic disturbances within the placenta lead to alterations in many fetal organ systems. Cardiovascular and central nervous system functions are best studied and provide the most practicable clinical means to document the progression of disease and assess the fetal condition.

Changes in fetal blood flow are related to placental resistance, fetal oxygenation, organ autoregulation, and vascular reactivity. Because of the parallel arrangement of the fetal circulation, placental dysfunction has specific effects on the relative distribution of right and left ventricular output. Increase in the right, or decrease in the left ventricular afterload shifts cardiac output toward the left ventricle, supplying well-oxygenated umbilical venous blood to downstream organs. In the compensated hypoxemic state, fetal cardiac output is increased and organ autoregulation maintained.[76,77] The response of the fetal trunk and cerebral circulation to hypoxemia differ from each other. The peripheral arteries constrict and truncal resistance increases, as evident by the elevated umbilical, thoracic, and descending aorta Doppler resistance indices ("hind limb reflex") that account for most of the increase in right

ventricular afterload.[78–81] The fetal cerebral circulation dilates in response to hypoxemia. Fetal cerebral vasodilatation is reflected in decreased Doppler indices (poorly described as "brain-sparing")[82,83] and reduces left ventricular afterload. This changing balance between right and left ventricular afterload decreases the cerebroplacental Doppler index ratio[84] and redistributes well-oxygenated left ventricular output to the heart and brain.[78,79,85,86]

Enhanced blood flow to individual organs is documented in the myocardium,[87] adrenal glands,[88] spleen,[89] and liver.[90] Conversely, blood flow resistance in the peripheral pulmonary arteries,[91] celiac axis,[92] mesenteric vessels,[93,94] kidneys,[95,96] and femoral and iliac arteries[97] increases. The overall effect is an improved distribution of well-oxygenated blood to vital organs, with preferential streaming of descending aorta blood flow to the placenta for reoxygenation. In contrast, blood flow to organs that are not vital for fetal survival is decreased. These Doppler-determined parameters are corroborated by direct measurements of cardiac output,[78] increases in umbilical venous volume flow,[54,98] and progressive decreases in amniotic fluid volume after long-standing redistribution.[96] Further, increased circulating levels of endothelin, arginine vasopressin, norepinephrine, epinephrine, vasoactive intestinal peptide, and atrial natriuretic peptide[99–101] are related directly to the severity of the acid–base disturbance. These adaptations are likely responsible for the enhanced vascular reactivity that may aggravate the patient's clinical status and increase the complication rate during cordocentesis.

The primary central nervous system effect of mild placental dysfunction is delayed maturation of several fetal behaviors. The normal behavioral sequence of development for the fetus proceeds from the appearance of movement, to coupling and cyclicity of behavior, and finally to integration of movement patterns into stable behavioral states. Likewise, the development of autonomic reflexes superimposed on intrinsic cardiac activity determines the characteristics of the fetal heart rate. These reflexes originate in the brain stem and are modulated by the ambient oxygen tension, signals from higher brain centers, the reticular activating system, and peripheral sensory inputs. Variations of heart rate and episodic accelerations coupled with fetal movement indicate normal functioning of these regulatory sites. Once organized behavioral states are established (typically by 28 weeks' gestation), diurnal and responsive cyclicity (e.g., to maternal glucose) and their coupling to heart rate variables (heart rate reactivity) are usually achieved.[102]

A delay occurs in all aspects of central nervous system maturation in fetuses with IUGR and chronic hypoxemia.[103–107] There is also a progressive decline in global fetal activity.[108] The combination of delayed central integration of fetal heart rate control, decreased fetal activity, and chronic hypoxemia results in a higher baseline heart rate, with lower short- and long-term variation (on com-

puterized analysis) and delayed development of heart rate reactivity.[106,107,109–112] Computerized heart rate analyses show that the changes in characteristics are particularly evident between 28 and 32 weeks. Progressive fetal hypoxemia is associated with a gradual decline in amniotic fluid volume, fetal breathing, gross body movement, tone, and computerized and traditional fetal heart rate variables. This decline is determined by the central effects of hypoxemia or acidemia, independent of cardiovascular status.[113–117]

Placental dysfunction affects many other fetal organ systems. Hypoxemia-stimulated erythropoietin release increases red blood cell mass through both medullary and extramedullary hematopoiesis.[60,67,118–120] More complex interactions are observed with persistent hypoxemia and progressive degrees of placental vascular damage. Nucleated red blood cell precursors enter the peripheral circulation independent of erythropoietin levels.[121,122] Placental platelet aggregation and consumption increases the risk of thrombocytopenia.[123,124] Other organ-specific alterations of note include thyroid dysfunction, increased cortisol level, vitamin deficiency, and immune deficiency. The effect of these fetal manifestations on short- and long-term outcome is unknown.

Fetal Decompensation

If placental dysfunction is progressive or sustained, the adaptive mechanisms become exhausted and decompensation begins. Multiple-organ failure as a result of placental dysfunction is caused by the metabolic milieu and the regulatory loss of cardiovascular homeostasis. Metabolic abnormalities are exaggerated, acidemia worsens, and the risks of intrauterine damage or perinatal death increase dramatically.

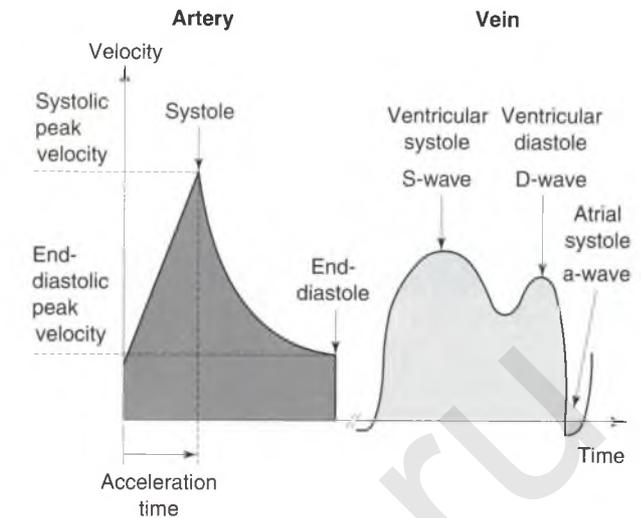
Forward blood flow in the venous system is determined by cardiac compliance, contractility, and afterload. The normal venous flow velocity waveform is triphasic and therefore more complex than the arterial waveform. It consists of systolic and diastolic peaks (S-wave and D-wave) that are generated by the descent of the arterioventricular ring during ventricular systole and passive diastolic ventricular filling, respectively. The sudden increase in right atrial pressure with atrial contraction in late diastole causes a variable amount of reverse flow, producing a second trough after the D-wave (A-wave) (Fig. 12–4). A decrease in forward cardiac function marks the onset of cardiovascular decompensation[76–78,125] and causes decreased forward velocity during atrial systole (A-wave). Impaired preload handling, as evidenced by increased venous Doppler indices (discussed later),[126,127] is documented in the precordial veins (ductus venosus, inferior vena cava,[128] and superior vena cava[129]), hepatic veins (right, middle, and left hepatic[130,131]), and head and neck veins (jugular veins[132] and cerebral transverse sinus[133]). If the failure to accommodate preload is pro-


FIGURE 12–4

Arterial and venous flow velocity waveforms. Absolute measurements for arteries include peak systolic and end-diastolic velocities, acceleration time, and heart rate. The venous flow velocity waveform has a triphasic profile. During ventricular systole and diastole, blood flows toward the heart, with a slight decrease after systole as the arteriovenous ring ascends. With the opening of the arteriovenous valves in diastole, antegrade flow increases again and produces the second peak (D-wave). Atrial contraction is associated with a sharp increase in atrial pressure, which is transmitted retrograde to the venous system and may be associated with brief retrograde flow (A-wave).

gressive, umbilical venous pulsations may be the ultimate reflection of increased central venous pressure (Fig. 12–5).[134] This finding is consistent with umbilical venous pressure measurements obtained at the time of cordocentesis. Simultaneously, autoregulation may be exaggerated in the coronary circulation[77,78] or may become dysfunctional in the cerebral and placental circulation.[135–137]

Progressive metabolic acidemia is associated with oligohydramnios and loss of fetal breathing, movement, and tone.[138,139] Abnormal fetal heart rate patterns, including overt late decelerations or a decrease in the short-term variation on computerized analysis, develop and appear to be related to metabolic status and concurrent worsening of cardiac function.[111,113,116,125,136,140] In the final stages of compromise, cardiac dilation with holosystolic tricuspid insufficiency, complete fetal inactivity, and spontaneous late decelerations may be seen before intrauterine demise.[141]

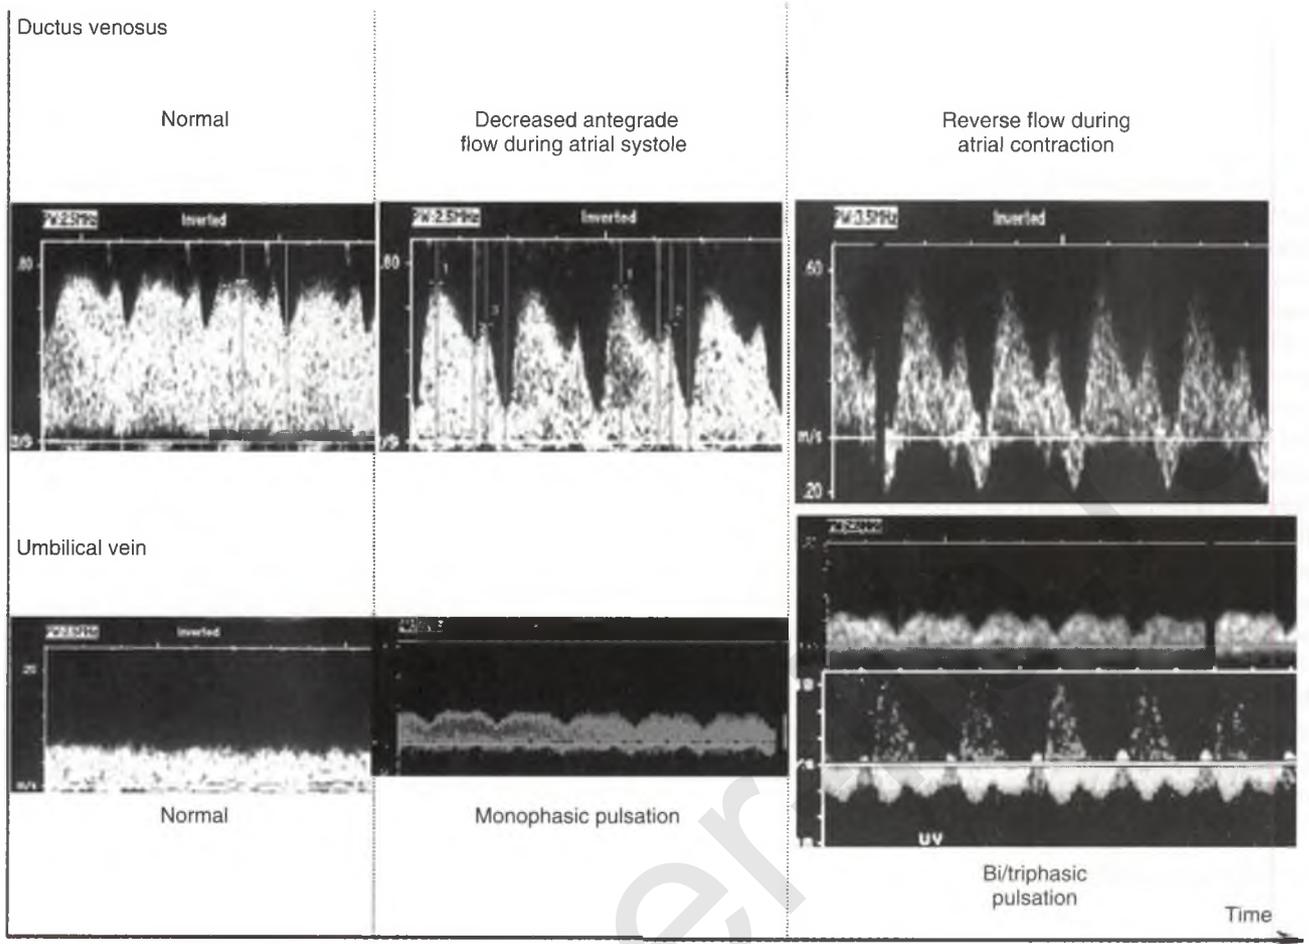
The sequence of deteriorating cardiovascular, biophysical, and heart rate parameters is reasonably predictable in 70% to 80% of fetuses with IUGR before 34 weeks.[114,142] Flow abnormalities confined to the umbilical or cerebral circulation are typically early changes.[143–145] The progressive decline in (computerized) heart rate variation and increasing venous Doppler indices are closely related.[133,146] Oligohydramnios, loss of fetal tone and or movement, abnormal venous flow, and overt heart rate decelerations are typically "late" changes.[145,146] Closer to term, the relationship between


FIGURE 12–5
Progression of abnormal venous flow patterns. The *left panel* shows normal flow in the ductus venosus, with antegrade flow throughout the cardiac cycle. The umbilical vein equally shows constant flow. An increase in the retrograde flow component during atrial contraction is believed to be the hallmark of decreased cardiac function and reflects increased cardiac end-diastolic pressures. Flow in the umbilical vein may show a monophasic pulsatile pattern, with nadirs corresponding to atrial contraction (*center panel*). In the most severe form of cardiac dysfunction, reverse flow occurs during atrial contraction in the ductus venosus. Pulsations in the umbilical vein may show a biphasic profile, with systolic and diastolic peaks or even retrograde flow during atrial contraction (triphasic) (*right panel*).

cardiovascular and biophysical deterioration is weaker, largely because of less prominent Doppler abnormalities.[147–149] In contrast, the correlation (but not necessarily the slope of the regression) between the deterioration of biophysical parameters and acid–base status is relatively independent of gestational age (Fig. 12–6).[102,111]

Summary

Macrosomia and IUGR are the principal abnormalities of fetal growth. Although several definitions apply at birth, antenatal diagnosis is based on estimates of fetal size and weight. The regulation of fetal growth is complex and exists on multiple levels in the maternal, placental, and fetal compartments. Accordingly, IUGR results from several underlying factors that interfere with normal development to produce a complex, multisystem fetal disorder. Because outcome is strongly dependent on

the cause, identifying the underlying disease is an essential step toward appropriate management. Several premonitory metabolic alterations affect long-term adult health. Fetal dynamic variables, Doppler parameters, and regulation of amniotic fluid volume reflect progressive deterioration and allow accurate antenatal detection of fetal hypoxemia and acidemia.

Screening Options for Growth Restriction

Clinical

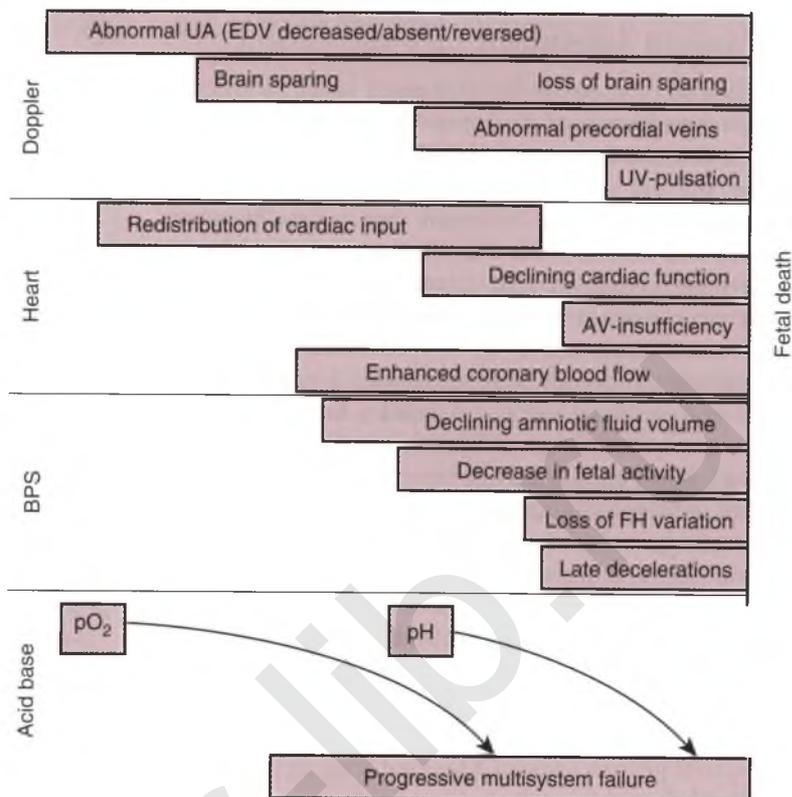
The maternal uterine fundus is objectively measured and charted during each antenatal visit. After 20 weeks' gestation, the normal symphyseal fundal height in centimeters approximates the number of weeks gestation, after appropriate allowances for maternal height and fetal station. The reported sensitivity for the detection of IUGR ranges from 60% to 85%, and the positive


FIGURE 12–6
Progressive deterioration in fetal cardiovascular and behavioral variables seen with declining metabolic status. In most fetuses with intrauterine growth restriction, Doppler abnormalities progress from the arterial to the venous side of the circulation. Although cardiac adaptations and alterations in coronary blood flow dynamics may be operational for a variable period, overt abnormalities of cardiac function and evidence of markedly enhanced coronary blood flow usually are not seen until the late stages of disease. The decline in biophysical variables shows a reproducible relationship with the acid–base status. If adaptation mechanisms fail, stillbirth ensues. AV, atrioventricular; EDV, end-diastolic velocity; FH, fetal heart rate; UV, umbilical vein.

predictive values are 20% to 80%. Although measurement of the symphyseal fundal height is a poor screening tool for the detection of IUGR, the accuracy of subsequent ultrasound prediction of IUGR is enhanced if there is clinical suspicion of IUGR, based on lagging fundal height.

Biochemical

At least four hormone or protein markers measured in the maternal sera early in the second trimester are associated with subsequent IUGR. These include estriol, human placental lactogen, hCG, and α-fetoprotein (see Chapters 7 and 8). Clinically, maternal serum α-fetoprotein is the most useful as a marker of abnormal placentation. Most studies conclude that a single, unexplained elevated value increases the risk of growth restriction 5- to 10-fold, proportional to the magnitude of the elevation. As a result, some argue that α-fetoprotein measurement is clinically useful, even after earlier aneuploidy screening by nuchal translucency measurement.

Uterine Artery Doppler Studies

Deficient placentation is highly associated with gestational hypertensive disorders, IUGR, and fetal demise.[150,151] A uterine artery Doppler resistance profile that is high, persistently notched, or both, identifies

women who are at high risk for preeclampsia and IUGR. Sensitivity is up to 85% when performed between 22 and 23 weeks' gestation.[152,153] Because low-dose aspirin treatment initiated this late in pregnancy improves neither placental function nor long-term outcome,[154] first-trimester screening tests are under investigation. They cannot be recommended clinically. The utility of first-trimester uterine artery screening appears to be profoundly affected by the target population. Although low risk patients derive little benefit, high risk patients (those with thrombophilia, hypertension, or a history of preeclampsia or a fetus with IUGR) who are given low-dose aspirin because of bilateral uterine artery notching at 12 to 14 weeks have an 80% reduction of placental disease compared with matched control subjects given placebo.[155] Although low-dose aspirin therapy initiated beyond the first trimester may have benefit in a highly select group of patients, uterine artery Doppler studies provide diagnostic and prognostic information beyond this point. The risk of complicating preeclampsia or HELLP affecting fetal outcome is increased more than 10-fold when abnormal umbilical artery Doppler findings are associated with bilateral uterine artery notching.[156] However, after 24 weeks, the response to an abnormal uterine artery Doppler waveform should be monitoring of blood pressure and not serial Doppler studies.

Ultrasound Assessment (See also Chapter 11)

Ultrasound biometry is the diagnostic tool of choice for the documentation of fetal growth disorders. The first step in the management of IUGR is the identification of fetuses that are truly at risk for an adverse outcome. This requires the exclusion of small, but normally grown fetuses and fetuses with IUGR that is caused by an underlying condition that cannot be altered through obstetric management (e.g., aneuploidy, nonaneuploid syndromes, viral infection). Because almost all fetal measurements change with gestation, accurate assessment of gestational age is a necessary first step so that percentile ranks of the absolute measurements can be derived. Once gestational age is assigned, the interpretation of an ultrasound growth study is based on the fetal anatomic survey, amniotic fluid volume, percentile rank of fetal size measurements, interval growth since the last study, and functional assessment of the fetoplacental unit with Doppler ultrasound (umbilical and uterine arteries).

The adequacy of fetal growth cannot be determined by a single sonographic examination without a preexisting estimate of gestational age. Even after several examinations, fetal growth assessment is facilitated by knowledge of the likely gestational age because the rate of growth for many parameters also varies with gestation. The traditional assessment of gestational age is based on the first day of the last menstrual period (LMP) (Naegle's rule). Yet, gestational age is uncertain in 20% to 40% of pregnant women who keep a written menstrual calendar.[157,158] This fact reflects both normal physiologic variation in the timing of ovulation and misinterpretation of implantation bleeding as menses by either the patient or the caregiver. Other potential and common variables that may explain an apparent discrepancy between sonographic and LMP-based gestational age include oral contraceptive use, increased cycle length, breast-feeding, and a limited number of coital exposures. Because all commonly used ultrasound tables are based on women with a known LMP rather than a known ovulation or conception date, they share the inaccuracy of menstrual dates (± 3 weeks). Because normal variation among fetuses also increases with advancing gestational age, the accuracy of the sonographic estimate of age diminishes. An estimated date of confinement (EDC) is based on the LMP when the sonographic estimate of gestational age is within the predictive error (7 days in the first semester, 10–11 days in the second trimester, and 21 days in the third trimester). Once the EDC is set by this method or a first-trimester ultrasound, it does not change, even if subsequent measurements deviate from the expected values. Repeated reassignments of the EDC are confusing to the physician and patient and interfere with the ability to diagnose fetal growth abnormalities.

After establishment of the best obstetric estimate of gestational age, the next critical step is the selection of appropriate reference ranges. Because the goal is to identify poorly growing fetuses, the reference tables for ultrasound measurements should not be population-based, but based on uncomplicated pregnancies delivered at term. Individualized reference ranges of growth potential that account for maternal, ethnic, and fetal variables provide the most accurate reference.[6]

Because fetal growth restriction has many underlying etiologies that affect the timing of onset and fetal features, no single sonographic method is adequate for diagnosis. Only a complete evaluation that includes the maternal history and fetal, placental, and amniotic fluid characteristics can direct an appropriate diagnostic workup and perinatal management.

Direct Measurements

BIPARIETAL DIAMETER

Although biparietal diameter is easy to measure, it is a poor tool for the detection of IUGR. The physiologic variation inherent with advancing gestation is high, cranial growth delay as a result of insufficient nutrition is relatively late, and the shape of the cranium is readily altered by external forces (e.g., oligohydramnios, breech presentation).[159] Further, a technically adequate biparietal diameter may be hard to determine if the fetal head is oriented in a direct anterior or posterior position.

HEAD CIRCUMFERENCE (Table 12–1)

Head circumference is not subject to the same extrinsic variability as biparietal diameter. The measurement technique is important because calculated head circumference measurements are systematically smaller than those directly measured. Thus, the table selected should be based on measurements obtained with the same method as your laboratory.

ABDOMINAL CIRCUMFERENCE (Table 12–2)

Abdominal circumference is the single best measurement for the detection of IUGR because it is related to liver size, which is a reflection of fetal glycogen storage.[160–162] The abdominal circumference percentile has the highest sensitivity and greatest negative predictive value for the sonographic diagnosis of IUGR, whether defined postnatally by birth weight percentile or by ponderal index.[10] Its sensitivity is further enhanced by serial measurements obtained at least 14 days apart.[163] Because of its high sensitivity, some type of abdominal measurement should be part of every sonographic growth evaluation. Because abdominal circumference reflects fetal nutrition, it should be excluded from the calculation of the composite gestational age after the early second trimester.

The most accurate abdominal circumference is the smallest value obtained at the level of the hepatic vein between fetal respirations because the smallest perimeter most closely approximates the plane perpendicular to the spine. The practice of averaging several measurements

only increases the error. A measured circumference is superior to either a calculated circumference or the sum of several diameters because the shape of the fetal abdomen is typically irregular.[164] Like bony measurements, the circumference of a healthy fetus grows within a fixed percentile range. An abrupt change in the percentile, especially an increase, suggests that the current measurement results from an oblique cut and should be repeated.

If a normal table based exclusively on healthy women delivering appropriately nourished neonates at term is used (see Table 12–2), an abdominal circumference above the percentile 2.5 for gestational age is inconsistent with IUGR.[10] If a table based on a cross-sectional population is used (i.e., including small for gestational age, appropriate for gestational age, preterm, and term newborns), the 10th percentile is more appropriate. The positive predictive value of a low abdominal circumference percentile for IUGR is approximately 50% in any given population. It is best not to label a fetus "growth-restricted" and trigger expensive fetal surveillance unless the circumference is far below normal or other ultrasound variables support the suspicion.

TRANSVERSE CEREBELLAR DIAMETER

Transverse cerebellar diameter is one of the few soft tissue measurements that correlates well with gestational age[165] in IUGR. This structure is relatively spared the effects of mild to moderate uteroplacental dysfunction. Whether its measurement offers an advantage over bony

measurements in the assessment of compromised fetal growth is controversial.[166,167]

Measurement Ratios

Approximately 70% of neonates with asymmetrical growth restriction have a head circumference-to-abdominal circumference ratio two standard deviations above the norm.[168] However, both the sensitivity and the positive predictive value of this ratio for growth restriction are worse than that of either abdominal circumference percentile or sonographically estimated fetal weight (discussed later).[10,169]

The cephalic index is the ratio of the biparietal diameter to the occipitofrontal diameter. Proposed as an age-independent aid to identify dolichocephaly and brachycephaly,[170] it is of limited value. Dolichocephaly is rare before the third trimester, and the ability to measure head circumference easily eliminated the need to recognize mild degrees of either dolichocephaly or brachicephaly as it relates to the prediction of gestational age. This ratio has also been proposed as an aid for the diagnosis of trisomy 21. The sonographic signs of aneuploidy are reviewed in Chapters 7 and 8.

The femur length (FL)-to-head circumference ratio was proposed as a tool to identify short-limbed dwarfism, hydrocephaly, or microcephaly.[171] However, the greatly improved resolution of modern ultrasound equipment makes this measurement unnecessary for the diagnosis of hydrocephaly (see Chapter 18); dwarfism, because the length of the fetal limbs is well below the 10th percentile for gestation (see Chapter 21); or microcephaly, which is diagnosed when head circumference is more than three standard deviations below the mean.

It would be attractive if the sonographic FL could be used to generate an index of fetal mass because it correlates with neonatal crown–heel length. Unfortunately, no clinically useful results have been obtained. The FL-to-abdominal circumference ratio has lower sensitivity, specificity, and positive and negative predictive values for the diagnosis of IUGR than either the abdominal circumference percentile or sonographic estimate of fetal weight.[10,172,173]

Sonographic Estimate of Fetal Weight

Many general purpose and special application formulas have been devised; several are listed in Table 12–3. The accuracy of most (±2 standard deviations) is 10% or greater, and none has proven superior to the first devised by Warsof and reported by Sheppard. Although an estimate of fetal weight does not routinely add to the abdominal circumference percentile for the diagnosis of IUGR, it adds a graphic image that is easy for both patient and referring physician to conceptualize. Although its sensitivity is considerably lower than that of the abdominal circumference percentile, the positive predictive value of a fetal weight estimate below the 10th percentile is greater.

Arterial and Venous Doppler Studies

Quantification of blood flow volume with Doppler studies is prone to error because of variations in insonation angle and the measurement of vessel diameter. Consequently, Doppler waveform analysis with angle-independent Doppler indices is preferred for fetal surveillance. The most widely used arterial indices are the systolic-to-diastolic ratio,[174] resistance index,[175] and pulsatility index (Table 12–4).[176] A relative decrease in end-diastolic velocities elevates each of the indices and usually reflects increased downstream resistance. When end-diastolic flow is lost, the systolic-to-diastolic ratio approaches infinity and the resistance index becomes 1. The pulsatility index offers the advantage of a smaller measurement error, narrower reference limits, and the theoretical advantage of ongoing numerical analysis, even when end-diastolic velocity is lost.[177]

In the venous system, the magnitude of flow reversal during atrial contraction varies considerably in individual veins. Reverse flow may occur during atrial contraction in the inferior vena cava and hepatic veins. In contrast, normal blood flow in the ductus venosus is forward throughout the cardiac cycle. Because of the complex nature of the venous flow velocity waveform, several venous Doppler indices are described (see Table 12–4).[128,145,178–181] No venous Doppler index appears to

Doppler Indices for Arterial and Venous Flow Velocity Waveforms

DOPPLER INDICES	CALCULATION
Arterial Flow	
Pulsatility index	$\dfrac{\text{Systolic–end-diastolic peak velocity}}{\text{Time-averaged maximum velocity}}$
Resistance index	$\dfrac{\text{Systolic–end-diastolic peak velocity}}{\text{Systolic peak velocity}}$
Systolic-to-diastolic ratio	$\dfrac{\text{Systolic peak velocity}}{\text{Diastolic peak velocity}}$
Venous Flow	
Preload index	$\dfrac{\text{Peak velocity during atrial contraction}}{\text{Systolic peak velocity}}$
Pulsatility index for veins	$\dfrac{\text{Systolic–diastolic peak velocity}}{\text{Time-averaged maximum velocity}}$
Peak velocity index for veins	$\dfrac{\text{Systolic–atrial contraction peak velocity}}{\text{Diastolic peak velocity}}$
Percentage reverse flow	$\dfrac{\text{Systolic time-averaged velocity}}{\text{Diastolic time-averaged velocity}} \times 100$
Ductus venosus preload index	$\dfrac{\text{Systolic–diastolic peak velocity}}{\text{Diastolic peak velocity}}$

offer a significant advantage over the others.[182] Except for the descending aorta pulsatility index, all fetal arterial and venous indices change with gestational age. Thus, interpretation of Doppler findings requires accurate knowledge of gestational age.

In many locales, it is standard practice to perform ultrasound twice during pregnancy to enhance the identification of fetuses with IUGR and improve outcome.[169] Although the cost–benefit ratio of this practice is unclear,[183,184] the combination of fetal biometry and umbilical artery Doppler is the best available tool for the identification of a small fetus at risk for adverse outcome.[185–188] Randomized trials and meta-analyses confirm that the use of umbilical artery Doppler in this setting is associated with a significant reduction in perinatal mortality rates and less iatrogenic intervention, despite the lack of a standardized response in those trials.[189–191] Before 34 weeks, small fetal size associated with an elevated umbilical artery Doppler index is likely to reflect placental dysfunction. Near term, when umbilical artery Doppler findings may be subtler, a decrease in the middle cerebral artery Doppler index or the cerebroplacental ratio increases suspicion for fetal growth restriction, even if the umbilical artery blood flow resistance index remains within the normal range.[149,188]

Although the umbilical artery flow velocity waveform is primarily determined by the architecture of the villous vascular tree (and therefore placental blood flow resistance), study of other fetal arterial vessels is required to determine the effect on the fetus. Changes in Doppler studies of numerous arteries are described in association with IUGR. However, it seems logical to use vessels that represent a single vascular bed, are easy to sample at a low insonation angle, and provide the most information about the fetal response to hypoxemia. For example, flow in the fetal descending aorta is affected by changes in the placenta as well as by the peripheral fetal vasculature, and these changes may be difficult to detect at a small insonation angle. In contrast, the middle cerebral artery is easily identified and examined at a favorable angle. The examination technique and the reference ranges also require standardization because measurements may vary significantly in different portions of the same vessel. Similarly, measurements of the cerebroplacental ratio are affected by the indices used in calculation, and a standardized approach with gestational reference ranges rather than single cutoff values should be used.[192]

With ongoing compromise, little further change in the middle cerebral artery Doppler waveform occurs, with the notable exception of "normalization" of the Doppler indices. Therefore, the next step after identifying evidence of fetal hypoxemia is to monitor cardiac function through study of the venous system. The inferior vena cava and ductus venosus Doppler indices and umbilical venous pulsations correctly predict acid–base status in a significant proportion of neonates with IUGR. This combination, rather than single-vessel assessment, provides the best predictive accuracy. Although the choice of Doppler index is guided by operator preference, familiarity with the examination technique for all three vessels is encouraged to offer the greatest flexibility in clinical practice.[182]

Biophysical Profile Score

The biophysical profile score (BPS) applies categorical cutoffs for a composite of dynamic variables, such as fetal tone, breathing, gross body movement, and amniotic fluid volume, as well as traditional fetal heart rate analysis. The cutoffs were chosen to account for biologic variation and maturational differences; therefore, they produce a reliable relationship with fetal acid–base status, regardless of gestational age and underlying pathology.[139,193] Although a gradual decrease in all of these parameters precedes an overtly abnormal BPS, analysis of percent change in these variables offers no advantage for the prediction of acidemia.[108] A normal score is usually achieved within the first 10 minutes of study. One notable disadvantage of the BPS is that, apart from amniotic fluid volume, it lacks variables that allow useful longitudinal prediction of compromise in pregnancies affected by IUGR.[117] This limitation must be considered if BPS is selected as the sole monitoring tool (discussed later).

Summary

Several biochemical markers, the clinical history, and uterine artery Doppler screening are effective in identifying patients who are at risk for preeclampsia or IUGR. However, once lagging fetal growth is suspected, abdominal and head circumference measurements based on normal population reference ranges, in combination with umbilical artery Doppler studies, are most likely to separate constitutionally small fetuses from those with growth restriction. Repeat uterine artery study is of no clinical value. A complete anatomic survey and assessment of amniotic fluid volume is a critical component of the ultrasound evaluation that addresses possible other etiologies and directs appropriate management. Arterial and venous Doppler indices provide an assessment of placental function, fetal response to placental dysfunction, and the onset of fetal compromise. The BPS has a reproducible relationship with fetal status, but in isolation, it is of limited value for the longitudinal prediction of compromise.

Diagnosis and Evaluation of Fetal Growth Restriction

The diagnosis of fetal growth restriction is based on the measurement of objective fetal parameters. Diagnosis requires knowledge of the features of normal and abnormal growth as well as the basis for these standards. Ideally, the estimate of gestational age is not based solely on a recent sonographic estimate.

The postnatal definition of IUGR is of pragmatic concern because it affects the stated accuracy of antenatal diagnosis. For example, a thin fetus whose estimated weight is normal might be classified postnatally as growth-restricted by the ponderal index. Practitioners must understand the diagnostic criteria used in their hospitals, and neonatal caregivers should not rely solely on birth weight percentiles.

"Asymmetrical" and "symmetrical" growth restriction should be considered descriptive terms and not diagnoses. More relevant than symmetry is the timing of onset. Late-onset growth restriction of structurally normal fetuses after 32 weeks' gestation usually results from placental dysfunction. These fetuses are slender, with normal head circumference and body length. In contrast, early-onset growth restriction is often associated with aneuploidy, congenital infection, or more severe forms of placental dysfunction (Table 12–5). Although these fetuses may be symmetrically small when delivered weeks or months after the initial diagnosis, they are often asymmetrical when first identified.

Maternal History and Examination

In view of the many maternal disorders that affect placental development, thorough maternal medical, medication, and obstetric histories should be obtained. A family history of unexpected thromboembolic events or a history of a previous pregnancy affected by early-onset IUGR or fetal demise should be sought. Maternal studies for antiphospholipid antibodies and thrombophilia are more likely to have a diagnostic yield with such a history.[194]

Two-Dimensional Ultrasound Assessment of Fetal Size

The most accurate prediction of fetal growth delay can be achieved if fetal growth parameters are related to customized growth curves.[6] When population-based reference ranges are used, a fetus is considered "at risk" for growth restriction when the abdominal circumference percentile is less than percentile 2.5 (or the 10th percentile, depending on the table selected), but the estimated weight is above the 10th percentile. Suspicion is strengthened when both the abdominal circumference percentile and the estimated weight are abnormally low or when progressive growth delay occurs. Serial ultrasound examinations at least 14 days apart allow assessment of growth patterns and may provide additional diagnostic clues. Fetuses that are constitutionally small

TABLE 12–5		
Causes of Severe Intrauterine Growth Restriction, University of Iowa, 1984–1992

Miscellaneous	7	6.2
Total	**113**	

are more likely to show normal interval growth.[163] In contrast, fetuses with aneuploidy or placental dysfunction are more likely to show progressive growth delay and to "fall off" the growth curve.[39,163,195] Because fetuses with "suspected" and "diagnosed" IUGR are managed similarly, and because the accuracy of the diagnosis based on a small abdominal circumference alone is only approximately 50%, there is no need to worry the parents unnecessarily by basing the diagnosis on a single parameter. Once the suspicion of IUGR is raised, evaluation of fetoplacental blood flow and anatomy is required.

Two-Dimensional Ultrasound of Fetal Anatomy and Possible Invasive Testing

A thorough ultrasound examination to detect major anomalies and markers of aneuploidy is mandatory in all fetuses with IUGR. Fetal echocardiography to detect major cardiac anomalies (e.g., atrioventricular canal defect) and evaluate cardiac function should be included. Echogenic bowel or liver or increased amniotic fluid volume suggests an increased risk of either aneuploidy or viral infection,[196,197] particularly in patients with normal umbilical and uterine artery Doppler findings.[39] A chromosomal abnormality is associated with 20% of cases of severe, early-onset IUGR. Although half of these abnormalities are lethal, a fetus with trisomy 21 may pose philosophical problems for both the physician and the patient. Knowledge of a major anomaly, such as atrioventricular canal defect, can lead the parents in one direction or another in terms of pregnancy termination or cesarean delivery for fetal distress.

Doppler Velocimetry of Arterial and Venous Circulation

The fetal vascular responses to placental dysfunction were discussed earlier. There is now considerable knowledge about the relationship between Doppler findings and perinatal outcome variables that allow for an accurate noninvasive assessment of the presence and severity of fetal hypoxemia. Until recently, the clinical role of Doppler ultrasound in the overall evaluation of fetal growth disturbance was unclear. Part of the problem was the diverse nature of the published studies. Investigators sought to predict a variety of neonatal outcomes with disparate etiologies using a single parameter, such as umbilical artery index. Not surprisingly, the positive and negative predictive values were, as a whole, unsatisfactory.

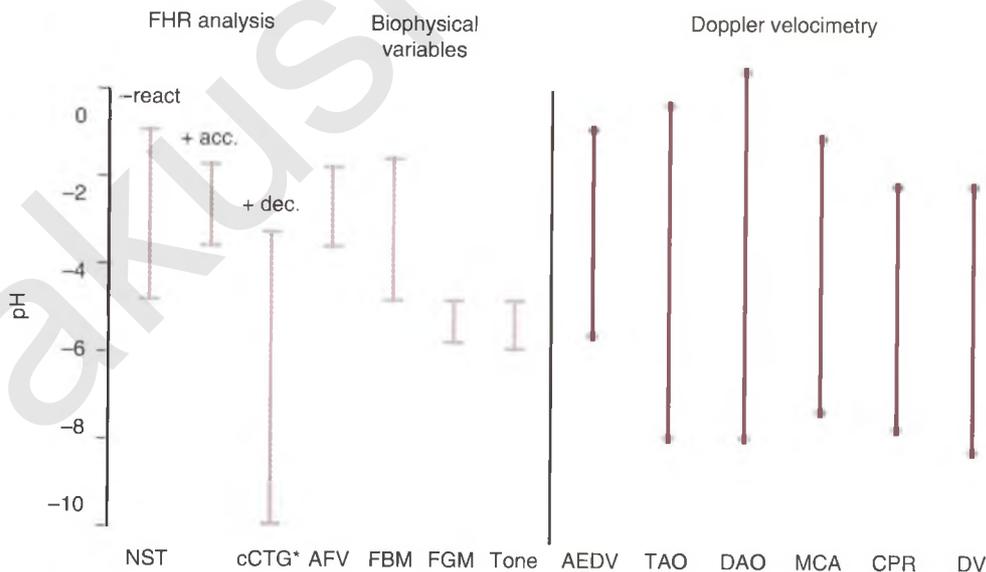
Based on the current level of knowledge, we designed a clinical evaluation algorithm that uses "progressive" Doppler studies of fetal vasculature. Although Doppler findings in each of the examined vascular beds correlate with fetal acid–base status, there is a wide variation in fetal pH with abnormal results (Fig. 12–7). However, as with most obstetric tests, the negative predictive values are superb. A normal umbilical artery Doppler index is inconsistent with fetal acidemia as a result of uteroplacental dysfunction. Absence of umbilical artery end-diastolic velocity indicates significant villous abnormality; however, the relationship between placental pathology and


FIGURE 12–7
Deviation in pH from the gestational age mean (ΔpH) with abnormal results on various antenatal tests. These include fetal heart rate (FHR) analysis with traditional nonstress testing (NST) and computerized cardiotocogram (cCTG). The same relationships are expressed for umbilical artery absent end-diastolic velocity (AEDV) and deviation of the arterial or venous Doppler index more than two standard deviations from the gestational age mean for the thoracic aorta (TAO), descending aorta (DAO), middle cerebral artery (MCA), cerebroplacental ratio (CPR), and ductus venosus (DV). +acc, accelerations present; +dec, obvious decelerations present; –react, nonreactive; AFV, amniotic fluid volume; FBM, fetal body movement; FGM, fetal gross movement. (From Baschat AA: Integrated fetal testing in growth restriction: Combining multivessel Doppler and biophysical parameters. Ultrasound Obstet Gynecol 2003;21:1–8.)

fetal acidemia is inconsistent both at cordocentesis and at birth.[59,61,198–200] This inconsistency may occur because the oxygen demands of the fetus vary with gestational age. A 23-week fetus can withstand a much higher degree of placental dysfunction than a 32-week fetus. Thus, evaluation of other fetal blood flow is necessary to determine the fetal response to the level of hypoxemia present and to refine the prediction of fetal acid–base balance. Brain-sparing (cephalization, or centralization), elevation of the thoracic and abdominal aortic pulsatility index, and an abnormal cerebroplacental ratio are associated with fetal hypoxemia and a decrease in pH of at least two standard deviations.[61,81,201] Elevation of the precordial venous Doppler indices (inferior vena cava and ductus venosus) provides the most consistent relationship to a significant decrease in umbilical venous pH (approximately four standard deviations) in fetuses with IUGR.[128,201,202] Because not all fetuses with IUGR have abnormal venous flow, venous Doppler has sensitivity of approximately 70% and specificity of 60% to 70% for the identification of significant fetal acidemia.[182,201,202] Umbilical venous pulsations occur at a late stage of compromise, and if they are observed concurrently with an elevated venous Doppler index, they improve sensitivity

in the prediction of birth pH of less than 7.20.[182] Normal fetal arterial pH in the absence of labor should be greater than 7.32 at term and even higher preterm (Fig. 12–8).

In preterm fetuses with IUGR, Doppler findings of progressive abnormality are associated with increased perinatal mortality and morbidity rates.[87,125,126,147] Although neonatal morbidity is determined primarily by the degree of prematurity, the risks of stillbirth and acidemia are significantly related to the extent of venous Doppler abnormality.[126,147] Therefore, multivessel Doppler studies that include the arterial and venous systems are required for the greatest prediction of critical outcomes in preterm infants with IUGR.[203]

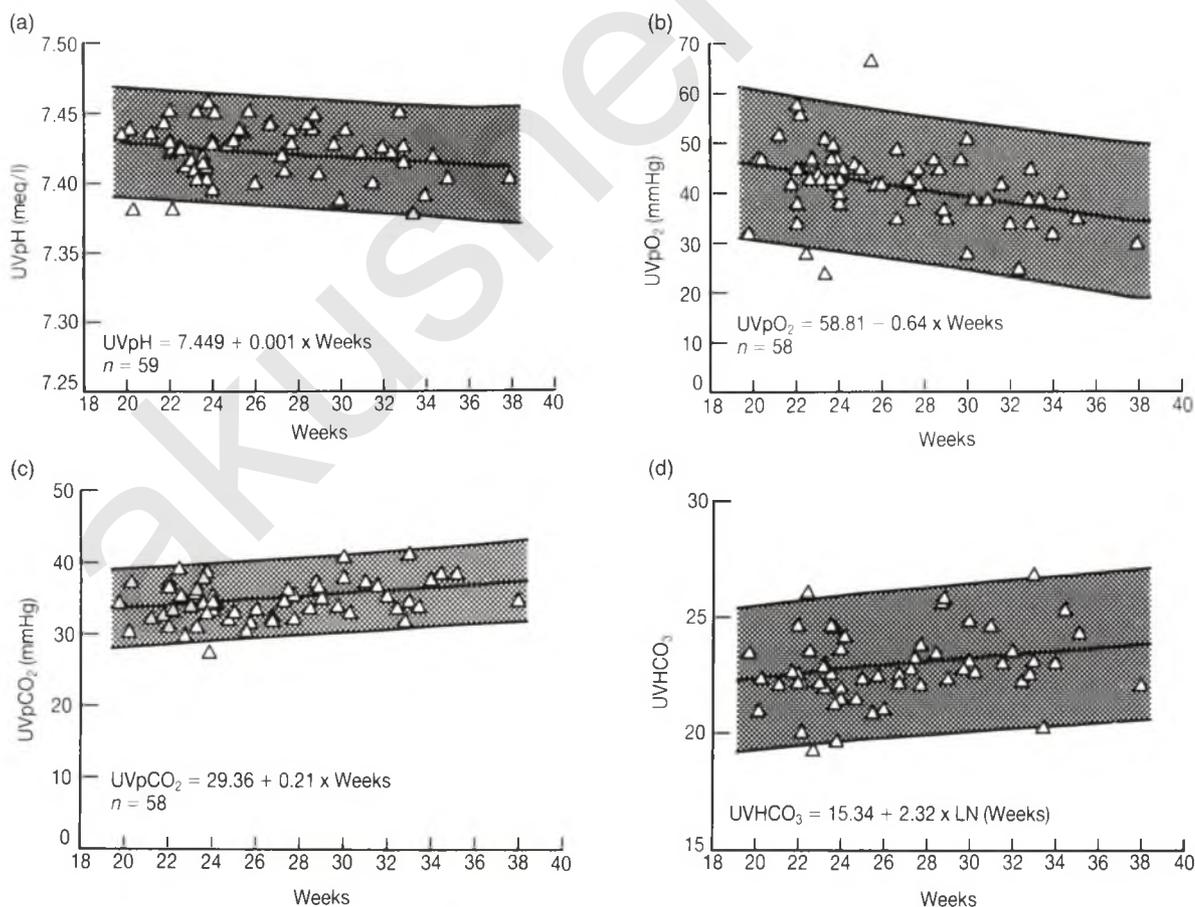
Our understanding of the relationships between Doppler-derived flow measurements and short-term outcomes has become more refined. Unfortunately, there is relatively little information on the intermediate- and long-term relationships between Doppler measurements and outcome parameters in infancy and adult life. Elevated fetal aortic blood flow resistance is associated with neurodevelopmental delay in early childhood.[204,205] Similarly, adverse long-term neurologic development at school age appears most closely related to reversal of umbilical artery end-diastolic velocity.[206] Although


FIGURE 12–8
Normal umbilical venous (UV) pH (a), Po_2 (b), Pco_2 (c), and base excess (d) shown as the 95% prediction interval across gestation. (From Weiner CP, Sipes SL, Wenstrom K: The effect of fetal age upon normal fetal laboratory values and venous pressure. Obstet Gynecol 1992;79:71.)

studies suggested a protective effect of brain-sparing on cognitive outcome, 5-year follow-up showed no sustained benefit.[207] The phrase would seem a misnomer. Detailed studies clarifying these relationships are urgently needed before surrogate markers for long-term outcome can be incorporated into perinatal management decisions.

Computerized Cardiotocography and Biophysical Profile Score

Like the observations made with Doppler measurements, a progressive decline in acid–base status is also demonstrable by fetal heart rate analyses and the assessment of breathing, tone, gross body movement, and amniotic fluid volume. Each component of the BPS relates to fetal oxygenation, but the five-component BPS most effectively predicts fetal acid–base status. Although a reactive cardiotocogram, even by criteria graded for gestational age, virtually excludes hypoxemia, a nonreactive cardiotocogram is associated with a wide range of pH values.[138,193] The prediction of acidemia is improved by computerized fetal heart rate analysis. All computerized variables (e.g., short-term, long-term, and mean minute variations) and episodic or periodic changes are related to a range of normal and abnormal fetal pH values.[109,111,112] In fetuses with IUGR, short-term variation below 3.5 msec as a result of prolonged episodes of low variation appears to be the best predictor of an umbilical artery pH of less than 7.20.[140] Although it is clearly abnormal in a nonlaboring patient, the clinical relevance of this pH value is not clear. Loss of fetal breathing movements is associated with moderate hypoxemia and a wide range of pH values at the time of either cordocentesis or birth. In contrast, the absence of fetal tone and gross body movement is almost always associated with acidemia (see Fig. 12–7). By accounting for physiologic variability, the BPS maintains its relationship with fetal pH in fetuses with IUGR, independent of gestational age. However, the BPS has limited utility in the prediction of longitudinal deterioration in these fetuses.[117,142]

Long-term relationships between the BPS parameters and long-term outcome were studied in large cohorts of patients. A low BPS is associated with neonatal complications, cerebral palsy, cortical blindness, and attention deficit disorder.[208] Although randomized testing was not performed, application of the BPS management algorithm appears to have significantly decreased the frequency of cerebral palsy in the tested population.

Integrated Fetal Testing

The combined use of multiple testing modalities to monitor fetuses with IUGR has several advantages because of the wide clinical spectrum and the variance in the relationship between testing and outcome variables.[209] Because deterioration of cardiovascular and biophysical parameters is initially independent, the information gained by combining them may be additive. Doppler studies provide good longitudinal assessment, and the BPS refines the relationship with fetal pH. This combined approach provides the most accurate fetal assessment, particularly in preterm fetuses with growth restriction.[210–214] The management details are described later.

Summary

It is important to differentiate between early- and late-onset growth restriction. The former has a strong association with aneuploidy, fetal infection, and severe placental dysfunction. Ultrasound is central to the diagnosis of IUGR, but is greatly aided by an independent assessment of gestational age. The single most sensitive parameter for the detection of IUGR is the abdominal circumference percentile, although its positive predictive value is only 50%. Doppler ultrasound is an important adjunct that provides diagnostic and correlative information on fetal oxygenation. Current evidence supports a progression from arterial to venous flow abnormalities associated with deteriorating blood gas values in IUGR and worsening perinatal outcome. Because of variations in fetal response to placental dysfunction, the combined assessment of cardiovascular and biophysical parameters offers the most comprehensive assessment of fetal status. Fetal monitoring that integrates arterial and venous Doppler studies and biophysical parameters is most useful in the preterm fetus with IUGR, when the balance between in utero risk and prematurity is critical. The long-term implications of these findings need further study.

Prenatal Management Options

Diagnostic and therapeutic interventions often go hand in hand when IUGR is suspected, and management options may need to be reevaluated as gestation advances. The goal of the initial evaluation is to make a presumptive diagnosis of IUGR and then to use the clinical presentation to direct additional diagnostic workup. Subsequently, antenatal surveillance is instituted and tailored to the severity of the fetal condition, considering the strengths and weaknesses of the available tests. Therapeutic interventions are dictated by the maternal and fetal condition as well as by gestational age, while respecting the wishes of the parents.

Presumptive Diagnosis of IUGR

Fetuses with a small abdominal circumference percentile are at risk for IUGR. A flattening growth curve on two consecutive examinations at least 14 days apart (in the third trimester, preferably 21 days apart) heightens diagnostic suspicion. Individualized reference ranges are based on normal pregnancies, and maternal characteristics are probably the most accurate.[6] Beyond 24 weeks,

an elevated umbilical artery Doppler index is strong corroborating evidence for IUGR as a result of placental dysfunction. A false-positive diagnosis is likely in a sonographically small fetus with normal findings on umbilical artery Doppler examination, and the risk of fetal distress in labor as a result of chronic hypoxia is low. After 34 weeks, the umbilical artery Doppler index may be within the normal range, and a decreased cerebroplacental ratio or middle cerebral artery Doppler index may be the only supporting evidence of placental-based IUGR.[149,187,215] After completion of the anatomic survey and assessment of amniotic fluid volume, the fetus is categorized as either likely or unlikely to have IUGR. Based on the combination of findings, the fetus may have evidence of one of four diagnoses: aneuploidy, viral infection, placental dysfunction, or nonaneuploid fetal syndromes.

Diagnostic Workup

It is important to determine the specific etiology of IUGR before delivery when possible. The wide availability of fluorescent in situ hybridization for fetal karyotyping for major chromosomal abnormalities from amniocytes offers the possibility of a result within 48 to 72 hours in many centers. Polymerase chain reaction of amniotic fluid samples can provide accurate and reproducible detection of the viral genome (see Chapter 27). Thus, amniocentesis should be offered to all patients with early-onset IUGR (<32 weeks) and those with symmetrical IUGR detected later in gestation UGR. In addition, women with known familial syndromes may be evaluated for single-gene mutations if appropriate gene probes are available. The relative ease of amniocentesis and the advances in antenatal surveillance that allow an accurate assessment of the fetal acid–base status have largely obviated the need for cordocentesis.

However, cordocentesis is the technique of choice if more in-depth diagnostic information is needed. For example, fetal blood sampling provides direct measurement of fetal acid–base status (of value, especially at the threshold of viability, where the variance of Doppler methods is much greater), hepatic transaminases, a complete blood count, serology, and polymerase chain reaction for evidence of fetal viremia, all of which increase the diagnostic yield. For example, although traditional serologic and culture techniques identify an infectious etiology in 5% of fetuses with IUGR,[216] the yield roughly doubles with polymerase chain reaction.[196] Although specific treatments for fetal infection are not available, antenatal diagnosis is important. First, the fetal response to infection is often transient; therefore, the opportunity for diagnosis is lost and the neonate is inappropriately excluded from specific follow-up if diagnostic efforts are delayed until delivery. Further, infected neonates typically shed virus. They should be isolated for the protection of pregnant staff and susceptible nursing mothers of other newborns. Finally, fetuses with IUGR

caused by congenital infection are well oxygenated in the absence of placentitis. Extensive antenatal testing geared toward the diagnosis of hypoxemia is unnecessary, and the need for iatrogenic intervention is low in the absence of oligohydramnios.

Measurement of hematologic parameters can shed light on the etiology while final karyotyping is pending and may provide additional information about the severity of disease. Fetuses with IUGR and chronic hypoxemia are more likely to have elevated erythropoietin levels and polycythemia. Macrocytosis is more typical of trisomic and triploid fetuses.[217,218] Despite an elevated nucleated red blood cell count, fetal thrombocytopenia and anemia are signs of chronic compromise associated with poor perinatal outcome.[67,118,121,122,218,220]

The diagnostic benefits of cordocentesis must be weighed against the risks on a case-by-case basis. Early-onset growth restriction increases the risk of reactive fetal bradycardia after cordocentesis in proportion to the severity of fetal hypoxemia.[221] There is approximately a 1 in 5 chance that a fetus with severe IUGR will have bradycardia after cordocentesis. The higher the umbilical artery Doppler index, the greater the likelihood of bradycardia. The mother of a fetus of borderline viability should decide in advance whether emergency cesarean delivery should be performed in the event of sustained bradycardia. Cordocentesis must be performed in close proximity to a delivery suite and only by individuals trained in surgical delivery.

Once the diagnostic workup is initiated, management and outcome are largely determined by the underlying condition and the decisions made by the parents. If aneuploidy is the explanation, the cause and risk of recurrence are known. This knowledge may help to reduce the inevitable parental soul-searching and guilt feelings that accompany any perinatal loss. The diagnosis of a structural anomaly that is incompatible with survival eliminates both the need for extensive (and expensive) antenatal monitoring and the high likelihood of cesarean delivery for fetal indications. Documentation of infection allows precautions to be taken to minimize the risks of infection in the nursery as a result of viral shedding. Management is difficult in fetuses with early-onset IUGR as a result of placental dysfunction. In these otherwise normal fetuses, outcome is determined by the condition at birth and the degree of prematurity.[126,147,222]

Maternal and Fetal Therapy

Intrauterine therapeutic options are limited in pregnancies complicated by IUGR. The first step is to reduce or eliminate potential external contributors, such as stress or smoking, and to encourage maternal rest in a lateral position. Although their efficacy is unproven, these steps should maximize maternal uterine blood flow. In addition, bed rest in the hospital should be considered

because it has theoretical advantages over rest at home. First, even the most motivated patient rests less and less as time passes. The family support structure may be poor, and the patient may not have any real opportunity to rest. Second, hospitalization facilitates daily fetal testing. The choice of inpatient versus outpatient management is based on the severity of the maternal or fetal condition and the local standard of care.

Although low-dose aspirin therapy (81 mg/day) does not help severe early-onset IUGR, it may help patients with mild placental dysfunction.[223,224] In view of its documented safety,[225,226] we typically consider low-dose aspirin therapy after the diagnosis of placental-based IUGR is made.

IUGR as a result of placental dysfunction is the most common fetal disorder that is potentially amenable to direct fetal therapy. To be a candidate for this therapy, the fetus must show a proportionate increase in fetal oxygen and substrate delivery. Techniques to achieve these goals are available. Maternal hyperoxygenation,[227,228] intravascular volume expansion,[229] and hyperalimentation[230] are reported. Many issues, such as the effect of therapy on outcome, patient selection, efficacy, and the requisite testing required to monitor the fetus during therapy remain to be resolved. Until these issues are clarified, this therapy is experimental.

Universally available therapeutic options that may improve outcome include antenatal administration of corticosteroids to hasten fetal lung maturity in the preterm fetus and delivery at an institution with a neonatal care unit that can carry out the complex management of the neonate with IUGR. Antenatal corticosteroids should be administered to any fetus with IUGR when delivery is anticipated before 34 weeks. The long-held belief that the "stress" of the intrauterine condition enhances maturation and protects against prematurity is not supported by large population studies of neonates with IUGR.[3,231]

Timing and Mode of Delivery

Because of the limited intrauterine treatment options and the possibility of continued fetal damage as a result of progressive metabolic deterioration, the timing of intervention is critical. Current recommendations are based on an incomplete understanding of background mortality and morbidity rates. Further, critical perinatal variables that affect short- and long-term quality of life must be better defined. Many fetuses with IUGR are hypoxemic before the onset of labor. Chronic in utero acidemia rather than chronic hypoxemia alone appears to be most strongly associated with intellectual impairment postnatally.[232] The gestational age at decompensation is the primary determinant of perinatal survival. Between 24 and 32 weeks, each day gained in utero may increase the neonatal survival rate by 1% to 2%.[117,222] After delivery, the condition of the neonate at birth as well as the degree

of prematurity affect perinatal complication and mortality rates. In survivors, neonatal complications have an additional significant effect on long-term outcome.[233] In principle, the timing of delivery is straightforward. Delivery takes place either at term, when fetal lung maturity is documented, if fetal distress occurs, or if the maternal condition dictates delivery. Between the age of viability and 32 weeks, however, the risks of perinatal damage from fetal deterioration compete with the risks of iatrogenic prematurity.

Prenatal Surveillance Tests (See also Chapter 11)

In euploid fetuses with presumed uteroplacental dysfunction, the patterns of deterioration are characteristic, but variable, and place specific demands on antenatal surveillance. In addition to acute assessments of fetal well-being, the likelihood of clinical progression necessitates a plan for longitudinal surveillance. Traditional fetal heart rate analysis, assessment of fetal activity (tone, movement, breathing), and evaluation of fetoplacental blood flow (arterial and venous Doppler) allow the most precise assessment of fetal well-being. Computerized fetal heart rate analysis, serial amniotic fluid volume measurement, and knowledge of arterial and venous Doppler status allow a reasonably accurate prediction of longitudinal progression.[133,142,145,146]

Management of IUGR with Integrated Fetal Testing

At the University of Maryland, we use an approach that combines fetal heart rate analysis with Doppler and biophysical assessment initiated at 24 weeks' gestation. The management algorithm is guided by the severity of the maternal and fetal condition and by gestational age. It includes arterial and venous Doppler studies and determination of the BPS (Fig. 12–9).

Integrated fetal testing has three core elements: correct diagnosis of IUGR; assessment of fetal well-being; and prediction of fetal deterioration to time delivery. Delivery is indicated when the results of fetal testing are grossly abnormal, when fetal lung maturity is documented, or when maternal disease poses a serious risk to the mother. Before 34 weeks, a single course of betamethasone should be completed over 48 hours, when delivery is anticipated, to ameliorate neonatal respiratory disease and reduce the risk of intraventricular hemorrhage.

Although local preferences for antenatal surveillance and management vary, several guiding principles apply. First, the limits of viability and intervention dictated by the accepted standard of care must be discussed with the patient when management is initiated. Second, because cardiovascular deterioration is such a prominent feature of IUGR, Doppler assessment must be an integral part of antenatal surveillance. No other method effectively predicts deterioration prospectively. Third, the management of IUGR is too complex to rely on a single surveillance modality. If alternative surveillance methods

IUGR UNLIKELY		
Normal AC, AC growth rate and HC/AC ratio UA, MCA Doppler, BPS and AFV normal	Asphyxia extremely rare Low risk for intrapartum distress	Deliver for obstetric, or maternal factors only, follow growth

IUGR		
AC < 5th, low AC growth rate, high HC/AC ratio, abnormal UA and/or CPR; normal MCA and veins BPS 8/10, AFV normal	Asphyxia extremely rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, fortnightly Doppler Weekly BPS
With blood flow redistribution		
IGUR diagnosed based on above criteria, low MCA, normal veins BPS 8/10, AFV normal	Hypoxemia possible, asphyxia rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, weekly Doppler BPS 2 times/week
With significant blood flow redistribution		
UA A/REDV Normal veins BPS 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia possible Onset of fetal compromise	> 34 weeks later: deliver < 32 weeks: antenatal steroids repeat all testing daily
With proven fetal compromise		
Significant redistribution present Increased DV pulsatility BPS 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia likely	> 34 weeks later: deliver < 32 weeks: admit, steroids, individualized testing daily vs. tid.
With fetal decompensation		
Compromise by above criteria Absent or reversed DV a-wave, pulsatile UV BPS < 6/10, oligohydramnios	Cardiovascular instability, metabolic compromise, stillbirth imminent, high perinatal mortality irrespective of intervention	Deliver at tertiary care center with the highest level of NICU care

FIGURE 12–9
Management algorithm for pregnancies complicated by intrauterine growth restriction (IUGR) based on the ability to perform arterial and venous Doppler as well as a full five-component biophysical profile score (BPS). AC, abdominal circumference; AFV, amniotic fluid volume; A/REDV, absent/reversed end-diastolic velocity; CPR, cerebroplacental ratio; DV, ductus venosus; HC, head circumference; MCA, middle cerebral artery; NICU, neonatal intensive care unit; NST, nonstress test; tid, three times daily; UA, umbilical artery. (From Baschat AA, Hecher K: Fetal growth restriction in placental disease. Semin Perinatol 2004;28:67–80.)

are used, longitudinal monitoring should be tailored to the limitations of the surveillance test. For example, traditional nonstress testing analysis lacks the sensitivity and interobserver agreement needed to facilitate longitudinal monitoring. For this purpose, computerized heart rate monitoring offers superior accuracy. Similarly, if the BPS is the sole method of surveillance in severe IUGR, daily testing may be necessary to provide longitudinal assessment.[234]

Delivery Management Options

The premature neonate with IUGR requires the highest level of neonatal intensive care, and intrauterine transport to an appropriate institution is recommended in all cases of early-onset IUGR. The route of delivery is dictated by the severity of the fetal and maternal condition, along with other obstetric factors. Cesarean section without a trial of labor is indicated when the risks of vaginal delivery are unacceptable. These circumstances include prelabor evidence of fetal acidemia, spontaneous late decelerations, or late decelerations with minimal uterine activity. When fetal testing shows less serious conditions and gestational age is more advanced, the delivery route is tailored to the cervical Bishop score and preinduction oxytocin challenge testing may be required. Pharmacologic or mechanical ripening of the cervix, placement of the woman in the left lateral decubitus position, and the use of supplemental oxygen increase the likelihood of successful vaginal delivery.

Summary

The management of pregnancies with suspected IUGR is initiated with a diagnostic workup, including assessment of maternal and fetal risk factors. After aneuploidy, fetal anomalies, and infection are excluded, uteroplacental dysfunction is the most likely underlying cause. Because antenatal therapeutic options are limited, tailored surveillance and timed delivery are the primary management goals. A combination of surveillance tests, including arterial and venous Doppler and BPS, provides the most accurate assessment of fetal status and the best prediction of longitudinal progression. They are the surveillance techniques of choice for severe early-onset IUGR (integrated fetal testing). The timing, route, and acuity level of the medical center for delivery are determined by gestational age at delivery and the severity of the fetal or maternal condition.

CONCLUSIONS

- Normal fetal growth is a dynamic process that is regulated throughout gestation on multiple levels in the maternal, placental, and fetal compartments.
- Fetal growth restriction is a complex multisystem syndrome. Identification of the small fetus that is most likely to benefit from surveillance and interventions requires exclusion of those etiologies such as aneuploidy and viral syndromes where outcome is mostly predetermined by the underlying condition.
- A sonographically measured fetal abdominal circumference (AC) below the 10 percentile (reference ranges based on a mixed group of high and low risk pregnancies) or below the 2.5th percentile (reference ranges based on normal pregnancies only) is the most sensitive biometric parameter to detect growth delay. If found in an anatomically normal fetus with low, or normal amniotic fluid volume and abnormal umbilical artery Doppler the clinical picture is strongly suggestive of placental insufficiency. However, the possibility of aneuploidy, syndromes and viral infection should always be considered and fetal karyotyping should be offered.
- Progressive deterioration of fetal status is reflected in dynamic variables (tone, movement, breathing, and heart rate characteristics), Doppler parameters and regulation of amniotic fluid volume following a reasonable predictable pattern.
- As the prenatal therapeutic options are limited, tailored surveillance and timed delivery are the primary management goals. Because of the variations in fetal responses to placental dysfunction, the combined assessment of cardiovascular and biophysical parameters (integrated fetal testing) offers the most comprehensive assessment of fetal status and is the suggested surveillance technique of choice for severe early onset IUGR where the balance between in utero risk and prematurity is center stage.
- The timing, route, and acuity level of the medical center for delivery is determined by gestational age at delivery, and the severity of the fetal or maternal conditions. Severe early onset fetal growth restriction prior to 34 weeks' gestation delivery frequently requires experienced multidisciplinary perinatal effort and should be managed accordingly.

SUMMARY OF MANAGEMENT OPTIONS
Intrauterine Growth Restriction

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
First Trimester			
Uterine artery Doppler in patients with thrombophilia, previous midtrimester loss, or previous IUGR. Give low-dose aspirin (81–100 mg/day) if bilateral notching occurs.	Ib	A	155
Second Trimester			
If bilateral uterine artery notching persists until 24 weeks, there is only a marginal benefit of low-dose aspirin in selected patients. There is no evidence of a harmful effect.	Ib	A	154,223–226
On Clinical Suspicion of IUGR			
Two abdominal circumference measurements are obtained at least 14 days apart, with umbilical and middle cerebral arteries, to distinguish between normally grown small and growth-restricted fetuses. Follow for IUGR if:	Ib, IIa	A, B	149,162,163, 187,189,190,215

IUGR, intrauterine growth restriction.

FETAL MACROSOMIA

Fetal macrosomia is excessive fetal growth, which is the opposite of fetal growth restriction. Two terms are used to identify excessive fetal growth: large for gestational age (discussed earlier) and fetal macrosomia, implying a birth weight above 4000 or 4500 g, regardless of gestational age. Unlike in IUGR, the morbidity and mortality rates for macrosomic fetuses are more closely related to absolute birth weight than to birth weight percentile. The sharp increase in birthweight beyond 4500 g makes this a more suitable diagnostic cutoff.[235–238] In the United States, 10% of neonates have a birth weight greater than 4000 g and in 1.5%, it is more than 4500 g.[239] Macrosomia is associated with significant fetal, neonatal, and maternal risks that emphasize the need for antepartum detection and modified intrapartum management. Maternal diabetes mellitus is a common cause of excessive fetal growth (see Chapter 45).

Etiology and Risk Factors

Genetic factors, such as parental height and race, and the level of maternal hyperglycemia during pregnancy are important determinants of birth weight. In decreasing order of importance, recognized risk factors for macrosomia include a previous macrosomic infant, prepregnancy maternal obesity or excessive maternal weight gain, multiparity,[240] a male fetus, post-term gestation, Hispanic race,[241] present maternal height and weight at birth, and maternal age younger than 20 years.[242]

The positive relationship between maternal height, weight, and body mass index and neonatal birth weight is likely the expression of genetically predetermined growth potential[6] as well as maternal glycemic status.[243,244] Women who previously delivered a child larger than 4000 g are 5 to 10 times more likely than negative control subjects to deliver an infant larger than 4500 g in a subsequent pregnancy.[242,245] Women who themselves had a birth weight greater than 3600 g are twice as likely to deliver a neonate larger than 4000 g.[246] Male infants are typically heavier than female infants at any gestational age, and more males than females have a birth weight greater than 4500 g.[238] As fetal growth continues, the proportion of infants larger than 4500 g increases from 1.5% at 40 weeks to 2.5% at 42 weeks.[239]

TABLE 12-6

Genetic Causes of Macrosomia

SYNDROME	CLINICAL FEATURES	INHERITANCE
Perlman syndrome	Fetal macrosomia with visceromegaly, ascites, and polyhydramnios; bilateral renal hamartomas; Wilms' tumor; cryptorchidism; facial abnormalities; micrognathia; volvulus; ileal atresia; diaphragmatic hernia; interrupted aortic arch; corpus callosum agenesis	Autosomal recessive
Lethal macrosomia with micropthalmia	Macrosomia, microphthalmia, median cleft palate; associated with respiratory infection in early life and early infant death	Autosomal recessive
Macrosomia adipose congenita	Macrosomia, voracious appetite, precocious skeletal development; death in first year common	Autosomal recessive
MOMO syndrome	Macrocephaly, retinal coloboma, nystagmus, mental retardation, delayed bone maturation	Autosomal dominant
Cleft lip or palate, characteristic facies, intestinal malrotation, congenital heart disease	Macrosomia, bilateral cleft lip or palate, flat facial profile, lethal complex congenital heart defect, bifid thumbs	Autosomal recessive
ABCD syndrome	Macrosomia, defective intestinal innervation, neonatal fatal intestinal dysfunction	Autosomal recessive
Simpson-Golabi-Behmel syndrome	Macrosomia, macrocephaly, coarse facies, hypertelorism, cleft palate, ventricular septal defect, pulmonic stenosis, transposition of great vessels, patent ductus arteriosus, lung segmentation defects, cervical ribs, pectus excavatum, 13 pairs of thoracic ribs, diaphragmatic hernia, polysplenia, duplication of renal pelvis, postaxial polydactyly, syndactyly of the 2nd–3rd fingers, clubfoot, corpus callosum agenesis, cerebellar vermis hypoplasia, hydrocephalus, embryonal tumors, Wilms' tumor	X-linked recessive
Weaver-Smith syndrome	Macrosomia with predominant developmental features	Autosomal dominant
CHIME syndrome	Early-onset migratory ichthyosiform dermatosis, seizures, mental retardation, cleft palate, tetralogy of Fallot, transposition of the great vessels	Autosomal recessive
CANTU syndrome	Generalized congenital hypertrichosis, narrow thorax, cardiomegaly	Autosomal recessive
Marfan syndrome	Macrosomia, micrognathia, enophthalmos, predominant features postdelivery	Autosomal dominant
Beckwith-Wiedemann syndrome	Macrosomia, macroglossia, cardiomegaly, omphalocele, Wilms' tumor	Autosomal dominant

Environmental and genetic interactions are complex. Much birth weight variation is unexplained, and most infants with macrosomia have no identifiable risk factor.[235] Further, no risk factor predicts macrosomia accurately. Several inheritable syndromes that may be responsible for fetal macrosomia are listed in Table 12–6.

Pathophysiology

Excessive fetal growth may result from excess substrate availability, optimal placentation, and overstimulation of the fetal insulin–insulin-like growth factor–leptin axis. Maternal diabetes mellitus is the primary example of excessive substrate availability and subsequent fetal hyperinsulinemia. Maternal obesity and excessive maternal weight gain are associated with intermittent periods of hyperglycemia and thus may act by the same mechanism. Progressive immune recognition and improved placentation with successive pregnancies could explain the increased birth weight observed in the multipara. Overexpression of placental substrate transporters has not been evaluated systematically.

The fetal growth pattern and type of tissue overgrowth reflects the underlying etiology. Insulin-sensitive tissues, such as the heart, liver and spleen, thymus, adrenal gland, subcutaneous fat, and shoulder girdle, can show differential glycogen and fat deposition when insulin levels are high. As a result, total body fat, shoulder and upper-extremity circumference, upper-extremity skin-fold thickness, and liver size are disproportionately greater in macrosomic infants of diabetic women compared with those of women without diabetes.[247,248] These differences in growth patterns are at least partially responsible for the significant associated fetal, neonatal, and maternal risks.

Fetal and Neonatal Risks

Macrosomia is associated with increased perinatal mortality; intrapartum risks, including shoulder dystocia; brachial plexus injury; skeletal injuries; meconium aspiration; perinatal asphyxia; and postpartum complications, including respiratory distress syndrome and neonatal hypoglycemia.[235,236,249,250] The complication rates reflect the absolute birth weight. Perinatal morbidity rates are increased in infants larger than 4500 g, and mortality rates are increased in infants larger than 5000 g.[251] Rates of shoulder dystocia and associated clavicular fracture increase 10-fold.[252] Yet, only a small percentage of macrosomic fetuses have complicated deliveries. The risk of shoulder dystocia is significantly affected by the underlying cause of macrosomia. In women without diabetes, shoulder dystocia occurs in 9.8% to 24% of deliveries with a fetus weighing more than 4500 g. This prevalence is doubled in women with diabetes.[237,253,254] Clavicular fracture and brachial plexus injuries, including

Erb-Duchenne palsy, are most frequently associated with shoulder dystocia.[252,255] However, the risk of brachial plexus injury is increased independent of the mode of delivery or the clinical diagnosis of shoulder dystocia. This finding suggests an in utero origin for at least some brachial plexus injuries.[256] When birth weight exceeds 4500 g, the risk of shoulder dystocia is 18- to 21-fold higher than that in neonates with lower birth weight.[238,248,257]

Maternal Risks

Maternal complications of macrosomia are also related to neonatal birth weight. The incidences of cephalopelvic disproportion and prolonged labor increase at birth weights greater than 4500 g, and as a result, the cesarean delivery rate doubles.[236,257] The incidence of postpartum hemorrhage greater than 1000 ml increases with birth weights above 4000 g.[258] The rate of third- and fourth-degree laceration is especially increased when shoulder dystocia is diagnosed.[259] Thromboembolic events and anesthetic complications are increased in great part because of the increased need for operative intervention.

Summary

Excessive fetal growth is associated with fetal, neonatal, and maternal risks. These risks are proportional to the absolute, rather than relative, birth weight. Although macrosomia is variably defined, a birth weight greater than 4500 g is associated with the highest risk of morbidity, whereas a birth weight greater than 5000 g is associated with an increased risk of perinatal mortality. Maternal hyperglycemia is the most common risk factor for macrosomia; it also affects perinatal outcome by altering neonatal body proportions and increasing the risk of shoulder dystocia and related birth trauma.

Diagnosis

There are no useful, general-purpose screening tools for the detection of macrosomia. A history of obstetric and maternal risk factors (discussed earlier) heightens the clinical index of suspicion. In addition, an unexplained very low serum maternal serum α-fetoprotein level is associated with increased birth weight and an increased prevalence of obstetric complications.[260]

Clinical Examination

Mothers of infants with birth weight greater than 4500 g have greater symphyseal fundal height than expected.[261] However, several variables, including amniotic fluid volume and maternal body habitus, limit the usefulness of this measurement unless it is combined with clinical palpation or Leopold's maneuvers.[262] Prospective studies of fundal height measurement combined with Leopold's maneuvers

report sensitivity of 10% to 43%, specificity of 99.0% to 99.8%, and positive predictive values of 28% to 53% for the detection of macrosomia.[263,264] Finally, the mother's subjective assessment of fetal weight can be as accurate as the clinical assessment by Leopold's maneuvers.[265]

Ultrasound

Ultrasound prediction of fetal weight loses accuracy above 4000 g does not exceed the diagnostic accuracy of clinical estimates.[265–267] Only 50% of fetuses larger than 4500 g weigh within 10% of the predicted weight.[268] In women without diabetes mellitus, the sensitivity of ultrasound for the detection of macrosomia (birth weight >4500 g) is 22% to 44%, with specificity of 99% and positive predictive values of 30% to 44%.[269,270] There are several reasons for these inaccuracies. First, even at lower weights, the typical error associated with sonographic estimates is 10%, a large error in a macrosomic fetus. Second, the accuracy of these formulas, when confined to macrosomic fetuses, is even lower, up to 13%.[271] Because the birth weight of macrosomic infants is largely determined by organ size and fat deposition, formulas that include abdominal circumference and exclude bony measurements perform better than those that do not.[269] Ultrasound methods that account for skin thickness[272] or incorporate algorithms to calculate fetal volume may have a role in the future.[273] Ultrasound can provide diagnostic information on fetal anatomy, organ size, and fat deposition. Further, ultrasound allows an objective assessment of amniotic fluid volume that may prompt further evaluation for underlying syndromes (see Table 12–6) or recommendation of a 3-hour glucose tolerance test when hydramnios is suspected. In women with diabetes mellitus, macrosomia may be a biologic indicator of suboptimal maternal metabolic control.

Management Options

In the absence of maternal diabetes mellitus, principal management considerations for suspected macrosomia focus on the timing and type of delivery and intrapartum management. Evidence suggests that labor induction for suspected macrosomia, defined as estimated fetal weight of 4000 to 4500 g,[274] increases the cesarean delivery rate without improving perinatal outcome.[275] Although seemingly logical, labor induction should not be undertaken in the absence of a high cervical Bishop's score.

Because perinatal and maternal risks increase with birth weight and cesarean section reportedly decreases the risks of birth trauma and brachial plexus injury,[236,248,252] it is logical to conclude that elective cesarean delivery should be offered beyond a certain estimated fetal weight. However, there is no adequate study to support this practice. No clinical studies show a significant reduction in the prevalence of birth injury by adopting such a practice,

although arguably, a much larger sample size is needed. Cohort and case–control studies show that a trial of labor is safe and cost-effective at estimated fetal weights of 5000 g or less.[276] Although the predictive accuracy of fetal weight estimates is poor at greater than 5000 g, most authors agree that prophylactic cesarean section should be offered.[236,257] For suspected fetal macrosomia less than 5000 g, prophylactic cesarean section does not appear to reduce birth trauma significantly in the absence of maternal diabetes mellitus. In these women and those with other risk factors, such as a history of shoulder dystocia in a macrosomic infant, estimated weight is important when planning the delivery route.

During labor, special attention is given to the progress of labor and the uterine contraction pattern. Cesarean delivery is indicated when the estimated fetal weight exceeds 4500 g; the second stage is prolonged (>2 hours), with documented adequate uterine contractions (>200 Montevideo units); or descent is arrested. The risk of shoulder dystocia is increased by assisted vaginal delivery. A trial of vaginal delivery after a previous cesarean delivery appears safe for both infant and mother, with success rates of 58% when birth weight is less than 4500 g and 43% when birth weight is higher.[277]

Summary

Antenatal prediction of fetal macrosomia is unsatisfactory because most women with a macrosomic fetus lack characteristic risk factors. Further, the predictive accuracy of diagnostic ultrasound decreases with increasing fetal weight. Manual assessment of fetal weight supplemented with Leopold's maneuvers is just as efficient as assessment with ultrasound. The main role of ultrasound is detecting fetal anomalies and quantifying amniotic fluid volume. In the absence of maternal diabetes mellitus, little evidence supports elective induction or cesarean section with estimated fetal weight of less than 5000 g unless other obstetric factors (e.g., high Bishop's score) are present. With an estimated fetal weight of greater than 4500 g, a prolonged second stage of labor or arrest of descent in the second stage is an indication for cesarean delivery. Although the diagnosis of fetal macrosomia is imprecise, prophylactic cesarean delivery may be reasonable when estimated fetal weight is greater than 5000 g in women without diabetes or greater than 4500 g in women with diabetes mellitus. Suspected fetal macrosomia is not a contraindication to attempted vaginal birth after a previous cesarean delivery.

CONCLUSIONS

- Excessive fetal growth is associated with fetal, neonatal, and maternal risks that are proportional to the absolute rather than the birthweight percentile. A birthweight greater than 4500 g identifies pregnancies at highest risk for morbidity, while a birthweight above 5000 g identifies those at increased risk of a perinatal mortality.
- Maternal hyperglycemia is the greatest risk factor for macrosomia by promoting accelerated fetal growth as well as altered body proportions that escalate the risk for shoulder dystocia and related birth trauma.
- Prenatal prediction of macrosomia is unsatisfactory due to the lacking of characteristic risk factors in many women and the inadequate accuracy of diagnostic ultrasound with increasing fetal weight.
- In the absence of maternal diabetes mellitus unfavorable obstetric factors, prolonged, or arrested second stage are indications for cesarean delivery in fetuses with an estimated weight in excess of 4500 g.
- Prophylactic cesarean section may be offered to all women carrying a fetus with an estimated fetal weight greater than 5000 g and to diabetic women if the estimated fetal weight is greater than 4500 g.
- Suspected fetal macrosomia with an estimated fetal weight below 5000 g is not a contraindication to attempted vaginal birth after a previous cesarean delivery.

Hydramnios and Oligohydramnios

Myles J. O. Taylor / Nicholas M. Fisk

INTRODUCTION

Amniotic fluid (AF) provides the fetus a protective low resistance environment suitable for growth and development. Essentially, AF volume is the sum of the inflow and outflow of fluid into the amniotic space, and as such reflects fetal fluid balance. In addition, the constitution of AF also reflects maternal hydration because fluid shifts freely across the placenta, predominantly in response to osmotic gradients. The clinical assessment of AF volume, including bimanual palpation and symphyseal-fundal height measurements, is unreliable, although any utility is greater for hydramnios than for oligohydramnios. AF volume derangement is usually severe when hydramnios or oligohydramnios is suspected clinically. Direct quantification of AF by dye dilution is described but rarely used because it requires two amniocenteses with attendant risks and relies on the dubious assumption that complete mixing of the injected dye indicator occurs within a 15- to 30-minute interval.[1,2] On the other hand, ultrasonic estimates of amniotic volume correlate directly with the measured volume change at both amnioreduction and amnioinfusion procedures.[3–5]

Accordingly, definitions of increased and decreased AF volume are based on sonographic criteria. The prevalence of hydramnios and oligohydramnios varies with the diagnostic criteria used, fetal number, and whether a referral or hospital-based population is studied. Semiquantitative methods include estimates of the deepest vertical pool (DP) and the amniotic fluid index (AFI). AFI, which summates the DP in each of four quadrants and is a more sensitive estimate of AF volume throughout gestation,[6,7] is preferred by many to the DP, because DP does not allow for an asymmetrical fetal position within the uterus and because the regression curve between AFI and gestational age is similar in shape to that between AF volume and gestational age.[8] On the other hand, a recent prospective survey concluded that the single DP was more reliable than either AFI or two diameter pocket measurements of AF because it is least likely to lead to a false-positive diagnosis of either oligo-

hydramnios or hydramnios.[9] Reference ranges for AFI and DP throughout gestation are available (Fig. 13–1).[7,9,10] The AFI is always less than that determined using gray-scale ultrasonography alone when color Doppler is employed to facilitate identification of the umbilical cord.[11] However, every method is influenced by transducer pressure, which may explain reported difficulties with reproducibility.[12] New methods for AF volume estimation such as three-dimensional (3D) ultrasound or magnetic resonance imaging may circumvent this problem.[13]

In multiple pregnancies, the assessment of AF volume should probably include an overall assessment of the AFI along with a DP measurement for each fetus. Attempts to measure AFI for each individual fetus are not feasible, particularly in monochorionic pregnancies in which the intertwin membrane is so thin as to hinder exact separate delineation and do not provide any additional information to the recommended technique.

HYDRAMNIOS

Definition

Hydramnios is variably defined as a DP of 8 cm or greater or an AFI above the 95th percentile for gestational age[7] (see Fig. 13–1). In older studies, hydramnios was reported to complicate 3.5%[14,15] of pregnancies, but a more recent study of a population undergoing routine anomaly scanning found the incidence to be much lower—0.2%.[16]

Etiology

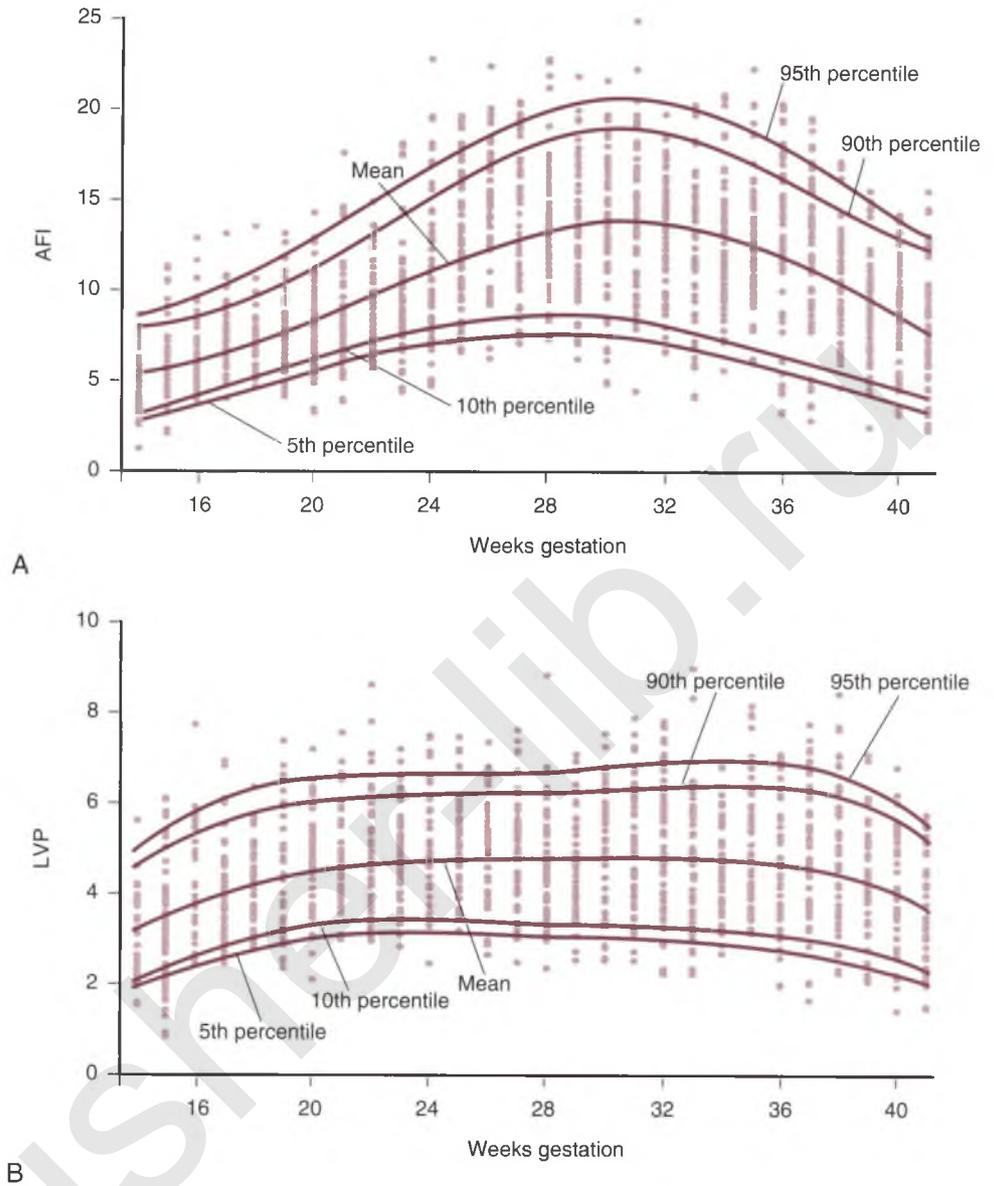
Common causes of hydramnios are shown in Table 13–1. Hydramnios may be mild (DP 8 to 12 cm), moderate (12 to 15 cm), or severe (>15 cm). Severe hydramnios occurs in only 5% of cases.[15] Although impairment of fetal swallowing is implicated in anencephaly, only 65% develop hydramnios. Although this


FIGURE 13–1
Normal range for amniotic fluid index, AFI (*A*), and single deepest pocket (lowest vertical pool, LVP) (*B*) from 14 to 41 weeks' gestation. (From Magann EF, Sanderson M, Martin JN, Chauhan S: The amniotic fluid index, single deepest pocket, and two-diameter pocket in normal human pregnancy. Am J Obstet Gynecol 2000;182(6):1581–1588.)[9]

association may reflect variation in the amount of brain tissue present, alternative mechanisms include fluid transudation across the meninges or vasopressin deficiency resulting in fetal polyuria.[17] The incidence of hydramnios secondary to maternal diabetes has declined from 26% to 22% in older series[1] to 13% to 5%[15] presumably as a result of tighter glucose control. Although fetal polyuria secondary to osmotic diuresis might seem an obvious mechanism in diabetes mellitus, Van Otterlo and associates[18] found normal fetal urine production rates in most diabetic pregnancies with mild hydramnios. However, Yasui and associates[19] observed increased fetal urine output during maternal fasting. On the other hand, fetal polyuria is clearly documented in recipient fetuses of twin-twin transfusion syndrome (TTTS) in association with increased atrial naturetic peptide levels.[20–23] These measurements are supported

by histologic demonstration of enlarged glomeruli and dilated distal convoluted tubules.[17,22] Increased cardiac output may underlie hydramnos in TTTS and in some cases of hydrops and Rh alloimmunization, although investigations in gravid sheep suggest this may be an oversimplification.[24] For example, an infusion of angiotensin I into fetal sheep with functional kidneys leads to hydramnios,[25] although the mechanism is poorly understood. Hydramnios in nonhydropic red blood cell (RBC) alloimmunization may in part be explained by a hypoxia-induced hyperlactinemia[26] as animal data reveal powerful osmotic effects as an elevated fetal plasma lactate draws fluid from the maternal into the fetal compartment.[24]

Rarer causes of hydramnios include substance abuse, in which the incidence of hydramnios is several times higher than in control subjects,[27] and maternal lithium

TABLE 13-1

Common Causes or Associations with Hydramnios

Maternal

Diabetes mellitus
Substance abuse
Lithium therapy

Fetal

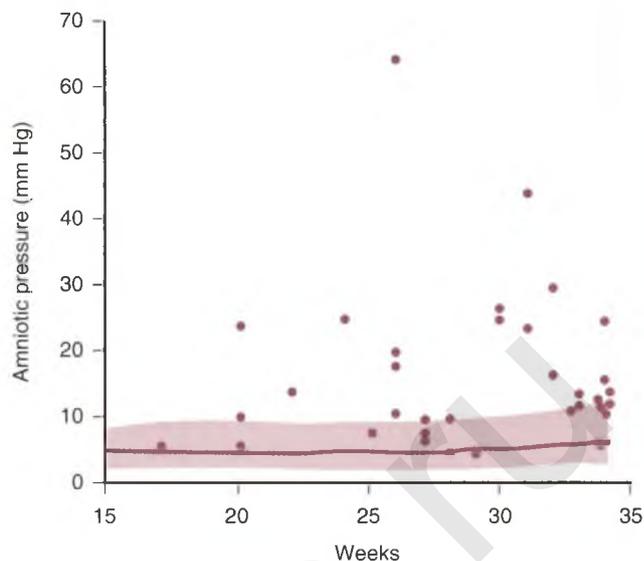
Obstruction of fluid transit through the gastrointestinal tract
Intestinal atresias (commonly duodenal)
Esophageal compression secondary to thoracic or
    mediastinal masses (including diaphragmatic hernia)
Neurologic impairment of swallowing
Central nervous system lesions (e.g., anencephaly)
Chromosomal abnormalities (e.g., trisomy 18)
Muscular dystrophies
Fetal polyuria
Twin-twin transfusion syndrome
Bartter syndrome
High-output cardiac failure
Fetal anemia
Sacrococcygeal teratoma
Chorioangioma
Congenital infection (e.g., syphilis, viral hepatitis)


FIGURE 13-2

Amniotic fluid pressure in 36 pregnancies complicated by hydramnios shown against the normal pregnancy reference range with continuous line representing the mean and the upper and lower limits of the shaded area, the reference range. (From Fisk NM, Tannirandorn Y, Nicolini U, et al: Amniotic pressure in disorders of amniotic fluid volume. Obstet Gynecol 1990;76(2):210–214.)[55]

therapy.[28,29] Bartter syndrome, an autosomal recessive condition characterized by hypokalemic alkalosis and hypercalciuria, may also present with hydramnios.[30] Matsushita and associates[31] conducted biochemical tests of both the amniotic fluid and maternal urine for antenatal diagnosis and concluded that the latter parameters may allow prediction of fetal Bartter syndrome. Amniotic fluid electrolytes, except for potassium, are high in a fetus with Bartter syndrome. Urinary chloride, sodium, and calcium are very low.

The incidence of idiopathic hydramnios is related to severity, with a cause identified in 75% to 91% when the DP is greater than 12 cm, compared to 17% to 29% with a DP of 8 to 12 cm.[15,32] If the sonographic evaluation is normal, the risk of a major anomaly approximates 1% with mild hydramnios, 2% with moderate hydramnios, and 11% with severe hydramnios.[33] The term "acute hydramnios" refers to a sudden accumulation of amniotic fluid associated with maternal symptoms. Acute hydramnios is almost exclusively a manifestation of TTTS before 26 weeks' gestation when there is a rapid accumulation in the sac of the recipient.[1,34]

Maternal Risks

Maternal complications are mostly attributed to uterine distention[35,36] and include abdominal discomfort, uterine irritability, postpartum hemorrhage, and compromised respiratory function. Intra-amniotic pressure is markedly elevated in most women with severe hydramnios (Fig. 13–2).[37,38] The incidence of cesarean section is also increased as a result of unstable lie and placental abruption, which may occur with the rapid decrease in intrauterine pressure that accompanies membrane rupture.[39,40] The higher incidence of preeclampsia may be a

manifestation of the "mirror syndrome" in association with fetal hydrops.[41] Ureteric obstruction occurs very rarely with gross uterine distention.[42,43]

Fetal Risks

Increased perinatal mortality rates (<5% in recent series[33,44]) associated with hydramnios are largely due to the presence of congenital malformations, preterm premature rupture of membranes, or preterm labor and delivery. Although the high incidence of fetal anomalies and multiple pregnancies makes the exact risk for spontaneous preterm labor difficult to determine, a 22% rate was reported after excluding malformations.[15] Hypoxic events secondary to cord prolapse, placental abruption and uteroplacental dysfunction also contribute to the high perinatal rates. Loss rates are lower when fetuses with structural defects are excluded,[1,15] but these associations do not entirely account for the high perinatal mortality rate. Six to14% of perinatal deaths occur antepartum in normally formed singletons.[1,15,45] One explanation may be an increased risk of hypoxemia and acidemia and raised intra-amniotic pressure observed in fetuses with hydramnios.[38] Based on the increased pressure, it is suggested uteroplacental perfusion can be impaired by extreme hydramnios. This hypothesis is supported by the observation that uterine blood flow increases substantially after amnioreduction in pregnancies complicated by severe hydramnios.[46–48] Further, multivariate analysis suggests hydramnios is an independent risk factor for intrapartum fetal death.[49]

Diagnosis

Objectives include an assessment of the following:

- Fetal number and chorionicity
- Degree of hydramnios
- Underlying etiology
- Presence of associated anomalies
- Karyotype
- Presence of viral infection

A recommended diagnostic approach is outlined in Table 13–2. Kirshon[50] observed that hourly fetal urine production rates (HFUPR) calculated by ultrasonic change in bladder dimensions over 20-min intervals[51] distinguished hydramnios secondary to fetal polyuria from that secondary to other causes. Unfortunately, the technique used may underestimate fetal urine production by more than 50%.[52] In multiple pregnancies, hydramnios can occur in dichorionic pregnancies as a consequence of any of the listed causes in singleton pregnancy, or alternatively, in monochorionic placentas secondary to TTTS or twin reversed arterial perfusion (TRAP) sequence. The bladder of recipient fetuses in TTTS remains chronically full, with its size at the upper limit of normal. Thus, there is little rationale in calculating HFUPR. In view of the up to 3%[53] association with chromosomal abnormalities, karyotyping was recommended in the past. However, more recent series generated when routine anomaly scanning was available suggest a much lower risk of aneuploidy (<1%)[33,44] if the fetus is sonographically normal.

Maternal diabetes mellitus should be excluded by carbohydrate tolerance testing, and alloimmunization excluded by maternal serologic testing. When fetal hydrops is present but unassociated with a structural malformation, fetal viral infection or anemia should be suspected (see Chapter 27).

TABLE 13–2

Diagnostic Evaluation of Hydramnios

History taking with emphasis on maternal symptoms, diabetes mellitus, red blood cell alloimmunization, maternal drug ingestion
High-resolution ultrasound to assess:
    The degree of hydramnios (amniotic fluid index)
    Presence of multiple gestation, growth deficiency, or macrosomia
    Fetal thorax
    Fetal central nervous system (midline structures, neural tube, tone)
    Fetal gastrointestinal system (mouth, stomach, small bowel, abdominal wall)
    Fetal bladder dynamics
    Middle cerebral artery peak systolic velocity for suspected fetal anemia
    Chorionicity in multiple pregnancy
Fetal specimens for karyotyping and viral infection

Management Options

General

The therapeutic aim is to relieve maternal symptoms and prolong gestation. Mild asymptomatic hydramnios is managed expectantly. There are no data to support dietary restriction of salts and fluids. Similarly, diuretics administered to the mother seem ineffective and may in fact reduce uteroplacental perfusion.[54]

Treatment is usually warranted only in moderate to severe hydramnios during the mid or early third trimester. The criteria for intervention include either excessive maternal symptoms or an AFI above 40 cm or DP over 12 cm (moderate hydramnios), above which thresholds intra-amniotic pressure may increase.[55] Although treatment should ideally be directed at the underlying etiology, this is possible only in a limited number of instances such as the correction of fetal anemia by transfusion, relief of obstructed cardiac return by drainage of pleural effusions, and more recently laser ablation of placental anastomoses in advanced stage TTTS.

Prostaglandin Synthase Inhibitors

INDOMETHACIN

Cifuentes and associates[56] first noted decreased urinary production rates in neonates receiving indomethacin for closure of the ductus arteriosus. Subsequently, maternally administered indomethacin was shown to reduce fetal urine production[57] and amniotic fluid volume.[58–60] The E class of prostaglandins antagonize the antidiuretic effect of arginine vasopressin on the collecting tubule of the kidney,[61] and prostaglandin inhibition enhances proximal tubular resorption of water and sodium.[62] Indomethacin is believed to decrease urine output by either or both of these mechanisms. Although decreased renal blood flow is postulated as a cause for the decreased urine production, Doppler flow studies do not reveal changes in the renal artery resistance indices during indomethacin therapy.[63] The dose of indomethacin varies between 50 and 200 mg/day, depending on the AF volume response assessed ultrasonically. The time interval between commencing treatment and achieving normal AF volume ranges from 4 to 20 days.[64,65] Amnioreduction prior to initiating indomethacin[66] may be beneficial by avoiding the delayed pharmacologic response should the maternal symptoms be severe, or there is concern for preterm delivery. AF volume is monitored to ensure that oligohydramnios does not ensue.

Most authors report that they discontinue treatment by 32 to 35 weeks because of reports of neonatal morbidity resulting from indomethacin use in late gestation.[58,60] Although the initial clinical experience was promising, there are concerns about the risks of:

- Premature closure of the ductus[66]
- Cerebral vasoconstriction in the fetus[67]
- Impaired renal function[68]

The need for caution in pregnancies less than 32 weeks is highlighted by a retrospective cohort study revealing an increased incidence of necrotizing enterocolitis (29% vs. 8%), intracranial hemorrhage (28% vs. 9%), and patent ductus arteriosus (62% vs. 44%) in infants treated with indomethacin in utero[69] compared to control infants. However, the conclusions of more recent studies suggest that neonatal complications after in utero exposure to indomethacin are inconsistent. Indeed, Abbassi and associates[70] and Panter and associates[71] observed no increased risk. Fetal echocardiography is recommended by some within 24 hours of starting treatment and weekly thereafter despite the fact the incidence of ductal constriction depends on gestation (approximately 5% before 27 weeks and increasing to nearly 50% by 32 weeks[72]). The indomethacin is discontinued if there is evidence of ductal constriction.[73] However, there is no definitive proof of an association between indomethacin and neonatal persistent fetal circulation and pulmonary hypertension.[74] Nor is there any evidence to suggest such monitoring is cost effective. Vermillion and associates reported that constriction of the fetal ductus arteriosus during indomethacin tocolysis may occur at any gestational age.[75] However, their study showed that ductal constriction was reversible with early identification and timely discontinuation of therapy; thus, they advised caution in its use over 31 weeks' gestation. Raised serum creatinine with or without renal failure has been described in neonates of women who received indomethacin antenatally but is usually a transient phenomenon. Treatment is also discontinued if oligohydramnios develops. Indomethacin is no longer used long term as renal failure and irreversible renal damage are observed in neonates with prolonged exposure to indomethacin in utero.[76] Its use is also contraindicated in TTTS because of the adverse effects on the oliguric donor twin.

The true safety of antenatally administered indomethacin requires a prospective randomized controlled trial. Until one is performed, the evidence indicates long-term indomethacin use should be avoided, but that cautious short-term use of indomethacin before 32 weeks of gestation will add minimal risks for neonatal complication.

SULINDAC

Sulindac is an alternative prostaglandin synthase inhibitor with similar structure to indomethacin. It appears to have a lesser effect on fetal urine output and the ductus arteriosus[77] and thus may be a safer alternative to indomethacin. Although the active form of sulindac (the sulfide metabolite) does cross the placenta,[78] fetal levels are half the maternal levels. This relationship contrasts with the inactive forms of sulindac, for which the fetal and maternal levels are similar. At a recommended dose of 200 mg every 12 hours, sulindac can reduce AF volume without evidence of ductal constriction during prolonged therapy in the second and early third trimester.[79] Any mild effect

on the fetal ductus is transient,[80] which is advantageous in the longer term management of hydramnios or threatened preterm labor.

The finding that sulindac may have fewer fetal side effects than indomethacin is perhaps explained by its greater selectivity against cyclooxygenase enzyme 2 (COX-2) than COX-1 (16-fold more selective). In contrast, indomethacin is an equipotent inhibitor of COX-1 and COX-2. This prompted some authors to suggest that a highly selective COX-2 inhibitor such as nimesulide, which is 25-fold more COX-2 selective than indomethacin, may be safer yet. Unfortunately, this supposition was not substantiated, at least after short-term exposure, in a recent randomized controlled trial in which nimesulide had a similar fetal side effect profile to indomethacin and sulindac.[81] These results suggest that the use of newer COX-2 specific drugs, developed for the treatment of preterm labor, are unlikely to be advantageous as they too will be limited by their fetal oliguric side effects.

Therapeutic Amniocentesis (Amnioreduction)

Amnioreduction describes transabdominal aspiration of amniotic fluid under ultrasound control. Several studies suggest it prolongs gestation in both singleton and multiple pregnancies[1,82,83] and improves perinatal survival.[83–88] The risks of the procedure include preterm premature rupture of the membranes, chorioamnionitis, placental abruption, membranous detachment, which follows multiple procedures and which appears to precede membrane rupture by several weeks, and perforation of the amnion separating monochorionic twins.

PROCEDURE

AMNIOREDUCTION

Preprocedure

Counsel the mother about the 0.3% procedure-related fetal loss rate, although preterm labor and amniorrhexis risk is considerable if already complicated by contractions and cervical dilatation.

Procedure

Choose a skin entry site and track to target on scan to (i) avoid placenta, (ii) avoid lateral entry through thick myometrium, which may induce painful contractions during the procedure, and (iii) allow for a reduction in uterine volume and thus fundal height. The ideal entry is through midanterior uterine wall with needle pointing slightly cephalad, moving slightly caudal as uterine volume diminishes.

Infiltrate local anesthetic (i.e., 5–10 mL 1% lidocaine) into superficial maternal tissues. Some authors recommend prophylactic antibiotic (i.e., cefuroxime 750 mg IV), though there is no evidence of efficacy.

Use a larger wide-bore needle (18–20 gauge) with sterile technique. The methods are described in Chapter 10.

Confirm intra-amniotic location free of membrane tenting by aspiration of aliquot of amniotic fluid. Collect diagnostic samples.

Attach a three-way tap via wide-bore tubing to needle hub, and commence aspiration using two 50-mL syringes serially.

If the mother has difficulty tolerating the procedure owing to problematic contractions, reposition the mother on her side, let go of cannula, and wait until the contractions have passed.

Confirm correct intra-amniotic positioning, either by continuous or frequent intermittent ultrasound. If flow stops, desist aspiration, check location, and consider readjusting needle position, especially in twins, in which the flow may be occluded by septum.

Continue drainage until the DP is 5 to 8 cm (or AFI 10–20 cm).

Postprocedure

Check umbilical artery Doppler; demonstrate to parents.

Administer anti-D antibodies IM to RhD-negative women.

After 26 weeks, consider CTG, especially if the procedure was complicated or the fetus compromised.

Amniodrainage may need to be repeated, even serially. In our own unit, a repeat procedure is indicated if the AFI rises above 40 to 45 cm, or the DP is over 12 cm, above which the level AF pressure, and hence the risk of preterm labor and amniorrhexis, is known to exceed the reference range.[55] Instead of using syringes to aspirate AF at amniodrainage, Jauniaux and associates[89,90] suggested using a suction bottle system, which, by enabling as much AF to be removed as possible, reduced the total number of amnioreductions required from a mean of 5.6 to 1.5 procedures in a series of 30 TTTS patients. After 37 weeks, the risks of amniodrainage, particularly of abruption, outweigh the benefits of prolongation of pregnancy and are thus rarely performed.

The perinatal mortality rate with untreated TTTS complicated by hydramnios presenting prior to 28 weeks approaches 80%.[91] A recent meta-analysis of those presenting before 28 weeks and treated by serial amniodrainage showed an overall survival rate in the region of 60% (see Chapter 24). Amniotic fluid reaccumulation in the sac of the oligohyramniotic donor is reported. One explanation offered for this change is that the relief of raised intra-amniotic pressure in the hydramniotic recipient twin improves the circulation to the "stuck" donor twin, thus restoring its renal function.[84] However, there is no evidence to support this theory, which seems to violate known laws of fluid mechanics. A more likely explanation is leakage of fluid into the sac of the "stuck" twin through needle puncture. Intentional amniotic septostomy (creating a hole in the septa between the sacs of the donor and recipient twin) was associated with an 83% survival rate in one small series.[92] It leads to equilibration of AF volume between the two sacs and although the mechanism appears uncertain, it could improve hemodynamics in the donor twin through restitution of swallowing. In a recent randomized controlled trial comparing amniodrainage versus septostomy in the treatment of TTTS, the perinatal survival rate (65%) was no different between therapies. However, septostomy reduced the requirement for repeat procedure due to recurrent polyhydramnios from 70% to 40%.[93]

Septostomy, laser and occlusive fetocide for polyhydramnios in complicated monochorionic twins are dealt with in Chapter 24.

SUMMARY OF MANAGEMENT OPTIONS
Hydramnios

Management Options	Quality of Evidence	Strength of Recommendation	References
Identify Cause (if possible)			
Take detailed history, especially maternal diabetes, maternal lithium therapy, family history of myotonic dystrophy or past history of skeletal dysplasia/arthrogryposis, red blood cell alloimmunization, and diabetes insipidus. Arrange blood sugar series/glucose tolerance test.	–	GPP	–
Determine severity: Polyhydramnios defined as AFI >25 cm or DVP >8 cm. Mild: AFI 25–35 cm, DVP 8–10 cm; moderate: AFI 35–45 cm, DVP 10–12 cm; severe: AFI >45, DVP >12 cm.	III	B	55
Make detailed assessment of the fetal anatomy to determine cause. Chance of fetal abnormality or genetic condition is related to severity, with 90% of mild cases idiopathic vs. only 10% of severe cases. Look for markers of aneuploidy	III	B	54

Hydramnios *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Identify Cause (if possible)—Continued			
and associated structural abnormalities, particularly those interfering with swallowing, intestinal transit, fetal movement, or venous return. Assess bladder dynamics qualitatively, with a chronically full, albeit normal-sized bladder suggestive of fetal polyuria as cause (mainly idiopathic, large baby, or volume overload, although rare renal defect/Bartter syndrome/diabetes insipidus is also possible).			
Aneuploidy risk depends on underlying cause, structural anomalies (1/3 for duodenal atresia), a priori risk, and severity. Karyotyping for isolated mild polyhydramnios controversial – only offer if increased a priori risk. Same probably applies to investigation for viral infection.	III	B	53
Treatment (relieve maternal symptoms; prolong gestation)			
If mild asymptomatic, manage expectantly; no evidence to suggest diuretics and salt or fluid restriction are of value.	–	GPP	–
Specific treatment depends on underlying cause (see relevant chapters).	–	GPP	–
Consider amnioreduction (see separate protocol) if AFI >40 cm or earlier if patient is symptomatic and prolongation of pregnancy indicated.	III	B	84
Consider sulindac (200 mg bid) in gestations <32 wk.	Ib	A	77,80
Avoid indomethacin because of adverse fetal affects.	Ib	A	77,80
Counsel patient about risks of PPROM (cord prolapse, infection) and preterm labor. If polyhydramnios persists, elective delivery at 38 wk in view of increased risk of unexplained stillbirth. Can deliver vaginally if singleton and stable cephalic presentation.	III III	B B	58 90
Alert pediatricians (need to assess upper gastrointestinal patency, risk of neonatal milk aspiration, etc.).	–	GPP	–

AFI, amniotic fluid index; DVP, deepest vertical pool; PPROM, preterum premature rupture of membranes.

OLIGOHYDRAMNIOS

Definition

Oligohydramnios has been defined as the DP devoid of cord or fetal limbs measuring less than 3, 2, or 1 cm,[94,95] the latter indicating moderate to severe oligohydramnios. An AFI below the 5th percentile for gestational age is a more popular definition today (see Fig. 13–1), though a recent study suggests this approach overdiagnoses oligohydramnios.[9] Likewise, the concurrent use of color Doppler may lead to the overdiagnosis of oligohydramnios.[96,97] Shipp and associates[98] noted a bimodal distribution in the diagnosis of severe oligohydramnios with more cases diagnosed at 13 to 21 weeks and at 34 to 42 weeks. Survival rate was lower when diagnosed during the second versus third trimester (10% vs. 85%), reflecting two different populations in terms of both etiology and prognosis.

The common causes of oligohydramnios are summarized in Table 13–3. Human data suggest that oligohydramnios associated with intrauterine growth restriction (IUGR) is secondary to fetal oliguria,[99] the degree of reduction in HFUPR correlating with the level of hypoxemia.[100] Doppler studies reveal increased resistance to flow through the renal artery.[101,102] HFUPR does decline after 40 weeks, but in contrast to IUGR, Doppler studies do not support a renovascular mechanism with redistribution of blood flow[102] away from the kidneys in postmature fetuses.

Prelabor rupture of the membranes (PROM) complicates 3% to 17% of pregnancies.[103] Although the clinical diagnosis is obvious in most cases, only 5% to 44% have ultrasonic evidence of oligohydramnios.[104, 105] The earlier the gestation, the lower the incidence of premature PROM (PPROM) as an explanation of oligohydramnios. In one series, PPROM complicated only 0.7% of pregnancies less than 25 weeks with oligohydramnios.[106]

TABLE 13–3
Common Causes of, or Associations with, Oligohydramnios

Preterm prelabor rupture of the membranes (PPROM)
Intrauterine growth restriction (IUGR)
Postmaturity
Fetal anomalies
    Renal agenesis or dysplasia
    Urethral obstruction
    Bilateral polycystic/multicystic kidneys
Congenital viral infection
Diabetes insipidus
Maternal dehydration

Observations of amniotic fluid reaccumulation after occlusion of the cervix with fibrin gel[107] and the demonstration that fetal urine production is unaltered in the presence of ruptured membranes[108] support the conclusion that physical leakage of fluid through a membranous defect is the mechanism.

Fifty-one percent of pregnancies with oligohydramnios diagnosed in the second trimester are associated with congenital malformation[98] compared to 22% for those diagnosed in the third trimester. Renal anomalies account for 33% to 57%[109] and include those with absent renal function (e.g., bilateral renal agenesis or multicystic or dysplastic kidneys) and those with lower urinary tract obstruction. Posterior urethral valves account for approximately half of the cases of antenatally diagnosed lower urinary tract obstruction (LUTO) and present on ultrasound with oligohydramnios, a thick walled, large bladder with a keyhole sign and bilateral hydronephrosis (Fig. 13–3). The keyhole sign represents the enlarged bladder and dilated proximal urethra. The remaining causes of LUTO are prune-belly syndrome and urethral atresia.[110] The prognosis is worse (95% mortality rate) in those diagnosed antenatally when midtrimester oligohydramnios is present. Poor prognostic factors on ultrasound include dilatation of the upper tract, increased

bladder wall thickness, and evidence of renal dysplasia (echogenic renal cortex and macrocystic renal change), especially before 24 weeks.[110,111]

Fetal urine analysis assists prognostication of lower urinary obstruction. Generally, good prognostic features in fetuses with obstructive uropathies include urinary sodium level below 100 mEq/L, chloride less than 90 mEq/L, osmolality less than 200 mosmol/L, and β2-microglobulin less than 6 mg/L. Gestationally referenced values are preferred though,[112–114] because urinary sodium falls as nephrogenesis continues and tubular function matures. Urinary sodium and calcium levels are higher in fetuses with renal dysplasia (see Chapter 19). Analysis of serial bladder aspirations may be more representative of renal reserve than a single urine sample from an obstructed fetal bladder.[112] Sequential urine sampling does improve the sensitivity for the prediction of renal function by urinary electrolytes while minimally reducing specificity. However, serial aspiration for electrolytes in practice is necessary only when the first sample predicts poor outcome.

Renal dysplasia may also be indicated by β2-microglobulin concentrations in the fetal urine or serum. This microprotein has a molecular weight of 11,800 Da, which renders transplacental passage unlikely.[115] One study investigated the predictive value of fetal serum β2-microglobulin for neonatal renal function and found that values above 5.6 mg/L had high sensitivity and specificity for poor function.[116] More recent studies question the role of these markers, as they have not improved the prediction of outcome, nor the selection of fetuses for fetal therapy.[117]

Maternal Risks

Oligohydramnios per se does not lead to maternal complications, although its underlying cause may. Irrespective of the etiology, the mother is at increased risk of a cesarean delivery for fetal distress secondary to either growth restriction, malformation, or umbilical cord compression.[95,118,119]

Fetal Risks

Perinatal Outcome

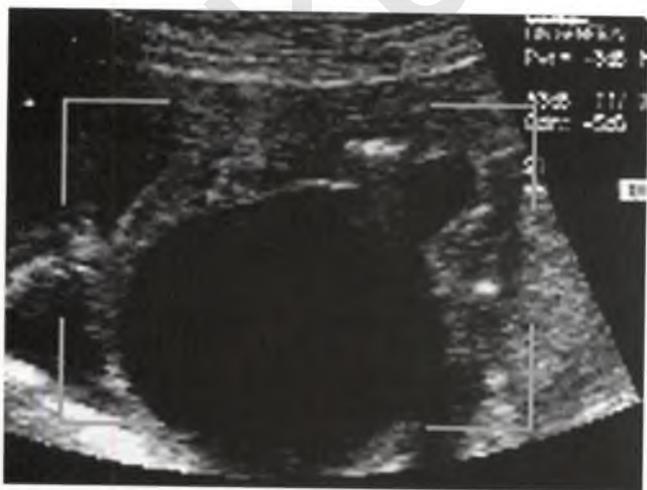
The increased perinatal mortality rate associated with oligohydramnios is in part related to the underlying etiology, in part to prematurity, and in part to the sequelae of PPROM including chorioamnionitis. A meta-analysis examining the outcome of over 10,000 pregnancies with an AFI of 5 cm or less concluded[120] that there is an increased risk of both cesarean delivery for fetal distress, both antepartum and intrapartum, and of a low Apgar score at 5 minutes. In a prospective study of over 3000 pregnancies,[121] those with an AFI of 5 cm or less had an increased risk of cesarean delivery for fetal distress (8% vs. 3.9%) and a higher likelihood (13% vs. 5%) of low birth weight (<10th percentile). Poor perinatal outcome


FIGURE 13–3
A transverse view of lower fetal abdomen on ultrasound at 16 weeks, showing a dilated bladder with a keyhole sign (see Color Plate 1).

in PPROM is principally confined to those with midtrimester membrane rupture prior to 29 weeks. Newborn survival rate after midtrimester PPROM has improved from 32% as reported in studies from the 1980s[122] to 54% to 66%,[123–125] reflecting a beneficial impact of obstetric and neonatal care.

Oligohydramnios Sequelae

Pulmonary hypoplasia (PH) and skeletal deformities are common complications of prolonged oligohydramnios. PH is a disorder of impaired lung growth. Characterized by diminished size and generational branching and vasculature, PH is found in 13% to 21% of perinatal autopsies,[126,127] with the common variable being oligohydramnios. The adverse effect of anhydramnios on fetal lung development is well documented in animal models[128] and in neonates born with bilateral renal agenesis who die of lung hypoplasia. Severe oligohydramnios from 16 weeks onward appears to preclude further pulmonary development. In contrast, oligohydramnios after the second trimester is unlikely to result in PH because the crucial canalicular phase of lung development (occurring between 16 and 25 weeks) has largely been completed by this stage. Thus, the prevalence of PH after oligohydramnios depends on several factors: the gestation at onset, the severity, and the duration.[129,130] In prolonged PPROM,[130] gestational age at rupture is the principal factor influencing the risk of PH, whereas the duration of PPROM is important for skeletal deformities. Using strict pathologic and radiographic criteria, Vergani and associates[131] showed that in women with PPROM before 28 weeks, the gestational age at rupture and the severity of oligohydramnios were independent predictors of PH (Fig. 13–4). Pregnancies with a pocket of amniotic fluid greater than 2 cm never had PH. Kilbride and associates reported a neonatal mortality rate greater than 90% in women with PPROM before 25 weeks and severe oligohydramnios (<1 cm) for over 14 days after membrane rupture.[123]

Management Options

The objective of management is to establish the etiology and determine the presence of associated anomalies (Table 13–4). The diagnosis of PPROM is usually obvious from the history and physical examination, with the exception of early rupture when small quantities of fluid lost vaginally may go unnoticed.[132]

Diagnostic Amnioinfusion

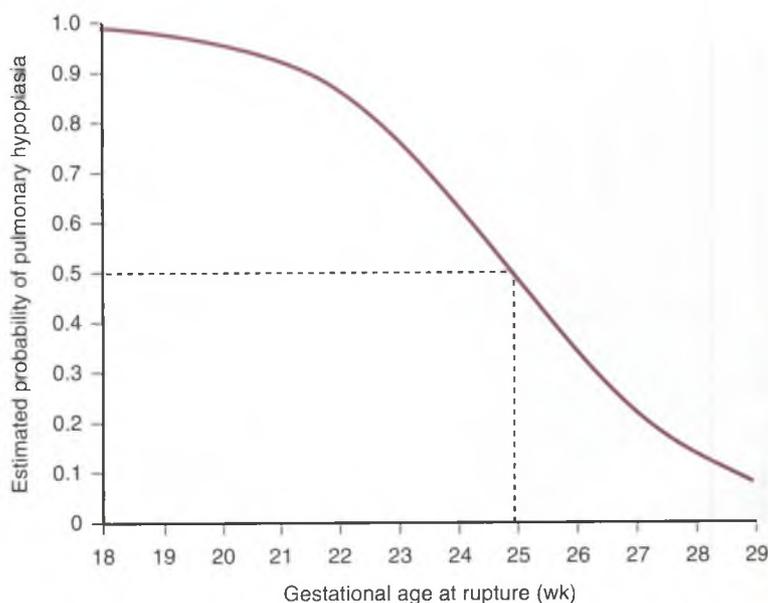
The ultrasonic visualization of fetal anatomy, particularly renal agenesis, is difficult in severe oligohydramnios/anhydramnios. Transvaginal ultrasonography may reduce the diagnostic error rate and is especially useful when the fetal abdomen overlies the lower uterus.[133] Maternal or fetal diuretic administration is not useful. There are numerous reports of false-negative diagnoses, and animal studies show that furosemide does not efficiently cross the placenta.[134,135] Sonographic resolution is improved by the infusion of fluid into the amniotic cavity.[132,136] In one series of 92 amnioinfusions[132] at 22 weeks in pregnancies complicated by severe oligohydramnios, a mean infusion volume of 181 mL increased the DP of AF to a mean of 3.2 cm. Suspected fetal anomalies were confirmed in 27 of 30 cases, and kidneys were clearly demonstrated in three fetuses suspected to have renal agenesis.


FIGURE 13–4
Estimated probability of developing pulmonary hypoplasia by gestation age of preterm rupture of membranes, derived from multiple logistic regression analysis in subgroup with oligohydramnios during latency period. (From Vergani P, Ghidini A, Locatelli A, et al: Risk factors for pulmonary hypoplasia in second-trimester premature rupture of membranes. Am J Obstet Gynecol 1994;170(5 Pt 1):1359–1364.)[131]

Diagnostic Evaluation of Oligohydramnios

History taking with an emphasis on maternal symptoms of hypertension, rupture of membranes, and congenital infection
High-resolution ultrasonography to assess:
    Degree of oligohydramnios
    Presence of growth deficiency
    Presence and structure of the kidneys
    Genitourinary malformations
Color Doppler ultrasonography
    Visualize the fetal renal arteries
    Determine the severity of oligohydramnios by excluding loops of cord
Amnioinfusion, if necessary, to improve ultrasonographic resolution
Fetal specimens for karyotyping and viral infection

PROCEDURE

AMNIOINFUSION

Preprocedure

Some clinicians recommend prophylactic antibiotic use (cefuroxime 750 mg IV), though no trials even suggest efficacy.

Procedure

Choose a skin entry site and track to the target on ultrasound. Plan a route to an accessible pool of amniotic fluid using color or power Doppler. If there is no cord-free pocket, aim for potential space in region of fetal limbs devoid of cord.

Infiltrate local anesthetic (5–10 mL 1% lidocaine) into superficial maternal tissues.

After assessing viability, plan response to possible major postprocedural bradycardia (usually from inadvertent or concomitant blood sampling).

Use a 20-gauge needle and sterile technique, with or without a needle guide; advance the needle under continuous ultrasound guidance. After guiding needle to target pool, locate space by aspiration of amniotic fluid. If no pool

exists, use test dose 2 mL saline flush to confirm position. Confirm successful infusion by injecting 10 mL saline and observing for intra-amniotic blooming.

Attach a three-way tap with wide-bore tubing to needle hub, and commence infusion using 50-mL syringes of warmed isotonic fluid (0.9% saline or Hartmann's).

For diagnostic infusions (usually 150–350 mL, depending on gestation), continue until AFI qualitatively is at lower limit of normal. For therapeutic infusions, continue until the DP is 6 cm or the AFI is 20 cm.

Concomitant karyotyping can be done on the initial amniotic fluid aspirate, on chorionic villi aspirated on needle withdrawal, or on fetal blood deliberately or inadvertently aspirated from a free loop of cord. Others have had success culturing the cells withdrawn after the amnioinfusion has been completed.

Postprocedure

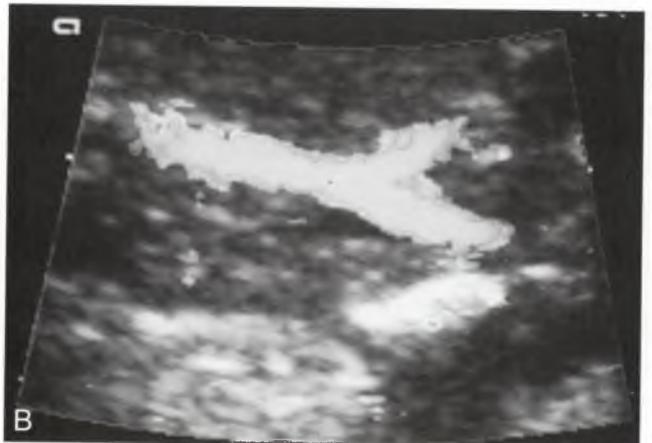
Check umbilical artery by Doppler.

Administer anti-D antibodies IM to RhD-negative women.

After diagnostic infusions, repeat the scan and arrange for pad checks. After test infusions, arrange for pad checks, and check the volume 24 to 48 hours later.

Some clinicians recommend repeating the therapeutic infusions weekly in the presence of recurrent severe oligohydramnios. The efficacy of this procedure in improving outcome remains to be clarified.

After 26 weeks, consider CTG if there are postprocedure complications or a compromised fetus.

The role of amnioinfusion has greatly diminished with the widespread availability and use of color Doppler to identify the renal arteries (Fig. 13–5). In 33 pregnancies referred with severe oligohydramnios to our center, absence of renal artery flow signals accurately predicted all cases of renal agenesis. The only false-positive diagnoses were in fetuses with severely dysplastic kidneys, and thus functionally similar to agenesis.[137] Doppler flow


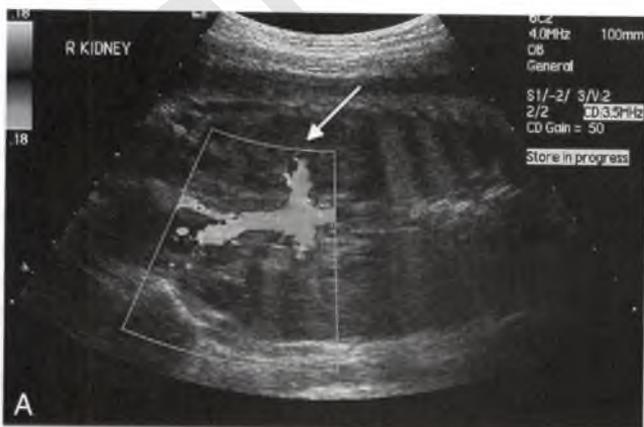


FIGURE 13–5
Color Doppler/power Doppler showing renal arteries in a normal fetus (*A*) but absent from a fetus with renal agenesis (*B*) (see Color Plate 2).

signals in renal arteries are an accurate, noninvasive way to predict the absence of renal function such as in renal agenesis or multicystic dysplastic kidney disease. In our experience, it has largely replaced amnioinfusion for the diagnosis of renal agenesis.

In contrast, lower urinary tract obstruction is relatively easy to diagnose because of the enlarged bladder or dilated upper collecting system. Visualization of other urinary structures such as the renal cortex and upper urethra has prognostic value. Visualization of extrarenal anatomy for associated anomalies remains suboptimal.

The severity of oligohydramnios is also assessed, not only for clues to etiology, but also for prognosis. Karyotyping should be considered; aneuploidy is detected in over 4%[98] of cases of severe oligohydramnios.

Therapeutic Options

Although the mechanism of oligohydramnios-related PH remains unknown, restoration of AF volume in animal models permits normal lung development.[138,139] Identification of fetuses at risk of pulmonary hypoplasia and who theoretically might benefit from AF replacement was previously based on ultrasonographic measurement of the fetal chest circumference,[140,141] lung length,[142] and Doppler studies[143] of the pulmonary vasculature. These parameters, however, are poorly reproducible in the absence of AF and seem predictive only after the end of the canalicular phase of lung development (~ 25 weeks), indicating established hypoplasia at a time too late for intervention.[140,144,145] Three-dimensional (3D) ultrasonography to assess lung volume[146] is becoming more widespread,[147] but its ability to predict pulmonary hypoplasia in the presence of oligohydramnios remains to be established.

Several treatments have been tried to maintain AF volume and thus promote lung development in pregnancies complicated by midtrimester oligohydramnios. These treatments include the following:

- Serial transabdominal amnioinfusions[132,148–152]
- Infusion of fluid via a transcervical catheter[153]
- Maternal hydration[154,155]
- Desmopressin (1- (3 mercaptopropronic acid)- 8-D-arginine vasopression; dDAVP)[156]
- Cervical canal occlusion with fibrin gel[107,157]
- Intra-amniotic sealing techniques[158,159]
- Vesicoamniotic shunting in obstructive uropathies[160]
- Fetal cystoscopy[110,161]

SERIAL AMNIOINFUSIONS

Cohort series suggest amnioinfusion improves outcome. Fisk and associates[132] performed serial amnioinfusion weekly in women with PPROM until the end of the canalicular phase of lung development in nine at-risk pregnancies with severe oligohydramnios prior to 22 weeks. Pulmonary hypoplasia was found in two (22%), which compared favorably to the 60% reported for severe oligo-

hydramnios diagnosed at or before 28 weeks.[162] Vergani and associates[149] observed that serial amnioinfusion in a population with PPROM at or before 25 weeks' gestation reduced the incidence of PH from 86% to 46%. Similarly, in the largest cohort study examining amnioinfusion, Locatelli and associates[150] found that amnioinfusion, if successful (when a pocket of AF >2 cm remained for at least 48 hours), reduced the rate of PH to that of so-called normal control subjects. In contrast, those with persistent oligohydramnios had a 62% incidence of PH. More recently, De Santis and associates found that amnioinfusion significantly increased the latency period between PPROM before 26 weeks and delivery (42 vs. 18 days), week of delivery (26 vs. 22 weeks), and neonatal weight (922 vs. 614 g). Unfortunately, there were no differences in overall survival or the incidence of PH compared to control subjects. Patients experiencing a slow loss of amniotic fluid between procedures seemed to benefit most. Thus, it is unlikely that amnioinfusion will prove advantageous in pregnancies that leak all the infused fluid immediately after the procedure.[151] In our center, we offer a test amnioinfusion first, as around 80% of patients with midtrimester oligohydramnios secondary to PPROM do not retain infused fluid after the procedure and would therefore not be candidates for serial amnioinfusion. Although serial amnioinfusion can prevent PH[163] in fetuses with renal agenesis, the ethics of such treatment remains controversial in the absence of successful neonatal or even infantile renal transplantation. In summary, there is mounting evidence of a role for amnioinfusion in the management of severe oligohydramnios in pregnancies with a structurally normal fetus. However, further research is needed, ideally in a context of a randomized controlled trial, to determine the following:

- The optimal gestation at which to commence and cease infusions
- The longevity of infused fluid within the amniotic cavity
- The optimal interval between infusions
- The optimal fluid to maintain AF volume

Studies should be directed toward identifying any particular subset of cases that will benefit from amnioinfusion.

TRANSCERVICAL FLUID REPLACEMENT, MATERNAL HYDRATION, AND DDAVP

Restoration of AF volume following infusion of normal saline through a cervical balloon catheter is performed in the third trimester but has not been evaluated for use earlier in pregnancy[153] for the prevention of PH.

Maternal hydration (drinking 2 L of water prior to ultrasound) increases the AFI in oligohydramnios and in normal[164] pregnancies by 2.01 cm (95% confidence interval 1.43 to 2.56) and 4.5 cm (95% confidence interval 2.92 to 6.08)[65] at term. These short-term improvements in AF volume persist into the longer term[166] when maternal hydration is continued (drinking at least 2 L/day for 1 week), suggesting a potential role in the management of oligohydramnios.

Ross and associates tested the hypothesis that[156] maintenance of maternal hypo-osmolality through a combination of maternal hydration and 1-deamino-8-D-arginine-vasopressin (DDAVP), a selective antidiuretic agonist, could increase AF volume in a series of 10 pregnancies at term. The AFI was increased at 8 hours (4.1 ± 0.6 to 8.2 ± 1.5 cm) and remained increased at 24 hours (8.2 ± 1.3 cm), suggesting a potential role for DDAVP in the prevention and treatment of oligohydramnios.

CERVICAL OCCLUSION

Cervical occlusion with fibrin gel was used in 12 patients with PPROM before 24 weeks.[157] In all instances, a reduction in the amount of amniotic leakage and an increase in AFI was observed. Larger trials are required to confirm the potential shown in this small series.

INTRA-AMNIOTIC SEALING TECHNIQUES

Intra-amniotic administration of gelatin sponge (Gelfoam) to 20 women with PPROM at an average of 18 weeks was associated with a 30% overall survival rate.[158] Similarly, endoscopic techniques have demonstrated some technical success in sealing the membranous defect but only after iatrogenic[167] rather than spontaneous PPROM. In seven pregnancies with iatrogenic PPROM, three did well with restoration of AF after intra-amniotic injection of platelets and cryoprecipitate (amniopatch), though two had sudden unexplained intrauterine death.[167] It is possible massive platelet degranulation of serotonin triggered severe vasospasm of fetal placental vessels. Case reports of using the amniopatch in patients with spontaneous PPROM note only limited success.[159,168] In vivo endoscopic visualization[169] in patients with spontaneous PPROM reveals that the size, location, and shape of the defect are such that it is unlikely to heal with an amniopatch.

VESICOAMNIOTIC SHUNTING

Despite the restoration of AF volume after vesicoamniotic shunting, perinatal mortality rates in obstructive uropathies remain high (see also Chapter 19). Complications occur in up to 45%[170] and include shunt blockage, shunt migration, preterm labor, urinary ascites, chorioamnionitis, and iatrogenic gastroschisis. A review of five large series involving[169] successfully placed shunts showed that the overall perinatal survival rate after intervention was only 47%.[110] Even in technically successful cases, end-stage renal disease occurred in 40% of survivors. If oligohydramnios was present before the shunt was placed, 56% of these babies died despite intervention. Failure to restore AF volume was associated with 100% mortality rate.

When intervention did improve the chances of postnatal survival, it did not appear to alter the renal outcome.[171] Freedman and associates[172] reviewed the long-term outcome of 34 fetuses that underwent vesicoamniotic shunt placement. Thirteen died, of which six deaths were due to PH. In the survivors, the ultimate diagnosis was mainly prune-belly syndrome or posterior urethral valves. Less than one third of the children needed ventilatory support in the neonatal period, and none of the children had pulmonary restriction to normal activities on follow-up. These children underwent a total of 62 surgical procedures, of which 47 were major (bladder augmentations and renal transplants). Six have maintained normal renal function, three have renal insufficiency, and five have progressed to renal failure. It appears that fetal therapy therefore only influences the outcome of fetuses with lower urinary tract obstruction that leads to midtrimester oligo- or anhydramnios by preventing PH, but does not seem to ameliorate the underlying kidney disease. This association is important, because parents need to be aware that there is still a 33% to 50% chance of renal failure in childhood.[173] They also need to be counseled that although affected children are expected to have normal cognitive abilities, participate in normal activities, and achieve a socially acceptable degree of continence, they will need considerable medical and surgical attention.

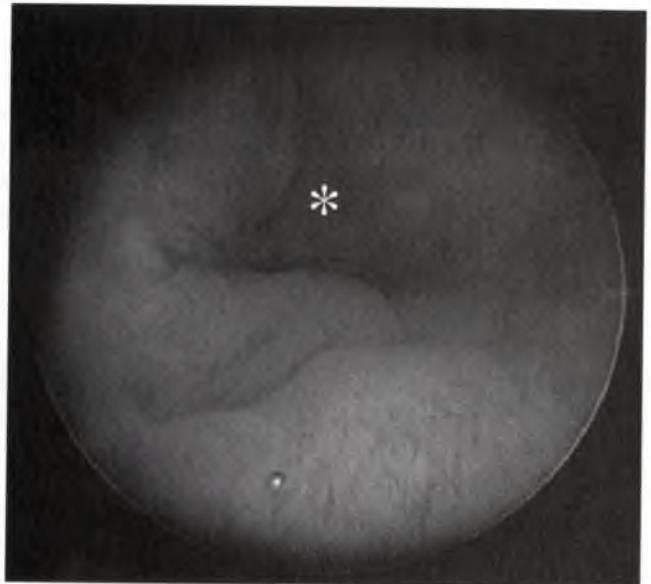
A retrospective review from the University of California, San Francisco,[174] of fetuses with posterior urethral valves who underwent fetal therapy (mainly vesicoamniotic shunting) after favorable urine analysis results confirmed a high fetal mortality rate of 42%. Chronic renal disease was diagnosed in 62% of the survivors, 25% of whom underwent renal transplantation. This study, like that of Freedman and associates,[172] suggests that fetal therapy does not cure fetuses with posterior urethral valves but may improve bladder function and decrease the morbidity rate of incontinence and recurrent infections.


FIGURE 13-6
Fetal cystoscopic view of a fetal bladder and the proximal urethra (*) (see Color Plate 3).

FETAL CYSTOSCOPY

Fetal cystoscopy can be both diagnostic and therapeutic, and is currently undergoing evaluation as a management option in lower urinary tract obstruction.[161] It allows exploration of the bladder and the proximal part of the urethra under endoscopic vision (Fig.13–6). Obtaining a clear view of the bladder neck and urethra is facilitated by the use of flexible scopes to help overcome the problem of negotiating the urethrovesical angle. Posterior urethral valves, if present, can be disrupted by laser, although there may be damage the adjacent bowel and other structures. Alternatively, gentler techniques such as insertion of a guide wire or simple pressure saline injection may work in some instances.[175]

SUMMARY OF MANAGEMENT OPTIONS
Oligohydramnios

Management Options	Quality of Evidence	Strength of Recommendation	References
Identify Cause (if possible)			
Detailed history to include drug exposure (nonsteroidal anti-inflammatory drugs as angiotensin-converting enzyme inhibitors), prior aneuploidy screening, and history suggestive of preeclampsia, PPROM, including bleeding in pregnancy, which may obscure liquor loss.	–	GPP	–
Ultrasonography (transvaginal may be helpful) to assess:	III	B	133
• Degree of oligohydramnios (AFI)			
• Presence of growth deficiency			
• Fetal and uterine blood flow studies			
• Presence and appearance of the kidneys			
• Genitourinary and other malformations			
In second trimester, PPROM accounts for 50%, fetal anomalies 15% (mainly renal tract), IUGR 20%, and idiopathic 5%. The more severe the oligohydramnios, the more likely it is secondary to a structural anomaly or PPROM.			
Color/power Doppler ultrasonography to:	III	B	96,137
• Visualize fetal renal arteries			
• Determine the severity of oligohydramnios by excluding loops of cord			
Oligohydramnios defined as AFI <5 cm or DVP <3 cm (<3 cm mild, <2 cm moderate, <1 cm severe).			
Amnioinfusion may also have a role in diagnosing or confirming suspected PPROM.	III	B	132,153
If structural anomalies, or soft markers, or early onset IUGR (<24 wk), offer rapid karyotyping, possibly with concomitant amnioinfusion.		GPP	–
Prognosis depends on cause. In PPROM, prognosis poor due to risk of prematurity, and chorioamnionitis. Even if pregnancy progresses past viability, oligohydramnios beginning <25 wk with a DVP of <1 cm lasting >2 wk results in >90% perinatal mortality rate, primarily from pulmonary hypoplasia.	III	B	98
Skeletal deformities and contractures usually only complicate prolonged severe oligohydramnios, and rarely occur in the absence of pulmonary hypoplasia.	–	GPP	–
Management (depends on etiology)			
PPROM (see Chapter 63)			
Growth deficiency (see Chapters 11 and 12)			
Prolonged pregnancy (see Chapter 66)			
Fetal renal anomalies (see Chapter 19)			

Continued

SUMMARY OF MANAGEMENT OPTIONS
Oligohydramnios (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Management (depends on etiology)—Continued			
Treatments tried in midtrimester oligohydramnios to maintain amniotic fluid volume and promote lung development:			
• Serial transabdominal therapeutic amnioinfusions with PPROM <25 wk (after initial trial infusion to determine if retained)	III	B	132,148-152
• Transcervical infusion not evaluated in early pregnancy	III	B	153
• Vesicoamnioic shunting in obstructive uropathies	III	B	172
• Cervical canal occlusion with fibrin gel	III	B	107,157
• Maternal hydration possibly of value	Ib	A	155
• DDAVP needs further study	III	B	156

AFI, amniotic fluid index; DVP, deepest venous pool; IUGR, intrauterine growth restriction; PPROM, prenatal premature rupture of membranes.

CONCLUSIONS

- Abnormal amniotic fluid volume complicates up to 7% of pregnancies, although in many instances the alteration is mild, is idiopathic, occurs in the third trimester, and does not produce sequelae.
- In contrast, severe oligohydramnios and hydramnios in the midtrimester are associated with substantial perinatal morbidity and mortality rates, reflecting both the underlying etiology and the complications of disordered amniotic volume.
- The investigation of hydramnios involves detection of anomalies by ultrasonography, karyotyping, and exclusion of carbohydrate intolerance.
- Transplacental indomethacin reduces fetal urine output, but its use in severe hydramnios to prolong gestation is limited by fetal side effects.
- Sulindac may have fewer fetal side effects than indomethacin and is thus preferred for this purpose.
- Serial amnioreduction seems to improve perinatal survival in monochorionic twin pregnancies with midtrimester hydramnios secondary to TTTS by prolonging gestation, but it does not address the underlying pathophysiology like laser ablation.
- Severe oligohydramnios, whether secondary to ruptured membranes, growth restriction, absent renal function, or fetal urinary tract obstruction, poses a diagnostic challenge because it impairs ultrasonographic resolution.
- Transabdominal amnioinfusion facilitates visualization of fetal anatomy and determines membranous integrity.
- Color Doppler visualization of renal arteries aids both the diagnosis of renal agenesis and the determination of the severity of oligohydramnios by identifying loops in apparent pockets of amniotic fluid. Karyotyping and transvaginal ultrasonography may also be indicated in oligohydramnios.
- In order to prevent pulmonary hypoplasia, vesicoamniotic shunting, fetal cystoscopy, and serial amnioinfusion have been used to maintain AF volume in selected euploid fetuses with functioning renal tissue.
- Serial amnioinfusion appears to improve outcome in cohort series, but most patients with midtrimester oligohydramnios secondary to PPROM are unsuitable because all their fluid leaks out immediately.

Fetal Hemolytic Disease

Carl P. Weiner

INTRODUCTION

Hydrops, anemia, and jaundice of the neonate were first recognized in 1932 as a single disease characterized by perinatal hepatosplenomegaly, extramedullary hematopoiesis, and nucleated red blood cells on the peripheral smear.[1] Levine and coworkers identified the cause of the anemia in 1941 when they found rhesus (Rh) antibodies on the red blood cells of affected but not unaffected neonates.[2] Seven years later, Chown proved transplacental fetal to maternal hemorrhage was a cause of maternal isoimmunization.[3] In 1961, hemolytic anemia became the first treatable fetal disease after Liley characterized its natural history and then successfully transfused ill fetuses intraperitoneally with adult red blood cells.[4,5] Freda and colleagues demonstrated in 1964 that passive immunization of Rh− individuals with Rh+ antibodies prior to purposeful exposure to Rh+ red blood cells prevented immunization.[6] In 1981, Rodeck and associates achieved a high survival rate for hydropic fetuses using intravascular transfusion.[7] And in 2000, Mari and coworkers demonstrated that the majority of moderately to severely anemic fetuses could be identified noninvasively by the measurement of the middle cerebral artery peak velocity.[8] Despite these landmark advances, fetal hemolytic disease remains a serious and common cause of perinatal illness and death.

INCIDENCE

Though antibodies to D antigen remain most common, the development of immunoprophylaxis has diminished its relative importance and enhanced that of the other antigen groups (Table 14–1). Yet, anti-D antibody remains the prototype for maternal red blood cell alloimmunization and is used for illustration throughout this chapter.

The incidence of Rh− individuals varies by race with a low of 1% in Chinese and Japanese to a high of 100% in the Basques, in whom the mutation likely originated.[9] In North American whites, the incidence of Rh− genotype is 15%, and in blacks it is 7% to 8%. Thus, the incidence of alloimmunization varies greatly among populations. The overall incidence of alloimmunization has declined dramatically over the last decade owing in part to immunoprophylaxis and smaller families.[10]

PATHOPHYSIOLOGY AND RISKS

Maternal red blood cell alloimmunization results from exposure and response to a foreign red blood cell antigen. Transplacental fetal to maternal hemorrhage is the most common cause of alloimmunization. Heterologous blood transfusion is the second most common cause overall, but the most common cause of sensitization to uncommon antigens (see Table 14–1). It is estimated that 75% of women have fetal red blood cells identified on a Kleihauer stained peripheral smear at some time during either pregnancy or delivery.[11] Both the frequency and magnitude of the bleed increase as pregnancy advances: from 3% and 0.03 mL, respectively, in the first trimester, up to 45% and 25 mL in the third trimester. Spontaneous abortion, too, is associated with fetal to maternal hemorrhage, but the incidence is less than 1% and the volume usually under 0.17 mL. In contrast, surgically induced abortion has a 20% to 25% risk of transplacental hemorrhage of a significantly greater volume.

There are three major nomenclatures for the rhesus blood group: Wiener and Wexler, Rosenfield, and Fisher and Race. The latter works best in clinical practice and has been confirmed genetically.[12] Three pairs of closely linked Rh antigens—Cc, Dd, and Ee—are inherited, one from each parent, as two sets of three alleles. An individual may be homozygous or heterozygous for each of the three alleles. The presence or absence of the D antigen site determines whether an individual is Rh+ or Rh−. Because certain combinations are more common than

TABLE 14-1

Antigens Causing Fetal Hemolytic Disease Requiring Treatment

women are at risk for D alloimmunization and should receive immunoprophylaxis when otherwise indicated.[13]

The primary immune response to the D antigen occurs over 6 weeks to 12 months. It is usually weak, consisting predominantly of IgM that does not cross the placenta. As a result, the first pregnancy is not typically at great risk. Fifteen percent of Rh− volunteers will become sensitized after a 1 mL exposure of Rh+ erythrocytes. The proportion increases to 30% after 40 mL and 65% after 250 mL. Three percent of women with uncomplicated pregnancies become sensitized at delivery after a small amount of fetal to maternal hemorrhage (0.1 mL). A second antigen challenge generates an amnestic response that is both rapid and almost exclusively IgG. Bowman[14] observed that the longer the interval between challenges, the greater the increase in both the quantity of antibody and the avidity that it binds the red blood cell. These features increase the risk of severe fetal disease.

Fetal hematopoiesis consists of three overlapping phases corresponding to the major hematopoietic organ: mesoblastic, hepatic, and myeloid. Erythropoiesis begins in the fetal yolk sac by day 21, then moves to the liver, and finally reaches the bone marrow by 16 weeks' gestation.[15] The decreasing contribution of the liver is characterized by an exponential decrease in the number of circulating erythroblasts. Contrary to ABO antigens, which are weakly expressed on fetal red blood cells, the Rh antigens are well developed by day 30 of gestation. Anti-D antibody-triggered hemolysis is not complement mediated. Rather, the anti-D-coated fetal red blood cells are destroyed extravascularly by the reticuloendothelial system at a rate faster than normal. The response of the affected fetus is quite variable, reflecting the quantity and subclass of IgG antibody, the efficiency of placental passage, the avidity the antibody binds the antigen site, the maternal HLA make-up, the maturity and efficiency of

others, the D genotype can be predicted from the phenotype obtained using antibody specific sera for D, C, c, E, and e (Table 14–2). The d antigen has never been detected, and its existence is questionable. The genes for all other Rh alleles are sequenced, and the genotype can be determined directly using polymerase chain reaction (PCR) technology.

The Rh blood group includes more than 40 other antigens, of which the Du variant is most common. There are more than 16 recognized epitopes. The first (and most common) type is the Du+ variant. Here, the patient is actually Rh+, but the D expression is weakened by the presence of a C allele on the complementary chromosome (e.g., Cde/cDe). These women are not at risk for D alloimmunization. The second type is sometimes termed Du−. Here, part of the D antigen is missing. As such, these

the reticuloendothelial system, and perhaps even the fetal sex.[16] For example, IgG1 and IgG3 appear to be the important subclasses for fetal hemolytic disease, and the maternal to fetal placental transport of IgG3 is significantly greater in pregnancies at risk for hemolytic disease.[17] Further, there is a strong correlation between HLA-DQB1 allele *0201 and both an indirect Coombs titer greater than 512 and fetal anemia.[18]

Hemolytic anemia may occur whenever the erythrocyte lifespan declines below 70 to 90 days and the hematopoietic system can no longer meet the demands. Anemia may develop slowly over several months in association with a gestationally low reticulocyte count and a gestationally normal bilirubin, or within a week in association with reticulocytosis and hyperbilirubinemia.[19,20] Significant fetal anemia is associated with increased erythropoietin, but in the absence of labor, the concentrations are lower than those observed in adults with the same hemoglobin deficit (Widness and Weiner, unpublished observation). Erythropoiesis may occur anywhere in the fetal-placental unit. Both the fetal liver and spleen are enlarged secondary to extramedullary hematopoiesis and congestion. Nucleated red blood cell precursors (erythroblasts) are released into the peripheral circulation, hence the term erythroblastosis fetalis. The greater the number of erythroblasts, the greater the likelihood an antenatal transfusion therapy will be necessary.

All fetal sequelae of hemolytic disease relate to the development of anemia. In general, the fetus tolerates mild to moderate anemia well. However, other metabolic alterations develop as the anemia worsens. Because the red blood cell is the principal fetal buffer, a metabolic acidemia with hyperlactatemia occurs in fetuses with extreme anemia.[21] The precise mechanism underlying the development of hydrops is uncertain, but the elements are clear. First, the hemoglobin deficit for gestation must be extreme.[22] Because the hemoglobin concentration rises with advancing gestation, hydrops occurs at higher absolute hemoglobin levels during late compared to early pregnancy and is rare before 20 weeks.

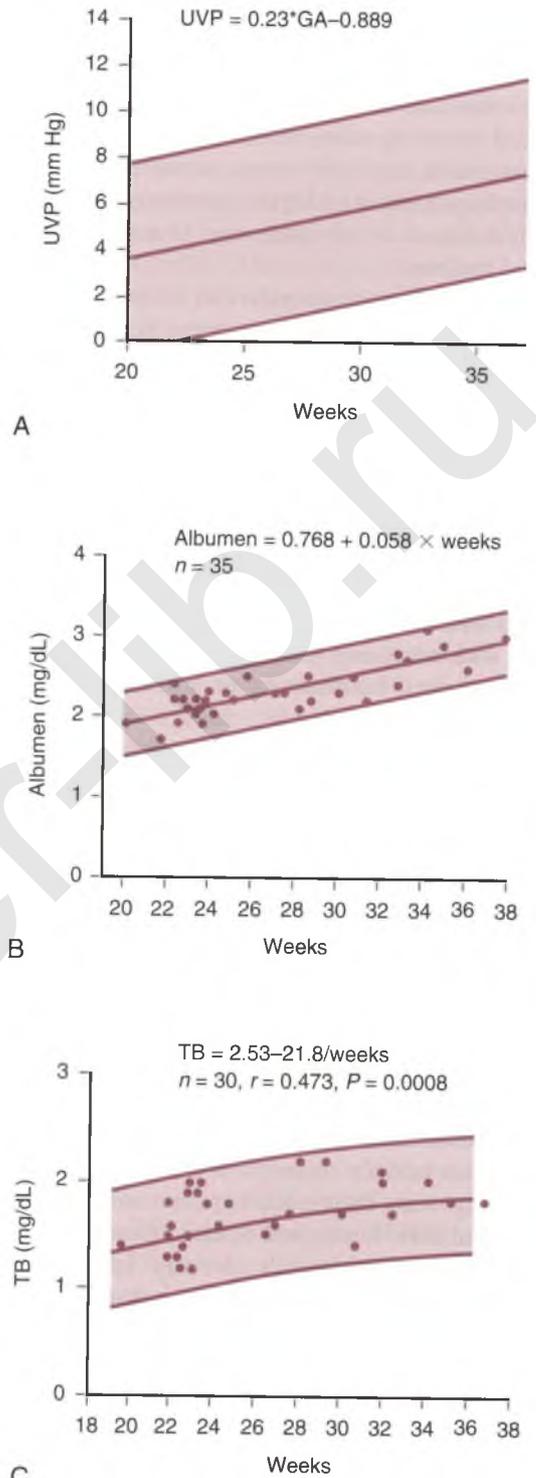
Second, though hepatomegaly could hinder cardiac return or cause portal hypertension, it cannot be the sole cause of hydrops in light of the findings listed here. Nor is hypoalbuminemia secondary to liver failure a contributing factor, as once thought based on postnatal studies,[23] because the albumin concentration is normal for gestation in all but premoribund, hydropic fetuses.[19,20] Finally, cardiac dysfunction, probably secondary to insufficient oxygen-carrying capacity, occurs in at least 90% of hydropic fetuses. This dysfunction is detectable immediately prior to the development of hydrops and resolves rapidly after transfusion with an increase in the fetal oxygen-carrying capacity. It is characterized by an increase in the biventricular cardiac diameter, systolic atrioventricular valve regurgitation, and an elevated umbilical pressure for gestation[24] (Fig. 14–1A). Consistent with ventricular dysfunction, the umbilical venous pressure


FIGURE 14–1

A, Normal umbilical venous pressure (UVP) (corrected for amniotic fluid pressure) across gestational age (GA) illustrated as the 95% prediction interval. (From Weiner CP, Heilskov J, Pelzer G, et al: Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease. Am J Obstet Gynecol 1989;161:714–717, with permission). B, Normal fetal serum albumin concentration across gestation illustrated as the 95% prediction interval. (From Weiner CP, Heilskov J, Pelzer G, et al: Normal values for human umbilical venous and amniotic fluid pressures and their alteration by fetal disease. Am J Obstet Gynecol 1989;161:714–717, with permission). C, Normal fetal serum total bilirubin (TB) across gestation illustrated as the 95% prediction interval.

rises to a greater extent in the hydropic fetus after intravascular transfusion compared to nonhydropic fetus.[25,26] Within 48 hours of the first red blood cell (RBC) transfusion and before the hydrops resolves, the umbilical venous pressure declines into the normal range. This reversal is too rapid for the occurrence of hydrops to be explained solely by hepatosplenomegaly. Thus, cardiac dysfunction is probably the immediate cause of immune hydrops.

Hyperbilirubinemia secondary to erythrocyte hemolysis is an important part of alloimmune hemolytic disease. Heme pigment is first converted into biliverdin by heme oxygenase and then to a water-insoluble, lipid-soluble bilirubin (the indirect fraction) by biliverdin reductase. Both the fetus and neonate have reduced levels of glucuronyl transferase, the enzyme necessary for the production of the water-soluble diglucuronide. Indirect bilirubin unbound to albumin penetrates the lipid neuronal membrane, causing cell death. During normal pregnancy, both the fetal serum albumin and bilirubin concentrations rise linearly with advancing gestation (Fig. 14–1B and C).[20,27] Virtually all fetal bilirubin under normal and hemolytic conditions is indirect bilirubin; there is no need routinely to fractionate it. The normal fetal total bilirubin is 5 to 10 times above normal adult levels, suggesting placental bilirubin transport is limited. Bilirubin rises progressively as the severity of hemolysis increases. The total bilirubin concentration in fetuses with hemolytic disease often exceeds 3 mg/dL before the development of anemia.[20]

The neonate with severe hyperbilirubinemia is at risk to develop an encephalopathy (kernicterus). The concentration of bilirubin necessary to cause kernicterus also rises with advancing gestational age. Thus, whereas a term neonate can tolerate a total bilirubin of 25 mg/dL, the extremely preterm neonate is at risk for kernicterus when the total bilirubin level exceeds 12 mg/dL. Affected neonates are initially lethargic and then become hypertonic, lying with their neck hyperextended, their back arched, and their knees, wrists, and elbows flexed. They suck poorly and ultimately develop apneic episodes. Fortunately, bilirubin toxicity is rarely observed with current monitoring protocols and treatment. Neural tissue in the auditory center is particularly sensitive to indirect bilirubin. Survivors often have profound neurosensory deafness and choreoathetoid spastic cerebral palsy. When severe signs of toxicity are present, the mortality rate approximates 90%.

MANAGEMENT OPTIONS FOR THE DETECTION OF ALLOIMMUNIZATION

The identification and management of potential fetal hemolytic disease employs several methods for the detection of antibodies either in the maternal serum or bound to the fetal red blood cell.

Agglutination Tests

Saline

Rh+ red blood cells suspended in saline agglutinate when serum added to the slide contains IgM but not IgG. IgM does not cross the placenta.

Colloid

Rh+ red blood cells suspended in a colloid medium such as bovine albumin agglutinate if serum containing either IgM or IgG is added to the slide. Thus, if both saline and colloid tests are positive, the antibody may be either an IgM or an IgG. Pretreating the serum with dithiothreitol disrupts the sulfhydryl bonds of IgM and prevents its binding to the red blood cell. IgG is unaffected by dithiothreitol.

Antiglobulin or Coombs Tests

INDIRECT

Red blood cells of specific or mixed antigen type are incubated with the patient's serum. The addition of antihuman antiglobulin causes agglutination if the red blood cells adsorb antibody from the patient's serum. The reciprocal of the highest dilution that causes agglutination is the titer. Indirect antiglobulin titers are one to three times more sensitive for the detection of RBC alloimmunization than colloid agglutination.

DIRECT

Antihuman antiglobulin is added directly to the red blood cells from the patient. Agglutination indicates antibody is bound to the red blood cell. It may be eluted off and identified by performing an indirect test using type-specific antigen type cells.

ENZYME PRETREATMENT

Red blood cells are incubated with either a proteinase-like trypsin or with bromelin to reduce the negative electric potential between cells. Treated cells lie closer together in saline and more readily agglutinate by the IgG bound to them. These are the most sensitive manual methods for the detection of RBC alloimmunization. The technique can be automated, permitting detection of microgram quantities of antibody.[28] Unfortunately, the automated techniques also produce false-positive tests and as a result are not widely used.

Other Serum Tests

Two other tests have been suggested—the Marsh Score and the Monocyte Monolayer assay. Neither in comparative study performs significantly better than the Coombs titers.[29,30] Preliminary study with monocyte-mediated chemiluminescence suggested it may be advan-

tageous for antibody quantification,[31] but the technique has not been pursued further.

MANAGEMENT OPTIONS FOR THE RH-NEGATIVE PATIENT IN PREGANCY

All women, regardless of past medical and obstetric history, should have on record at least two blood type determinations that are in agreement. Typically, blood is drawn in nulliparous women for the determination of her ABO and Rh blood type during the first prenatal visit and after delivery. All pregnant women should have a red blood cell antibody screen (both indirect and direct Coombs tests) performed at booking. This includes women previously typed as Rh− or found to have a negative antibody screen. Laboratory errors remain a significant contributing cause of anti-D prophylaxis failure. Further, almost 50% of patients managed by the author since 1983 have an RBC antibody directed against an antigen other than D.[19] Although there is controversy on how Rh+ women can be cost-effectively managed after an initial negative screen, the most complete approach is to repeat the antibody screen at 32 weeks in search of newly developed non-anti-D antibodies.

Nonsensitized Rh-Negative Women

Ideally, the indirect Coombs test is repeated monthly beginning at 18 to 20 weeks in at-risk Rh− women without evidence of sensitization. For financial and practical reasons, many units screen for new alloimmunization far less frequently. In some societies, it may be reasonable to test the father, and if he is Rh−, repeat the screen only once between 32 and 34 weeks' gestation. However, paternity is on occasion other than claimed or simply unknown. If the father is tested, the patient should be informed in private of the potential risk for management error should paternity be other than that stated. The decision how to approach paternity is best left to the physician's discretion.

Maternal-fetal ABO incompatibility reduces the risk of D alloimmunization.[14] If the father is heterozygous Rh+, there is a 50% chance the fetus will be Rh−. If the father is also ABO incompatible with the mother, there is a 60% chance that the fetus will be ABO incompatible. If the fetus is both Rh+ and ABO incompatible with the mother ($0.5 \times 0.6 = 0.3\%$ probability), than the risk of maternal Rh alloimmunization is reduced from approximately 16% to 2%.

Successful passive immunization for Rh factor isoimmunization with anti-D immunoglobulin was first achieved in 1964. The Food and Drug Administration approved its use in 1968 after confirming efficacy in male prisoners. Anti-D immunoglobulin is extracted by cold alcohol fractionation from the sera of individuals with high titers. This extraction process removes viral pathogens such as HIV and hepatitis B, and an infectious risk from anti-D immunoglobulin has not been substantiated. Anti-D immunoglobulin binds D antigen sites on fetal erythrocytes present in the maternal circulation. Presumably, blockade of these sites prevents immune recognition by B lymphocytes, and the transformation of activated B lymphocytes to IgG-producing plasma cells never occurs. Anti-D immunoglobulin has a half-life of 24 days, and a standard 300-µg dose provides 12 weeks of protection against exposure to up to 30 mL of blood, or 15 mL of erythrocytes. Before the introduction of anti-D immunoglobulin, 10% of susceptible pregnancies developed hemolytic disease of the fetus and newborn. Approximately 90% of these were due to fetomaternal hemorrhage at term. Administration of anti-D immunoglobulin within 72 hours of delivery reduces this incidence by 90%. The administration of an additional dose at 28 weeks produces a further decline in incidence from 2% to 0.1%. Although the 72-hour limit is based on the original study protocol evaluating the efficacy of anti-D immunoglobulin, beneficial effects may still be present with administration up to 28 days after delivery.

Current guidelines for management of Rh− women with uncomplicated pregnancy are focused on the prevention of isoimmunization from physiologic fetomaternal hemorrhage (Table 14–3). If a patient is Rh− and the antibody screen is negative on the first prenatal visit, the screen is repeated at 28 weeks and anti-D immunoglobulin administered if negative. Another antibody screen is repeated in labor. If the father is Rh− and there is no question on paternity, the prophylactic doses of anti-D immunoglobulin can be omitted.

Women with vaginal bleeding of unknown origin should receive anti-D immunoglobulin prophylaxis (see Table 14–3). Routine antenatal anti-D immunoglobulin therapy is cost effective and should be administered to all nonsensitized Rh− women at 28 weeks' gestation.[32] Anti-D immunoglobulin is also administered after amniocentesis if the fetal Rh genotype is unknown, as it carries a 2% risk of maternal sensitization even when performed under ultrasound guidance.[33] Umbilical cord blood is obtained at delivery from Rh− women to determine the neonatal ABO and Rh blood type and to seek red blood cell bound antibodies. Anti-D immunoglobulin (300 mg) prevents maternal sensitization secondary to fetal-maternal hemorrhage when the volume is less than 30 mL of Rh+ blood.[34,35] Maternal blood is screened by Kleihauer testing for evidence of a fetal-maternal hemorrhage in excess of 30 mL. This test exploits the relative resistance of fetal hemoglobin to acid denaturation. Acid citrate buffer is used to remove adult hemoglobin, leaving red blood cell ghosts. The maternal blood is examined on a counting chamber after fixation with 80% ethanol and hematoxylin-eosin staining. The amount of fetal blood in the maternal circulation can be

TABLE 14-3

Preventive Guidelines for Rh− Women in Pregnancy

TIME	TEST	ANTI-D-IG DOSE
First prenatal visit	ABO and Rh blood typing, direct and indirect Coombs test	None
28–29 wk	Direct and indirect Coombs test for newly developed antibodies	300 µg*
32 wk	Direct and indirect Coombs test for newly developed antibodies	None
At birth	Neonatal cord blood for ABO and Rh type as well as direct Coombs test for red blood cell bound antibodies	
Within 72 hr of delivery	Rosette test, Kleihauer-Betke estimate of fetoplacental hemorrhage	300 µg (individualize for Kleihauer-Betke result)
First trimester spontaneous miscarriage		50–200 µg
First trimester therapeutic abortion		300 µg
Following prenatal diagnosis by chorionic villous sampling of amniocentesis		300 µg
Other high risk situations—abdominal trauma, placental abruption, antepartum hemorrhage	Rosette test, Kleihauer-Betke estimate of fetoplacental hemorrhage	300 µg (individualize for Kleihauer-Betke result)

* Some protocols recommend the use of a lower dose of anti-D Ig at 28 weeks followed by a further dose at 34 weeks in nonimmunized Rh− women.
Anti-D Ig, anti-D immunoglobulin.

approximated from the number of fetal red blood cells per grid using this formula: fetal cells/number of maternal cells = estimated blood loss/estimated maternal blood volume in milliliters (85 mL/kg). About 1/400 women suffer a larger bleed and require more anti-D immunoglobulin.[35] Cesarean section and manual removal of the placenta each increase the risk and magnitude of fetal-maternal hemorrhage. In situations in which the estimated bleed exceeds 30 mL, 150% to 200% of the estimated anti-D immunoglobulin requirement is given.

Postpartum, anti-D immunoglobulin may be withheld if the last administration was given less than 21 days previously and passively acquired antibodies are still demonstrable on the antibody screen. The rosette test may also be performed in maternal blood to assess the need for further administration of anti-D immunoglobulin. Rosette formation indicates the presence of fetal red blood cells, and dosage of anti-D immunoglobulin may have to be adjusted, guided by the Kleihauer-Betke test.

Rh-Negative Sensitized Women

Noninvasive Evaluation

Once an alloimmunized woman is identified, the medical professional caring for the mother must make some estimate of the risk of fetal disease. The prediction of fetal risk by combining the maternal obstetric history and serologic examination is an imprecise art. The magnitude of fetal and neonatal disease typically progresses from one pregnancy to another. The risk of hydrops in the undiagnosed and untested pregnancy approximates 10% in the first sensitized pregnancy.[14]

If maternal indirect Coombs antibody titers are performed in the same hospital using constant techniques, the results are both reproducible and of clinical value in predicting the risk of severe fetal disease. In every laboratory, there is a titer below which severe fetal hemolytic disease does not occur. The practitioner must be familiar with the laboratory's threshold to avoid clinical error. When the maternal titer is below that threshold, it should be repeated at monthly intervals. In the absence of a relevant clinical history, the fetus may be followed noninvasively by the measurement of the peak middle cerebral artery velocities once that critical titer is exceeded. The utility of antibody titers above the threshold in predicting fetal risk is greatest during the first sensitized pregnancy. In subsequent pregnancies, titer and history are inadequate measures upon which to base management. Bowman reported in 1965 a lethal management error would occur in a third of severely sensitized fetuses if only maternal obstetric history and antibody titer were relied upon.[36]

One of the most important advances in the management of fetal hemolytic anemia over the last 5 years is the development and application of molecular tools to determine the fetal genotype for most of the offending RBC antigens. It is possible using polymerase chain reaction (PCR) to rapidly determine from either amniocytes or a placental biopsy specimen the fetal antigen status.[37–41] Determination of the fetal Rh genotype should be standard after any second trimester amniocentesis or chorionic villus sampling (CVS) in an at-risk woman. Though genetic heterogeneity can be problematic, the technique is as accurate as serologic testing.[42] A negative finding obviates the need for further follow-up. More exciting

for Rh– women sensitized only to D for the future is the ability to determine fetal D status from fetal DNA extracted from the maternal blood. Sensitivities in excess of one-third are reported.[43]

Anticipation of the disease onset or ultrasound evidence of fetal anemia determines the timing of invasive fetal testing. The approach depends on the number of previously affected pregnancies. Brass and colleagues first observed in adults a relationship between the systolic flow velocity in the middle cerebral artery and hematocrit.[44] Subsequently, several investigators demonstrated that the development of fetal anemia is associated with increased middle cerebral artery peak systolic velocities (Fig. 14–2).[45–47] Though we found that at least half of anemic fetuses have normal peak velocities,[48] high peaks corrected for gestational age typically indicate anemia.

Other sonographic findings have been claimed to either precede the development of hydrops or predict fetal anemia, including amniotic fluid volume, liver and spleen length or thickness, placental thickness, increased bowel echogenicity, and the cardiac biventricular diameter.[21,49,50] Unfortunately, none of these sonographic markers has proved reliable. Further, the fetal hematocrit may change rapidly. We have observed fetuses with a normal hematocrit become hydropic over a 7-day period without a change in the maternal antibody titer. Each had a completely normal two-dimensional ultrasonographic examination 7 days before the detection of hydrops.

In summary, the measurement of middle cerebral artery peak velocities is an excellent noninvasive tool for the monitoring of fetal anemia. Other than that, ultrasonography is an adjunct to, not a replacement for, invasive fetal studies.

Invasive Evaluation

Two invasive methods are used to search for fetal anemia secondary to hemolytic disease:

- Indirect: spectrophotometry (the $\Delta OD450$) using a specimen of amniotic fluid obtained by ultrasound-guided amniocentesis.
- Direct: fetal blood studies using a sample obtained by cordocentesis.

Each method has advantages and disadvantages, proponents and opponents. The method selected should reflect the facilities available and the physician's experience. Because the incidence of maternal alloimmunization is declining, so is the number of physicians experienced with its management. The author concurs with Craig, who opined that these services should be centralized.[51] The alloimmunized patient should be referred either to a fetal medicine specialist or to the individual in the geographic locale with the greatest experience in managing fetal hemolytic disease once RBC alloimmunization is confirmed.

AMNIOTIC FLUID SPECTROPHOTOMETRY

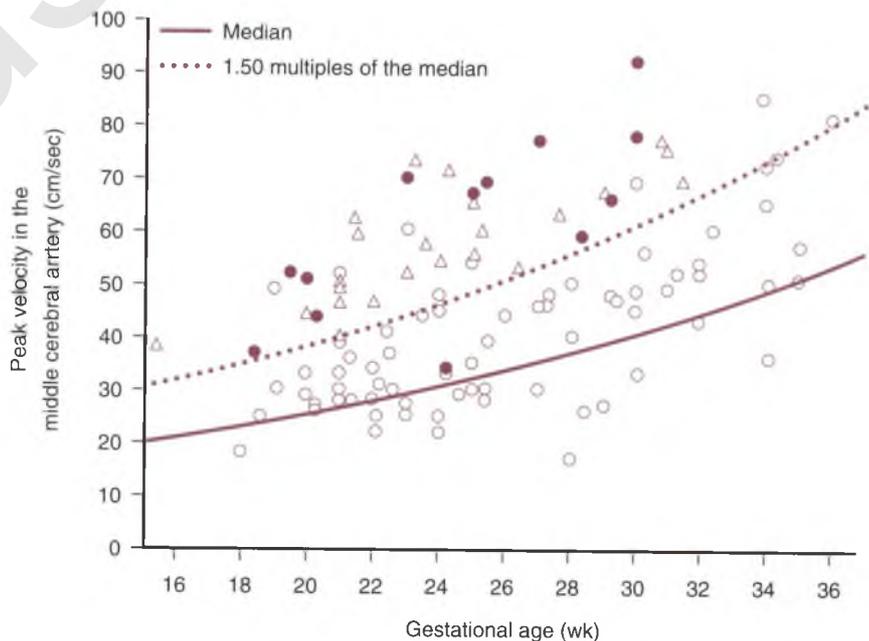
The fetus with hemolytic anemia frequently has an elevated serum bilirubin (Fig. 14–3).[20] By the middle of the second trimester, the amniotic fluid consists predominantly of fetal urine and tracheopulmonary effluent; thus, the amniotic fluid bilirubin is also elevated. Although William Liley was not the first to use amniotic fluid spectrophotometry for the management of rhesus disease, he standardized an approach that has remained essentially unchanged since first reported in 1961.[4] Although the $\Delta OD450$ satisfactorily predicts the


FIGURE 14–2
Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anemia due to maternal red-cell alloimmunization. Open circles indicate fetuses with either no anemia or mild anemia (≥0.65 multiples of the median hemoglobin concentration). Triangles indicate fetuses with moderate or severe anemia (<0.65 multiples of the median hemoglobin concentration). The solid circles indicate the fetuses with hydrops. The solid curve indicates the median peak systolic velocity in the middle cerebral artery, and the dotted curve indicates 1.5 multiples of the median. (From Mari G, Deter RL, Carpenter RL, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses. N Engl J Med 2000;342(1):9–14.)

relative fetal hematocrit when used appropriately, it is best at predicting hydrops.

The principal advantage of amniocentesis is that most obstetricians are familiar with the technique and find it simple. Amniotic fluid is obtained by ultrasound-guided amniocentesis (see Chapter 10), transported to the laboratory in a light-resistant container to prevent degradation of bilirubin, centrifuged, and filtered. If the fetal blood type is unknown, an aliquot of the sample should be subjected to PCR to confirm the fetal genotype is antigen positive.

The optical density (OD) is measured between 700 and 350 nm and plotted on semilogarithmic graph paper with the wavelength on the *x*-axis. A line parallel to the *y*-axis is drawn through 450 nm, and the deviation from linearity of the absorption trace measured at that point. The result is plotted on semilogarithmic paper with gestational age on the *x*-axis and the $\Delta OD450$ on the *y*-axis (Fig. 14–4). Based on the study of 101 amniotic fluid specimens obtained between 28 and 35 weeks' gestation, Liley observed that the $\Delta OD450$ normally declines with advancing gestation (the opposite direction of the fetal serum bilirubin concentration) (Fig. 14–5).[4] The graph is divided into three ascending zones. Zone 1 represents mild or no fetal dis-

ease. Zone 3 indicates severe disease with the possibility of hydrops developing within 7 days. Zone 2 is intermediate, with the disease severity increasing as zone 3 is approached. Amniocentesis is repeated at 1-to 2-week intervals, depending on the gestational age, the zone of the $\Delta OD450$, and the change from the preceding sample. Management is dictated by the trend revealed by serial values. A fetal blood sample is considered when either the $\Delta OD450$ is in zone 3 or serial amniotic fluid specimens reveal a progressive and rapid rise of the $\Delta OD450$ into the upper 80% of zone 2. Based on that result, the decision is made for either transfusion or delivery.

The determination of hemolytic disease severity by amniotic fluid spectrophotometry has several important disadvantages. First, its application requires serial invasive procedures over the space of several weeks. In a 20-year experience that included 1027 women, Bowman and associates[14] performed a mean of 3.1 procedures per patient. Each procedure carries a risk of enhanced maternal sensitization, as well as a loss from either amnionitis or premature rupture of the membranes. Though there are no large series reported of women undergoing amniocentesis after 22 weeks' gestation to document the frequency of such complications, some conclusions may be drawn from studies of second trimester genetic amniocenteses. Amniocentesis performed under ultrasound guidance is clearly associated with sensitization, amnionitis, and rupture of membranes (in our experience approximately 1 in 300). Simplicity of a procedure is not synonymous with safety.

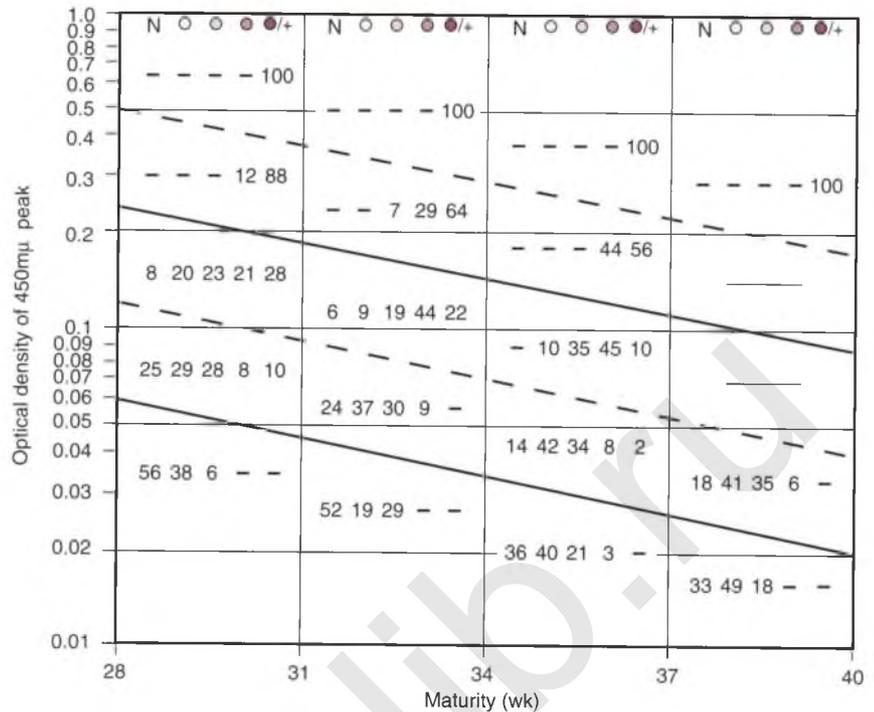
Second, amniotic fluid spectrophotometry is an indirect test for fetal anemia. The natural history studies by Liley revealed a wide range of disease severity for a given $\Delta OD450$ at any gestational age between 28 and 34 weeks (see Fig. 14–5).[4,5] Liley's postnatal observation is confirmed antenatally using cordocentesis. Though most obvious for zone 2, it is also true for zone 3 measurements. In a series of 11 fetuses with a $\Delta OD450$ in zone 3 followed for several weeks, 30% had a clinically accept-


FIGURE 14–5
Relationship between the ΔOD450, hemoglobin, and gestational age. Note, for example, that of fetuses between 28 and 31 weeks and a ΔOD450 in low zone 2, 25% are unaffected, whereas 18% are either profoundly anemic or dead. (From Liley AW: Liquor amnii analysis and management of pregnancy complicated by rhesus immunization. Am J Obstet Gynecol 1961;82:1359–1368.)

able hematocrit at birth.[52] Gottval and Hilden[53] concluded that the maternal indirect Coombs titer was actually superior to the ΔOD450 for the prediction of fetal anemia, and yet the titers were useful only when less than 32 or more than 1000. Bowman opined that the "experience and judgment of the individual assessing the amniotic fluid findings were more important than the method used."[14] Yet, in their almost unparalleled experience, 9% of the predictions based on a zone 2 ΔOD450 (which comprised almost 50% of the measurements) were erroneous. Few clinicians in this era of anti-D immunoglobulin prophylaxis have a comparable breadth of experience with amniotic fluid spectrophotometry.

The third disadvantage of amniocentesis and the ΔOD450 is that the system was modeled on anti-D alloimmunization. This author and others[54–56] have shown that Kell alloimmunization has salient pathophysiologic differences that account for the very poor performance of the ΔOD450 reported in the past.[57] Fetuses with Kell alloimmunization have lower serum bilirubin concentrations, and lower reticulocyte levels for their degree of anemia compared to D-alloimmunized fetuses. Vaughan and associates[58] found that monoclonal IgG and IgM anti-Kell antibodies inhibit the growth of Kell-positive erythroid burst-forming units and colony-forming units in a dose-dependent fashion. This suggests that the fetal anemia secondary to Kell reflects erythroid suppression at the progenitor cell level.

The fourth disadvantage of amniocentesis is that the normal ΔOD450 in the second trimester is mid zone 2 of the Liley curve. Some have concluded that there is no clinically useful correlation between the ΔOD450 reading and the fetal hemoglobin before 28 weeks.[59] Yet, amniocentesis is often initiated weeks earlier. Experienced practitioners rely, in this situation, on the trend of several amniocenteses or the finding of an extraordinarily high ΔOD450 value (e.g., >0.400). Unfortunately, the published experience validating this practice is small.

The fifth disadvantage of the ΔOD450 measurement is that it is subject to a variety of extrinsic errors that can interfere with its laboratory measurement, for example, maternal hyperbilirubinemia and specimen contamination with blood or meconium.

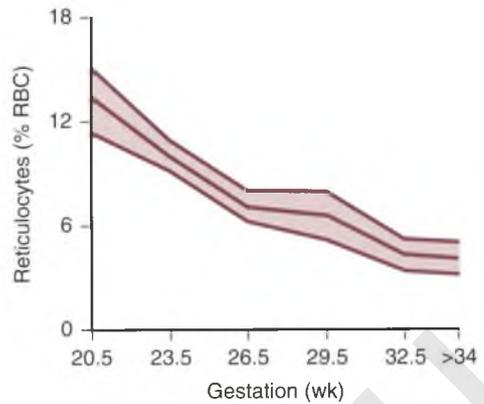
Finally, the correlation between hemoglobin and the peak middle cerebral artery velocity has rendered amniocentesis for the measurement of the ΔOD450 an outdated tool because transfusion therapy should never be initiated without confirming fetal anemia.

FETAL BLOOD SAMPLING

The accuracy of cordocentesis for the evaluation of fetal anemia was never an issue. The concerns were safety (immediate vascular accidents and the longer-term risk of worsening sensitization) and how to decide if and when to repeat the cordocentesis. The safety of cordocentesis is detailed in Chapter 10. The loss rate reflects the indication for the procedure, the presence of hypoxemia, the vessel actually punctured, and the technique used (needle guide versus free hand).[60,61] It has been estimated that technique accounts for at least 30% of losses. Using a needle guide, the loss rate for alloimmunization is less than 0.3%, a rate similar to amniocentesis. Further, the size of the fetal-maternal bleed after cordocentesis when a needle guide is used and the placenta is not punctured is similar to that after amniocentesis.[62] In contrast, the magnitude of the bleed is much greater when the free-hand technique is used.

The first cordocentesis is performed either a few weeks before the last sensitized fetus required transfusion, or when the peak middle cerebral artery velocity becomes elevated. Laboratory tests performed on the first and subsequent fetal blood samples are listed in Table 14–4. Either a strongly positive direct Coombs test or a manual reticulocyte count outside the 95% confidence interval (Fig. 14–6) are high risk factors for the development of antenatal anemia if the fetus is not anemic when sampled.

A sensitive and specific assessment of the risk for developing anemia can be made using direct fetal hematologic and serologic tests. A prospectively validated protocol for risk assessment and the timing of any repeat cordocentesis are shown in Table 14–5. There is a direct correlation between the reticulocyte count, the strength of the direct Coombs test, the risk of fetal anemia, and the trimester in which it occurs.[17] Approximately 50% of alloimmunized women require only one cordocentesis (Fig. 14–7). With ultrasonography as a backup, delivery may be safely deferred until 37 to 38 weeks with less than 2% risk of unexpected anemia (only twice in the experience of the author covering more than 400 alloimmu-

nized pregnancies).[63] About 80% of pregnancies requiring more than one cordocentesis ultimately need a fetal transfusion for a hematocrit less than 30%. This protocol predicts antenatal anemia only and not postnatal hyperbilirubinemia. Untreated neonates remain at significant risk for postnatal complications (Table 14–6).[63]


Delivery of the nontransfused fetus is planned between 37 and 38 weeks' gestation in a medical center capable of caring for a neonate with potentially severe hyperbilirubinemia.

Direct testing of the fetus has several advantages over amniotic fluid testing. Both sensitivity and specificity for the diagnosis and the prediction of fetal anemia are much greater than the $\Delta OD450$. Direct testing of the fetus for anemia has a zero false-positive rate and a very low false-negative rate. Fewer invasive procedures are necessary, reducing the overall risk of premature rupture of the membranes, amnionitis, and worsening of sensitization, especially if a needle guide is used.

Treatment Options

SUPPRESSION OF MATERNAL ANTIERYTHROCYTE ANTIBODIES

Several methods are used to suppress or ameliorate either the maternal antibody concentration or its effect on the fetus. None are of documented efficacy, and only two appear to have limited potential.

Plasmapheresis. Although plasmapheresis reduces antibody concentration by as much as 80%,[64] the decline is transient. Current information suggests plasmapheresis may delay the need for fetal transfusion by a few weeks. This costly procedure is indicated only when there is a history of hydrops prior to 20 to 22 weeks and the father is homozygous for the offending antigen. Plasmapheresis is begun at 12 weeks, removing 15 to 20 L

per week. It entails a risk of hepatitis and should not be undertaken lightly.

Immunoglobulin. The maternal intravenous infusion of immunoglobulin (400–500 mg/kg maternal weight every 4 weeks) reportedly reduces the severity of fetal hemolytic disease.[65] There are no prospective randomized trials. Rarely indicated alone in light of the currently available therapies, intravenous immunoglobulin may be effective as an adjunct to plasmapheresis.[66] Another option is to administer the immunoglobulin directly to the infused fetus. Several abstracts suggest that such fetal therapy has the potential to reduce the frequency of transfusion therapy. Yet, the interval between transfusions at those institutions is normally shorter than recommended here.

FETAL TRANSFUSION

Fetal transfusion therapy should not be undertaken in the absence of hydrops without first confirming that the fetus has significant anemia. The author has used a hematocrit below 30% because it is below the 2.5 percentile for all gestational ages greater than 20 weeks (see later discussion under Intravascular Transfusion). These procedures should be performed whenever possible only by individuals with considerable and regular experience, namely 8 to 10 transfusions per year as a minimum.

Intraperitoneal Injection. The original, but now least preferred method for fetal transfusion is the intraperitoneal injection of packed red blood cells. The protocol is shown in Table 14–7. The blood is absorbed via the lymphatic vessels and requires fetal respiration for absorption. Approximately 10% of the transfused cells are absorbed each day by the nonhydropic fetus. Absorption is poor in the hydropic fetus. The volume infused is a compromise between the amount necessary to correct the estimated hemoglobin deficit and the amount that will safely fit into the intra-abdominal cavity. The formula of Bowman is quite practical and recommended:

$$\text{Volume} = (\text{weeks gestation} - 20) \times 10 \text{ mL}$$

Once absorption is complete, the residual hemoglobin concentration may be estimated by the following equation:

$$\text{Residual hemoglobin concentration} = ((0.8x)/(125y)) \times ((120 - z \text{ days})/120 \text{ days})$$

where x is the amount of donor blood in grams transfused, y is the estimated fetal weight, z is the interval in days since the last transfusion, and 120 the estimated life (in days) of the transfused blood.

The second transfusion is performed when the first has been completely absorbed and thereafter at 3- to 4-week intervals. If the fetus is hydropic and survives the first intraperitoneal transfusion, the fetal abdomen is drained at the second transfusion to minimize pressure and maximize the amount of fresh packed cells infused. The last transfusion is performed no later than 32 weeks' gestation.

Intraperitoneal transfusion has many drawbacks. In addition to a slow correction of the hemoglobin deficit, there is a higher risk of trauma and the unique risk of obstructing cardiac return should the intra-abdominal pressure rise too high. Intraperitoneal transfusion has no advantage over intravenous transfusion except when percutaneous access to the fetal vasculature is problematic (e.g., prior to 18 weeks). Nor is there any advantage to combining intravascular and intraperitoneal transfusions. The intravascular route already allows routine spacing of 3 to 5 weeks (see later discussion), and a combined transfusion approach does not reduce the actual number of required needle punctures. Further, there is a lower risk of trauma and death for both hydropic and nonhydropic fetuses from the intravascular approach. The highest reported survival rates with intraperitoneal transfusion are well below those for intravascular transfusion[67–69] In a comparison of historical data from an experienced team in Winnipeg, Canada, the risk of death per transfusion was six times that of intravascular transfusion.[69] Intraperitoneal transfusion is rarely indicated in the modern practice of fetal medicine.

Intravascular Transfusion. In contrast to intraperitoneal transfusion, the goal of intravascular transfusion therapy is the delivery of a healthy, nonanemic neonate at term when it can better transition to ex utero life and withstand hyperbilirubinemia. Transfusions are begun

TABLE 14-7

Protocol for Fetal Intraperitonal Transfusion

Preparation

Confirm fetal hematocrit <30%
Prepare donor blood as fresh as possible and compatible with both mother and fetus
Buffy coat poor, washed in saline × 3, and irradiated
Final hematocrit 90% ideal
Prepare two sets of tubing with three-way valves for transfusion; filters are mandatory
Diazepam, 5–10 mg slow IV for maternal comfort
Lateral displacement of the uterus, support lower back
Acetone wipe to remove ultrasound contact gel from the skin
Popovidine or alcohol surgical preparation of the skin
Drape as desired and prepare surgical tray
   20 gauge Tuohy needle 25 cm long
   20 mL syringe
   5 mL normal saline
   gauge spinal needle
   pancuronium, 0.3 mg/kg estimated fetal weight
Sterile prepare ultrasound transducer

Transfusion

Target fetal abdomen between umbilicus and bladder; avoid liver
Administer pancuronium intramuscularly targeting the fetal buttock
Insert Tuohy needle into selected site
Confirm intra-abdominal, extravascular location by injecting saline
Infuse donor blood in 1 mL aliquots over 10 min checking the fetal heart rate after each aliquot
Continue transfusion until planned volume infused calculated by: volume = (wk gestation – 20) × 10 mL

Follow-up

Continuous heart rate monitoring until fetal movement resumes
Document complete absorption of donor blood by serial ultrasonography
Examinations every 2–3 days
Second transfusion after complete absorption; thereafter, repeat at 4-wk intervals

when the fetal hematocrit declines below 30%.[24] Though most fetuses tolerate a hematocrit of 25% or lower without clinically significant sequelae, this cutoff point has proved a pragmatic threshold for the following reasons:

- Hematocrit of 30% is below the 2.5th percentile after 20 weeks' gestation (Fig. 14–8).
- Women referred often travel great distances and cannot come either semiweekly or even weekly without great hardship.
- It is difficult to predict with certainty how fast the fetal hematocrit will decline.
- Treatment of anemia prevents the development of hydrops that would greatly increase the chance of an adverse outcome.

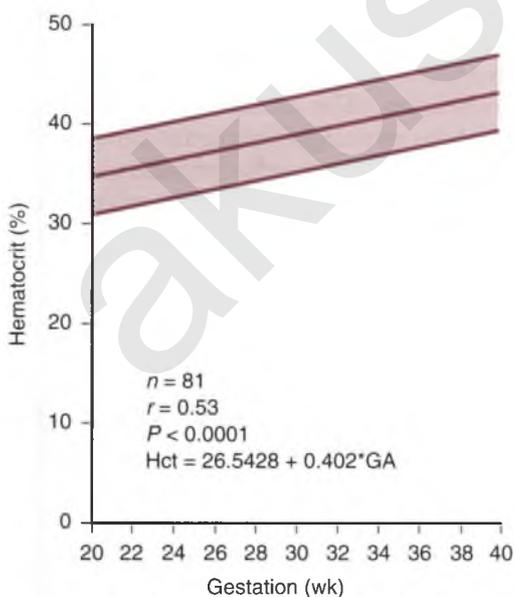
The protocol used for intravascular transfusion is shown in Table 14–8. Blood for the transfusion should be fresh when available, and compatible with both mother and fetus. Infectious agents routinely tested for include cytomegalovirus (CMV), hepatitis A through C, and human immunodeficiency virus. Some blood banks use a lymphocyte filter in lieu of serologic testing for CMV. This procedure has the added benefit of reducing the risk of graft versus host disease without irradiating the blood. The blood is prepared on the day of transfusion, rendered leukocyte poor, and washed several times in saline to remove particles associated with viral transmission infection. It is then resuspended in saline to a hematocrit between 70% and 80%. Blood with a higher hematocrit mixes poorly; that with a lower hematocrit unnecessarily increases the volume required.


FIGURE 14–8
Normal fetal hematocrit across gestation illustrated as the 95% prediction interval. (From Weiner CP, Williamson RA, Wenstrom KD, et al: Management of fetal hemolytic disease by cordocentesis: I. Prediction of fetal anemia. Am J Obstet Gynecol 1991;165:546–553.)

The patient is made comfortable with pillows under her knees to take pressure off the lower back. The uterus is displaced laterally to avoid supine hypotension during the transfusion. Because the transfusion takes on average 25 to 30 minutes, diazepam 5 to 10 mg IV is given to enhance maternal comfort and cooperation. The abdomen is surgically prepared and draped, and the operator's hands are gloved. Neither a surgical mask nor cap is necessary. Nor is there evidence that prophylactic antibiotic administration is either effective or cost efficient. The skin is the main source of bacterial contamination. The operator must never touch the shaft of the needle. A new needle is used if one must be removed after insertion into the skin. With this protocol, our incidence of amnionitis is less than 0.5%. The skin is infiltrated with 1% lidocaine in light of the duration of time the needle is in situ.

The easiest approach to the umbilical vein is selected; 35% of the author's transfusions are performed in a free

TABLE 14–8

Protocol for Fetal Intravascular Transfusion

Preparation

Confirm fetal hematocrit <30%
Preparation of donor blood as fresh as possible and compatible with both mother and fetus
Buffy coat poor, washed in saline × 3, irradiated
Final hematocrit 70–80%
Preparation two sets of tubing for transfusion and measurement of umbilical venous pressure (UVP)
Filters are mandatory
Diazepam, 5–10 mg slow IV for maternal comfort
Lateral displacement of the uterus, support lower back
Acetone wipe to remove ultrasound contact gel from the skin
Popovidine or alcohol surgical preparation of the skin
Drape as desired and prepare surgical tray
    Eight 1-mL tuberculin syringes
Flush three with heparin (100 U/mL); fill one with lidocaine (1%) and fill one with desired dose of pancuronium (0.3 mg/kg sonographically estimated fetal weight)
Three 3-way valves
One 5 22-gauge needle
Three 4 × 4 gauze sponges
Prepare transducer

Transfusion

Puncture vein at most accessible site
Immediately administer pancuronium — paralysis will be rapid
Aspirate 1 mL for complete blood count, Kleihauer stain and reticulocyte count; check hematocrit immediately
Aspirate 1 mL for venous blood gases
Measure pressure and confirm puncture is of umbilical vein
Begin infusion of packed red blood cells after double checking there is no air in the system
Infuse half the estimated requirement (see Table 14–9)
Repeat blood sampling and pressure measurement
Halt transfusion if the rise in the UVP has exceeded 10 mm Hg; check heart rate to rule out bradycardia as an explanation
If UVP acceptable, calculate remaining volume necessary to achieve a hematocrit of 50%; infuse that volume
Repeat blood sampling and pressure measurement; remove needle if UVP at acceptable level
Monitor fetus until spontaneous movement resumes

loop of cord. The vein is punctured with a 22-gauge nee-dle. A larger gauge needle unnecessarily increases the risk of premature rupture of the membranes, and there is no significant hemolysis. Immediately following the free return of blood, the fetus is paralyzed with pancuronium (approximately 0.3 mg/kg of the estimated fetal weight [EFW], range 0.2 to 0.6 mg/kg), regardless of the punc-ture location because any fetal movement may lacerate the vessel or dislodge the needle. Should the latter occur dur-ing transfusion, a catastrophic Wharton's jelly hematoma with concomitant decrease in umbilical blood flow may result. There is no advantage in not paralyzing the fetus. Pancuronium, as opposed to other agents used for neuro-muscular blockade, has the advantage of increasing heart rate secondary to catecholamine release. Without pan-curonium, intravascular transfusion decreases both the fetal heart rate and cardiac output, prolonging the time required for the fetus to clear the acid contained in the preserved banked donor blood. With pancuronium, the fetal heart rate remains at or above the pretransfusion rate. The injection of the pancuronium, followed by the meas-urement of the umbilical venous pressure, allows the definitive identification of the vessel punctured. The nee-dle is removed if the artery is inadvertently entered because the risk of fetal bradycardia can rise fivefold. Though furosemide is used (3 mg/kg EFW) by some, including the author, clinical and laboratory investigations have failed to show measurable benefit.[70]

The equipment for an intravascular transfusion is illus-trated in Figure 14–9. The blood must be filtered imme-diately prior to transfusion to remove aggregates that may obstruct the microvasculature. Careful attention is paid to purge the system of air. With a series of three-way valves, an assistant injects the donor blood while the operator is free to concentrate on the fetus and needle placement. The assistant must remain poised to halt the infusion if there is any abrupt change in the resistance to flow. To minimize the time the needle is in place, the blood is infused with haste up to 5mL/minute.

Except for the first transfusion of a hydropic fetus, the target for the post-transfusion fetal hematocrit is 48% to 55%. The volume required depends on gestational age and the initial hematocrit. Assuming similar opening and closing hematocrit measurements, the volume infused is dependent on gestational age (Table 14–9). The volume required for correction frequently equals or exceeds the calculated total fetal-placental intravascular volume.

HYDROPS

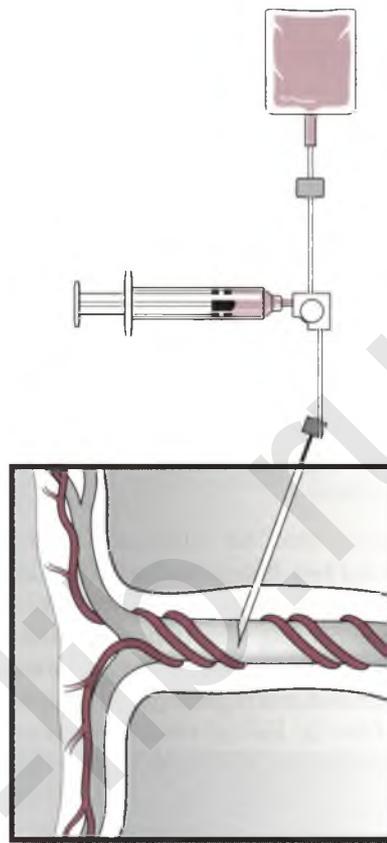
Because most hydropic fetuses have myocardial dysfunc-tion that prevents them from tolerating the required infusion volume,[26] the target hematocrit after their first transfusion is only 25% (see Pathophysiology). Twenty-four hours later, the hematocrit can be safely brought to 50% during a second transfusion. The decline in umbil-ical vein pH (UVpH) that normally occurs during trans-fusion is especially important to the severely anemic


FIGURE 14–9
Set-up for an intravascular transfusion.

fetus. The red blood cell is the principal fetal buffer, and the pH of the citrated banked blood is 6.98 to 7.01. Our losses of hydropic fetuses after transfusion occurred even though the increase in their umbilical venous pressure during the procedure was acceptable and there was no acute bradycardia. All losses, however, were associated with a profound acidemia, and the deaths occurred hours after transfusion. The author believes the acidemia aggravated the myocardial failure and now infuses bicar-bonate in 1-mEq increments to maintain the UVpH above 7.30. There have been no further losses since that practice was initiated in 1988. In point, the overall sur-vival rate for hydropic fetuses using this protocol now exceeds 90%.

TABLE 14–9	
Approximate Volumes of 72% Hematocrit Blood Required for Intravascular Transfusion after the First Transfusion	
GESTATION (WK)	**VOLUME (ML)**
≤ 22.5	25–40
22.5–27.49	45–65
27.5–32.49	75–90
≥32.5	100–120

Several formulae have been proposed to calculate the volume of blood necessary to correct the hemoglobin deficit. Though reasonably accurate, none are reliable enough to remove the needle without first checking the hematocrit. Further, there is a possibility of overtransfusion when any formula is relied upon blindly. The author prefers to transfuse half the estimated total volume and then check the hematocrit. Based on the increase in hematocrit achieved following the first aliquot, the remaining volume necessary is rapidly and accurately calculated. Contrary to the adult or child, donor blood with a hematocrit below 80% equilibrates rapidly, perhaps because of the rapid fluid exchange across the placenta. On multiple occasions, the author has found that the hematocrit 24 hours after the transfusion is within a few percentage points of the closing hematocrit. However, transfused blood with a hematocrit higher than 80% is more viscous and does not equilibrate as rapidly.

The decline in hematocrit after transfusion is more rapid and variable between the first and second transfusions compared to subsequent procedures. This variability results from the differing rates of destruction of disparate amounts of fetal antigen positive and banked antigen negative red blood cells. Except for the hydropic fetus, the second transfusion is performed 2 weeks after the first. Subsequently, the decline in hematocrit per week is predictable for any given fetus (Fig. 14–10). The rate at which the hematocrit declines between transfusions with advancing gestation is such that by 34 to 35 weeks, delivery may be safely delayed 4 to 5 weeks without another transfusion. These findings have been confirmed.[71]

The fetus is monitored during transfusion using a variety of methods. Many prefer to image the fetal heart at periodic intervals to rule out bradycardia; although important, it is of limited value. A second option is umbilical venous pressure measurement, which has several advantages. First, an occasional nonhydropic fetus (frequency of approximately 5% in the author's experience) with a low hematocrit does not tolerate the transfusion volume necessary to correct the hemoglobin deficit. An increase in the umbilical venous pressure of more than 10 mm Hg is associated with an increased perinatal mortality rate. The transfusion should either be halted, or an appropriate volume of blood removed to reduce preload if the pressure rises more than 10 mm Hg. Second, fetal bradycardia increases the umbilical venous pressure. The third option is pulsed Doppler, which can also help differentiate the two causes of an elevated umbilical venous pressure by dropping a Doppler gate on the umbilical artery. Whichever technique is selected, it is important to keep the needle in place because any resuscitative efforts necessitated by a fetal bradycardia are facilitated by access to the fetal circulation.

Intravascular transfusion has many effects on the fetus (Table 14–10) other than raising the hematocrit.[72–74] Some, such as the increases in atrial natriuretic peptide and prostacyclin, help the fetus tolerate a volume load that postnatally would be lethal. Prostaglandin synthetase inhibitors are contraindicated for two reasons: (1) an increase in fetal prostacyclin and prostaglandin E_2 (PGE_2) is part of the normal adaptive response to the abrupt increase in intravascular volume,[74] and (2) there is no evidence they are of any utility.

Adequate transfusion therapy rapidly suppresses fetal erythropoiesis. The fetal erythropoietin level declines, and the average reticulocyte count is less than 1% by the

FIGURE 14–10
The rate at which the hematocrit (HCT) declines per week after a transfusion. Open triangles reflect the interval decline between the first and second transfusion. The solid black triangles and the regression line reflect the decline in hematocrit per week between subsequent transfusions. Thus, if the fetus was transfused to 50% hematocrit at 22 weeks, we would expect it to decline approximately 9% per week. Based on this estimate, the transfusion would be repeated in 2.5 weeks.

In figure: $n = (22/28)$ $r = -0.34/-0.84$ $P = 0.11/<0.0001$. Y-axis: ΔHCT/week. X-axis: Gestation (wk).

TABLE 14–10
Acute Nonhematologic Effects of Intravascular Transfusion
Cardiovascular
Increased intravascular volume
Decreased heart rate (without pancuronium)
Decreased cardiac output (without pancuronium)
Increased umbilical venous pressure
Increased renal blood flow
Decreased placental resistance measured by Doppler
Decreased aortic resistance measured by Doppler
Biochemical
Acidemia (blood preservative, inadequate fetal buffer capacity)
Increased oxygen-carrying capacity
Increased viscosity
Increased atrial natriuretic peptide
Increased prostacyclin
Increased prostaglandin E_2
Increased iron stores (chronic)

third transfusion. It is advantageous to perform at least two transfusions 3 weeks apart prior to delivery because postnatal complications of hyperbilirubinemia are significantly less likely to occur after two or more antenatal transfusions.[25] In experienced hands, losses are uncommon and confined to the previable fetus. In the author's view there is no justification for routine preterm delivery. The last transfusion can be performed at 34 to 35 weeks' gestation and labor induced at 37 to 38 weeks.

DELIVERY

The obstetric philosophy need not be altered for the nonanemic, transfused fetus. Antenatal transfusion is not a reason to deny a vaginal birth after cesarean section. If the final hematocrit at the end of the last transfusion was 50%, it will be in the mid-30s in the umbilical cord at delivery. Typically, the neonatal hematocrit increases approximately 15% within 8 hours of delivery, reflecting a massive shift of extracellular and intravascular fluid. The hematocrit then declines to or below the delivery level over the next few days to weeks.

POSTNATAL CARE

Postnatally, infants who received in utero transfusion therapy do remarkably well with an average hospitalization stay of less than 7 days (unpublished data). Because they are delivered at term, a higher peak neonatal bilirubin concentration is tolerated and is normally manageable with just phototherapy. Double volume exchange transfusion is rarely needed when two or more antenatal transfusions are performed. Small, simple transfusions are frequently necessary, beginning at several weeks of age, because the banked blood transfused 5 weeks earlier is at the end of its life span. This anemia is typified by a low reticulocyte count. The neonatal hematocrit and reticulocyte count should be monitored weekly. If not, a severe anemia may escape detection with resulting high output failure and failure to thrive. The pediatric goal is to keep the neonate asymptomatic but with a modest anemia to maintain an erythropoietic stimulus. Newborns may be 16 weeks old before reticulocytes reappear on the peripheral smear. Once a reticulocytosis is noted, further transfusion therapy is generally not needed. The need for neonatal transfusion can be decreased significantly by the administration of recombinant human erythropoietin.[75]

Effect of Anemia and Treatment on the Fetus

It is remarkable how well the fetus tolerates all but the most severe anemia. Fetuses who have a mild, chronic anemia are neither growth deficient nor acidemic. Though mild to moderate anemia is not associated with dramatic antenatal sequelae, severe anemia clearly is. As

dramatic as hydrops fetalis may be, it is for the most part preventable and completely reversible. Hydropic fetuses not yet severely acidemic recover quickly with appropriate transfusion therapy and on long-term follow-up appear without specific sequelae[76,77] (unpublished data).

Transfusion therapy has a predictable and desirable effect on fetal erythropoiesis. With adequate RBC replacement, the reticulocyte count and percentage of circulating red blood cells of fetal origin drops rapidly (Fig. 14–11). Part of this decline is due to consumption of newly formed fetal RBCs as they emerge from the fetal bone marrow and liver. However, after two transfusions correcting the hematocrit to 50%, smears of neonatal bone marrow reveal decreased erythrogenic precursors.[78] The greater the number of antenatal transfusions (i.e., the longer the period of fetal erythrocytic suppression) performed, the less severe the hyperbilirubinemia postnatally and the longer the suppression of erythropoiesis postnatally.[25] These findings coupled with the decrease in fetal plasma erythropoietin concentrations after several transfusions are indicative of marrow and liver suppression.

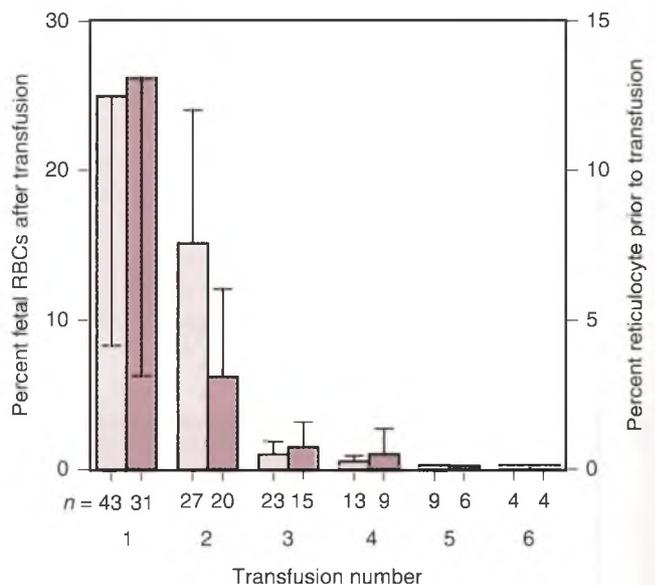
The long-term outcomes of the most severely affected fetuses have until recently been the subject of scant study. We conducted a case-control study of all 16 consecutive children born at the University of Iowa between July 1985 and August 1990 who as fetuses had intrauterine intravascular transfusion therapy for alloimmune hydrops fetalis.[79] Eight nonhydropic older siblings were control subjects. Hospital records were reviewed, and parents completed behavioral questionnaires and were interviewed. Affected children and their sibling controls


FIGURE 14–11
Effect of simple intravascular transfusion on the circulating fetal red blood cell (RBC) percentage (M left x-axis) and the percentage of RBCs that are reticulocytes (M right x-axis).

received comprehensive neuropsychological evaluations, hearing tests, and neurologic examinations. The hydrops children had cranial computed tomography (CT) scans for the measurement of brain and ventricular volumes. No significant differences were noted between the hydrops group and the sibling control group on neuropsychological measures (Table 14–11). Modest but statistically significant correlations were noted between the severity of anemia at the time of hydrops and composite standardized testing of nonverbal and computational skills at follow-up. The first child treated was electively delivered at 35 weeks. He suffered complications of kernicterus associated with a maximum bilirubin of 28 mg/dL. A second child who at 25 weeks' gestation experienced a prolonged fetal bradycardia (heart rate of 40 bpm for 5 minutes) due to technical difficulties during an intra-arterial transfusion followed by delivery had cerebral palsy. The remaining 13 children had physical, neurologic, and neuropsychological findings within the normal range. Of the 16 CT scans, 14 were normal, and 2 revealed minor structural abnormalities. Mean total intracranial volume was 1477 mL. All intracranial volumes were within published normative values.

ABO INCOMPATIBILITY AND MINOR BLOOD GROUP ANTIGENS

ABO incompatibility rarely causes fetal disease because the antibodies are often IgM and because these antigens are not strongly expressed on the fetal erythrocyte. Alloimmunization to minor blood group antigens is usually due to blood transfusion. Although Lewis antibodies are most common, they are almost always IgM and do not pose a risk for fetal disease. Further, the antigen is poorly expressed on the fetal erythrocyte. Therefore, the risk for hemolysis is low.

Kidd, Kell, and Duffy are the most common minor blood group antigens that cause perinatal hemolytic disease. Kell alloimmunization is of particular interest because the pathophysiology differs from the others. The

clinical course is particularly unpredictable by indirect fetal assessment because the anti-Kell IgG antibodies damage or inhibit erythrocyte progenitors. Severe anemia and hydrops may develop rapidly with low antibody titers and ΔOD450 values. Management is similar to Rh isoimmunization with monitoring and intervention tailored to the individual circumstances.

OTHER CAUSES OF HEMOLYTIC DISEASE

Rare causes of fetal and neonatal hemolytic disease include hemoglobinopathies, RBC membrane defects, and RBC enzyme deficiencies. Because thallassemia can affect the α and β hemoglobin chains, it may result in disease in utero. Bart's hemoglobin (deletion of all four α chain genes) is the most severe form and causes hydrops fetalis. Hemoglobin H disease (deletion of three α chain genes) is less severe, but the affected patient requires lifelong transfusion treatment. In contrast, sickle cell disease (defective β chain) does not manifest in utero owing to the protective effect of fetal hemoglobin.

FUTURE PREGNANCIES, PREPREGNANCY CONSULTATION

Modern approaches to fetal hemolytic disease have drastically reduced the impact of this disease on the family. Though we may be cognizant that it may occur, we do not expect to lose a fetus to hemolytic disease. Several women under our care have, after presenting with a hydropic fetus in the first treated pregnancy, gone on to a second and a third treated pregnancy. Though not unreasonable to suggest, there is no reason to badger these women toward either an undesired surgical sterilization or a pregnancy by artificial insemination with an Rh– donor to avoid a recurrence. It is, however, essential they understand the time demands required of them, along with the costs and risks involved. This information is best supplied prior to conception.

TABLE 14–11

Long-Term Outcome of Consecutive Hydropic Fetuses Treated in Utero

CONCLUSIONS

Pathophysiology and Risks

- Fetal hemolytic disease remains a major cause of perinatal morbidity.
- Maternal alloimmunization results either from fetal to maternal hemorrhage or heterologous blood transfusion.
- Only IgG class antibodies cross the placenta and bind to the fetal red blood cells. Anti-D alloimmunization remains the most common type
- All sequelae of the disease are secondary to hemolysis or severe anemia.
- Severe anemia leads to the development of hydrops fetalis, reflecting cardiac and hematologic events.
- There is clear evidence of cardiac dysfunction in most hydropic fetuses that precedes the development of hydrops and resolves promptly after fetal transfusion.
- Postnatally, the affected neonate is at risk for complications of hyperbilirubinemia that include neural deafness and encephalopathy.
- All complications of fetal hemolytic anemia are potentially preventable.

Options for Antibody Detection and Management of Non-Immunized Rh-Negative Women

- RBC alloimmunization is detected using a combination of indirect and direct methods.
- Unless previously documented on two or more occasions, all women should be tested on registration for prenatal care.
- Nonimmune Rh– women should be tested regularly (ideally monthly) throughout pregnancy for evidence of alloimmunization.
- Anti-D immunoglobulin effectively prevents maternal alloimmunization. It should be given after amniocentesis, episodes of vaginal bleeding, at 28 weeks' gestation, and after the delivery of a Rh+ child
- The recommended dose of anti-D immunoglobulin for these potential sensitization events varies among countries.

Management of Sensitized Rh-Negative Women

- The management of the pregnant alloimmunized woman utilizes both direct and indirect methods of maternal/fetal evaluation.
- Serial indirect Coombs tests are performed at monthly intervals after 18 weeks' gestation until the critical titer for the laboratory is exceeded.
- At that time, serial peak middle cerebral artery velocity measurements are performed weekly. The correlation between hemoglobin concentration and the peak middle cerebral artery velocity has rendered amniocentesis for the measurement of the ΔOD450 an outdated tool because transfusion therapy should never be initiated without confirming fetal anemia.
- Cordocentesis is performed when the peak middle cerebral artery velocity is elevated.
- The care of these pregnancies should be under the guidance of a consultant skilled in the area.
- During the first sensitized pregnancy, the Coombs titer correlates with the severity of fetal disease. However, these titers are poorly predictive after the first sensitized pregnancy.

Treatment of Hemolytic Fetal Anemia

- The treatment of significant fetal hemolytic anemia prior to 34 weeks' gestation is transfusion.
- Successful transfusion eliminates the antenatal and, largely, the postnatal complications of fetal hemolytic disease.
- Intravascular transfusion is the procedure of choice.
- However, whether the transfusion is intravascular or intraperitoneal, the most experienced person or team available should perform it.
- Delivery may be safely delayed until 37 to 38 weeks if intravascular transfusion is done.
- By maintaining the hematocrit at the high end, fetal erythropoiesis is minimized, reducing the risk of postnatal hyperbilirubinemia.

Fetal Hemolytic Disease

Management Options	Quality of Evidence	Strength of Recommendation	References
Prevention of Rh Hemolytic Disease in Nonimmunized Women			
Routine screening in Rh– women at booking and regularly through pregnancy	III	B	19
Antenatal prophylaxis at delivery	Ib	A	34
Antenatal prophylaxis at 28–34 wk and at delivery	IIb	B	32
Prophylaxis after potential sensitizing events	III	B	33
Prediction of Disease Severity in Immunized Women			
Refer to experienced center when critical antibody titer reached	–	GPP	–
Prenatal determination of fetal RhD status	III	B	38
Measure maternal serum anti-D antibody concentration serially	III	B	19
Sonographic imaging to predict severity of disease—poor without evidence of frank hydrops	III	B	50
Middle cerebral Doppler appears to be reliable noninvasive technique to determine severity of anemia	III	B	45
Amniocentesis bilirubin/ΔOD450 from 27–41 wk—three zones helpful in managing patients (true level of anemia not known)	III	B	4
Liley curves of amniotic fluid bilirubin/ΔOD450 between 18–25 wk detected only 32% of fetuses with a Hb <6 g/dL (appropriate management and survival may not be directly correlated with Hb <6 g/dL)	III	B	59
An extrapolated Liley curve from 20–27 wk can be used to appropriately manage patients	III	B	80
Fetal blood sampling: variation exists in practice over which method to use and when to perform it	III	B	19
Treatment			
Fetal blood transfusion is treatment of choice; intravascular (Table 14–8) is preferable to intraperitoneal (Table 14–7)	IIa	B	69
Intravascular transfusion is associated with a >90% survival rate	III	B	25
	IIa	B	69
Fetal transfusion via the intrahepatic vein has similar success rates to intravascular transfusion	III	B	81
Decline in donor red blood cells is approximately 2% /day	III	B	71
The efficacy of intravenous immunoglobulin (IVIG) as a treatment for severe fetal hemolytic disease has not been established; the same is true for plasmapheresis; many reserve these for women with a history of early onset hydrops (?<22 wk)	IIb	B	65 82
Long-term neurodevelopmental outcome after intravascular transfusion is normal in most cases	III	B	76,77
Kell sensitization does not behave like Rh disease	IV	C	55
Kell sensitization is due to inhibition of erythroid progenitor cells by anti-Kell antibodies	III	B	58
Delivery Options			
In Nontransfused Fetus	–	GPP	–
At 37–38 wk			

SUMMARY OF MANAGEMENT OPTIONS
Fetal Hemolytic Disease *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Delivery Options			
In Transfused Fetus	–	GPP	–
Last intravascular transfusion at 34 weeks (unless dangerous or difficult) and deliver at 37 weeks			
32–34 wk (with prior maternal steroid therapy) for intraperitoneal transfusion			
Neonatal Care			
Pediatric surveillance from birth	–	GPP	–
Phototherapy			
Exchange transfusions if severe			
Top-up transfusions and long-term hematinic supplementation may be necessary

Fetal Thrombocytopenia

Humphrey H.H. Kanhai / Anneke Brand

INTRODUCTION

Thrombocytopenia is diagnosed in approximately 0.9% of newborns.[1] The incidence of thrombocytopenia during the neonatal period is 3% to 5%.[2] Pathologic conditions associated with fetal/neonatal thrombocytopenia include preterm birth, severe intrauterine growth restriction (IUGR), asphyxia, congenital malformations (e.g., TAR syndrome, trisomy 21), congenital infection, platelet iso- or alloimmunization, and red blood cell alloimmunization. Maternal disorders such as cocaine abuse, HIV (human immunodeficiency virus) infection, preeclampsia, and systemic lupus erythematosus (SLE) are associated with maternal, but not usually fetal, thrombocytopenia. Hemorrhagic disorders such as von Willebrand's disease and hemophilia may lead to coagulation disorders in the fetus/newborn other than thrombocytopenia. Thrombocytopenia secondary to either platelet allo- or isoimmunzation is found in 0.3% of newborns.[1] Alloimmune thrombocytopenia (AITP) (also known as neonatal alloimmune thrombocytopenia [NAIT] or fetal/neonatal alloimmune thrombocytopenia [FNAIT]) and isoimmune thrombocytopenia (ITP) (also known as idiopathic or autoimmune thrombocytopenic purpura) are immune-mediated thrombocytopenias. They are the focus of this chapter.

DEFINITIONS

Neonatal thrombocytopenia is defined as a platelet count below 150×10^9/L. It is further classified according to the severity:

- Mild thrombocytopenia (100–150×10^9/L) generally does not require treament.
- Moderate thrombocytopenia (50–99×10^9/L) also does not require treament, but both mild and moderate thrombocytopenias require careful observation for further deterioration and may trigger additional diagnostic tests.

Severe thrombocytopenia ($<50 \times 10^9$/L) generally mandates a diagnostic evaluation and some type of treatment. Very severe thrombocytopenia ($<20 \times 10^9$/L) is a serious condition that requires action, often including platelet transfusion.

Isoimmune thrombocytopenic purpura (ITP) (also known as autoimmune and previously as idiopathic thrombocytopenia) is an autoimmune process whereby the mother produces antibodies against her own platelets. IgG type antibodies may cross the placenta and lead to perinatal thrombocytopenia.

Alloimmune thrombocytopenia of the fetus/newborn (AITP) is caused by the placental transfer of maternal immunoglobulin G (IgG) antibodies that react with a paternal human platelet antigen (HPA) expressed on the fetal platelets.

ISOIMMUNE THROMBOCYTOPENIA

Incidence

Adult ITP has an annual incidence of 6 per 100,000 population[3,4] and most often affects young women. Consequently, a past or present history of ITP complicates 1 to 5 per 10,000 pregnancies.[5] Typically, the woman either has a history of ITP and presents with or without thrombocytopenia, or is currently being treated for ITP. Occasionally, asymptomatic ITP is accidentally discovered during pregnancy.

Risks

Maternal

Platelet counts in pregnant women with ITP tend to decrease, reaching their nadir during the third trimester.[6] Unless the counts are very low, the patient is either asymptomatic or experiences easy bruising. However, some patients do bleed despite platelet counts above 20×10^9/L ("wet" thrombocytopenia). In these instances,

it is assumed that the autoantibodies interact with functional receptors on the platelet surface. Women who do not respond to treatment are at risk for bleeding during pregnancy and delivery. The lowest maternal platelet count during the prior pregnancy is fairly predictive of the extent of thrombocytopenia in successive pregnancies.

Fetus and Newborn

The perinatal mortality rate is around 0.6% with virtually all losses secondary to related medical illnesses rather than fetal thrombocytopenia.[7] Severe in utero bleeding is not documented in ITP, which contrasts with alloimmune thrombocytopenia (see later discussion). It is the neonate who is at greatest risk. The chance of neonatal thrombocytopenia below $50 \times 10^9/L$ ranges from 9% to 15%.[7–11,15] In large series, neonatal intracranial hemorrhage (ICH) is reported in 0% to 1.5%.[12,13] The nadir neonatal platelet count and the highest risk for hemorrhage occur 1 to 4 days after birth.[6,14,15]

Because the majority of patients with ITP during pregnancy have a benign course, several investigators sought to predict the risk of fetal thrombocytopenia. This information is of practical importance as it could dictate the center selected for delivery. In most studies, there was only a weak correlation between the maternal and newborn platelet counts, the presence of antibodies in the maternal serum, or a history of splenec-tomy.[3,7,8,12,16–18] A few studies reported a higher correlation between the newborn platelet count and a maternal history of splenectomy.[11,15,19] Perhaps the strongest predictive factor for neonatal thrombocytopenia is an older sibling with a platelet count below $50 \times 10^9/L$.[20] A report that HLA (DRB3*) type in the mother is protective requires confirmation.[21] Even though each of these factors is relatively weak alone, the combination of a prior sibling with thrombocytopenia and a mother with a history of splenectomy and thrombocytopenia less than $50 \times 10^9/L$ during the current pregnancy creates a high probability (>50%) of neonatal thrombocytopenia and indicates the need for delivery in a tertiary hospital.[15]

Management Options (Fig. 15–1)

None of the published guidelines for the management of ITP in pregnancy and neonates[3,12,16,17] are based on a high level of evidence, and most are based on clinical cohort studies.

Prepregnancy

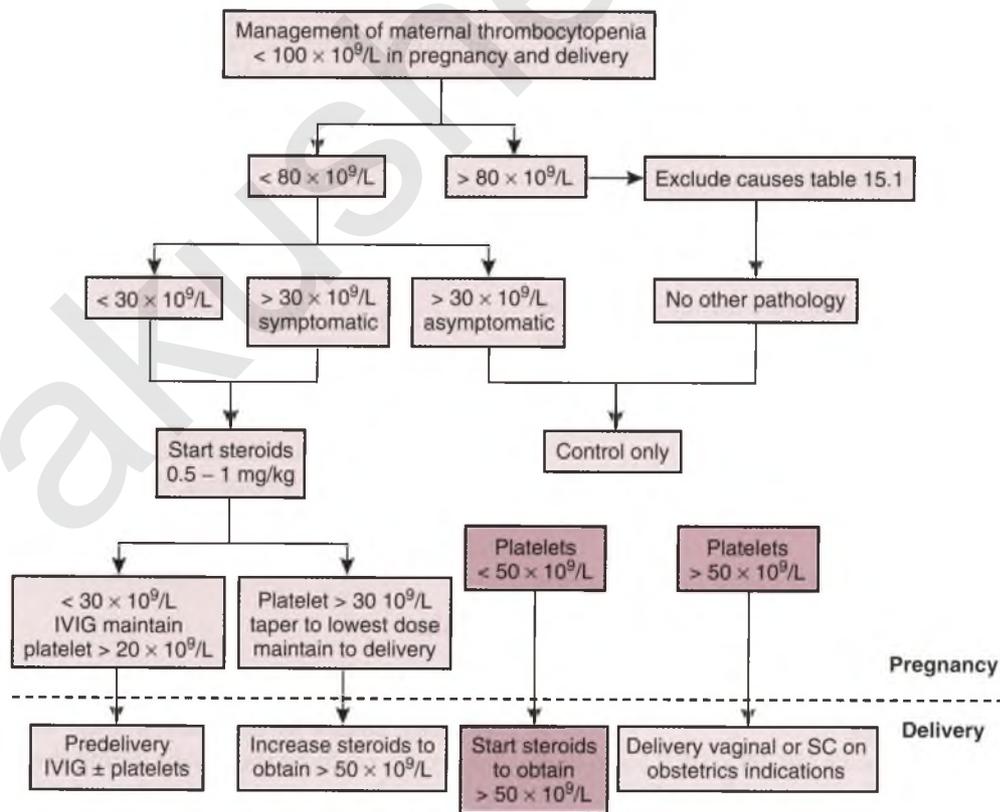
ITP is not a reason to avoid pregnancy, except perhaps for those women refractory to corticosteroids and splenectomy, and who cannot maintain a platelet count above $30 \times 10^9/L$ despite immunosuppressive drugs.[12,17]


FIGURE 15–1
Management of maternal thrombocytopenia. IVIG, intravenous immunoglobulin.

Although the risk of fetal and neonatal thrombocytopenia cannot be predicted from the maternal platelet count, it approaches the background rate in asymptomatic women. A history of a thrombocytopenic older sibling enhances the likelihood of a thrombocytopenic child.[20,22]

Prenatal

LABORATORY INVESTIGATIONS

These studies are summarized in Table 15–1.

Women with No History of ITP. Thrombocytopenia below $100 \times 10^9/L$ occurs in 1% to 2% of pregnant women.[6] The most common cause is gestational thrombocytopenia (GT), which has an overall frequency of 5% to 8%. In 95% of pregnant women, the platelet count is between 100 and $150 \times 10^9/L$.[6,14] Preeclampsia, HIV (human immunodeficiency virus), or rarer causes, such as von Willebrand's disease type IIB[23] and underlying systemic diseases such as SLE, antiphospholipid syndrome, thyroid dysfunction, and hematologic disease, must be excluded (see Table 15–1). No further analysis is indicated to distinguish GT from ITP after the aforementioned pathologic conditions are excluded as long as the maternal platelet count is above $80 \times 10^9/L$. As neither condition poses risks for mother or child, management decisions with respect to center and mode of delivery are unnecessary. The performance of a diagnostic bone marrow aspiration is reserved for special indications. There is little value in testing for maternal platelet-associated IgG antibodies because the rates of false-positive and false-negative results are high.[3,12,16–18] The platelet count should be monitored every 2 weeks. If the count falls below $80 \times 10^9/L$, the patient is managed based on the assumption she has ITP.

Women with a History of ITP. If a woman has a history of ITP (with or without prior splenectomy), the platelet count should be monitored at an interval dependent on the initial platelet count every 2 weeks if it is below $80 \times 10^9/L$. The need for antenatal therapy is based exclusively on maternal indications[3,17] with the goal of maintaining the count above $20 \times 10^9/L$ (or higher in case of bleeding symptoms). The first line of treatment is the lowest effective dose of corticosteroids. Intravenous immunoglobulin (IVIG) is a second-line treatment, in case of corticosteroid refractoriness or side effects and because of its transient efficacy. The effect of IVIG lasts 2 to 3 weeks and often decreases or ceases with repetitive dosing. IVIG is best reserved for use late in pregnancy or immediately prior to delivery. Immunosuppressive drugs (azathioprine or vincristine—best avoided in the first trimester) and splenectomy (the second trimester is the best time) may rarely be needed. There is no demonstrable effect of maternal treatment such as corticosteroids[24,27] or IVIG on the fetal platelet count.[25] However, higher dosages of corticosteroids have not been investigated in controlled studies.

Labor and Delivery

A history of splenectomy, current maternal thrombocytopenia or treatment for ITP, or thrombocytopenia in a sibling at birth dictates delivery at a center with expertise in maternal-fetal medicine. A maternal platelet count above $50 \times 10^9/L$ is generally considered safe for either vaginal or cesarean delivery, though the factual basis for this recommendation is weak. Many members of a consensus panel consider a platelet count of $>30 \times 10^9/L$, without bleeding, safe for vaginal delivery.[12] A low platelet count may in point be an argument against cesarean delivery. Should the count be below $50 \times 10^9/L$, either platelet transfusions or preferentially IVIG, or both may be given in time to raise the counts during labor and delivery. A maternal platelet count above 70 to $80 \times 10^9/L$ is often recommended if epidural anesthesia is planned.[3,26]

The evidence is convincing that route of delivery does not alter the risk of severe perinatal internal hemorrhage,[3,6,12,16,17] and cesarean delivery is undertaken for traditional obstetric indications. However, it is prudent to avoid invasive manipulations such as fetal scalp blood sampling, or vacuum extraction or rotational forceps.[3,12,26]

Several investigators have suggested either cordocentesis or fetal scalp blood sampling to estimate the perinatal platelet count. However, this practice cannot be condoned because altering the route of delivery based on the perinatal platelet count does not change the outcome. Further, scalp blood samples are subject to technical errors, and the maternal and fetal risks of cordocentesis clearly exceed the risk of fetal hemorrhage from ITP.

Routine thrombosis prophylaxis in case of surgical delivery, immobilization, or individual risk factors should be undertaken unless there is either bleeding or severe thrombocytopenia ($<50 \times 10^9/L$). When the platelet

count is between 50 and 100×10^9/L, the risks of thrombosis and bleeding should be carefully weighed against each other.[3]

Postnatal

The maternal platelet counts generally improve over the first 6 weeks. Either tranexamic acid (1 g given three times daily) or hormonal therapy may help reduce excessive vaginal bleeding. Breastfeeding is not contraindicated.[12,24]

The newborn's platelet count, even if normal at birth, should be tested for at least the first 5 days, as one third develop a delayed thrombocytopenia.[7,15] Neonates with counts below 50×10^9/L may bleed, and the risk for intracranial hemorrhage is 0% to 1.5%.[12,13] IVIG, with or without corticosteroids, is the first-line treatment for the neonates whose counts are below 50×10^9/L and is combined with platelet transfusion if the counts are below 20×10^9/L or there is bleeding.[3,7,17,68] Brain imaging e.g., ultrasound is recommended in these cases.

Summary

The management of ITP during pregnancy is based on several large and well-designed clinical cohort studies that demonstrate that ITP runs a benign course in pregnancy for both mother and child. Severe fetal bleeding and in utero intracranial hemorrhage remain unreported. Should one be confronted with such a case, other bleeding disorders and alloimmune antibodies must be sought before assuming the explanation is ITP.

CONCLUSIONS

- ITP is relatively common during pregnancy, but in instances of thrombocytopenia above 80×10^9/L, gestational thrombocytopenia is 10 times more common.
- In pregnancies with a history of ITP, the likelihood of a nadir neonatal platelet count below 50×10^9/L is 9% to 15%, and the risk of major (intracranial) bleeding 0% to 1.5%. In a third of the cases, thrombocytopenia develops during the first 4 days postnatally.
- The probability of fetal thrombocytopenia is higher if a prior sibling was thrombocytopenic, or the mother has had splenectomy, or has severe thrombocytopenia and requires ITP treatment during pregnancy.
- Severe in utero bleeding has not been documented.
- Cesarean section is not indicated for presumed fetal thrombocytopenia.
- Cordocentesis is not recommended, and a scalp platelet count is unreliable.
- Minimize fetal blood sampling in labor and assisted vaginal delivery.

SUMMARY OF MANAGEMENT OPTIONS
Isoimmune Thrombocytopenia

Management Options (see Fig. 15–1)	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Risk of neonatal thrombocytopenia is increased if there was a previously affected pregnancy.	III	B	20, 22
Avoidance of pregnancy arguably is an issue only in women refractory to splenectomy, steroids, and immunosuppression.	III	B	12
Prenatal			
Laboratory investigations:			
• Exclude other causes (see Table 15–1).	II	B	6,7
• Monitor maternal platelet counts fortnightly through pregnancy of history ITP or platelet count <80×10^9/L.	IV	D	3,12
Treatment:	III	B	3,17
• Threshold target titer varies between 30 and <50×10^9/L.			
• Corticosteroids are first-line therapy (<0.5–19/kg); toper to lowest dose.	IV	C	3,12
• IVIG (intravenous immunoglobulin) is best reserved for administration between 36 and 37 weeks (predelivery).	IV	D	3,12

SUMMARY OF MANAGEMENT OPTIONS
Isoimmune Thrombocytopenia *(Continued)*

Management Options (see Fig. 15–1)	Quality of Evidence	Strength of Recommendation	References
Prenatal–Continued			
• Consider splenectomy with severe ITP in early pregnancy with no response to steroids or IVIG; immunosuppressives (vincristine and azathiaprine) are options for refractory disease in late pregnancy.	–	GPP	–
Labor and Delivery			
Plan delivery in center with appropriate multidisciplinary expertise.	–	GPP	–
Aim for platelet count >50 × 10⁹/L for delivery.	III	B	3,17,27
Maternal platelet transfusion is needed to cover delivery if the platelet count is <50 × 10⁹/L.	–	GPP	–
Epidural anesthesia likely safe if platelet count >80×10⁹/L	III	B	26
No evidence that cordocentesis at 38–39 weeks and fetal scalp blood sampling in labor are justified.	III	B	3,6,12,16,17
Cesarean section is performed entirely for obstetric indications; no evidence shows that any fetal/neonatal hemorrhage risk is lessened by elective cesarean section.	III	B	3,6,11,12,16,17
Minimize (some advocate avoidance of) fetal scalp sampling and assisted vaginal delivery, especially by vacuum extraction.	III	B	3,12,16,17
Episiotomy should be avoided if possible with low maternal platelet counts.	–	GPP	–
Postnatal			
Monitor neonatal platelet counts for 5 days:	III	B	3,7,17
• IVIG if <50 × 10⁹/L	IV	B	68
• Platelet transfusion if <20 × 10⁹/L if clinically indicated			
Breastfeeding is not contraindicated.	III	B	24,27

ITP, isoimmune thrombocystic purpura; IVIG, intravenous immunoglobulin.

ALLOIMMUNE THROMBOCYTOPENIA

Incidence

Alloimmune thrombocytopenia in the perinate results from maternal antibodies directed against an alloantigen on the fetal platelet membrane, localized to glycoprotein (GP) IIIa (CD61) of the GP IIb/IIIa complex. The preferred terminology for these alloantigens is presently human platelet antigen (HPA), though other names linger in the literature. The first discovered antigen system was named Zw (Zwᵃ and Zwᵇ) after the first two letters of the patient's family name.[28] A few years later, the PLᴬ system, which appeared to be identical to Zw, was described.[29] The International Platelet Antigen Working Party suggests the name human platelet antigen (HPA).[30] The nomenclature is based on the chronologic numbering of alloantibodies in the order of their discovery. The letter "a" or "b" is assigned to the high- and low-frequency alleles, respectively. "W" marks an HPA system antigen of which only one allele is identified so far. Finally, a few "private" or family-restricted antigens are described that have been identified only on the platelets of members in one family, and thus do not qualify for an HPA number.

The incidence of a particular HPA varies by race.[31] In whites, 2% are negative for HPA-1a, which accounts for about 85% of FNAIT. Anti-HPA-1a antibodies are produced in approximately 11% of the HPA-1a negative mothers.[32,33] The other antigens most commonly involved in FNAIT among whites are the HPA-5b and HPA-3a.[31]

The development of anti-HPA-1a antibodies is strongly associated with the presence of the HLA class type II DRB3*0101. The absence of DRB3*0101 in a HPA-1a negative woman virtually precludes the development of antibodies. About a third of HPA-1a negative women who are DRB3*0101 positive develop antibodies.[32,34–40] The incidence of severe thrombocytopenia caused by anti HPA-1a antibodies approximates 1 in 1100 pregnancies.[32] Antenatal screening is not warranted.

Risks

In contrast to red blood cell immunization, platelet alloimmunization affects the first pregnancy in half of the cases.[41] Most infants with FNAIT are born either without symptoms or with petechiae or bleeding from puncture sites. The most serious complication of FNAIT is internal hemorrhage, such as gastrointestinal, lung, and intracranial bleeding, occurring in either the fetus or newborn. Intracranial hemorrhage (ICH) is the most common internal hemorrhage in FNAIT and causes serious perinatal morbidity and even death.[42,43] Serious bleeding, including ICH, is often associated with HPA-1a immunization. The risk of perinatal ICH as a result of HPA-1a incompability approximates 11% excluding and 15% including fetal deaths.[44] The results of two large, prospective antibody screening programs (25,000 women in Cambridge, England,[32] and 100,000 women in Norway [Husebekk, personal communication]) document in aggregate two severe ICH and one ICH without clinical consequence. Most cases of FNAIT are identified after the birth of an affected child. The degree of fetal thrombocytopenia reportedly remains similar or increases in 80% of subsequent pregnancies when the father is homozygous for the offending antigen.[45–51] Unfortunately, the predictive value of the antibody titer for the severity of fetal thrombocytopenia is inconsistent, though some studies observe that severe thrombocytopenia is associated with an anti–HPA-1a titer ≥1:32.[32,33] Antenatal screening is not practiced given the low prevalence of ICH in an unselected population and the appropriate reticence for unnecessary population-based screening.

The risk for ICH in a subsequent pregnancy of HPA-1a alloimmunized women depends on the obstetric history. In the large majority of FNAIT cases, the chance of an ICH in a subsequent pregnancy with an HPA-1a positive fetus, after the birth of a thrombocytopenic sibling without ICH, approximates 7%.[44] In contrast, the recurrence rate of ICH in subsequent offspring of women with a history of FNAIT and ICH in the older sibling approximates 75%.[44] In one review, ICH was reported to occur in utero in 80.5% of the at-risk pregnancies.[43] Most cases of ICH in utero occur in the third trimester, though ICH has been documented before 20 weeks.[52,53] ICH in utero may cause either fetal death or, if the fetus survives, fetal hydrops or hydrocephalus.

It is unknown why one fetus with AITP may experience severe antenatal (intracranial) bleeding in contrast to another fetus with a comparable degree of thrombocytopenia due to maternal ITP who does not suffer this complication. In addition, there is only mild bleeding in the majority of ITP patients when it does occur in the fetus/newborn, whereas in alloimmune (anti-HPA-1a) thrombocytopenic conditions, as in post-transfusion purpura, bleeding may be life-threatening. The GP IIb/IIIa complex on the platelet membrane carries not only the amino acid difference between HPA-1a (Leu[33]) and HPA-1b (Pro[33]) but also most of the autoantigens involved in ITP antibodies. The IIb/IIIa complex is expressed not only on platelets but also on vascular endothelium. Although no data are available, one may postulate that the density of antigenic molecules of HPA-1a and the autoantigens on IIb/IIIa may be different. Differences in antigen density or in the nature of the antibodies may result in antigen-antibody reactions initiating different immune-mediated cascades involving complement, coagulation activation, and cytokine induction. A severe bleeding risk in a fetus or neonate often affects cerebral vessels, whereas in adults other bleeding sites emerge.

Management Options (Fig. 15–2)

Prepregnancy

Prepregnancy management begins with an accurate diagnosis of FNAIT in the newborn with thrombocytopenia. Platelet alloimmunization should be part of the differential diagnosis in all cases of neonatal thrombocytopenia (platelet count $<100 \times 10^9$/L in term infants). The laboratory evaluation includes the following:

- Confirming the presence of anti-HPA autoantibodies against platelets in maternal serum.
- Cross-matching of the maternal serum with paternal platelets, both untreated and chloroquine-treated (to remove HLA antigens that may cause a "false positive" test).
- HPA pheno- or genotyping of mother and father.
- Exclusion of maternal thrombocytopenia.

When the diagnosis of FNAIT is established, and the couple is considering another pregnancy, careful prepregnancy counseling in a specialized center is advised. Counseling should include documentation of disease severity in the index case, the antibody specificity, and the hetero/homozygosity of the father. The option of artificial insemination with the sperm of a donor negative for the offending antigen should be discussed.

Prenatal

Antenatal diagnosis is feasible when the father is heterozygous for the offending antigen. Although fetal genotyping is possible using chorionic villi, amniocentesis in the early second trimester is generally preferable because of its lower risk of boosting sensitization and pregnancy loss. Genotyping for all-important HPAs is possible using polymerase chain reaction (PCR). In very severe instances, donor insemination or preimplantation diagnosis using single cell of the blastomere can be considered.[54] When the fetus is positive for the offending antigen and at risk for severe thrombocytopenia, the pregnancy should be managed in or in collaboration with

a specialized fetal medicine center. Monitoring of anti-HPA antibodies cannot accurately predict the severity of fetal thrombocytopenia,[55,56] but a high titer (>1:32) may imply severe thrombocytopenia.[32,33]

Several strategies can be used for the monitoring and treatment of pregnancies at risk for FNAIT,[45–51] including fetal blood sampling with platelet transfusion when indicated, and maternal treatment with high-dose intravenous immunoglobulin (IVIG) and corticosteroids. In

one review of the literature, 26 different combinations of treatment were reported.[43] Unfortunately, no controlled trials compare intervention to nonintervention, and all recommendations are based on historical control subjects and natural history surveys. With these limitations, the current treatment of choice is a weekly maternal infusion of immunoglobulin at a dose of 1 g/kg of maternal weight. Several case series published since the initial report of Bussel and associates in 1988[57] confirm that weekly IVIG effectively increases the fetal platelet count to a variable degree.[58-61] The result of a multicenter, prospective randomized trial comparing IVIG with or without dexamethasone revealed a 70% response rate with IVIG alone,[62] and dexamethasone did not improve the effect when used routinely. Significantly, there were no instances of ICH in IVIG-treated perinates in this study and others,[61,63] even if they failed to respond with an increased platelet count.

Although cordocentesis is the only tool available to directly monitor the severity of fetal thrombocytopenia, its routine use is not advised. Fetal blood sampling has caused fatal hemorrhage from the umbilical cord puncture site in fetuses with a low platelet count. Special precautions may lower the risk of complications in these patients (Table 15–2). The published literature reports a mean fetal loss rate of cordocentesis in FNAIT pregnancies of 1.6% per procedure. In addition, there is a risk of procedure-related complications such as emergency cesarean section for fetal bleeding and bradycardia in 2.4% per procedure.[44,61,64,65] The reported complications might be method-related, as no increase was seen when a needle guide was used.[66] Platelet transfusion is problematic because the half-life of transfused platelets is only 4 to 5 days. Thus, fetal blood sampling and platelet transfusions are required frequently throughout pregnancy once initiated, introducing a cumulative risk for complications. The transfused platelets may degranulate and release serotonin, compounding the risk of a bradycardia. The cumulative risk of fetal loss with transfusion therapy approximates 6% per pregnancy.[66,67] Given the 70% likelihood that the initial fetal platelet count at cordocentesis between 20 and 28 weeks in FNAIT pregnancies with affected siblings is $\leq 50 \times 10^9/L$,[45] we suggest IVIG be begun as a precaution after the amniocentesis genotype results confirm an affected fetus.

TABLE 15–2

Extra Safety Precautions for Fetal Blood Sampling in Pregnancies at Risk for Severe Thrombocytopenia

The procedure should be performed by the most experienced members of a fetal medicine unit.

Sample in the umbilical vein and thus avoid puncturing the artery.

Use a hematologic cell counter in order to obtain the platelet count within 2 minutes.

If the fetal platelet count is $<50 \times 10^9/L$, compatible platelets should be infused before withdrawal of the needle.

The antenatal management protocols in FNAIT should be based on the following principles. First, the primary goal is the prevention of ICH and not just fetal thrombocytopenia per se. Second, the protocol should reflect the obstetric history. Given the fact that the large majority of patients have a sibling with a history of more or less severe thrombocytopenia, but without ICH, and the risk of ICH approximates the procedure-related complication rate of invasive therapy, it is best to avoid cordocenteses in these patients. Considering that the majority of in utero ICH occurs later in pregnancy and the cost of IVIG, treatment of pregnancies with no ICH history may be delayed to 28–32 weeks (see Fig. 15–2). We have seen no ICH or other serious morbidity applying this approach to 40 women in Leiden over the past few years.[67] In fetuses whose siblings experienced an ICH, IVIG should be initiated to 12 to 18 weeks followed by cordocentesis at 24 to 28 weeks to evaluate the response. When the anticipated risk of complication from cordocentesis is higher (e.g., less experienced operators), the IVIG can be continued until delivery without periodic cordocentesis (see Fig. 15–2). In recent years, we treated eight pregnancies in six women with an older sibling with ICH according to this less invasive protocol. Each received IVIG (median 20 weeks; range 8–24 weeks) without initial or follow-up cordocentesis. In four pregnancies, one fetal blood sampling, with platelet transfusion was performed at term. In these pregnancies labor was induced between 37 and 38 weeks, within 3 days of the intrauterine platelet transfusion. Elective cesarean section was performed in five pregnancies between 34 and 37 weeks. All perinates had a platelet count of less than 50×10^9/L (three were $< 20 \times 10^9$/L), either at birth or in the predelivery cordocentesis sample. Four of the neonates received one platelet transfusion after birth. None of the neonates showed any signs of internal or external bleeding. In the very rare case, a patient with a history of ICH might benefit from either rescue corticosteroids or a higher dose of IVIG despite the early initiation of IVIG (1 g/kg/week).

Labor and Delivery

Ideally, labor should be planned by the obstetrician in close consultation with the fetal medicine and pediatric teams and the blood bank to assure compatible platelets

are available shortly after birth. A term delivery can be achieved in almost all pregnancies treated with IVIG. If serial fetal platelet transfusions are necessary for local reasons, we suggest elective delivery after 32 weeks because of the risks of the procedure.

There is no consensus about the safety of vaginal birth in FNAIT infants. However, there is no evidence that a vaginal birth enhances the risk for ICH in a treated term infant with FNAIT. The preponderance of perinatal ICH in FNAIT occurs before the start of labor.[43,44] Similar to ITP, we suggest an instrumented vaginal delivery be avoided if the fetal platelet count is unknown. In Leiden, we perform cesarean delivery for obstetric indications only in women with platelet alloimmunization, whose prior child did not suffer ICH and who has been treated antenatally with IVIG. Last, cesarean delivery does not guarantee protection against the perinatal occurrence of ICH in a severe thrombocytopenic infant.

Postnatal

In platelet alloimmunized pregnancies, the newborn's platelets count should be tested daily for the first 5 to 7 days. In case of thrombocytopenia the neonate may respond to IVIG. In case of fetal thrombocytopenia, brain imaging should be performed. In severe cases and infants treated prenatally with at least 4 weeks with IVIG, transfusion with compatible platelets is the first-line treatment. Breastfeeding is not contraindicated in FNAIT newborns.

Summary

Severe platelet alloimmunization, leading to perinatal ICH is a rare but potentially disastrous condition. Management strategies should focus on the prevention of ICH and not thrombocytopenia per se. There is a lack of adequately sized, well-designed control studies regarding management. After the index pregnancy, the obstetric history is one of the important factors for risk estimation of ICH. The majority of ICH cases occur during fetal life. Maternally administered IVIG is the first line of therapy in pregnancies at risk for severe disease, and appears to significantly reduce the risk of ICH even when there has been no reponse in the fetal platelet count.

CONCLUSIONS

- Because there is no effective screening, the diagnosis of alloimmune thrombocytopenia is typically made after the birth of an affected child.
- Antenatally, the diagnosis of FNAIT should be considered in fetuses with ICH, hydrocephalus, hydrops, or tumor in cerebrum.
- Intravenous immunoglobulin given to the mother is first-line therapy, with steroids being used for the IVIG-resistant cases. Timing depends on obstetric history.

- Cordocentesis can be avoided in women with no history of ICH in the older sibling.
- When there is an older sibling with ICH, IVIG may be given without cordocentesis, especially if the risk of the procedure is anticipated to be high.

SUMMARY OF MANAGEMENT OPTIONS
Alloimmune Thrombocytopenia

Management Options (see Fig. 15–2)	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Review history of index case, including severity.	–	GPP	–
Investigate:	–	GPP	–
• Confirm human platelet antigen (HPA) antibodies in mother.			
• HPA genotyping of both parents is needed.			
• Exclude maternal thrombocytopenia.			
• Cross-match maternal serum with paternal platelets.			
Provide careful counseling of parents about risks (main risk is intracranial hemorrhage, ICH) and potential management (including donor insemination from HPA-negative donor).	–	GPP	–
In addition to the parents, members of the mother's family should be typed to establish whether her sisters are at similar risk during their pregnancies.	–	GPP	–
Prenatal			
Management requires specialist center.	–	GPP	–
With heterozygous father, perform amniocentesis early in second trimester to determine fetal genotype by polymerase chain reaction	III	B	55, 56
No further action is taken if the fetus types as HPA negative.	–	GPP	–
Maternal titer does not predict severity.	III	B	55, 56
Treatment regimen varies and is controversial:	IV	C	43
• Maternal administration of IVIG (intravenous immunoglobulin) weekly (1–2g/kg maternal weight) is the main approach; timing might be determined by severity in previous baby.	III	B	57, 58–62
• Fetal blood sampling for fetal platelet count might be reserved only for those with previous ICH; advisable to defer sampling until after IVIG regimen is under way because >70% of fetuses will be <50 × 10⁹/L; timing also might be determined by severity in previous baby (see Table 15–2).	III	B	64
• No evidence shows that initial use of oral corticosteroids with IVIG yields any better response than using IVIG alone.	Ib	A	63
• Some reserve use of oral corticosteroids for IVIG-resistant cases.	III	B	57
• Repeated fetal platelet sampling and intravascular transfusions of fresh platelets are used only in those cases that fail to respond to maternal therapy.	III	B	57, 58–62
Regular ultrasound of fetal brain is needed.	–	GPP	–
Labor and Delivery			
Close liaison with pediatric staff is necessary.	–	GPP	–
Mode of delivery depends on the fetal platelet count. A trial of labor is reasonable if the count is >50 × 10⁹/L.	III	B	43, 44

Fetal Cardiac Arrhythmias: Diagnosis and Therapy

Christopher S. Snyder / Joshua A. Copel

INTRODUCTION

Clinical Significance

Fetal cardiac arrhythmias are common in clinical practice. Most reflect transient, isolated ectopic beats. However, sustained episodes can occur and, if not treated appropriately, can lead to congestive heart failure, nonimmune hydrops, and even fetal or neonatal demise. In this chapter we define fetal arrhythmias and review their frequency, the methods of detection, and their basic mechanisms. With this foundation, we will provide the recommendations for the detection and differentiation of arrhythmias as well as their management. We illustrate the importance of a team approach to fetal arrhythmia management, involving physicians from each subspecialty needed to care for mother, fetus, and the newborn.

History

Cremer first described fetal electrocardiography in 1906.[1] Fetal electrocardiography proved reliable for identifying tachycardias but was limited in its ability to determine the etiology. In the 1950s, Smyth described invasive electrocardiographic monitoring with an intra-amniotic electrode.[2] Despite this technologic advance, its use remained limited because it required ruptured membranes for access.

With the advent of echocardiography, and specifically M-mode, the field of fetal arrhythmia detection and differentiation blossomed. Robinson and Shaw-Dunn detailed the use of M-mode in the evaluation of fetal arrhythmias during the early 1970s.[3] As ultrasound technology expanded to include two-dimensional and both spectral and color Doppler modes, numerous authors described additional echocardiographic techniques for the identification and differentiation of fetal arrhythmias.

Definition

A fetal dysrhythmia is best defined as an irregularity in the fetal cardiac rhythm or a regular rhythm that remains outside the normal range. The currently accepted normal range in clinical practice is between 100 and 160 bpm, although no standard rate has been formally established, and somewhat higher rates may be seen during labor, especially with maternal fever. The American College of Obstetrics and Gynecology (ACOG) established a range at term as "usually 120–160 beats per minute."[4] This range does not exclude hypoxic fetuses. Davignon found the minimum heart rate for infants younger than 1 day of age was 88 bpm, the mean was 123 bpm, and the maximum was 168 bpm in a study of nearly 200 healthy children.[5] Any of these ranges may serve as a guide, and the identification of heart rate may be based on data collected for an extended period to assure that any deviations are not associated with uterine contractions, periodic decelerations, maternal fever, or physiologic fetal activity such as hiccupping.

Frequency

Fetal arrhythmias are relatively common at routine obstetric visits, with a frequency ranging from 1% to 3% of all pregnancies.[6,7] The most common causes of irregularities are either extrasystoles or respiratory sinus arrhythmia. Respiratory sinus arrhythmia is the variation in the heart rate related to respiration, increasing with inspiration and decreasing with expiration. It is not associated with symptoms or abnormalities and requires no further evaluation. Extrasystoles occur in upwards of 14% of term, healthy newborns[8] and account for 43% to 98% of fetal arrhythmia referrals.[9,10] The vast majority of the extrasystoles are atrial in origin, with premature ventricular contractions accounting for less than 4%.[9–11]

TABLE 16-1

Fetal Cardiac Arrhythmias

ARRHYTHMIA	NUMBER
Isolated extrasystoles	1213
Tachycardias	114
Supraventricular tachycardia	69
Atrial flutter	21
Sinus tachycardia	7
Ventricular tachycardia	7
Atrial fibrillation	4
Atrial ectopic tachycardia	4
Junctional tachycardia	2
Bradycardias	51
Complete AV block	39
Second-degree AV block	10
Sinus bradycardia	2

The fetal arrhythmias diagnosed in 1384 patients evaluated at our institution over 20 years are listed in Table 16–1. The experience reflects the general findings of others that extrasystoles are the most common cause of fetal arrhythmias and that tachycardias are more than twice as common as bradycardias.[7,10] The most common causes of fetal tachycardias are atrioventricular (AV) reentry supraventricular tachycardia (SVT), atrial flutter, and sinus tachycardia. Rare causes of SVT include atrial ectopy, atrial fibrillation, junctional tachycardia, and ventricular tachycardia, each constituting less than 1% of fetal arrhythmias.[9,10,12] The most common cause of fetal bradycardia is complete AV block, which accounts for more than three quarters of cases. Other, less frequent causes of bradycardia include isolated sinus bradycardia, advanced second-degree AV block, prolonged QT interval syndrome, and fetal toxicity.[13,14]

ASSESSMENT OF A FETAL ARRHYTHMIA

A variety of methods are available for the evaluation of fetal cardiac arrhythmias. The majority of techniques are noninvasive, though invasive techniques, such as scalp electrodes, are used occasionally. Herein, we focus on the commonly used noninvasive techniques, their advantages and disadvantages, and the future of fetal arrhythmia detection and differentiation.

When a fetal dysrhythmia is detected, the physician must determine the etiology of the abnormal rhythm. Multiple factors must be considered, given that fetal dysrhythmias can result from maternal connective tissue disorders, drugs, hyperthyroidism, or infection, or can be a sign of fetal compromise or an arrhythmia.[14–18] A complete maternal assessment should be made, including inquires regarding recent illnesses, medicinal and recreational drug use, caffeine intake, and signs of hyperthyroidism. A complete family history is essential with an emphasis on the presence of inherited causes of arrhythmia, such as prolonged QT interval syndrome, deafness

(associated with prolonged QT interval syndrome), previous fetal demise, sudden unexplained death in family members younger than 50 years of age, and tuberous sclerosis. In addition, the fetus must be thoroughly evaluated for signs of hydrops, compromise, or structural cardiac disease.

Auscultation

The simplest method to detect a dysrhythmia is auscultation with a stethoscope. The technique is a quick, easy, and readily reproducible tool for ascertaining fetal heart rates. It was also the most common method of fetal heart rate assessment prior to electronic fetal monitoring (EFM).[19] Since the advent of EFM in the 1960s, the use of fetoscopic auscultation has dwindled. If a brady- or tachyarrhythmia is detected during auscultation, further investigation into the cause of the dysrhythmia is indicated.

Doppler

Doppler ultrasound is the most commonly used screening tool for fetal dysrhythmia detection. A beam of sound is directed toward fetal cardiac structures such as valves, walls, and aortic pulsations that is reflected back to the transducer at a slightly different frequency due to tissue or blood movement. Doppler principles are employed in two readily available devices; the handheld Doppler device, which is frequently used for routine office assessment of the fetal heart rate, and as part of cardiotocography. Both devices have proved to be highly effective tools for the detection of fetal dysrhythmias. The handheld devices can be used from the 12th week of gestation, while cardiotocography is not usually used before 24 weeks.

Fetal Electrocardiography

The fetal electrocardiogram (FECG) is another method for the detection of fetal dysrhythmia. It is similar in principle to standard electrocardiography, with the placement of electrodes on the maternal abdomen to record the differences in electrical potential arising from the fetal cardiac electrical activity. Most fetal QRS complexes are easily identified from the raw signal with FECG, and with signal averaging, the P waves can be located occasionally. T waves are rarely seen on these recordings. Fetal heart rate tracings can be obtained in approximately 60% of long-term (8–24 hours) recordings in late gestation.[20]

The advantage of FECG is that it is a reflection of the cardiac electrical and not the mechanical activity. When P waves are visible on the FECG, the exact cause of the arrhythmia can be deduced. In addition, FECG tracings can be obtained quickly, and because the units are small and simple, they can be used for long-term outpatient

monitoring. The major problems are poorly reliability and limited signal acquisition. The fetal cardiac signal is attenuated by amniotic fluid, the distance from the electrical activity to recording surface, and the small size of the fetal heart. Because of limited signal acquisition, atrial activity is rarely recorded, limiting the FECG's current clinical use in arrhythmia diagnoses.

Magnetocardiography

Described by Kariniemi in 1974, fetal magnetocardiography (FMCG) has evolved from a research tool to an important clinical modality.[21] FMCG noninvasively records the cardiac magnetic activity of the fetal heart generated by electrical excitation, and with specialized offline analysis of the magnetic activity, an equivalent of the surface electrocardiogram (ECG) is created. Its use and reliability are documented from 20 weeks to birth.[22] Numerous studies demonstrate the accuracy of FMCG for the diagnosis of fetal arrhythmias such as atrial and ventricular ectopy, supraventricular tachycardia (SVT), atrial flutter, complete atrioventricular (AV) block, torsades de points, and ventricular tachycardia (VT).[23–25]

The advantages to FMCG over FECG include the following: it takes less time (seconds vs. minutes), it overcomes the assumption mechanical activity correlates with electrical activity, and it has greater reliability. And because FMCG is currently the only antenatal method of measuring cardiac repolarization, it is the only way to antenatally diagnose prolonged QT interval syndrome. Conversely, the disadvantages of FMCG are its size, high cost, and limited availability of the equipment, and these factors limit its use in current clinical practice.

Echocardiography

Fetal echocardiography is the current gold standard for the diagnosis and monitoring of fetal arrhythmias. Its status is due, in part, to its widespread availability and relative ease of use. A significant advantage of fetal echocardiography is its safety throughout pregnancy, starting as early as 11 weeks[26] with a transvaginal probe and 14 weeks transabdominally. Both fetal atrial and ventricular rates along with the AV activation sequence are readily seen. Knowledge of the activation sequence facilitates differentiation of the arrhythmia into ventricular or supraventricular and long or short AV tachycardia. In addition, fetal well-being, cardiac structure, and hemodynamics can be evaluated concurrently with the arrhythmia assessment.

In addition to a careful examination of the fetal heart and circulation, assessment of a fetal arrhythmia should result in a detailed, full sonographic examination of the fetus, looking for syndromic features, especially chromosomal.

The two most common echocardiographic methods of arrhythmia analysis are M-mode and spectral Doppler. Although either method alone is reliable in the majority of fetuses, comfort in performing and interpreting both techniques is essential in the event that fetal position or ultrasound window access limits the use of one or the other method. In the following sections, the methods, advantages, and disadvantages of the M-mode and Doppler techniques of fetal arrhythmia assessment are outlined.

M-mode

In M-mode echocardiography, the M-mode line is positioned by two-dimensional (2D) image guidance to transect one structure that represents atrial contraction (atrial wall) and one that represents ventricular contraction (ventricular wall, or aortic or pulmonary valve). Atrial systole is represented by the onset of atrial wall movement or the A peak of the mitral or tricuspid valve, and ventricular systole is represented by the onset of ventricular wall movement or the opening of either the aortic or pulmonary valve. The fetal cardiac mechanical movements are then plotted against time. From a hard copy of the M-mode tracing, a "ladder diagram" of atrial and ventricular activity can be constructed[27] (Fig. 16–1). Cardiac time intervals are then measured from the M-mode tracing along with the sequence of atrial and ventricular events and intervals (VA and AV).

The main limitations of M-mode echocardiography are technical (obtaining properly positioned and interpretable tracings) and the assumption that mechanical cardiac events reflect electrical events. The latter can lead to an errant diagnosis with junctional ectopic tachycardia, which occurs when the electrical focus originates in the AV node. By M-mode echocardiography, the mechanical activity of the ventricle precedes the atria, thus mimicking ventricular tachycardia. Atrial wall motion may be minimal in atrial fibrillation or in the setting of a dilated, poorly contractile atrium. Lastly, discerning the A waves of the mitral or tricuspid valve can be quite challenging.

Spectral Doppler

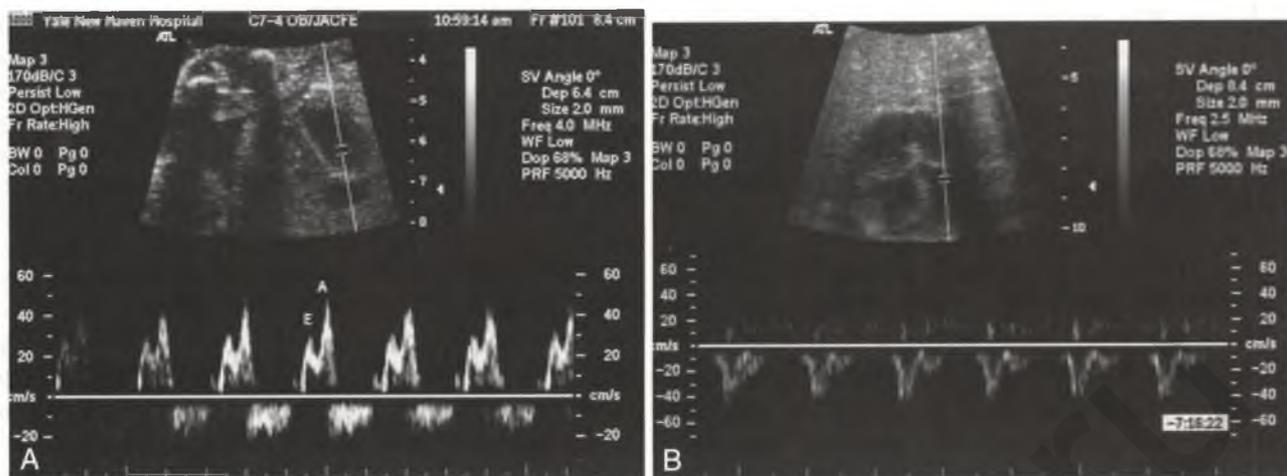
Spectral Doppler is the second echocardiographic method for fetal arrhythmia assessment. Similar to M-mode, the sample volume is placed under 2D image guidance in a location that allows for the simultaneous recording of flow events that represent atrial and ventricular systole. The sample volume can be placed in a number of locations, such as the left ventricular outflow tract, which will record mitral valve inflow and ventricular outflow, the pulmonary vein and pulmonary artery, the inferior vena cava and the aorta or the superior vena cava and aorta.[28–32] The simplest to obtain is left ventricular inflow and outflow from an apical 4-chamber view (see Fig. 16–1). After the appropriate sample volume position has been attained, a tracing of the flow velocity is recorded, a ladder diagram is constructed, and the sequence of atrial and ventricular events and intervals is


FIGURE 16-1

A, Doppler flow velocity waveform of normal flow across the mitral valve. Note that early ventricular filling (E) has a lower velocity than active atrial systole, reflecting the dependence of the fetal myocardium on atrial systole to overcome the inherent stiffness of the immature muscle. *B*, Doppler flow velocity waveform of flow across the mitral valve in a fetus with reentrant tachycardia. Note the reversal of the normal E:A ratio. Time scale is twice that shown in *A*.

deduced similar to M-mode. The main limitation is that this requires proper fetal positioning and the need to place the Doppler sample volume from an apical four-chamber view so as to maximize both inflow and outflow velocities.

MECHANISMS OF TACHYARRHYTHMIAS

Fetal arrhythmias are generally first detected during routine prenatal visits or ultrasound examinations. Transient fetal rhythm disturbances represent 20% to 30% of all indications for fetal cardiac evaluations at tertiary centers.[33] Frequently, the cause of these transient arrhythmias is extrasystoles. The incidence of malignant fetal arrhythmias, ventricular and supraventricular, is unknown but are felt to be rare. The most common causes of fetal tachycardias are AV reentry supraventricular tachycardias (SVT), atrial flutter, and sinus tachycardia. Rare causes of fetal tachycardia include atrial ectopy, atrial fibrillation, and junctional and ventricular tachycardia, which constitute less than 1% of fetal arrhythmias. Knowledge of the incidence, mechanism, and associated morbidity and mortality rates of the different arrhythmias is critical in determining the appropriate treatment for the fetus.

IRREGULAR HEART RATE

Premature Atrial Contractions

Premature atrial contractions (PACs) are the result of nonsinus atrial depolarization that occurs earlier than the expected sinus beat. PACs can originate from either the right or left atrium and are conducted through the AV node either in the normal fashion or aberrantly, or they may block at the level of the AV node. PACs are the most common fetal dysrhythmia, with a prevalence of 1% to 3% of all pregnancies.[34] PACs are associated with illicit drug use, trisomy 18, and hyperthyroidism.[35] It is also hypothesized that PACs are caused by an aneurysm of the flap valve of the foramen ovale.[36] Rarely, isolated PACs are reported to trigger episodes of sustained SVT. Fetal PACs are easily recognized either by their characteristic early atrial wall movement (M-mode) or mitral inflow (Doppler) pattern.

Management Options

Isolated PACs require no treatment, but because of their association with SVT, weekly auscultation of the fetal heart rate is prudent until the ectopic beats resolve. There is no increase in the incidence of structural heart disease in affected fetuses.[9] Patients are advised to avoid caffeine and medications that may increase ectopy, such as β-adrenergic drugs (e.g., terbutaline). Persistent postnatal ectopy warrants only a neonatal ECG and consideration for a 24-hour Holter monitor.

Premature Ventricular Contractions

Premature ventricular contractions (PVCs) are caused by early, nonsinus depolarization of the ventricles. A compensatory pause may be observed if the PVC is conducted retrogradely through the AV node to the atrium. PVCs produce a characteristic Doppler flow pattern with absence of diastolic flow across the AV (mitral) valve prior to the initiation of ventricular systole (aortic outflow). They account for approximately 2% to 4% of all fetal ectopy.

Management Options

PVCs are usually benign and generally warrant simple maternal avoidance of cardiac stimulants such as caffeine. Under rare circumstances, PVCs may be a harbinger of cardiomyopathy, myocarditis, structural cardiac malformations, or long QT interval syndrome.[37] Postnatal ectopy requires an ECG to evaluate the corrected QT interval and a 24-hour Holter monitor.

TACHYCARDIAS

Sinus Tachycardia

Sinus tachycardia in a fetus is defined as a sustained heart rate between 160 and 210 bpm. If the rate is greater than 210 bpm and is nonvariable, SVT should be considered. Persistent fetal sinus tachycardia may be secondary to acidosis, hypoxic ischemic encephalopathy, myocarditis, infection, maternal fever, and maternal drug ingestion.[38] Even though maternal thyroid hormone does not cross the placenta, prenatal thyrotoxicosis secondary to transplacental passage of thyroid-stimulating immunoglobulin (TSiG) with maternal Graves' disease has also been associated with fetal sinus tachycardia.[39] Management of persistent sinus tachycardia involves recognition and treatment of the underlying cause. Sinus tachycardia should be differentiated from ventricular tachycardia (see later discussion). In sinus tachycardia, atrial systole precedes ventricular contraction, whereas in ventricular tachycardia, ventricular contraction precedes the atrial systole. This can be difficult to distinguish in utero.

Supraventricular Tachycardia

Fetal SVT may present at any time after 15 weeks. SVT is a general term used to describe an arrhythmia originating at or above the bundle of His, and thus it is characterized by a narrow QRS complex (Fig. 16–2). The causes of SVT are categorized by their dependence on the AV node for propagation of the arrhythmia. Those that require the AV node to maintain the tachycardia (Wolff-Parkinson-White [W-P-W] syndrome, AV node reentry tachycardia [AVNRT], permanent junctional reciprocating tachycardia [PJRT], concealed accessory pathway [CAP] and Mahaim pathways) are referred to as AV node dependent. Those that do not (atrial fibrillation, atrial flutter, atrial and junctional ectopic tachycardia) are referred to as AV node independent tachycardias.

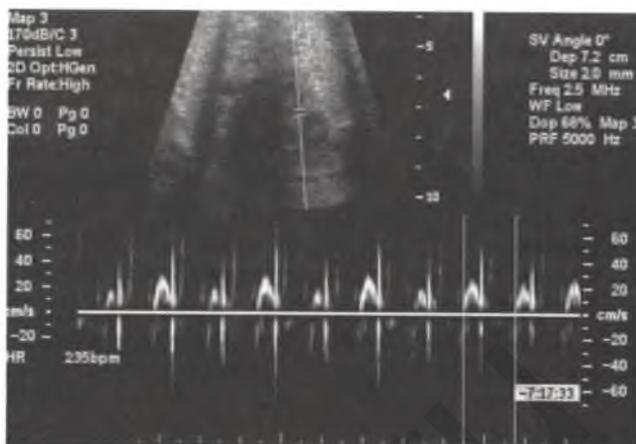
Based upon their mechanism of propagation, the AV node dependent SVTs are further divided into the short and long ventriculoatrial (VA) tachycardias. This distinction is important in determining the correct medication to control fetal tachycardia. The VA time in tachycardia is determined by simultaneous Doppler interrogation of


FIGURE 16–2
Doppler flow velocity waveform of flow into pulmonary artery in a fetus with reentrant supraventricular tachycardia. Typical rate of 235 bpm is shown.

either the SVC (A) and ascending aorta (V), or by measuring mitral (A) and aortic (V) flow in the left ventricular outflow. The VA time is considered long if it is greater than one half of the V-V interval.

AV Node Dependent SVT

SHORT VA TACHYCARDIA

The most common form of SVT is the short VA, AV node dependent SVT. This category includes concealed accessory pathways, W-P-W syndrome, and typical AV node reentry. Characteristics unique to these tachycardias include rates of 220 to 300 bpm (typically close to 240 bpm), little rate variability, and 1:1 VA concordance. Atrial and ventricular ectopies typically trigger abrupt initiation and secession of the tachycardia. The distinction between these arrhythmias generally cannot be made in utero. On rare occasions when a short VA SVT occurs in conjunction with structural cardiac disease (e.g., rhabdomyoma, ventricular inversion, or Ebstein's anomaly of the tricuspid valve), W-P-W syndrome should be suspected because of its known association with these lesions.

Management Options. In general these arrhythmias respond to transplacental digoxin or beta-blocker therapy. Occasionally, when digoxin or beta-blockers fail, second tier antiarrhythmic agents such as flecainide, sotalol, or amiodarone become necessary and are usually effective. Preterm delivery is rarely, if ever, indicated in nonhydropic patients with this form of SVT. When found close to term or with documented fetal lung maturity, delivery is preferable to attempts at in utero treatment. At a minimum, all patients should have a postnatal ECG to determine the etiology of the tachycardia, which will help guide further medication. If structural cardiac disease is suspected, a transthoracic echocardiogram should be performed. Usually, the

antiarrhythmic medication(s) are continued up to a year postnatally to avoid recurrence.

LONG VA TACHYCARDIA

Incessant slow fetal SVT may be due to a slowly conducting accessory pathway found in the permanent form of junctional reciprocating tachycardia (PJRT). The incidence of this fetal tachycardia is extremely rare. It is characterized by long VA times, an incessant nature, and slower rates (180–220 bpm) which can be misdiagnosed as sinus tachycardia. Due in part to its incessant nature, it can be a relatively dangerous arrhythmia, causing severe cardiac dysfunction and hydrops fetalis.

Management Options. PJRT rarely responds to digoxin or beta-blockade, so flecainide or sotalol would be the appropriate choices.

AV Node Independent SVT

ATRIAL FLUTTER

Atrial flutter accounts for 30% to 40% of all fetal tachycardias.[35] This rapid, regular atrial reentrant rhythm is characterized by atrial rates of 400 to 550 bpm. Because the reentry cycle occurs within the atrium, propagation through the AV node is not necessary to maintain the tachycardia. The ventricular rates vary, depending on whether there is uniform conduction of atrial beats. The most common form of AV conduction in fetal atrial flutter is 2:1 AV block. The diagnosis of atrial flutter can be made by a fetal echocardiogram showing a fast atrial rate with variable AV conduction or the typical sawtooth appearance on a fetal magnetocardiography (Fig. 16–3). Atrial flutter is associated with structural cardiac defects that dilate the atrium, such as Ebstein's malformation, atrial septal defects, hypoplastic left heart syndrome, and cardiomyopathy as well as with W-P-W syndrome.[34]

FIGURE 16–3
Flow in ductus venosus of a fetus with reentrant supraventricular tachycardia. Normal flow is unidirectional in contrast with bidirectional flow shown here (see Color Plate 4).

Hydrops occurs in upwards of 35% of the fetuses with incessant atrial flutter.

Management Options. The management of atrial flutter is based on either termination of the intra-atrial reentry, or by ventricular rate control. Ventricular rate control can be accomplished with the maternal administration of digoxin in the absence of hydrops fetalis. Sotalol has shown to be effective for termination of the arrhythmia in 80%.

It is prudent to continue transplacental treatment throughout pregnancy once the fetal rate is successfully converted, with careful attention to maternal drug levels, ECG, and symptoms to avoid adverse treatment effects. The prognosis for fetal atrial flutter is excellent if delivery is at term and there is no associated structural cardiac disease. After successful conversion to sinus rhythm, the majority of pediatric patients do not experience recurrence and require no treatment. Early delivery is indicated only if the fetus fails to respond to medications or has hydrops fetalis.

ATRIAL FIBRILLATION

Atrial fibrillation is a rare fetal arrhythmia with a reported incidence of 0.2%.[35] It is characterized by an extremely rapid, chaotic atrial rate of greater than 500 bpm with variable ventricular conduction. In cases of fine atrial fibrillation, the atria may appear to actually stand still during fetal echocardiography. Atrial fibrillation can occur in association with Ebstein malformation of the tricuspid valve, thyrotoxicosis, and cardiac tumors.

Management Options. No antiarrhythmic agent has to date been used to convert fetal atrial fibrillation to sinus rhythm. Ventricular rate control may be achieved with transplacental digoxin administration. The prognosis for atrial fibrillation is unknown, due in part to its relative rarity and the fact that the majority of cases are associated with structural and other conduction abnormalities. Postnatally, newborns are converted to a sinus rhythm through DC cardioversion. Atrial fibrillation is not an indication for early delivery unless hydrops fetalis develops, or fetal compromise is suspected based on biophysical testing.

ATRIAL TACHYCARDIA

Ectopic or chaotic atrial tachycardias are rare but are occasionally seen in the later stages of pregnancy. This arrhythmia is characterized by regular or irregular atrial and ventricular Doppler flow patterns depending on the atrial rate and AV conduction. It is typically well tolerated and hydrops fetalis is rare.

Management Options. Once the diagnosis is established, medical management should be initiated, but the arrhythmia is frequently resistant to basic drug therapies such as digoxin and beta-blockers.[40] Flecainide is the drug of choice for fetal atrial ectopic tachycardia. Postnatal recognition and treatment may be needed if the tachycardia is persistent.

JUNCTIONAL ECTOPIC TACHYCARDIA

Congenital junctional ectopic tachycardia (JET) is an extremely rare, incessant form of ectopic focus SVT. The focus is located within the AV node, resulting in near simultaneous electrical activation of the atria and ventricles, though dissociation of the ventricles from the atria can occur, mimicking ventricular tachycardia. This arrhythmia is unique in its inheritance pattern; approximately 50% have a close family member affected. JET is very difficult to diagnose in utero without magnetocardiography and is frequently resistant to conventional therapy. The mortality rate approaches 35% in infancy.[41]

Management Options. Fetuses with JET may respond to either amiodarone or sotalol.

VENTRICULAR TACHYCARDIA

Ventricular tachycardia (VT) is another relatively rare form of tachycardia with the focus originating in the ventricle(s). It may be associated with fetal myocarditis, myocardial dysfunction of any cause, or long QT interval syndrome. The most common form of VT is called slow ventricular tachycardia or accelerated idioventricular rhythm. The rate is between 160 and 200 bpm and does not warrant any intervention. Ventricular tachycardia is diagnosed when faster heart rates, greater than 200 bpm, are observed. In addition, AV dissociation is frequently seen, with the ventricular rate being faster than atrial rate.

Management Options. Sustained fast fetal ventricular tachycardia with or without hydrops fetalis is often refractory to treatment, which requires agents such as amiodarone or sotalol. Beta-blockers should be used in suspected long QT interval syndrome.

BRADYCARDIAS

Fetal bradycardia is defined as a persistent heart rate below 100 bpm not associated with uterine contractions or periodic decelerations. A thorough investigation into fetal well-being and cause of the dysrhythmia is warranted when fetal bradycardia is detected. First, extrinsic, noncardiac causes of fetal bradycardia such as drugs, maternal hypothermia, and mechanical compression of the umbilical cord must be excluded.[14,42] If the bradycardia persists and no obvious extrinsic causes are evident, the next step is to determine the exact rhythm (e.g., sinus bradycardia, partial or complete AV block) to facilitate appropriate management. As previously noted, a maternal history or screening for connective tissue disorders or drug use, along with a complete family history, probing for arrhythmias, pacemakers, and structural heart disease in close family members, is warranted.

Sinus Bradycardia

Sinus bradycardia can be differentiated from other causes of fetal bradycardia by Doppler or M-mode echocardiography. The hallmark of sinus bradycardia is the presence of a normal AV activation sequence. Confirmation that any slow heart rate is due to sinus bradycardia is mandatory to rule out advanced or complete AV block or blocked premature atrial ectopic beats. In addition to rhythm confirmation, a thorough fetal assessment is necessary to seek signs of fetal compromise, hydrops fetalis, or structural cardiac disease. Well-known causes of fetal sinus bradycardia include long QT interval syndrome and heterotaxy syndrome with left atrial isomerism, in which the fetus has two left atria, and thus lacks a true sinus node and right atrial structure.

Management Options

The management of a fetal sinus bradycardia depends on the cause, as well as the clinical status of the fetus. Close observation generally is all that is necessary if the fetus is not compromised, and all extrinsic causes of sinus bradycardia are removed. A postnatal ECG should be performed to rule out or confirm the presence of a prolonged QT interval.[43]

Atrioventricular Block

The designation AV block describes an abnormality in the conduction of atrial impulses through the AV node to the ventricles. This abnormality can range from a simple delay in impulse transmission, as in first-degree AV block, to a complete interruption of signal transmission, classified as complete or third-degree AV block. Each form of AV block has a distinct anatomic or physiologic cause for the electrical abnormality and can be either transient or permanent in nature. In utero, these abnormalities are diagnosed using either fetal echocardiography or FMCG with postnatal confirmation by ECG. The following sections focus on the definition, evaluation, and treatment of the more advanced forms of fetal AV block.

Second-Degree AV Block

Second-degree AV block is defined as the failure of at least one, nonpremature atrial impulse to be conducted to the ventricles. A number of different forms of second-degree AV block exist. Mobitz type I, or Wenckebach, is the most common, but least significant. Wenckebach is characterized by a progressive prolongation of the PR or AV interval with an eventual dropped ventricular beat. The delay occurs in the AV node, proximal to the bundle of His.[44] This conduction abnormality is generally transient in nature and is caused by vagal influence. In rare instances, it can be caused by digitalis toxicity or inflammatory disorders that affect the cardiac muscle. No treatment is necessary in asymptomatic fetuses. Mothers should be screened for presence of anti-Ro anti-La antibodies and the fetus should be observed closely.

The more pathologic forms of second-degree AV block include Mobitz type II and the advanced types.

Type II second-degree AV block is characterized by a constant P-P and PR intervals followed by a non-conducted atrial impulse. The anatomic site of block is at or below the bundle of His.[45] High-grade or advanced second-degree AV block is when two or more successive sinus atrial impulses are not propagated through the AV node. If either form of AV block is identified, the presence of prolonged QT interval syndrome or maternal connective tissue disorders must be investigated and the fetus followed closely for progression to pre- or postnatal complete AV block.[46]

Complete Atrioventricular Block

Fetal complete AV block (CAVB), or third-degree AV block is the complete failure of sinus atrial impulse conduction to the ventricles. In addition, the atrial rate must be faster than the ventricular rate to assure that the AV dissociation is not due to accelerated junctional or ventricular rhythm (e.g., sinus bradycardia with appropriate junctional response, or an accelerated junctional or ventricular rhythm). The prevalence of complete AV block in live born infants is 1 in 20,000.[47] The majority of affected fetuses fall into one of two distinct groups: those with structural cardiac disease and those with maternal connective tissue disorders.[48–50]

The association between fetal CAVB and maternal autoimmune disorders is well established.[17,18,51,52] It occurs in fetuses of women with systemic lupus erythematosus (SLE), Sjögren syndrome, rheumatoid arthritis, scleroderma, and undifferentiated connective tissue disorders.[53–55] Specifically, it is strongly associated with maternal autoantibodies designated anti-SS-A/Ro, anti-SS-B/La, or both.[55,56] Many women carrying a fetus with CAVB do not have symptoms of any connective tissue disorder at the time, with half demonstrating only serologic evidence of disease.[57] In addition, the vast majority of mothers with SLE do not have children with CAVB.[58] The risk of a woman with SSA/Ro and SSB/La antibodies having a fetus with heart block is 1% to 2%.[59] The risk of recurrence of CAVB in subsequent pregnancies after delivering an affected infant is 10% to 16%.[49,56]

The conduction system is damaged by maternal antibodies that cross the placenta and react with their corresponding antigens expressed on the surface of cells in the fetal cardiac conduction system, resulting in immunoglobulin deposition on the cells. The resulting local inflammatory reaction leads to permanent damage of the fetal cardiac conduction system due to localized cellular apoptosis.[60–64]

The second group of fetuses with CAVB have structural cardiac disorders. The etiology of nonimmune complete AV block was postulated by Lev to be the result of a developmental abnormality of the AV node. This abnormality can result from either the complete absence of the AV node, lack of union between the AV node and distal conduction system, or the presence of an aberrant, non- or poorly functioning system.[65] The most common structural cardiac abnormalities associated with CAVB are AV septal defects, both with and without associated left atrial isomerism, and AV discordance with ventriculoarterial discordance (corrected transposition of the great arteries).[48,50] Additional cardiovascular malformations (tetralogy of Fallot, atrial septal defects, transposition of the great vessels, and tricuspid atresia) are described, without any apparent association between the structural abnormality and the conduction defect.[48,50]

In addition to those with well-known immunologic and structural causes, a small group of patients were recently identified with a genetic mutation that results in CAVB. An autosomal dominant mutation in the cardiac transcription factor Nkx2.5 can result in familial atrial septal defects and AV node conduction abnormalities including Holt-Oram syndrome and atrial septal defects. There are also fetuses with structurally normal hearts but a mutation in SCN5A, a sodium ion channel, that is responsible for long QT interval and Brugada syndrome, who can have a range of AV conduction abnormalities including complete block.[66]

In contrast to the oft-quoted dogma that the majority of fetuses with CAVB without structural cardiac abnormalities have few if any problems with gestation and delivery, recent studies document an exceptionally high mortality rate among these perinates. The mortality rates range from 7% to 33% with structurally normal heart and as high as 86% for those with structural cardiac lesions.[48–50,57,67] Poor outcomes are associated with the presence of structural cardiac disease, hydrops, ventricular rates below 55 bpm, atrial rates below 120 bpm, AV valve regurgitation, a dilated cardiomyopathy, prolonged corrected QT interval, or delivery at or before 32 weeks' gestation.[48–50,57,67]

Management Options for Heart Block

Second-degree AV block (Mobitz type I/Wenckebach): No treatment is necessary in asymptomatic fetuses. Mothers should be screened for presence of anti-Ro anti-La antibodies and the fetus observed closely.

Second-degree AV block (Mobitz type II and advanced types): Management of these conduction abnormalities is similar to that of complete AV block (see next item).

Third-degree/complete AV block: The goal of management of a fetus with complete AV block is the birth of a healthy, viable infant. This outcome is best achieved through a two-tiered approach. First, early intervention(s) is required at the first sign of fetal compromise. Second, early identification of the fetus at risk for developing CAVB is extremely important, allowing for the initiation of therapies in an attempt to prevent the onset or progression of the conduction abnormality or its sequelae. These goals may be accomplished by increasing the fetal heart rate or contractility or by blunting or removing the inflammatory stimulus through immune suppression.

The maternal or direct fetal administration of sympathomimetic agents like ritodrine, terbutaline, isoproterenol, and salbutamol has shown some efficacy increasing both fetal chronotropy and ionotropy.[48,68–71] Reported fetal responses to these agents range from no improvement to complete resolution of hydrops and survival.[48,68,69,71,85] The applicability of these results is limited by the small number of patients treated, the highly variable clinical situations, and concomitant use of additional therapies. We believe it is unlikely this therapy works, as it does nothing to restore AV concordance. The relative stiffness of the fetal ventricular myocardium, and the consequent reliance of the fetus on atrial systole for normal ventricular filling, makes the fetus exquisitely sensitive to interruption of this relationship.

Another approach to increase the fetal heart rate is through ventricular pacing. Transvenous and epicardial ventricular pacing was accomplished in fetal animal models, and transuterine-transthoracic pacing is reported in a few human fetuses.[86–88] Despite the fact the pacing was successful, all treated fetuses died. With the advent of new, smaller (1.4 Fr), soft-tipped temporary pacing wires, transvenous ventricular pacing may become more feasible and less risky to mother and fetus in the future, although placement would require open fetal surgery with the pacemaker generator itself buried under the fetal skin, to avoid exposure of the fetus to entanglement in free-floating wires in the amniotic sac.

Reduction of the maternal antibody titer or the fetal inflammatory response to the antibodies is accomplished either through suppression or removal of the offending agents. Removal of the anti-SSA/Ro and SSB/La antibodies was reported in a few cases by plasmapheresis with variable results. Intravenous gamma globulin has also been reported to reduce the maternal anti-Ro antibody titer.[89] Despite their encouraging results, only a limited number of patients have undergone these therapies during pregnancy. Further studies are warranted.

Fluorinated steroids such as dexamethasone and betamethasone have been used for prevention and treatment of CAVB.[61,62,69,90–92] A recent retrospective case control investigation compared pregnancy outcomes of those treated with fluorinated steroids to those untreated. Although steroid use for fetuses with complete AV block failed to resolve the AV conduction defect, it was associated with some improvement in hydrops and other symptoms. Steroids administered early after the onset of early AV block (second degree) reversed the block and prevented its advancement in at least some fetuses.[93] These findings suggest that fluorinated steroids are a therapeutic option in fetuses with early forms of AV block to prevent progression and potentially cure the abnormality. Their use should also be considered in fetuses with hydrops.

In summary, fetal complete AV block is a relatively rare condition with rapidly evolving management. We recommend early fetal echocardiography in all mothers with anti-Ro and anti-La antibodies (SSA and SSB). Fetuses with structural cardiac disorders associated with CAVB should be closely observed for signs of arrhythmia. In the fetus of a mother with a connective tissue disorder, early detection of advanced AV conduction abnormalities should prompt the consideration of fluorinated steroids with the goal of preventing the progression of the inflammatory process. The presence of hydrops or ventricular rates below 55 bpm should prompt reconsideration of therapy with steroids. Additional studies on the benefits of plasmapheresis and intravenous immunoglobulins are needed. In addition, the patient should be referred to a center with expertise in high risk obstetrics and fetal cardiology, as well as pediatric and neonatal pacemaker implantation and management.

Management of Fetal Tachyarrhythmias—General

The management of a fetus with a dysrhythmia should involve a coordinated team approach including experts in obstetric imaging, maternal-fetal medicine, electrophysiology, and pediatric cardiology. Medications are often administered to pregnant women with hopes that the beneficial effects of the drug will be transferred to the fetus. In many instances, the kinetics of drug transfer are poorly studied. When transplacental antiarrhythmic therapy is to be administered, the authors feel an adult electrophysiologist should be available to guide dosage selection and assist in monitoring the mother for adverse events and side effects. In support, Strasburger and associates[72] observed a higher rate of cesarean section (84% vs. 18%) and lower gestational age at delivery (37 weeks vs. 39 weeks) in infants managed at nontertiary centers without prenatal pediatric cardiology support.

Hydrops Fetalis (See also Chapter 25)

Hydrops fetalis is an abnormal collection of fluid in at least two areas, such as ascites, pleural or pericardial effusions, polyhydramnios, or skin or placental edema. Cardiac reasons for the development of hydrops include structural cardiac defects and rhythm disturbances, which constitute up to 50% of all nonimmunologic hydrops.[73] Multiple risk factors for hydrops fetalis and subsequent poor outcome are suggested and include prematurity, sustained SVT exceeding 12 hours, structural cardiac defects, and ventricular rates exceeding 220 bpm.[74] In subsequent studies, the correlation between hydrops and ventricular rate or duration of the tachycardia was not substantiated.[75,76] Untreated hydrops fetalis can be associated with decreased fetal movement, fetal metabolic acidemia, myocardial dysfunction, and poor tolerance of labor. In addition, placental edema may contribute to decreased placental drug transfer requiring more drugs (two vs. one) or more days (12.5 vs. 3) to control their arrhythmia.[77] Mortality rate may be as high as 13% in a term, hydropic fetus and increases as gestation falls.[76]

Therapeutic Options

One must ask if it is worth the effort before initiating medical therapy for fetal tachyarrhythmia. We are currently unsure of the exact pharmacokinetics of many of the medicines used in transplacental treatments. All the drugs we might use have potentially dangerous side effects. They may not be effective, and there could be spontaneous resolution of the tachycardia even without treatment. Therefore, the treatment for fetal tachycardia depends on a multitude of factors, including the type of arrhythmia, gestational age of the fetus, maternal and fetal health, and the presence of either structural cardiac disease or hydrops.

Therapeutic options for a fetal tachyarrhythmia include monitoring without pharmacologic intervention, transplacental or direct administration of antiarrhythmic medications to the fetus, or delivery of the fetus with postnatal arrhythmia management. The management choice for most fetuses with tachycardia at or very near term ($\geq$34–35 weeks) is delivery. The nonhydropic fetus with an intermittent tachyarrhythmia can often be safely and effectively induced with oxytocin for vaginal delivery as long as there are sufficient intervals of normal rhythm present to permit electronic fetal heart rate monitoring. Whether new techniques such as fetal pulse oximetry, which requires rupture of the membranes and sufficient cervical dilation to place the transducer, will permit adequate monitoring of the fetus with a sustained tachycardia remains speculative, but this approach is worth evaluating in selected pregnancies. In pregnancies with evidence of fetal compromise or impending cardiac dysfunction, a complete fetal and maternal assessment must be performed and the pros and cons of all available treatment options weighed by the treatment team and family.

When the treatment of a fetal arrhythmia is indicated, a number of options are available. Transplacental therapy is preferred for a stable arrhythmia when both the fetus and mother are in excellent health. If, for some reason, transplacental therapy is not an option, consideration must be given to direct fetal therapy with drug infusion into the umbilical vein, into the amniotic fluid, or by direct fetal intramuscular injection. The following sections will review the advantages as well as the risks of each of these therapeutic options and provide data and clinical scenarios that apply to each therapy.

When a fetal arrhythmia is detected, signs of fetal compromise must be sought. Delivery of infants less than 34 to 35 weeks' gestational age with hydrops is associated with very high mortality rate and is indicated only under exceptional circumstances, such as failed transplacental/direct therapy, worsening diastolic dysfunction, or a poor fetal biophysical profile.[78] When iatrogenic premature delivery is anticipated, documentation of fetal lung maturity by amniocentesis may help with the decision. If the pregnancy is at or before 34 weeks, appropriate doses of betamethasone or dexamethasone should be administered to hasten fetal lung maturation.

Pregnancies close to term should be delivered rather than exposing the mother to these potent medications. The aim of transplacental therapy is to use the normal function of the placenta as a fetal drug delivery mechanism. Transplacental therapy is indicated in fetuses with a stable biophysical profile and sustained tachycardia.[79] Those fetuses with tachycardia less than 30% of the time without hydrops can probably be left untreated and instead followed closely. This decision should be individualized and based on the ability to follow the patient closely. We believe twice weekly echocardiographic evaluation of nonhydropic infant is warranted. In contrast, almost all neonates with any episodes of nonsinus tachycardia will receive antiarrhythmic medications for up to 1 year of age to minimize their risk of developing congestive heart failure.

Antiarrhythmic medicines should be initiated under close supervision. With the exception of β-blockers, most antiarrhythmic drugs require close monitoring of both fetus and mother for side effects as well as a successful conversion to a sinus rhythm. We believe that when most antiarrhythmic drugs are used, the mothers should be monitored as inpatients on cardiac telemetry with consultation of an adult electrophysiologist to monitor the maternal ECG, electrolytes, and vital signs. Conversion can generally be achieved within a few days. Once control or steady state is achieved, the patients may be discharged with close follow-up. Successful conversion rates of fetal SVT range from 80% to 90%.[80] The resolution of hydrops after successful treatment of tachycardia may take several weeks. Acceleration of fetal maturity with corticosteroids should be considered if elective preterm delivery seems likely.[35]

Pharmacokinetics and Choice of Antiarrhythmic Agents

Transfer of any drug across the placental barrier is promoted by low molecular size, low ionization, and high lipid solubility.[81] The rate of diffusion is also dependent on fetal-maternal concentration gradient and the thickness of the placental membrane. Higher doses of drugs are often required to achieve therapeutic levels in pregnancy because of increased blood volume and distribution, increased protein binding of drugs, increased hepatic metabolism, and greatly increased glomerular filtration rate in the mother. The placenta is able to transfer, concentrate, and metabolize drugs to inactive metabolites. Fetal metabolism of drugs is primarily renal or placental because hepatic enzymes are immature (only 20%–50% active). The transplacental transfer of drugs is poor in the presence of hydrops fetalis, therefore making management of fetal SVT with associated hydrops more difficult. To circumvent mitigating factors that affect transplacental transfer, direct umbilical or fetal intramus-

TABLE 16-2

Pharmacologic Agents Used to Treat Fetal Arrhythmias

DRUG	ADVERSE EFFECT	DOSING RANGE	THERAPEUTIC LEVEL
Digoxin	Nausea, bradycardia, vision disturbance, first- and second-degree atrioventricular block, rhythm disturbances	Loading dose: 1200–1500 µg/24 hr IV; Maintenance: 375–875 µg/day po divided bid	1.5–2.5 ng/dL
Propranolol	Low birth weight, hypoglycemia, bradycardia, increased uterine tone	80–320 mg/day po in 3–4 divided doses	25–50 ng/mL
Flecainide	Fetal demise, conduction defects, QT interval prolongation, proarrhythmia	100–400 mg/day po divided bid	0.2–10 µg/mL
Sotalol	Tiredness, dizziness, nausea, QT interval prolongation, torsades de pointes	40 mg bid increasing to 160 mg po bid	Not known
Amiodarone	Nausea, thrombocytopenia, visual disturbances, QT interval prolongation, hypothyroidism	Loading dose: 600 mg po q6h; Maintainance: 100–200 mg/day po	0.7–2.8 µg/mL

cular administration of drugs has been used to treat the fetus directly.[82,83]

The proper diagnosis of the type of tachycardia is required to guide therapy. Based on a 1998 survey of 15 institutions treating fetal arrhythmias, the commonest drug used was digoxin (78%) followed by flecanide (18%), verapamil (7%), procainamide (6%), quinidine (6%), amiodarone (6%), propranolol (2%), and sotalol (2%).[81] Verapamil is contraindicated in newborns owing to the risk of profound hypotension and shock and should be used rarely and with extreme caution, if at all, in fetuses. In addition, quinidine has proarrhythmic effects and also should used rarely. Amiodarone is effective in 90% of the reentrant SVTs and 60% of the atrial flutter. However, the long half-life of amiodarone, measured in weeks, and the potential for profound fetal hypothyroidism, as a result of exposure and consequent goiter and even cretinism, mandates great caution when considering amiodarone. The maternal ECG and side effects should be monitored along with desired fetal effect and the dose titrated for optimal response. Standard doses and some common side effects of different drugs are listed in Table 16–2.

Prognosis

The perinatal mortality rate for fetal tachycardia with hydrops ranges from 3.5% to 30% in different studies. The differences may relate to use of different antiarrhythmic agents, some with proarrhythmic effects, the incidence of premature delivery, and fetal interventions including cordocentesis.[84] Marked acidosis, prematurity, and prolonged tachycardia may be associated with long-term postnatal sequelae. Postnatal pharmacologic therapy is needed in 50% of cases with SVT irrespective of the presence of hydrops, with over 75% having no clinical episodes after 1 year of age.

CONCLUSIONS

- Discovery of a fetal arrhythmia should lead to a careful ultrasound examination for
  - Nature of the arrhythmia (including M-mode)
  - Anatomy of heart and vascular connections
  - Exclusion of other abnormality and syndromes (with karyotyping if syndrome suspected)
- Maternal history and examination are necessary to exclude precipitating factors.
- Most conditions should be managed by a center with expertise in high risk obstetrics and fetal cardiology, as well as pediatric and neonatal pacemaker implantation and management.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Arrhythmias

Management Options	Quality of Evidence	Strength of Recommendation	References
Irregular Fetal Heart Rate			
Prenatal Diagnosis			
Careful history and examination to exclude	IV	C	35
Familial long QT interval syndrome			
Maternal illicit drug use			
Maternal hyperthyroidism			
Fetal echocardiography to confirm cardiac normality; detailed fetal sonography to exclude syndromes; consider karyotype if aneuploidy (especially trisomy 18) suspected	III IV	B C	9 35
Prenatal Treatment			
No treatment if isolated (as in the majority of cases)	–	GPP	–
Avoid caffeine and drugs that promote ectopy (e.g., beta-sympathomimetics)	–	GPP	–
Weekly ausculation to confirm no progression to supraventricular tachycardia (SVT)	–	GPP	–
Postnatal			
If ectopic beats persist in the neonatal period, perform electrocardiogram (ECG) and 24-h Holter monitor to exclude long QT interval syndrome.	IV	C	37,43
Tachycardias			
Prepregnancy			
Counseling of those with history of			
Wolff-Parkinson-White (W-P-W) syndrome	IV	C	35
Familial long QT interval syndrome	IV	C	37,43
Prenatal Diagnosis			
Auscultation and fetal echocardiography for sustained fetal rate > 180 bpm	–	GPP	–
Ultrasound evaluation of cardiac structure, function, presence of hydrops, and mechanism of arrhythmia (including M-mode and spectral Doppler)	III	B	6
Search for other abnormalities with ultrasound; consider karyotype if aneuploidy suspected.	–	GPP	–
Prenatal Treatment			
Depends on	–	GPP	–
Underlying mechanism/diagnosis			
Persistence of tachyarrythmia			
Presence of hydrops			
Gestational age			
Nonsustained tachycardia requires monitoring but no treatment unless hydrops is present.	–	GPP	–
Medical (Transplacental) control of sustained tachycardia; five drugs are commonly used:	III & IV	B,C	41,77,79,84
Digoxin			
Beta-blockers			

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Arrhythmias *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal Treatment			
Flecainide			
Soltalol			
Amiodarone			
Sinus tachycardia—Treat cause (e.g., maternal thyrotoxicosis).			
Short VA SVT—preceding five drugs have been used.			
Long VA SVT—use flecainide, soltalol.			
Atrial flutter—digoxin, soltalol.			
Atrial fibrillation—no intrauterine drug is effective; DC after birth.			
Atrial tachycardia—flecainide.			
Junctional ectopic tachycardia—soltalol, amiodarone.			
Ventricular tachycardia—soltalol, amiodarone.			
Monitor maternal ECG and drug levels with use of these drugs.			
Therapy delivered directly to the fetus has been effective, particularly in the setting of hydrops.	III	B	82,83
Delivery is an option if close to term (34+ w); short trial of drug therapy before delivery if hydrops even if close to term is a controversial option because newborns with hydrops have poor prognosis.	–	GPP	–
Postnatal			
12-lead ECG to confirm W-P-W or long QT interval syndrome and precise diagnosis.	IV	C	37,43
Take local advice re prophylactic treatment for tachycardia—some will not use this routinely. Some centers will treat asymptomatic neonates for 6–12 months and review.	–	GPP	–
Treat recurrent tachycardia in infancy (medical therapy or ablation).	III	B	77,78
Bradycardias			
Prepregnancy			
Counseling of women with the following risk factors for complete atrioventricular block (CAVB):			
Previous child with CAVB	III	B	83
Maternal anti-SSA (Ro) or SSB (La) antibodies (1–2% risk)	III	B	55,59
Maternal heart block	–	GPP	–
Previous child with left atrial isomerism	–	GPP	–
Familial prolonged QT interval syndrome is a possible risk factor.	IV	C	37,43
Prenatal Diagnosis			
Detailed and serial echocardiography (every 1–2 weeks) of antibody-positive mothers and those with a positive family history.	–	GPP	–
Fetal echocardiography for persistent fetal rate <100 bpm.	–	GPP	–
Serial echocardiography (every 1–2 weeks) for emerging block (second- or third-degree heart block).	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Arrhythmias (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal Diagnosis (Continued)			
Irregular rhythms	–	GPP	–
If occasional, clinical follow-up.			
If persistent, fetal echocardiography and intensify follow-up.			
Evaluation of asymptomatic mothers for anti-Ro and anti-La antibodies and autoimmune disease (rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus, or undifferentiated autoimmune syndrome).	III	B	55,59
Prenatal Treatment			
Early steroids (dexamethasone/betamethasone) are common first-line treatment; no evidence of benefit of prophylactic steroids.	III	B	70,89,93
More research is needed into role of plasmapheresis and intravenous immunoglobulin (IVIG).	IV	C	70,89
Inotropic/chronotropic support is of limited benefit.	III	B	71,85
Fetal pacing has been attempted but without success.	IV	C	88,90
Consider early delivery in tertiary center if hydrops is evident, but generally try to avoid preterm delivery.	–	GPP	–
Mode of delivery—intrapartum monitoring of fetal distress may be difficult in CAVB.	–	GPP	–
Postnatal			
Temporary pacing may be necessary.	III	B	49,67
Permanent pacemaker for rate <60 bpm, symptoms, or structural disease.	III	B	49,67

Va SVT, ventriculoatrial supraventricular tachycardia.

Fetal Cardiac Abnormalities

Giuseppe Rizzo / Alessandra Capponi

INTRODUCTION

Major advances in diagnostic ultrasonography incorporating echocardiographic techniques[1] such as pulsed and color Doppler allow the study of normal and abnormal cardiac anatomy and function. Structural and functional abnormalities do affect the development of the heart, and the importance of antenatal diagnosis is well recognized in modern perinatal practice. Congenital heart disease occurs in 0.4% to 1.1% of live births[2] and accounts for 35% of infant deaths secondary to congenital disease.[3] Cardiovascular anomalies are frequently associated with other anomalies.[4,5] In this chapter, the indication and the sonographic technique for assessing fetal cardiac status are reviewed, the principal structural cardiac diseases are described, and the management options available are discussed.

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

"Routine" Fetal Echocardiography

Despite the high incidence of congenital heart disease, "routine" fetal echocardiography (i.e., all pregnancies) remains unavailable because it requires sophisticated equipment, a skilled operator, and meticulous scanning. Thus, it is not presently practical to screen the entire obstetric population. Moreover, the pregnancies at greatest risk of congenital heart disease are those in which an abnormality of the fetal heart is suspected during the routine 18- to 22-week anatomic scan. This underscores the importance of a meticulous scanning of the fetal heart in all pregnancies at this gestational age in order to identify those who should be referred for fetal echocardiography.

Selective Fetal Echocardiography

Fetal echocardiography is performed in selected pregnancies at increased risk of carrying a fetus with a congenital heart disease. Risk factors can be divided into familial, maternal, and fetal (Table 17–1).

An association has been shown between increased nuchal translucency (NT) measured between 11 and 14 weeks and congenital heart disease (see Chapters 7 and 8).[6] Indeed, the risk of a congenital heart disease is 6% in fetuses with a NT above the 99th percentile (i.e., >3.5 mm) and a normal karyotype.[6] Further, abnormalities of cardiac function have also been demonstrated in fetuses with normal cardiac anatomy,[7] suggesting a pivotal role for NT measurement in the screening of fetuses who should undergo fetal echocardiography.

The sensitivity of screening for congenital heart diseases reported in the literature is incredibly wide—10% and 81%.[8,9] These differences may be explained in part by the characteristics of the study population (low or high risk), the study design (prospective and retrospective), training and experience of the operators, content of the examination (four-chamber view or four-chamber view plus outflow tract visualization), and quality of follow-up (postnatal clinical examination or postnatal echocardiography). Moreover, the technology has not been stagnant. With the latest technology and proper training of the examiners, demonstration of the four-chamber view allows for the detection of 40% to 50% congenital heart disease in low risk pregnancies. The addition of outflow tract visualization increases the sensitivity of detecting cardiac lesions to 65% to 70%. It is not likely sensitivity can improve much more, considering the evolving nature of cardiac lesions.

ULTRASONOGRAPHIC EXAMINATION OF THE FETAL HEART (Table 17–2)

Timing of Fetal Echocardiography

Women should be seen within 48 hours of referral when an anomaly is suspected to avoid growing parental anxiety during the interval between detection of the

TABLE 17-1

Indications for Fetal Echocardiography

Family history
    Previous affected fetus or child
    Maternal or paternal congenital heart disease
    History of a single-gene disorder (DiGeorge, Noonan,
        Marfan, William, Holt-Oram syndromes)
Maternal history
    Metabolic diseases
        Insulin-dependent diabetic mother
        Maternal phenylketonuria
        Connective tissue disease
    Exposure to teratogens
        Alcohol
        Valproic acid
        Phenytoin
        Isoretinoin
        Lithium
        Hydantoin
    Infections
        Rubella
        Parvovirus
        Coxsackievirus
        Cytomegalovirus
Fetal history
    Arrhythmias
    Extracardiac anomalies
    Hydrops
    Hydramnios
    Growth restriction
    Chromosomal defects
    Increased nuchal translucency thickness at 11–14 weeks'
        gestation
    Abnormal heart at 18–20 weeks' routine scan (usually
        abnormal four-chamber view)

TABLE 17-2

      atrium

Color Doppler Echocardiography
  Apical four-chamber view
    Normal ventricular filling
    Absence of regurgitation
  Ventricles outflow tracts
    Normal aortic and pulmonary artery color visualization
    Absence of flow reversal
  Three-vessel view
    Same color direction in pulmonary artery and aorta
  Pulsed Doppler
  Apical four-chamber view
    Mitral and tricuspid velocity waveforms flow only during
      diastole (E and A waves)
    Ventricle outflow tract
    Aortic and pulmonary velocity waveforms flow only
      during systole (peak velocity, time to peak velocity
      cardiac output?)
  Ductus arteriosus flow
    Flow throughout all the cardiac cycle
    Highest velocities in fetal circulation
    Exclude ductal constriction (P1 < 2)
  Venous flow
    Inferior vena cava reflects overall cardiac function
    Poor cardiac function is associated with increased reverse
      flow during atrial contraction (high preload index)

possible anomaly and the consultation. Planned fetal echocardiography is typically performed between 20 and 22 weeks. The maternal abdominal wall thickness, prior abdominal surgery, and the number of fetuses each influence the ideal time for study.

Transvaginal ultrasonography permits a detailed view of the fetal anatomy early in gestation, and some investigators believe fetal echocardiography can be performed well between 14 and 16 weeks of gestation.[10,11] We currently limit performance of these early scans to women with a prior affected child or with insulin-dependent diabetes.[12] Because the sensitivity of early transvaginal echocardiography is at a maximum 60%,[10,13] it should be repeated between 20 and 22 weeks even if the first finding was normal, as an additional 20% of the congenital heart defects will be evident later.[13]

General Principles

It is imperative that the mother be informed before the examination in a clear and considerate manner about the reason for the fetal cardiac evaluation and its efficacy and limitations. The findings of the scan should then be explained at the end of the examination. Fetal echocardiography consists of several steps:

- Determine the fetal cardiac orientation and position.
- Evaluate the cardiac anatomy.
- Evaluate the cardiac hemodynamics and function using color and pulsed Doppler techniques.

Fetal Cardiac Orientation and Position

The examination begins with identification of the fetal head and spine so that the fetal right and left sides are known. The fetal visceral orientation, known as situs, is easily identified by noting the location of the following landmarks while viewing a transverse section of the upper abdomen (Fig. 17–1):

1. The stomach and spleen are on the left.
2. The abdominal aorta is a circular, pulsating structure on the left, anterolateral to the spine without another vessel posterior.
3. The inferior vena cava is an elliptical structure on the right of the spine in a plane anterior to the aorta.
4. The umbilical vein bends to the right, continuing in the portal sinus.

The arrangement described here constitutes *situs solitus*. An abnormal visceral-vascular arrangement may be either *situs inversus* or *situs ambiguous*. In the former, the visceral-vascular arrangements are the mirror image of *situs solitus*, so that the stomach and aorta are on the right and the inferior vena cava and the liver are on the left side. *Situs ambiguous* refers to an abnormal arrangement of the abdominal and thoracic organs and is usually associated with cardiosplenic syndromes.

Normal Fetal Cardiac Anatomy

A sequential approach is applied to fetal echocardiography derived from the pathologic and angiographic examination of the heart.[14] The main steps include identification of the cardiac position within the body, identification of the cardiac chambers, study of atrioventricular connections, study of ventriculoarterial connections, and study of venous return to the atria. This is accomplished by examining the following standardized, echocardiographic planes.

Apical Four-Chamber View

The apical four-chamber view is found in a cross-sectional scan of the fetal thorax just above the level of the diaphragm where the normal heart is almost horizontal, mainly on the left side of the chest with the apex pointing left. *The apical four-chamber view is the single most important view of the heart and provides the following anatomic information* (Fig. 17–2):

1. The heart is correctly situated in the thorax with apex on the left, and it occupies about one third of the

FIGURE 17–1
Transverse section of the upper fetal abdomen showing the spleen, the stomach (ST), aorta (AO), inferior vena cava (IVC), and umbilical vein (UV).

FIGURE 17–2
Apical four-chamber view of the fetal heart (*A*). In the magnified image (*B*) the arrow indicates the moderator band of the right ventricle. LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle.

thorax. The ratio between the cardiac and thoracic circumferences in this view during end diastole (i.e., while the atrioventricular valves are closed) is constant across gestation with an upper limit of 0.58.[15] Larger values suggest either cardiomegaly or a small chest.

2. There are two atria of equal size. The two ventricles are approximately equal in size and thickness, and in real time, their contractility appears similar.
3. The right ventricle is on the right and near the anterior thoracic wall. It has a septomarginal trabeculum, or moderator band, located near the apex in contiguity with the interventricular septum. The left ventricular cavity is smooth.
4. Two atrioventricular valves open in real time, and the insertion of the tricuspid valve is located more toward the apex than the mitral valve.
5. The interatrial septum, the foramen ovale, and the interventricular septum are visualized. The atria and ventricular septa meet at the level of atrioventricular valve, generating a crux.
6. The pulmonary veins enter the left atrium.

Although the four-chamber view is an essential component of any study of the fetal heart, it alone is insufficient, as less than a third of congenital defects are detectable.

Lateral Four-Chamber View

This view allows visualization with higher resolution of certain structures lying perpendicular to the line of ultrasound transmission. The artifactual dropout at the level of the high portion of the interventricular septum and of the atrium septum secundum common in the apical four-chamber view is avoided, and the integrity of the interventricular and interatrial septa is optimally demonstrated. This view also allows enhanced imaging of the foramen ovale and the movement of its valve into the left atrium (Fig. 17–3).

FIGURE 17–3
Transverse section of the fetal thorax showing the lateral four-chamber view. The muscular portion of the interventricular septum is visualized as well as the foramen ovale (FO). LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle; PV, pulmonary vein.

Left Ventricle Outflow Tract

It is possible to obtain a long axis view of the fetal heart in an oblique section of the fetal thorax. This section reveals the following landmarks (Fig. 17–4):

1. The mitral valve is seen between the left atrium and left ventricle, and the posterior leaflet is shorter than the anterior leaflet.
2. The anterior leaflet of the mitral valve is continuous with the posterior wall of the aorta.
3. The anterior wall of the aorta is continuous with the interventricular septum.
4. The aortic valve and its movement are seen at the base of the aorta. By orienting the transducer from the left shoulder to the right hemithorax, the aortic arch and the origin of the brachiocephalic vessels are fully visualized (Fig. 17–5).

Right Ventricle Outflow Tract

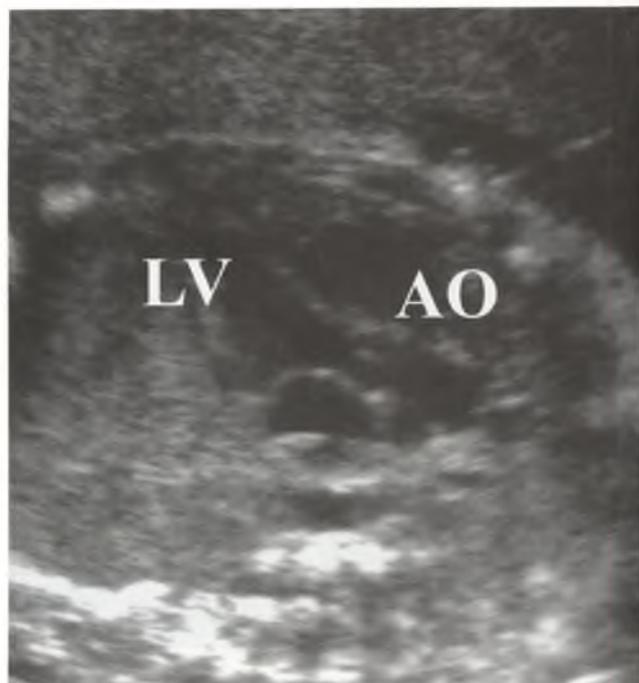
This view is a transverse cross section of the fetal thorax. The pulmonary artery is seen arising from the right ventricle anterior to and left of the ascending aorta (circle and sausage image) (Fig. 17–6). The movement of the pulmonary valve is seen. With slight movement of the transducer, the longitudinal view of the ductal arch is obtained. It is also possible to visualize the bifurcation of the main pulmonary artery and the ductus arteriosus connecting to the descending aorta in this section (Fig. 17–7).


FIGURE 17–4
Long-axis view of the fetal heart showing the continuity between left ventricle (LV) and aorta (AO).

FIGURE 17–5
A, Longitudinal view of the aortic arch and of brachiocephalic vessels. *B*, Same section with power Doppler superimposed showing the arch with its three branches: innominate artery (I), left carotid artery (C) and subclavian artery (S) (see Color Plate 5).

FIGURE 17–7
Longitudinal view of the ductus arteriosus arch. RV, right ventricle; PA, pulmonary artery; RPA, right pulmonary artery; DUCTUS, ductus arteriosus; AO, descending aorta.

Three-Vessel View

From the four-chamber view, the transducer is moved parallel in the direction of the upper thorax. In this view, the pulmonary trunk with the ductus arteriosus, the aortic arch with aortic isthmus, and the superior vena cava are seen. (Fig. 17–8). The aorta and pulmonary trunk are seen in a longitudinal view and form a V-shaped area in the posterior thorax on the left side of the spine.[16] In this section, the trachea is a circular structure with an echogenic wall adjacent and to the right of the aorta. In front of the trachea, the superior vena cava can be seen. The following landmarks are contained in this view:

1. Three vessels are seen from left to right: pulmonary artery, aorta, and superior vena cava.
2. These vessels are listed in descending order of size: pulmonary artery, aorta, superior vena cava.
3. Each vessel lies posterior to the other: pulmonary artery anterior to aorta, aorta anterior to superior vena cava.

FIGURE 17–6
Short-axis view of the fetal heart showing the outflow tract of the right ventricle. PV, pulmonary valve; PA, main pulmonary artery; RPA, right pulmonary artery; DA, ductus arteriosus; AO, descending aorta.

FIGURE 17–8
Transverse section of the fetal thorax at the level of the three-vessel view. The pulmonary artery (PA) is the largest of the three vessels, the aorta (AO) is between the PA and the superior vena cava (SVC), which is the smallest and most posterior vessel. The trachea (Tr) is visualized posterior to the aorta.

4. Pulmonary artery arises closest to the anterior chest wall.
5. Trachea and thymus can be visualized.

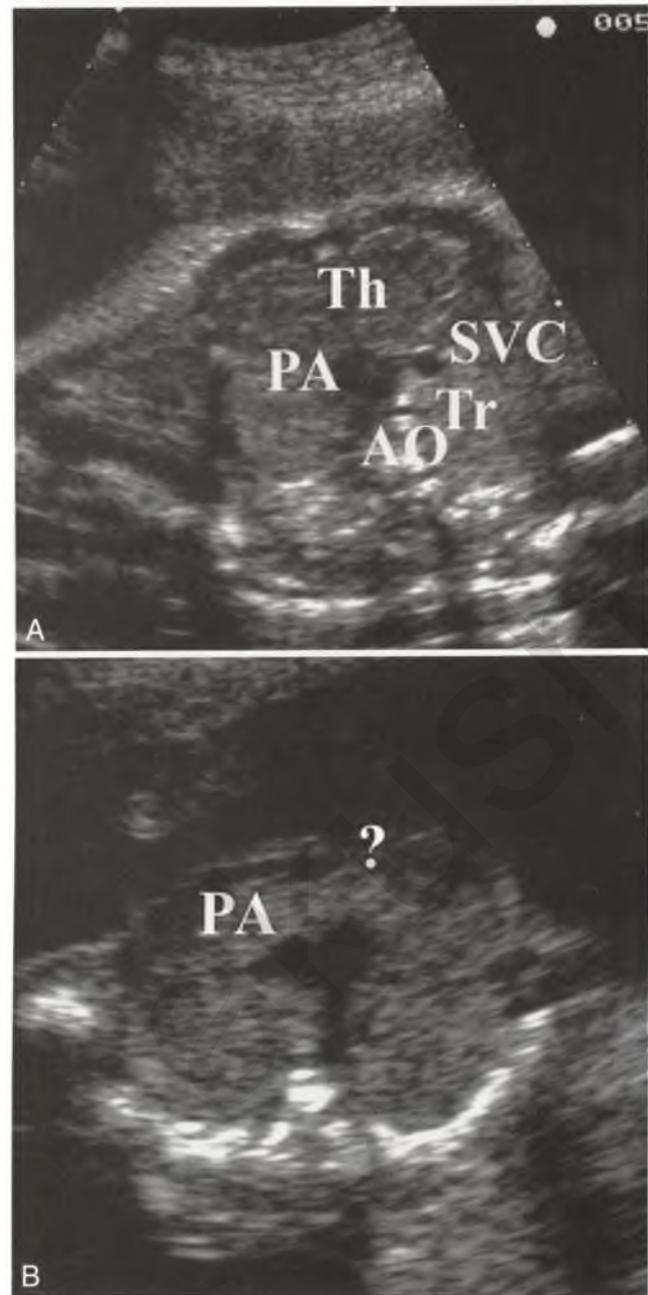
The position of the trachea in comparison to these vessels may be used to differentiate a normal, left-sided aortic arch from an abnormal right-sided aortic arch.[17] Furthermore, the thymus can be seen in front of these vessels (Fig 17–9A), and its absence is a possible marker of congenital heart disease associated with a microdeletion deletion of chromosome 22q11 (Fig 17–9B).[18]


FIGURE 17–9

B, Three-vessel view in a fetus with a microdeletion deletion of chromosome 22q11 with an absent pulmonary valve, resulting in a dilated pulmonary artery (PA) and absent thymus (?).

FIGURE 17–10
Parasagittal view of the fetal trunk showing the inlet in the right atrium of the superior vena cava (SVC) and inferior vena cava (IVC).

Venous Return

The systemic venous return is assessed using a right parasagittal scan of the fetal thorax to demonstrate the inferior and superior vena cava entering the right atrium (Fig. 17–10). The pulmonary veins are seen entering the left atrium from either the apical or lateral four-chamber views (Fig 17–11).

DOPPLER EXAMINATION OF THE FETAL HEART

General Principles

Although real-time imaging provides information on the structural integrity of the fetal heart, Doppler ultrasonography provides information that enhances both the definition of the presence and the severity of structural and functional cardiac disease. The parameters used to describe fetal cardiac velocity waveforms differ from those used to describe the peripheral fetal vessels. In the latter, pulsatility, resistance, or systole/diastole indices are used. They are derived from the relative ratios of systolic, diastolic, and mean velocities and are independent

of the absolute velocity and the angle of insonation[19] (see also Chapter 11).

In contrast, the measurements at the cardiac level are absolute values and require knowledge of the angle of insonation, which may be difficult to obtain accurately. The error in the absolute velocity measurement resulting from angle uncertainty is strongly dependent on the magnitude of the angle itself. For example, the error is insignificant if the angle is less than about 20 degrees. However, when the angle is greater than 20 degrees, the cosine term in the Doppler equation converts the small uncertainty in the measurement to a large error in the velocity equations.[19] Thus, recordings should be obtained with the Doppler beam as parallel to the bloodstream as possible. All recordings with an estimated angle greater than 20 degrees should be rejected.

The use of color Doppler velocimetry can help solve many of these problems by revealing in real time the flow direction so that the beam can be properly aligned. Pulsed Doppler is generally preferred over continuous wave Doppler because of its superior range of resolution. The sample volume is placed immediately distal to the location to be studied (e.g., distal to the aortic semilunar valves to record the left ventricle outflow). The continuous wave Doppler may be useful when there are particularly high velocities (e.g., in the ductus arteriosus) because it avoids the aliasing effect.

Parameters Measured

The following parameters are commonly used to describe the cardiac velocity waveforms:

- The *peak velocity* (PV) is expressed as the maximum velocity at a given moment (e.g., systole, diastole) on the Doppler spectrum.
- The *time to peak velocity* (TPV) or acceleration time is expressed as the time interval between the onset of the waveform and its peak.
- The *time velocity integral* (TVI) is calculated by planimetering the area beneath the Doppler spectrum.

It is possible to calculate absolute cardiac flow from both atrioventricular valve and outflow tracts by multiplying as follows:

$$TVI \times valve\ area \times fetal\ heart\ rate$$

The calculation of the measurement valve area is also prone to inaccuracy. It is derived from the measurement of a valve diameter that is near the limit of ultrasonographic resolution. The measurement is then halved and squared in the calculation, amplifying potential errors. Despite these limitations, absolute cardiac flow can be used in longitudinal studies over a short duration during which the valve dimensions are assumed constant. It is also possible to calculate accurately the relative ratio between the right and left cardiac output (RCO/LCO) and avoid the valve measurement completely because the

relative dimensions of the aortic and pulmonary valves remain similar through gestation in the absence of cardiac structural diseases.[1]

Site of Recordings; Velocity Waveform Characteristics and Their Significance

Blood flow velocity waveforms can be recorded at all cardiac levels including venous return, foramen ovale, atrioventricular valves, outflow tracts, pulmonary arteries, and ductus arteriosus. Factors affecting the morphology of the velocity waveforms include preload, afterload, myocardial contractility, ventricular compliance, and fetal heart rate.[1,19] As it is impossible to obtain simultaneous recordings of pressure and volume, these factors cannot be fully investigated in the human fetus. However, as each waveform parameter and the site of its recording are specifically affected by one of these factors, it is possible to elucidate indirectly the underlying pathophysiology by performing the measurements at various cardiac levels.

Venous Circulation

Blood flow velocity waveforms can be recorded in the superior and inferior vena cava, ductus venosus, and pulmonary, hepatic, and umbilical veins. The vessel most intensively studied to date is the inferior vena cava (IVC). Waveforms recorded just distal to the entrance of the ductus venosus[20,21] have a triphasic profile. There is a first forward wave concomitant with ventricular systole, a second forward wave of smaller dimension occurring in early diastole, and a third but reverse wave during atrial contraction (Fig. 17–12). Several indices have been proposed for the analysis of the IVC waveforms. We found

that the preload index (PLI) expressed as the ratio between the peak velocities during atrial contraction and systole (PLI = A/S) is the most reproducible and efficient index.[22] This index is related to the pressure gradient between the right atrium and ventricle during end diastole, which is a function of both ventricular compliance and ventricular end-diastolic pressure.[23] Decreased cardiac function is associated with an increase in the A wave, and as a consequence, the PLI increases.

The ductus venosus (DV) is seen in a transverse section of the upper fetal abdomen at the level of its origin from the umbilical vein. Color Doppler is superimposed and the pulsed Doppler sample volume is placed just above its inlet (close to the umbilical vein) at the point of maximum flow velocity as expressed by color brightness. The DV flow velocity waveform has a biphasic pattern with a first peak concomitant with systole (S), a second peak concomitant with diastole (D), and a nadir during atrial contraction (A) (Fig. 17–13). Among the indices suggested to quantify DV velocity waveforms is the ratio of the S peak velocity to A peak velocity (S/A). This index is angle independent and describes DV hemodynamics efficiently.[24] The hemodynamic significance of the DV is similar to the IVC. In the presence of poor cardiac function, the A wave is reduced or negative and the S/A ratio increases.

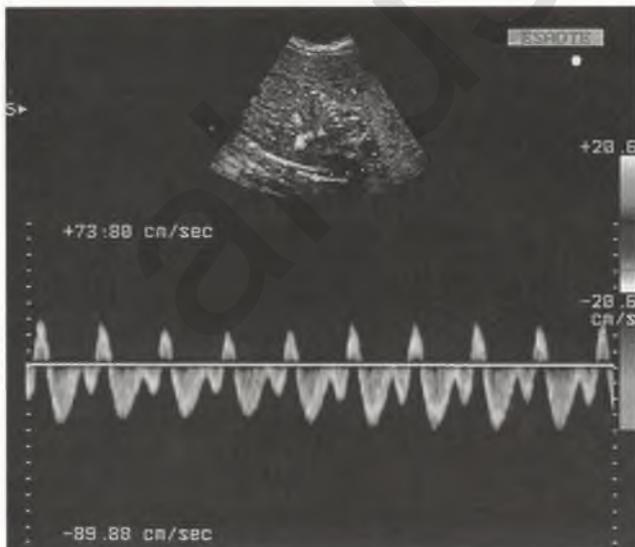
Pulmonary vein velocity waveform is recorded at its entrance into the left atrium. The waveform morphology is similar to that of the DV and is characterized by positive velocities during atrial contraction (Fig. 17–14). The striking variation in the velocity waveform morphology between IVC and pulmonary vein reflects the different hemodynamic conditions of the fetal systemic and pulmonary venous circulations. Indeed, an abnormal pattern has been described in corrected transposition of the great


FIGURE 17–12

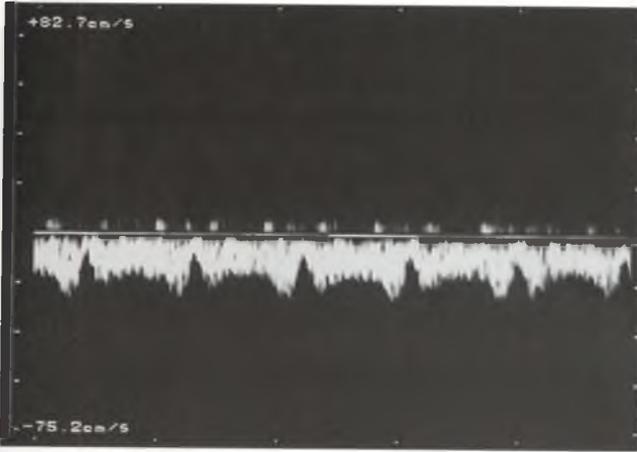

FIGURE 17–14
Velocity waveforms from the pulmonary vein showing the presence of forward flow for all the cardiac cycle.

arteries, a condition in which the afterload of the left ventricle is altered.[25]

Umbilical venous blood flow is usually continuous. However, pulsations in the umbilical venous flow reflecting the heart rate occur in the presence of a relevant amount of reverse flow in the inferior vena cava during atrial contraction. In normal pregnancies, these pulsations cease after the 12 weeks of gestation. Before 12 weeks, they are secondary to ventricular stiffness, which causes a high percentage of reverse flow into the inferior vena cava.[1] The presence of pulsations in the umbilical vein after 12 weeks indicates severe cardiac compromise.[1] *In clinical practice, the venous circulation is evaluated in sequence moving away from the heart. The further the pulsations are from the heart, the greater the stiffness/cardiac compromise.*

Atrioventricular Valves

Flow velocity waveforms at the level of mitral and tricuspid valves are recorded in the apical four-chamber view of the fetal heart. They are characterized by two diastolic peaks corresponding to early ventricular filling (the "E" wave) and active ventricular filling during atrial contraction (the "A" wave) (Fig. 17–15). The ratio between the E and A waves (E/A) is a widely accepted index of ventricular diastolic function and is an expression of both the cardiac compliance and preload conditions.[26,27]

Outflow Tracts

Flow velocity waveforms from the aorta and pulmonary artery are recorded respectively from the five-chamber and short-axis views of the fetal heart (Figs. 17–16 and 17–17). PV and TPV are the most commonly used indices. The former is influenced by several factors, including valve size, myocardial contractility, and afterload, whereas the latter is believed to reflect the mean arterial pressure.[26]

Pulmonary Vessels

Velocity waveforms may be recorded from the right and left pulmonary arteries or from peripheral vessels within the lung. The morphology of the waveforms varies according to the sample site, and their analysis has been used to study the normal development of the pulmonary circulation.[27]

Three-Vessel View

In this view, the pulmonary artery and ascending aorta have the same flow direction and thus have the same

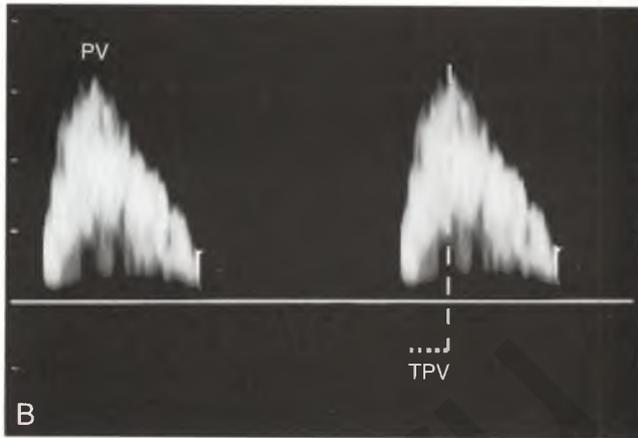
FIGURE 17–15
A, Apical flow chamber view of the fetal heart showing the normal filling of the two ventricles (*red color*). *B,* Pulsed Doppler tracing from tricuspid valve. Note the typical morphology (E and A waves) and the absence of flow during systole (see Color Plate 9).


FIGURE 17–16
A, Short-axis view of the fetal heart with the color Doppler superimposed showing the outflow of the right ventricle (*blue*). *B*, Pulsed Doppler tracing at the level of the pulmonary valve and the typical velocity waveform recorded. PV, peak velocity; TPV, time to peak velocity (see Color Plate 10).

The parameter most commonly analyzed is the PV during systole or, similarly to peripheral vessels, the pulsatility index[28]:

$$PI = (systolic\ velocity–diastolic\ velocity)/mean\ velocity$$

Normal Ranges of Doppler Cardiac Indices

The velocity waveforms are recordable from 11 weeks on.[29] The cardiovascular indices change dramatically at all levels up to 20 weeks. The PLI of the IVC decreases

color when imaged with color flow Doppler (Fig. 17–18). Severe outflow obstruction to one of the ventricles leads to reverse flow in the pulmonary artery (right side obstruction) or in aorta (left side obstruction) (Fig. 17–19).

Ductus Arteriosus

Ductal velocity waveforms are recorded in a short-axis view showing the ductal arch. They are characterized by continuous forward flow throughout the cardiac cycle.[26]

FIGURE 17–17
Long-axis view of the fetal heart with the color Doppler superimposed showing the outflow of the left ventricle (*blue*). The sample volume is placed at the level of the aorta and the typical velocity waveform recorded (see Color Plate 11).

FIGURE 17–18
Three-vessel view with the color Doppler superimposed showing pulmonary artery (PA) and ascending aorta (AO) with the same flow direction (see Color Plate 12).

FIGURE 17–19
Three-vessel view in a fetus with pulmonary atresia. *A*, The pulmonary artery is not evidenced (?) in real-time image. *B*, With the color Doppler superimposed, a small caliber pulmonary artery is identified with reversal flow (*red*) indicating retrograde perfusion from the systemic circulation to pulmonary circulation (see Color Plate 13).

DV.[22] At the level of atrioventricular valves, the E/A ratios increase progressively, reaching a value near 1 at term.[19,20] Similarly, the PV increases linearly at the level of both the pulmonary and aortic valves.[26] The PV of the aortic valve is usually greater than at the pulmonary artery, and under normal conditions, it is always below 100 cm per second. The change in TPV is minimal.[26] TPV measurements at the level of pulmonary valve are lower than at the level of the aortic valve, suggesting the blood pressure in the pulmonary artery is slightly higher than in the ascending aorta.[26] Quantitative measurements reveal the right cardiac output (RCO) is higher than the left (LCO), and that the RCO/LCO ratio remains constant from 20 weeks onward, with a mean value of 1.3.[1,26] This is lower than that reported in fetal sheep (RCO/LCO = 1.8) and may reflect the higher brain weight of humans, requiring a higher left cardiac output.[26]

The ductus arteriosus PV increases linearly with advancing gestation, and its values represent the highest velocities in the fetal circulation under normal conditions.[26] Ductal constriction is suggested by a systolic velocity measurement above 140 cm per second in conjunction with a diastolic velocity greater than 35 cm per second or a pulsatility index value less than 2.[28]

CARDIAC STRUCTURAL ANOMALIES

Septal Defects

Septal defects are the most common congenital heart defects with an estimated incidence of about 0.5 per 1000 live births.[2] They are either atrial, ventricular, or atrioventricular septal in location.

Isolated atrial septal defects have been diagnosed in utero, but the diagnosis remains difficult because of the foramen ovale. Echocardiographic diagnosis requires demonstration of either the absence or reduction in the dimension of the foramen ovale valve flap (ostium secundum defect). Dropout of echoes at the level of the outlet of the atrial septum in a perpendicular view suggests the presence of an ostium primum defect or an incomplete form of atrioventricular canal.

Atrial septal defects do not impair fetal cardiac function and only rarely do so in the neonate. However, atrial septal defects are associated with other cardiac malformations (coarctation and conotruncal anomalies), an abnormal karyotype (e.g., trisomy 21), and genetic syndromes (e.g., Holt-Oram syndrome).

Ventricular septal defects are classified by their location in the septum: perimembranous, inlet, trabecular, and outlet. Perimembranous defects are most common (80%), and involve the membranous portion of the interventricular septum just below the aortic valve. They can extend a variable degree into the muscular portion. Septal defects are not responsible for fetal compromise.

significantly,[1,24,26] the E/A ratio at both atrioventricular levels increases dramatically,[1,26] and the PV and TVI of the outflow tracts, particularly at the level of pulmonary valve, increase.[26] These changes are consistent with rapid development of ventricular compliance (explaining the decrease in the IVC PLI and the increase in the E/A) and a shift in the cardiac output toward the right ventricle as placental resistance falls, decreasing right ventricular afterload.

After 20 weeks, the IVC PLI declines less dramatically while there is a significant decline in the S/A ratio of the

FIGURE 17–20
Lateral four-chamber view showing the interventricular septum with an evident defect (*arrows*) in the muscular portion.

FIGURE 17–21
This small perimembranous septal defect is visualized with the help of color Doppler. High-velocity jet from the left to the right ventricle is due to the association of aortic stenosis (see Color Plate 14).

Because the pressure of both ventricular cavities is similar, even large defects cause only small bidirectional shunts that do not affect intracardiac hemodynamics. The vast majority of infants with interventricular septal defects are asymptomatic in the neonatal period. It is calculated that a quarter of the ventricular septal defects close spontaneously during intrauterine life,[31] and another third of the remaining defects close during the first year of life.[30]

Echocardiographic diagnosis relies on the demonstration of echo dropout in the interventricular septum. Care is necessary to avoid artifact due to the inherent limitations in the lateral resolution of ultrasound. The diagnosis is made only when the ultrasound beam is perpendicular to the septum (Fig. 17–20). Color Doppler is useful for demonstrating the shunt between ventricles. This is particularly clear when the outflow of one ventricle is obstructed (unidirectional shunt) (Fig. 17–21). The application of new generation equipment with high-resolution color and power energy Doppler (in which flows are independent of the angle of insonation) is also helpful for detection of isolated ventricular septal defects.[32] The prognosis for an infant with an isolated interventricular septal defect is good. However, it is essential that other cardiac and extracardiac anomalies be carefully excluded and a normal fetal karyotype documented.[4,5]

Abnormal development of both the atrial and ventricular septa is described as an atrioventricular septal defect; either the endocardial cushion or an atrioventricular canal forms. The typical appearance is of a single, atrioventricular valve opening above and bridging the two ventricles (Figs. 17–22 and 17–23). The common atrioventricular valve may be incompetent, with systolic regurgitation leading to fetal heart failure and hydrops.

Atrioventricular septal defects are frequently associated with fetal aneuploidy (50% of the cases, particularly trisomy 21),[5] cardiac isomerism (cardiosplenic syndromes), and other extracardiac anomalies.[4]

Hypoplastic Left Ventricle

A small left ventricle secondary to mitral or aortic stenosis/atresia characterizes the hypoplastic left heart syndrome. Blood flow to the head and coronary artery is supplied by retrograde flow through the ductus arteriosus and the aortic arch. The incidence of hypoplastic left heart

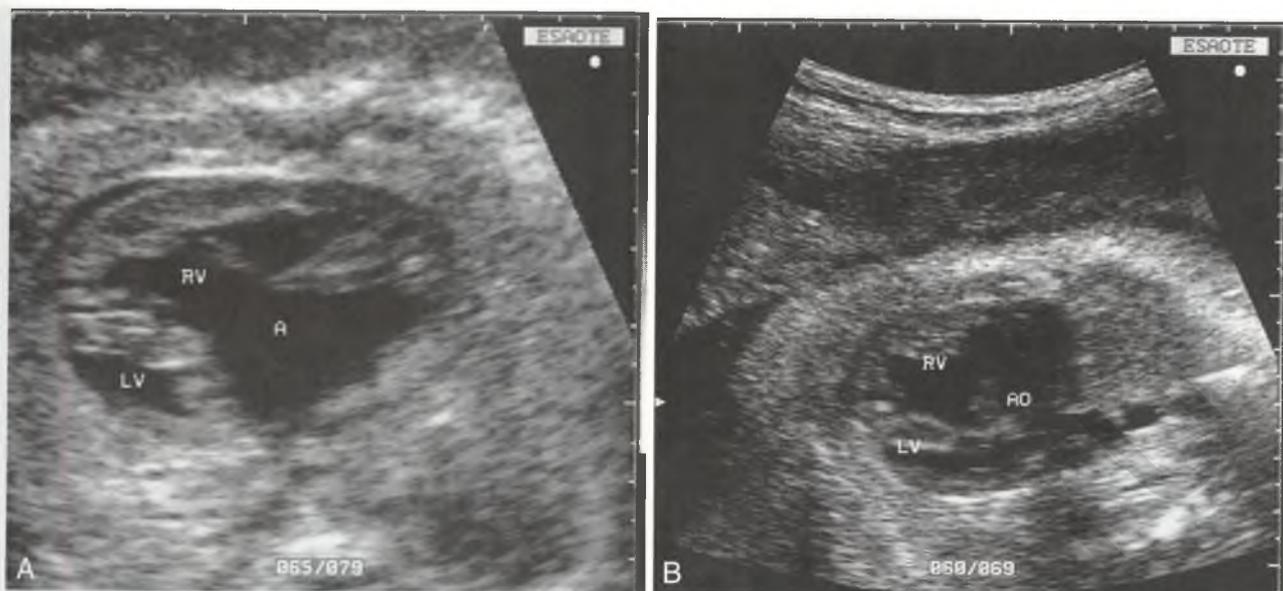
FIGURE 17–22
Apical four-chamber view showing a defect of the atrioventricular septum in a case of atrioventricular canal. A, atrium; LV, left ventricle; RV, right ventricle.


FIGURE 17–23
A, Lateral four-chamber view of the fetal heart showing a common atrium (A) with a huge defect of the atrioventricular septum and, *B*, the small dimensions of the left ventricle (LV) and aorta (AO) with respect to the right ventricle (RV), demonstrating the presence of an atrioventricular canal with right ventricle dominance.

syndrome approximates 0.16 per 1000 live births, and constitutes about 10% of infants with congenital heart diseases[33] and up to 20% of those detected in utero.[34]

Echocardiographic diagnosis begins with the demonstration of a small left ventricle (Fig. 17–24). The ascending aorta is severely hypoplastic, and the right atrium,

FIGURE 17–24
Lateral four-chamber view showing the hypoplasia of the left ventricle. LV, left ventricle; RV, right ventricle.

right ventricle, and pulmonary artery relatively enlarged. Color and pulsed Doppler flow examination may reveal absent flow from the left atrium to the left ventricle (mitral atresia) (Fig. 17–25) and retrograde flow in the aortic arch.

A hypoplastic left ventricle is well tolerated in utero, and congestive heart failure is unusual. However, the postnatal prognosis is poor. This lesion is responsible for 25% of cardiac deaths during the first week of life.[35,36] Surgical options are limited. Norwood's three-stage operation was developed to correct this disease. And even though the reported survival rate in selected centers reaches 60%, the long-term prognosis for these children after three procedures remains uncertain.[37] Cardiac transplant programs for the neonate have also been developed, but the long-term results of these, too, are disappointing.[38]

Pulmonary Atresia With Intact Ventricular Septum

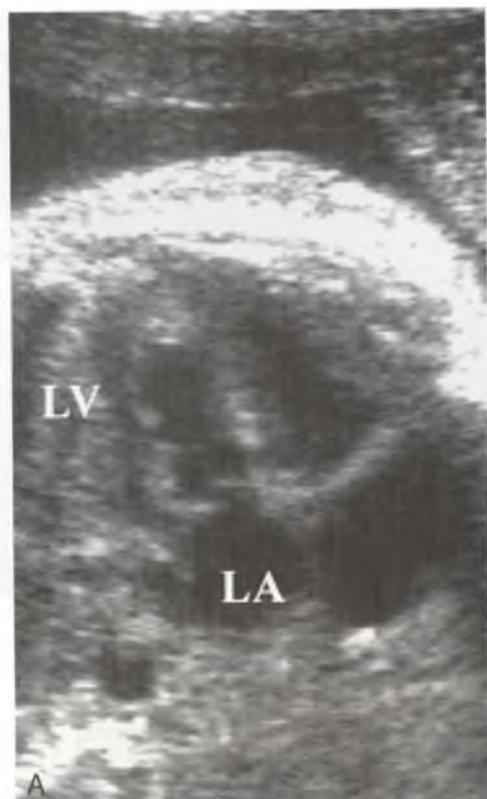
Pulmonary atresia with intact ventricular septum makes up 3% to 4% of neonatal and prenatal series.[2,33] There are two forms of pulmonary atresia found in the fetus. In about 75%, the right ventricle is hypoplastic,[28] and in the remaining 25%, the right ventricle is enlarged (see Fig. 17–27).[33] In the former instance, the tricuspid valve is atretic (Fig. 17–26), and in the latter case, it is typically insufficient (Fig. 17–27). Echocardiographic diagnosis relies on the demonstration of a small pulmonary artery with an atretic pulmonary valve. The four-chamber view is abnormal and shows variable degrees of right ventricular hypoplasia.


FIGURE 17–25

A, Apical four-chamber view of the fetal heart in a hypoplastic left ventricle. *B*, The color Doppler shows the normal filling of the right ventricle (*red*) and the absent filling of the left ventricle (mitral atresia) (see Color Plate 15). LV, left ventricle; RV, right ventricle.

FIGURE 17–26

A, Four-chamber view of the fetal heart in the presence of a pulmonary atresia and intact septum. The right ventricular size is reduced, and the tricuspid valve is hyperechogenic. *B*, Color Doppler shows the absent filling of the right ventricle (tricuspid atresia) (see Color Plate 16). LV, left ventricle; RV, right ventricle.

Color and pulsed Doppler studies reveal retrograde flow in the pulmonary artery and either the absence (atresia) of or retrograde flow (insufficiency) across the tricuspid valve. Heart failure and hydrops often develop with tricuspid regurgitation. Anomalies of the coronary arteries are common and can complicate surgical correction. Extracardiac anomalies are unusual.

Factors that affect prognosis are strictly related to ventricular size and presence of coronary fistulas. If a postnatal two-ventricular repair can be achieved, the long-term outcome can be good. On the other hand, if the right ventricle is a severely hypoplastic right ventricle and addressed therapeutically with a Fontana procedure (placement of a circuit between the right atrium and the main pulmonary artery), the action is considered palliative, associated with several short- and long-term complications. Transplantation often becomes necessary during young adult life.[39,40]

Outflow Tract Obstructions

Aortic Stenosis and Coarctation of the Aortic Arch

Aortic stenosis is found in 0.04 per 1000 live births[2] and may be supravalvular, valvular, and subvalvular.[41] The

FIGURE 17–27
Apical four-chamber view in the presence of a pulmonary atresia and intact septum. The right ventricular size is normal and the right atrium is increased (*A*). When the color Doppler is superimposed a high-velocity retrograde jet is seen (*blue*) (*B*) and a holosystolic high velocity (>2 m/sec) tricuspid regurgitation is measured by pulsed Doppler (*C*) (see Color Plate 17). LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle.

pressure in the left ventricle is increased. In severe cases, the left ventricular pressure overload decreases coronary perfusion, leading to subendocardial ischemia, secondary endocardial fibroelastosis, and in utero congestive heart failure. The echocardiographic diagnosis requires demonstration of a small and abnormal aortic valve usually associated with an enlarged, poststenotic ascending aorta. Doppler examination will show increased flow velocities in the ascending aorta distal to the stenotic site (Fig. 17–28) and, in the severe cases, regurgitation across the mitral valve.

Several fetal medicine specialists have attempted in utero balloon dilation of the stenotic aortic valve by transthoracic puncture of the fetus. In several instances, the procedure was a technical success with a reduction in severity. Unfortunately, antenatal treatment has yet to produce a survivor past the neonatal period.[42,43]

Coarctation is a narrowing of a portion of aortic arch, usually between the left subclavian artery and the ductus arteriosus. In some cases, the narrowing encompasses the proximal aortic arch and is defined as a hypoplastic aortic arch or, if completely interrupted, an interrupted aortic arch. The incidence approximates 0.18 per 1000 live births and is frequently associated with other cardiac anomalies (up to 90%) including ventricular septal defect, aortic stenosis, and transposition of great arteries.[2,41] Extracardiac anomalies including diaphragmatic hernia, renal agenesis, esophageal atresia, Turner syndrome, and the chromosome 22q11 deletion syndrome are also frequent.

Coarctation has no significant impact on intrauterine hemodynamics because it is the right ventricle that mainly supplies the descending aorta via the ductus arteriosus. Symptoms develop in the neonatal period. The only in utero echocardiographic evidence of coarctation

FIGURE 17–28
Color Doppler image with the pulsed Doppler sample placed on the aortic valve showing high velocities (PV > 220 cm/sec) suggestive of aortic stenosis (see Color Plate 18).

FIGURE 17–29
Short-axis view of the fetal heart showing the small size of the aorta (AO) with respect to pulmonary artery (PA) (*A*) and arch view showing severe hypoplasia of the aortic arch (*B*).

may be a relatively enlarged right ventricle compared to the left ventricle. Additional signs of coarctation include an echogenic shelf in the aortic lumen at the level of the isthmus, a relative decrease in the diameter of the aorta compared to the pulmonary artery (Fig. 17–29*A*), and a hypoplastic arch (Fig. 17–29*B*).[44] Hypoplasia of the left ventricle may develop in more severe cases (hypoplastic arch or interruption).[45] The surgical mortality rate reported for coarctation of the aorta is less than 10%. However, surgical mortality rate may be higher when there are additional lesions, particularly if there is a significant left-sided heart obstruction, and the surgical approach and thus morbidity overlaps with the correction of hypoplastic left heart syndrome.[46]

Pulmonary Stenosis

Pulmonary stenosis occurs in about 0.9 per 1000 live births and is generally thought to result from fusion of the pulmonary valve leaflets.[2] Associated cardiac and extracardiac anomalies are less common than they are with aortic stenosis but can include atrial septal defects and total anomalous pulmonary venous return. It is usually present in Noonan's syndrome.

The relevant hemodynamic concerns for pulmonary stenosis are the same as aortic stenosis. The right ventricular pressure is increased in proportion to the degree of stenosis. The resulting ventricular wall hypertrophy may cause tricuspid regurgitation. The echocardiographic diagnosis relies on identification of a small, sometimes thickened pulmonary valve with a characteristic abnormal movement (doming). A poststenotic enlargement of the pulmonary artery is common.[47] Doppler examination reveals increased velocities at the level of the pulmonary valve (Fig. 17–30) and tricuspid insufficiency. The progression from stenosis to atresia in utero is well documented.[48] The prognosis is usually good, and postnatal balloon valvuloplasty is usually the only treatment required.

Conotruncal Malformations

Conotruncal malformations are a heterogeneous group of defects affecting the connection between the ventricles and the great arteries. They constitute 20% to 30% of all cardiac anomalies.[2] Conotruncal malformations include the following four anomalies:

- Transposition of the great arteries
- Tetralogy of Fallot
- Double outlet right ventricle
- Truncus arteriosus

Unfortunately, they are commonly missed during the routine obstetric sonographic examination if limited to the four-chamber view, as the ventricles are usually similar in size. Undiagnosed conotruncal malformations can result in neonatal emergency with considerable morbidity and even death. However, the outcome is generally good if promptly recognized and early corrective surgery is undertaken.

Transposition of Great Arteries

The prevalence of transposition approximates 0.2 in 1000 live births.[2] The complete form, characterized by atrioventricular concordance and ventricular-arterial discordance is most common. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Either a ventricular septal defect or pulmonary stenosis is present in about half, though complete transposition is only rarely associated with extracardiac anomalies or an abnormal karyotype. Echocardiographic

diagnosis requires demonstration that the left ventricle in the long-axis view connects to a great vessel with a posterior course that bifurcates (pulmonary artery) (Fig. 17–31). In the short-axis view, the vessel originating from the right ventricle has an upward course and gives rise to the brachiocephalic vessels (Figs. 17–32 and 17–33).

The parallel circulatory model of the fetus permits normal development, and hemodynamic compromise is unusual. However, newborns may be cyanotic and deteriorate rapidly, depending on the size of the shunt at the level of the foramen ovale or across any associated ventricular septal defect. Identification of a small foramen ovale prenatally may be an indication for a balloon atrial septostomy (Rashkind procedure) immediately after birth. Cardiac surgery consists of switching the great arteries and is usually performed during the neonatal period. The survival rate ranges between 85% and 90%.[49]

Tetralogy of Fallot

Tetralogy of Fallot occurs in 0.4 in 1000 live births[2] and includes stenosis of the infundibulum of the pulmonary artery, a ventricular septal defect, an aortic valve overriding the interventricular septum, and hypertrophy of the right ventricle. The hypertrophy usually develops only after birth. In about 20%, the pulmonary valve is atretic, a condition usually described as pulmonary atresia with ventricular septal defect. Tetralogy of Fallot is associated with other cardiac defects such as an atrioventricular canal (4%) or pulmonary valve absence (1%). Extracardiac anomalies (particularly chromosomal) are frequent.

The echocardiographic diagnosis requires demonstration of an enlarged aortic root overriding the intraventricular septum (Fig. 17–34A),[50,51] an intraventricular septal defect (Fig. 17–35), and a small pulmonary valve. Color flow mapping will reveal systolic jets from both the right and left ventricles into the overriding aorta with a Y shape (Y sign) (see Fig. 17–34B). The presence of increased velocities in the pulmonary artery corroborates the diagnosis of pulmonary stenosis (see Fig. 17–35), while the absence of anterograde flow across the valve or retrograde flow in the ductus arteriosus supports the diagnosis of pulmonary atresia. Cardiac failure in utero or during the first days of life is uncommon. In the absence of extracardiac defects, the survival rate after corrective surgery approximates 95%. This percentage is lower when associated with pulmonary atresia.[50] In that instance, the diameter of any available pulmonary artery is crucial.

Double Outlet Right Ventricle

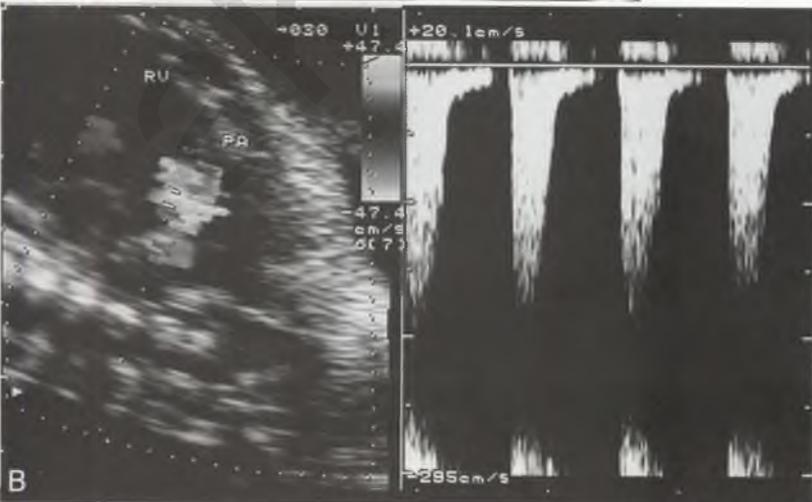
The prevalence of double outlet right ventricle approximates 0.32 per 1000 live births.[2] It is characterized by a ventricular septal defect associated with an aorta and pulmonary artery that arise from the right ventricle anterior


FIGURE 17–30
Short-axis view of the fetal heart in a fetus with pulmonary stenosis. *A*, Narrowing of the valve. *B*, Color Doppler superimposed showing high velocities in pulmonary artery (PA). Pulsed Doppler demonstrates high-velocity waveforms (180 cm/sec) consistent with pulmonary stenosis (see Color Plate 19).

FIGURE 17–31
Example of correct transposition of great artery with intact septum. The heart is seen in long axis, and in contrast to normal, both great arteries are seen in this projection. They arise in parallel orientation with the aorta (AO) from the anterior right ventricle (RV) and the pulmonary artery (PA) from the posterior left ventricle (LV) (see Color Plate 20).

to the ventricular septum (Fig. 17–36). The position of the great arteries relative to each other may vary from normal to transposition. Associated anomalies include mitral valve atresia, atrioventricular canal, and pulmonary stenosis. Extracardiac and chromosomal anomalies are common. Distinguishing double outlet right ventricle from tetralogy of Fallot can be difficult when the relationship between the great arteries is normal and pulmonary artery stenosis is present.

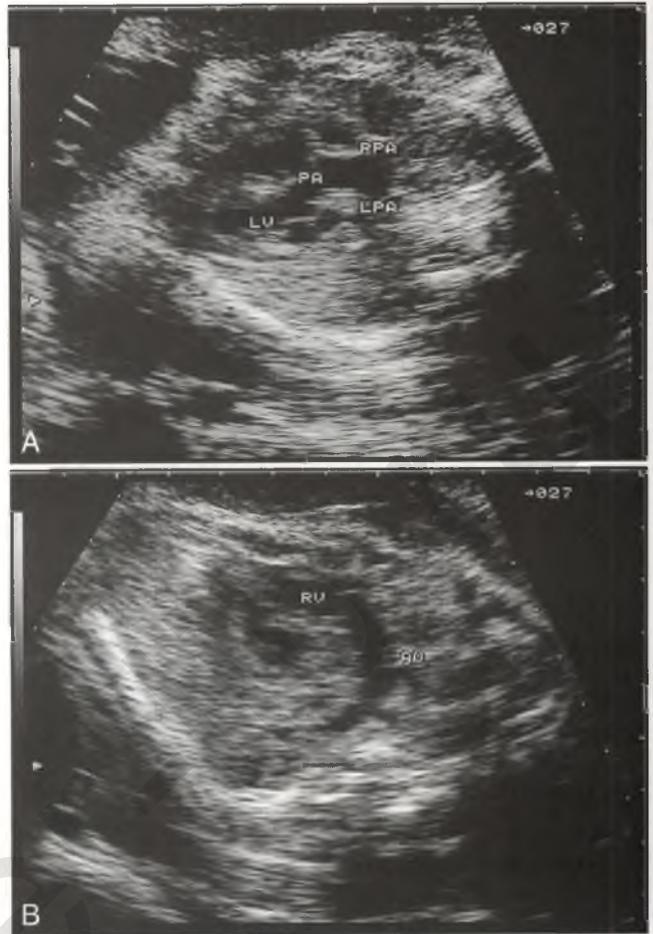
The hemodynamic effects of this malformation are similar to tetralogy of Fallot. Cardiac decompensation is


FIGURE 17–32
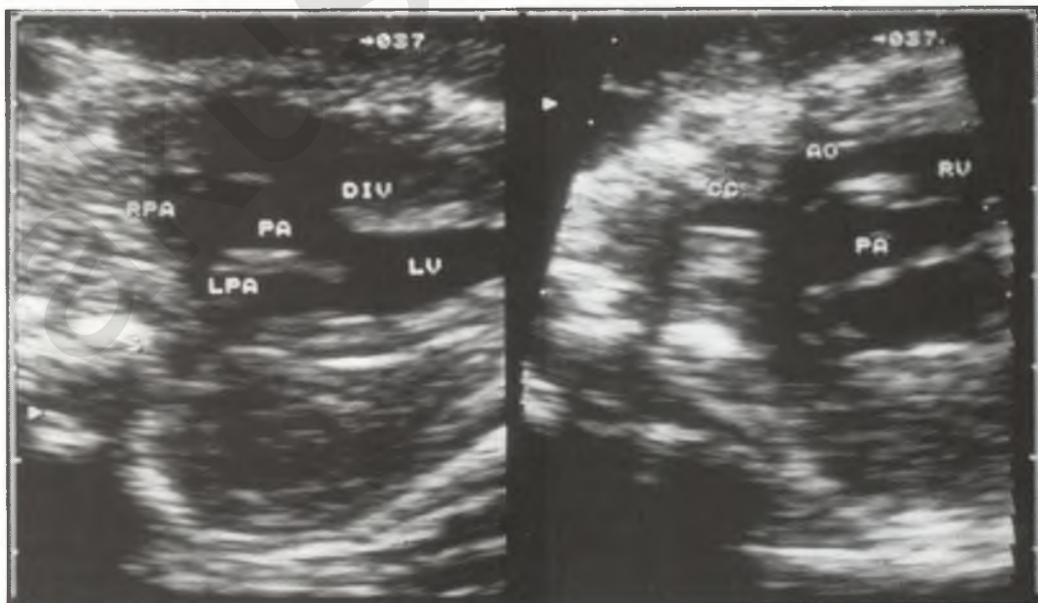
Example of correct transposition of great artery and intact septum. A, From the long-axis view the left ventricle (LV) is connected to the pulmonary artery (PA) that bifurcates into the right (RPA) and left (LPA) branches. B, The right ventricle (RV) is connected to the aorta (AO).


FIGURE 17–33
Example of correct transpotion of great artery associated with a ventricular septal defect (DV). From the long-axis view the left ventricle (LV) is connected to the pulmonary artery (PA), which bifurcates into the right (RPA) and left (LPA) branches (*left panel*). The right ventricle (RV) is connected to the aorta (AO) (*right panel*).

FIGURE 17–34
Long-axis view of the fetal heart in a fetus with tetralogy of Fallot. *A,* The aorta (AO) is overriding the left (LV) and right ventricles (RV) in real time. *B,* The color Doppler shows the perfusion during systole from the left (LV) and right (RV) ventricles into the overriding aorta (AO) (Y sign) (see Color Plate 21).

unusual in utero as well as in the early neonatal period. Long-term survival after corrective surgery is good (70%–80%) in the absence of associated anomalies.[52]

Truncus Arteriosus

Truncus arteriosus complicates approximately 0.01 of 1000 live births.[2] It is characterized by a single great artery, usually larger than the aorta, arising from both ventricles and overriding the ventricular septum. The truncus supplies the systemic, coronary, and pulmonary circulations. A ventricular septal defect may be present (type A) or absent (type B). Type A has four subclasses according to the origin of the pulmonary arteries.[31] Associated intracardiac anomalies are common and

FIGURE 17–35
Tetralogy of Fallot. *A,* Presence of ventricular septal defect with the aorta (AO) overriding the right (RV) and left (LV) ventricles. Color Doppler demonstrates the presence of the ventricular septal defect (*B*) and pulsed Doppler placed at the level of pulmonary valve demonstrates the presence of high velocities (>2 m/sec) consistent with pulmonary stenosis (*C*) (see Color Plate 22).

FIGURE 17–36
Double outlet right ventricle. Both great vessels originate from the right ventricle (RV). However, there is an associated transposition of the great vessels, and the aorta (AO) is posterior to pulmonary artery (PA) (*A*). Furthermore the PA is atretic and a retrograde flow (*blue*) is evident, suggesting that the pulmonary circulation depends on the aorta (*B*) (see Color Plate 23).

include mitral atresia and aortic arch hypoplasia and interruption (type A4). Extracardiac malformations are also common.

The echocardiographic diagnosis is based on the identification of a single great vessel overriding both ventricles whose dimensions are usually larger than the aorta (Fig. 17–37). The diagnosis requires that the pulmonary arteries originate from the truncus. Distinguishing truncus arteriosus from a tetralogy of Fallot with an atretic pulmonary valve may be difficult in utero.

As with other conotruncal malformations, truncus arteriosus is not associated with cardiac decompensation in utero, but it may occur during the first days of life. Surgical correction is often complex because the dysplastic truncal valve must be transformed into an aortic valve and a circuit created from the right ventricle to the pulmonary arteries. The reported survival rate at 10 years is less than 80%.[53]

Tumors of the Heart

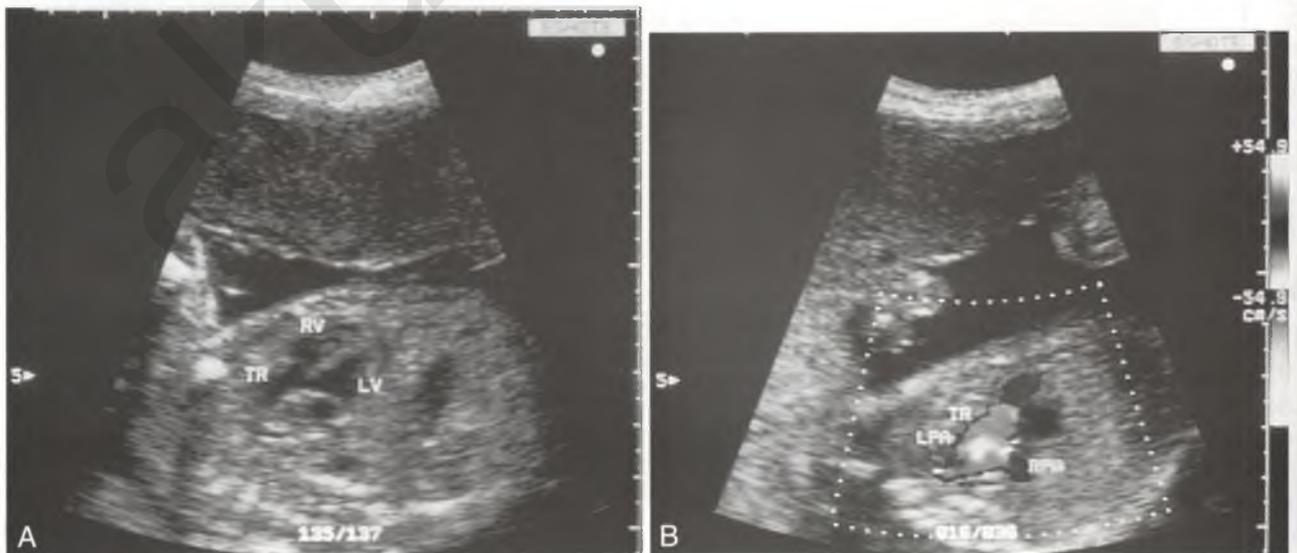
Congenital tumors of the heart are extremely rare with an incidence estimated at 0.1 in 1000 live births. The most common is rhabdomyoma. They tend to be multiple and involve the septum. Cardiac tumors are usually isolated, but are present in 50% to 86% of fetuses with tuberous sclerosis. Frequently, they are the only detectable sign of tuberous sclerosis in utero.


FIGURE 17–37
Truncus arteriosus. *A*, A single vessel (TR) overrides the two ventricles (RV, right ventricle; LV, left ventricle). *B*, Color Doppler allows the visualization of the origin of the right (RPA) and left (LPA) pulmonary arteries from the truncus (TR) (see Color Plate 24).

FIGURE 17–38
A, Apical four-chamber view showing a rhabdomyomas (∗) in the right atrium (RA). *B*, Lateral four-chamber view of the fetal heart showing that the left ventricle is filled by rhabdomyomas (∗∗). RV, right ventricle; RA, right atrium; LA, left atrium.

The echocardiographic diagnosis is based on finding one or more hyperechogenic masses within the heart (Fig. 17–38). They can create mechanical obstruction to ventricular inflow and outflow with the subsequent development of congestive heart failure. Cardiac dysrhythmias are also seen. The postnatal prognosis depends on the presence of tuberous sclerosis. Surgical excision is necessary in selected cases. Intracardiac tumors not associated with tuberous sclerosis may also shrink postnatally and remain asymptomatic.[54]

ABNORMAL DOPPLER EXAMINATION OF THE STRUCTURALLY NORMAL HEART

Real-time ultrasonography remains the primary tool for the examination of the fetal heart. However, color and pulsed Doppler flow studies are essential for a complete study. Demonstration of normal blood flow direction, a lack of turbulence, and normal velocity waveforms confirm "normal flow" in the cardiac structures and support the impression of an anatomically and functionally normal heart. On the other hand, Doppler studies may reveal abnormal flow patterns in a heart that on real-time ultrasonography appears to be structurally normal, indicating the need for additional study.

Valve Regurgitation

Valve regurgitation is characterized by bidirectional flow across the valve on Doppler interrogation. There is unidirectional flow from the atrium to the ventricle during diastole with regurgitant flow during systole. Regurgitation is uncommon across the fetal semilunar valves, but if it occurs, the regurgitation occurs during diastole.

Valve regurgitation may either be primary from valve dysplasia (e.g., tricuspid dysplasia)[52] or secondary due to increased ventricular pressure (e.g., pulmonary atresia or stenosis with intact septum) or papillary muscle dysfunction (cardiomyopathy).[56] The diagnosis of AV valve regurgitation requires demonstration of an abnormal color jet from the ventricle into the atrium during systole when imaged in the apical four-chamber view (see Fig. 17–27B). The amount of regurgitation is proportional to the peak velocity of the regurgitant jet. High velocities can cause frequency aliasing on pulsed Doppler. As a result, continuous wave Doppler is preferable when measuring the peak velocities. Although the amplitude of the jet is directly related to the pressure gradient across the valve by the Bernoulli equation ($P = 4V2$), it should not be used to quantify the severity of the disease because the pressure is influenced by both the severity of the obstruction and the ventricular contractility. A severe obstruction can be associated with a low amplitude jet if ventricular contractility is too impaired to generate an adequate pressure gradient. Analogously, a low-grade stenosis associated with a normally functioning ventricle can generate a high-velocity jet in the absence of hypertension.

The duration of the regurgitant jet is of particular clinical importance.[56] Regurgitation limited to early systole is usually benign, whereas a jet that is holosystolic suggests severe hemodynamic compromise (see Fig. 17–27C). Here, venous return is impaired and venous hypertension develops. Heart failure and hydrops may result.

Normal flow direction with high velocities

This pattern of flow may result from hemodynamic adaptation to a hypoplastic or atretic structure in the contralateral side. For example, the flow across the tricuspid and pulmonary valves is increased in the presence of a hypoplastic left ventricle. Likewise, the flow across the mitral and aortic valves is increased in the presence of

pulmonary atresia. The diagnosis is made when pulsed Doppler interrogation reveals a normal velocity waveform associated with increased PV and TVI.

Increased velocities may also occur with stenotic lesions such as pulmonary or aortic stenosis. In this setting, the flow is turbulent and the velocities high. Color Doppler allows for the identification of turbulent flow, and the velocity waveforms obtained with pulsed or continuous wave Doppler reveal an irregular profile and a high PV. Again, the value of the PV is not used clinically to define the severity of the stenosis because it also reflects ventricular contractility.

Absent Filling

No flow in a cardiac chamber suggests atresia of either the mitral (left ventricle) (see Fig. 17–25B) or tricuspid (right ventricle) valves (see Fig. 17–26B). For accuracy, the equipment must have the correct settings and the angle of insonation must parallel the expected direction of flow (apical four-chamber view). Further, the gain, pulse repetition frequency, and filter must be set correctly to avoid artifact. Flow in the contralateral ventricle (apical four-chamber view) is proof of proper technique.

Abnormal Flow Direction

Because of the parallel nature of the fetal circulation, arterial blood can flow in a reverse direction if the flow from one ventricle is either absent or severely reduced. Examples include hypoplastic left heart syndrome or a severe aortic stenosis in which the aortic arch is perfused in a retrograde manner from the ductus arteriosus (Fig. 17–39). In this way, the right ventricle can supply the cerebral and coronary circulations. On the other hand, both pulmonary atresia and severe ductal stenosis are associated with reversed aortic arch flow as the pulmonary

FIGURE 17–39
Arch view in presence of a hypoplastic left ventricle. The arch is perfused in the reverse direction (blue color is seen instead of red) suggesting that the brain and coronary circulation depend on the right ventricle. AO, aorta (see Color Plate 25).

circulation depends on the left ventricle. Such abnormal hemodynamics are particularly important after birth.

Abnormal flow direction may be detected at the level of the foramen ovale or at the level of a ventricular septal defect. Visualization of these abnormal flow patterns suggests the presence of a malformation that alters the pressure equilibrium between the right and left heart chambers. Examples include reverse direction flow (left to right) through the foramen ovale with a hypoplastic left ventricle, or a unidirectional jet across an interventricular septal defect when there is an outflow tract lesion (see Fig. 17–21).

ADVANTAGES OF DOPPLER EXAMINATION FOR THE EVALUATION OF FETAL HEART DISEASES

An investigation of the cardiac flows helps the assessment of cardiac disease in several ways:

- *Define the nature of the cardiac malformation.* Copel and associates[57] observed retrospectively that color Doppler was essential for establishing the correct diagnosis in 29%, helpful in 47%, and neither helpful nor misleading in the remaining fetuses. We analyzed prospectively 145 fetuses with congenital heart disease, and found that the combination of color and spectral Doppler was essential for the diagnosis in 34 fetuses (23%, mainly outflow tract stenosis or complex heart diseases such as isomerism and double outlet right ventricle with atresia of one semilunar valve), useful in 62 fetuses (42%, mainly congenital heart disease complicated by valve atresia or outflow tract obstruction causing abnormal flow direction), and not helpful in the remaining 49 fetuses (34%, mainly complete atrioventricular canal and ventricular septal defects).

- *Evaluate the hemodynamic consequence of congenital heart disease.* The consequences of the sonographically same congenital heart disease may range in utero from no effect to cardiac failure and hydrops. This wide range of hemodynamic effects reflects the severity of the primary lesion, the presence of associated anomalies, the cardiac rhythm, and any impairment of ventricular function. The detection of regurgitation at the level of atrioventricular valve by Doppler is a particularly useful predictor of hydrops. The presence of holosystolic, tricuspid regurgitation either isolated or associated with mitral regurgitation predicts the development of hydrops fetalis with subsequent poor prognosis. Study of the systemic venous circulation also provides a valuable index of the overall cardiac performance. Although there is no general agreement on the significance of the venous indices and on the vessel of choice, it is our experience that the velocity waveforms from IVC show a higher correlation with cardiac function than either the DV or umbilical vein.[22] This information is helpful as the health care team formulates a plan, predicts prognosis, and counsels the parents (also see Chapters 11 and 12).

- *Monitor the evolution of congenital heart diseases.* Doppler echocardiography is not only helpful in establishing the correct diagnosis, but is also valuable longitudinally to follow the natural history and progression of a malformation. One example is the evolution of pulmonary stenosis or atresia in fetuses with primary tricuspid valve regurgitation, which is presumably due to the lack of forward flow in the pulmonary artery. This has been described in both fetuses with tricuspid regurgitation due to a dysplastic tricuspid valve and fetuses with presumed cardiac overload secondary to presumed twin-to-twin transfusion syndrome.[58] Similarly, a progressive increase in the severity of pulmonary stenosis of tetralogy of Fallot up to atresia is documented.[59,60] Knowledge of the pathologic evolution can be useful for timing delivery and for developing prenatal treatments such as balloon valvuloplasty in fetuses with deteriorating function.
- *Plan neonatal management.* The hemodynamic information gained from antenatal Doppler studies helps predict problems after birth. For example, the neonate with a critical stenosis or atresia at the level of the outflow tract (e.g., hypoplastic left ventricle, pulmonary atresia with intact septum) is ductal dependent after birth and will require continuous intravenous prostaglandin E_1. Closure of the ductus would have disastrous consequences because either systemic (left obstruction) or pulmonary (right obstruction) blood flow depends on ductal patency. Another example is the detection of a small (restrictive) foramen ovale in a fetus with complete transposition of the great arteries and an intact septum. Here, it can be anticipated that the shunt between the two circulations after birth will be insufficient, and cyanosis with rapid deterioration expected. A pediatric cardiologist should be present at delivery to promptly perform a balloon septostomy (Rashkind procedure) if needed. Advanced knowledge of these issues permits a planned delivery at a tertiary center where the facilities exist to optimize outcome.[61]

MANAGEMENT OPTIONS FOR THE FETUS WITH CONGENITAL HEART DISEASE

Cardiac malformations are the most common birth defects. Experienced fetal diagnosis units can detect a high percentage of major malformations (type 1 lesions, though typically requiring a surgical treatment). Once the diagnosis of a cardiac malformation is made, the following steps are recommended.

General

A plan of management should be formulated in concert with a multidisciplinary team that includes a perinatal obstetrician, a pediatric cardiologist, and where appropriate, a cardiac surgeon.

Define the Malformation and Search for Associated Anomalies

Extracardiac anomalies and a normal karyotype are common in fetuses with congenital heart defects (10% in our series). Consequently, a detailed ultrasonographic evaluation in an experienced fetal medicine center is mandatory. The presence of an associated anomaly may well influence the prognosis and postnatal management.

Search for Chromosomal Abnormalities

A karyotype is mandatory, as the result may alter management. The choice of the technique is based on the gestational age of the fetus and experience of the center (see Chapter 10). Chromosomal abnormalities are present in 10% to 40%.[5] In our prospective series of 489 fetuses with congenital heart diseases, autosomal trisomy (trisomy 18, 13, and 21) and Turner's syndrome (45XO) was the most common abnormality and accounted for 19.4% (Table 17–3). The incidence of aneuploidy varies with the type of malformation, being extremely high with some (e.g., atrioventricular canal) or unusual with others (e.g., transposition of a great artery). This information should be part of the patient counseling.

A detailed study of chromosome 22 is indicated in fetuses with a conotruncal malformation because a microdeletion at the critical region 22q11,2 occurs in high frequency of fetuses patients with this anomaly. The 22q11,2 syndrome (in the past also called CATCH 22)[63] consists of several genetic syndromes including velocardiofacial syndrome, DiGeorge syndrome, Opitz G/BBB syndrome, and conotruncal anomaly face syndrome. Patients with these syndromes have some or all of the following features:

- Mental retardation, learning disabilities, and psychiatric illness
- Congenital heart diseases, mainly conotruncal defects
- Palatal anomalies: overt and submucous cleft palate, velopharyngeal insufficiency
- Facial anomalies: long face with prominent nose, malar hypoplasia, retrognathia, and minor ear anomalies
- Thymus aplasia or hypoplasia associated with hypocalcemia and immunologic deficiency

The estimated prevalence of this deletion in the general population is 1 in 4500,[64] which makes the 22q11.2 deletion syndrome the second most common genetic condition after Down syndrome. The prevalence of this syndrome in fetuses with conotruncal anomaly approximates 20%,[18] and the syndrome cannot be detected by routine karyotypic analysis. It is necessary to use either quantitative hybridization or fluorescence in situ hybridization (FISH) techniques that are now standards in most genetic laboratories. It is also important to extend the genetic diagnosis of affected fetuses to the parents, because inherited microdeletions occur in 30%

TABLE 17-3

Incidence of Chromosomal Abnormalities in 167 Fetuses with Congenital Heart Disease Diagnosed at Fetal Medicine Center of Università of Roma "Tor Vergata" between 1992 and 1996

ANOMALY	NO.	NO. OF CHROMOSOMAL DEFECTS	PERCENT
Atrial septal defect	3	2	66.67
Ventricular septal defect	46	12	26.09
Atrioventricular canal	20	8	40.00
Hypoplastic left heart	14	0	0
Pulmonary atresia intact septum	4	0	0
Pulmonary stenosis	11	0	0
Aortic stenosis, coarctation, hypoplastic arch	16	1	6.25
Transposition of great artery	6	0	0
Tetralogy of Fallot	14	5	35.71
Double outlet right ventricle	8	3	37.50
Truncus arteriosus	2	0	0
Cardiac tumor	10	0	0
Others	16	1	6.25
Total	167	32	19.16

with the remainder being de novo. The transmission is autosomal dominant; thus, a parent with the syndrome has a 50% risk of transmitting the deletion to the offspring.[63,64]

Counseling the Parents

The parents are formally counseled by the care team after all useful information is acquired (correct and complete diagnosis of the malformation, presence or absence of associated structural and chromosomal abnormalities). It is essential the care team include, when possible, the perinatal obstetrician, the pediatric cardiologist, and the cardiac surgeon. They should describe the malformation, the possibility of surgical correction, the chance of short- and long-term survival, and the quality of life expected after the correction. Further, the parents should be provided information on the possible neurologic complications of the surgical procedures. Indeed, the correction of malformations requiring deep hypothermic cardiopulmonary bypass is associated with neurologic impairment in up to 10% of survivors.[65] After complete information is provided and all questions asked by the parents answered, the parents should be allowed freedom of choice to continue or end the pregnancy. It is particularly helpful to make an appointment a few days later to discuss their thought processes and decision and, when available, to offer psychological support.

Prenatal Monitoring

The development of the malformation should be followed serially, particularly by using Doppler ultrasonography every 2 to 4 weeks. The interval is based on the likelihood of an in utero complication developing (e.g., 4 weeks for a transposition of great artery, 2 weeks for tetralogy of Fallot). Furthermore, it is important in the third trimester to monitor fetal growth, amniotic fluid volume, Doppler velocity waveforms from peripheral fetal vessels, and fetal heart rate patterns, because the prevalences of suboptimal growth and acute fetal distress are increased.

Place, Timing, and Method of Delivery

The need to deliver in a tertiary referral center will vary with the diagnosis and upon the local resources and geographic constraints. It is important to anticipate before birth the type of assistance that may be needed. This may range from simple observation in the nursery (e.g., small ventricular septal defect), to assistance in neonatal intensive care unit or pediatric cardiology unit (e.g., ductal-dependent congenital heart disease, hydrops, immaturity), to immediate postnatal treatment (e.g., balloon septostomy in transposition of great artery with small foramen ovale).

Most fetuses with congenital heart disease tolerate labor well in the absence of uteroplacental dysfunction. There is no a priori indication for cesarean delivery. Further, it is rarely necessary for a cardiac reason to induce labor early, though it may facilitate postnatal management if the delivery is planned between 38 and 40 weeks.

Postnatal and Neonatal Management

Postnatal management includes further cardiac evaluation by the pediatric cardiologist to confirm the diagnosis and to assess the hemodynamic environment. The neonate is stabilized and the necessary treatments (interventional catheterization or surgery) are planned. Continued communication with the parents during the additional diagnostic steps and on the therapeutic strategies is extremely important.

CONCLUSIONS

- Although the prenatal identification of congenital heart disease is difficult, most cardiac anomalies can be identified by echocardiography.
- Prenatal recognition offers the chance to identify associated structural and chromosomal anomalies and to make prognostic statements about the evolution and treatability of these diseases.
- The use of appropriate antenatal and postnatal management protocols may positively impact on the care and outcome of fetuses with cardiac malformations.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Abnormalities

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
All Women:	Ib	A	66
~1% risk of congenital heart defects (CHD) in pregnancy.	IIa	B	67
Most babies with CHD are born to mothers perceived to be low risk.			
Multifetal pregnancies are at increased risk of CHD (3%).			
Periconceptual folic acid and multivitamin preparations reduce risks of CHD as well as neural tube defects.			
High risk groups (see Table 17–1):	III	B	68, 69
Maternal/paternal CHD; sibling or relatives with CHD			
Maternal insulin-dependent diabetes mellitus			
Maternal illness (phenylketonuria, epilepsy, autoimmune antibodies [e.g., SLE], drugs [e.g., lithium])			
Possibility of multifetal pregnancy (assisted conception)			
Genetic study chromosome 22 in parents if previous child with conotruncal heart malformations			
Prenatal—Screening and Diagnosis			
Increased nuchal translucency with normal karyotype indicates higher risk of cardiac anomaly and need of careful cardiac scan in second trimester.	III	B	6, 7
Routine level 2 anomaly scanning at 20 weeks should include situs and orientation, apical four-chamber view, lateral four-chamber view, left outflow tract, right outflow tract, three-vessel view, and venous return.	III	B	14, 15, 16
Refer all high risk groups for level 3 (tertiary) fetal echocardiography (see Tables 17–1 and 17–2).	–	GPP	–
Prenatal—Management			
Multidisciplinary team includes specialist obstetrician, pediatric cardiologist, and where appropriate, cardiac surgeon.	–	GPP	–
Establish clear plan of management.	–	GPP	–
Establish morphologic diagnosis and severity of circulatory compromise.	–	GPP	–
Search for other cardiac and extracardiac anomalies.	IV	C	4
	III	B	5
Offer fetal karyotyping including 22q deletion.	IV	C	4
	III	B	5
	III	B	70

Continued

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Abnormalities (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal Management—Continued			
Multidisciplinary counseling and psychological support for parents:	–	GPP	–
Give full explanation of all findings.			
Discuss possible treatments (medical and surgical) and their implications and complications, prognosis (short- and long-term), and impact on neurodevelopment.			
Offer further meeting/discussions.			
In most cases the only options are to continue with pregnancy or termination.			
Continue monitoring defect (structural and functional) to document progression of disease.	–	GPP	–
Monitor fetal health generally in chromosomally normal fetuses (growth, amniotic fluid volume, behavior, Doppler of peripheral vessels).	–	GPP	–
Labor and Delivery			
Plan delivery in center with appropriate obstetric, pediatric, and cardiologic facilities (varies with abnormality and anticipated neonatal compromise).	III	B	71
Vaginal delivery is usually appropriate for isolated cardiac defects.	–	GPP	–
Fetal monitoring is advised in labor but may not be useful (e.g., in fetal complete heart block).	–	GPP	–
Elective delivery at 38–39 weeks may be appropriate for fetuses with complex defects such as hypoplastic left heart syndrome and for optimizing pediatric facilities.	III	B	72, 73
Postnatal and Neonatal			
Stabilize the neonate, confirm the diagnosis by detailed echocardiography, and manage accordingly.	–	GPP	–
After termination of pregnancy or perinatal death, obtain postmortem examination whenever possible and arrange for bereavement counseling and discussion of the full diagnosis and implications for future pregnancies.	–	GPP	–

Fetal Craniospinal and Facial Abnormalities

Robin B. Kalish / Jane Streltzoff / Frank A. Chervenak

INTRODUCTION

Craniospinal and facial defects are among the most commonly diagnosed congenital anomalies and have a profound impact on survival, physical appearance, and function in society. Because the central nervous system is the earliest organ system to form, and facial development completes near the end of embryogenesis, teratogenic exposures such as drug ingestion, maternal illness, and infection may cause craniospinal or facial malformations at any time during embryogenesis. Genetic syndromes and chromosomal abnormalities frequently affect the development of the neuraxis and face. Further, the fetal brain continues to develop throughout gestation. Consequently, it is vulnerable to disorders of growth, as well as vascular, infectious, and traumatic insults.

OPEN NEURAL TUBE DEFECTS: ANENCEPHALY, CEPHALOCELE, AND SPINA BIFIDA

General

Neural tube closure occurs in the third to fourth weeks after fertilization. Fusion begins in the region of the fourth somite and then extends both rostrally and caudally. Closure in the region of the developing head and sacrum is completed approximately 24 and 26 days after conception, respectively. Neural tube defects most likely result from either a primary overgrowth of neural tube tissue within the line of closure, or a failure of induction by adjacent mesodermal tissues that interrupt closure. Depending on the timing and the extent of the interruption, defects may occur at both cranial and caudal ends of the neural tube. Large or small and continuous or noncontinuous regions of the neuroaxis can be affected. Anencephaly is a lethal disorder in which the brain and the overlying calvarium are absent. It is thought to result from failure of the entire rostral portion of the neural tube to close. Less extensive failure of closure in the rostral region results in cephalocele. Failure of neural tube closure in the more caudad regions results in spina bifida.

Open neural tube defects (ONTDs) are multifactorial in origin, arising from a combination of genetic and environmental factors that exhibit a threshold effect. Thus, the incidence of ONTD is highly variable, depending on geographic location, ethnicity, and gender. In particular, the incidence of ONTD is reportedly higher in Hispanic patients,[1,2] in female fetuses,[3] and in areas with low maternal folic acid intake.[4] Additional at-risk groups include women with insulin-requiring diabetes[5] or obesity.[6,7] In addition, women with a seizure disorder taking anticonvulsants including valproic acid,[8] women consuming high doses of vitamin A,[9] and women with folate or vitamin B_{12} insufficiency may be at increased risk.[10] It is important to note that women who themselves are affected, or who have had an affected infant or sibling, have a higher incidence of ONTD than the general population. ONTD also may be associated with aneuploidy and other rare genetic syndromes.[11]

Diagnosis

Screening for ONTD may be either biochemical via measurement of the maternal serum α-fetoprotein (MS-AFP) concentration or sonographic (see Chapter 8). MS-AFP screening does not detect all cases of ONTD, as the MS-AFP concentration can be normal if the lesion is predominantly skin-covered. The definitive antenatal diagnosis is made by visualizing the defect using sonog-

raphy, which can be accomplished as early as the first trimester.[12] Amniocentesis for the measurement of amniotic fluid AFP and the detection of acetylcholinesterase (AChE) is usually no longer required, but remains an adjunct to ultrasonography when the MS-AFP is elevated but no defect is visualized. However, most ONTDs can be definitively diagnosed sonographically and do not require amniocentesis for the measurement of amniotic fluid AFP or AChE.[13] The use of three-dimensional ultrasound and fetal magnetic resonance imaging (MRI) are reputed to assist in the detection and localization of ONTDs in high risk patients[12,14–16] but do not, at this time, have broad applicability.

Anencephaly

The antenatal sonographic diagnosis of anencephaly is based on the absence of the fetal calvaria, the domelike portion of the cranial vault. A mass of thin-walled channels, known as the area cerebrovasculosa, is often seen protruding from the base of the skull above the orbits (Fig. 18–1). Though easily diagnosed during the second and third trimesters, first-trimester diagnosis of anencephaly is sometimes difficult because the normal immature brain may be difficult to differentiate from the area cerebrovasculosa. However, the bony structures of the skull above the orbits should be visualized by 10 weeks' gestation. Other diagnoses should be excluded before finalizing the diagnosis of anencephaly. For example, in severe microcephaly, the bones of the skull are present but may be difficult to see sonographically. Also, constricting bands in the early amnion-rupture sequence may prevent the normal formation of the skull. In this instance, the malformation is usually asymmetrical and brain tissue is present. Amniotic bands may produce a spectrum of abnormalities from anencephaly to asymmetrical defects. Encephalocele may simulate anencephaly until a brain-filled sac is identified. Lastly, acrania, in which there is a normally formed brain with an absent skull, is often difficult to distinguish from anencephaly.

Cephalocele

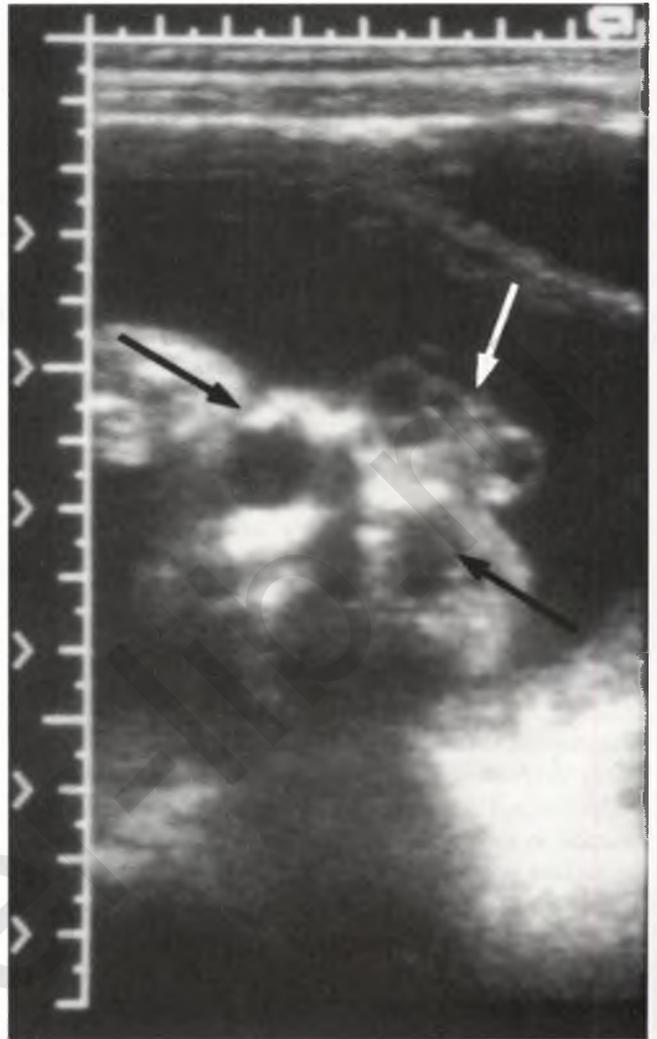
A cephalocele resembles a saclike protrusion from the head not covered with bone. The malformation is termed an encephalocele when the brain has herniated into the sac. In contrast, a cranial meningocele does not contain brain substance. Although large amounts of brain tissue are readily seen on ultrasound, the precise diagnosis can be difficult as smaller amounts may be undetectable by ultrasonography.[17] The contents of the herniated sac are typically heterogeneous (Fig. 18–2*A* and *B*). The position of the defect can be determined using the bony structures of the face, spine, and when possible, the midline echo of the brain for orientation. Most cephaloceles are occipital, but they may also be


FIGURE 18–1

parietal, frontal, or nasopharyngeal.[18] The incidence of anterior lesions is considerably higher in Asia (Fig. 18–3).[19,20] Defects away from the midline or in other atypical locations are suggestive of the amnion-rupture sequence, rather than a failure of the neural tube closure. The diagnosis of cephalocele is certain only if the bony defect in the skull is detected. Otherwise, the diagnostic possibilities include cystic hygroma, teratoma, hemangioma, and subcutaneous cyst (Fig. 18–4).

Spina Bifida

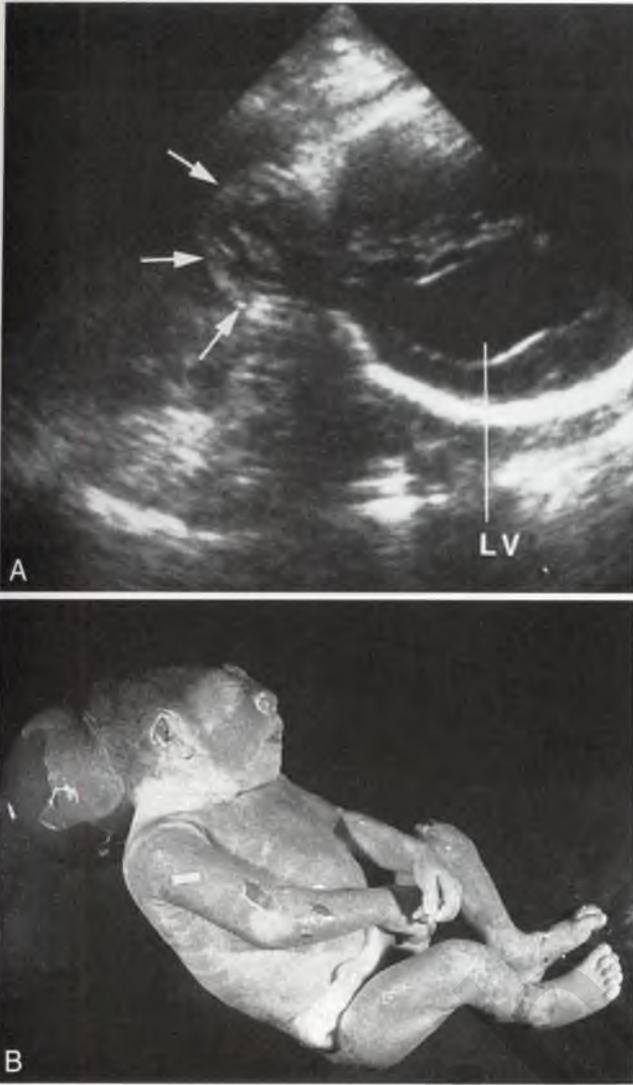
Viewed longitudinally on ultrasound, the normal spine narrows progressively as the transducer is moved caudally. In defective vertebrae, the posterior ossification centers are more widely spaced than those in vertebrae above and below the defect. Whereas an ONTD is detectable on a longitudinal ultrasound image by the loss of skin continuity (Fig. 18–5), meticulous transverse examination of the entire vertebral column is


FIGURE 18–2

FIGURE 18–3
Transverse section of the fetal head demonstrating cephalocele (C) protruding between bony orbits, resulting in hypertelorism. (From Chervenak FA, Isaacson G, Rosenberg JC, et al: Antenatal diagnosis of frontal cephalocele in a fetus with atelosteogenesis. J Ultrasound Med 1986;5:111–113.)

usually necessary to detect smaller defects. In the transverse view, spina bifida appears as a splaying of the posterior ossification centers (Fig. 18–6). In the second and third trimesters, posterior vertebral elements, including the laminae and spinous processes, are normally visible sonographically. Their absence supports the diagnosis of spina bifida. When the sonographic examination is not definitive, three-dimensional ultrasound and fetal MRI can be effective, noninvasive tools for the assessment of the fetal CNS, allowing precise localization of the lesion and evaluation of any associated hydrocephalus.[14–16] However, two-dimensional ultrasound remains the diagnostic tool of choice for evaluation of fetal anomalies including myelomeningocele.

The majority of cases of spina bifida are associated with the Arnold-Chiari malformation in which the cerebellar vermis, fourth ventricle, and medulla are displaced caudally. Nicolaides described the now classic sono-

graphic signs of the Arnold-Chiari malformation: the "lemon" and the "banana" signs (Fig. 18–7).[21] A lemon-like configuration is seen in axial section during the second trimester and is caused by scalloping of the frontal bones owing to caudal displacement of the cranial contents within a pliable skull (Fig. 18–8). As the cerebellar hemispheres are displaced into the cisterna magna, they are flattened rostrocaudally and the cisterna magna is

FIGURE 18–4

obliterated, causing a flattened, centrally curved, banana-like sonographic appearance (Fig. 18–9). These ultrasound markers are present in over 95% of second trimester fetuses with open spina bifida.[22] Eventually, the flow of cerebrospinal fluid (CSF) becomes obstructed, causing some degree of ventriculomegaly/hydrocephalus in most cases.

Management Options

Prenatal

The management of pregnancies with ONTD depends on the severity of the lesion and parental wishes. A comprehensive survey of the entire anatomy must be undertaken in all fetuses with an ONTD by an experienced sonographer to exclude other structural anomalies. Ventriculomegaly is present in the majority of cases, and the degree of hydrocephalus and subsequent macrocephaly likely impacts on the prognosis.[23] ONTDs are also

FIGURE 18–7
Schematic representation of the "lemon" and "banana" signs described by Nicolaides and associates. (From Nicolaides KH, Campbell S, Gabbe SG, Guidetti R: Ultrasound screening for spina bifida. Cranial and cerebellar signs. Lancet 1986;ii:72–74.)

seen in association with a variety of genetic syndromes, some of whose features are detectable by ultrasonography. Thus, a fetal karyotype is recommended in all instances.

Anencephaly is lethal. Most affected fetuses are stillborn or die shortly after birth.[24] Because anencephaly can be diagnosed confidently by antenatal ultrasound with a high degree of accuracy, termination of pregnancy is an ethical option at any time in gestation.[25] If it is diag-

FIGURE 18–8

nosed in the third trimester and the parents elect termination, a number of methods are available.

The most important prognostic indicators for a poor outcome with cephalocele are the presence of brain in the protruding sac and the presence of additional congenital abnormalities.[26–28] In several series, 50% to 65% of affected fetuses had additional anomalies. Burdick and associates observed that only two of eight liveborns survived infancy.[29] Brown and associates reviewed 34 cases of neonatal cephalocele and noted an overall mortality rate of 29%.[30] Perhaps the most optimistic report came from Martinez-Lage and associates, who reported an overall mortality rate of 36% in 46 newborns with cephalocele with 20 infants free of neurologic sequelae.[31] In general, about half the infants with an isolated occipital cephalocele develop normally after surgery. The outlook is dismal for children with microcephaly secondary to brain herniation. The impact of concurrent hydrocephalus has been reduced by modern shunt therapy, and thus, hydrocephalus has less impact than the presence and amount of brain herniation. Frontal cephaloceles have a better prog-

nosis than those in other locations because they tend to be smaller with less brain herniation.[32] Further, the loss of frontal cortex may produce fewer or less significant neurologic deficits than other areas of cortical loss.

The prognosis for spina bifida is variable. The extent and severity of the neurologic deficits depend on the presence of neural tissue in the meningeal sac and the spinal level and length of the lesion, as the spinal cord below the lesion is dysplastic.[33,34] Generally, lower extremity paralysis and incontinence of bowel and bladder are common; intelligence may be affected from either the lesion itself or the impact of treatment (e.g., shunt placement). A comprehensive fetal ultrasound examination should be performed to exclude genetic syndromes associated with encephalocele. For example, Meckel-Gruber syndrome has a 25% recurrence risk. Overall, 75% of infants born with spina bifida survive long term.[35]

Twenty- to 25-year outcome was reported in one study of 118 children treated neonatally for the myelomeningocele. Of the 99 patients with follow-up, 28 had died.[35] Of the 71 survivors, 85% reached high school. One quarter suffered seizures. In another study of 117 patients born with open spina bifida, 54% had died within 38 years of closure.[36] The neurologic status of the survivors ranged from normal to severe disability. Thirty-nine of the 54 survivors had an IQ of 80 or higher; 16 could walk without assistance, 22 lived independently in the community, and only 11 were fully continent. Although improvements in the management of patients with open spina bifida have reduced the infant mortality rate, long-term disability is still significant, and late deterioration is common. Dise and Lohr examined the cognitive skills of adolescents born with spina bifida up to 23 years of age.[37] All patients, regardless of IQ, had significant impairments of mental flexibility, efficiency of processing, conceptualization, or problem-solving ability. There was a high degree of variability within profiles, all containing at least one area of dysfunction. These deficits may underlie the "motivational" and academic difficulties commonly observed in these patients.

Still, affected children can grow to be productive adults with normal intelligence. Early closure of the defect, ventriculoperitoneal shunting of any associated hydrocephalus, management of urinary and fecal incontinence by surgery, dietary management, and feedback techniques are in part responsible for these improvements. It is unclear whether cesarean delivery improves the prognosis.[38] A selection bias brought about by antenatal diagnosis with termination of the most severely affected fetuses may account at least in part for the reportedly improved outcomes. The prognosis for the severely affected newborn remains serious, with gross permanent multisystem defects. It is difficult to accurately predict the prognosis in the first half of pregnancy when the diagnosis is frequently made. The option for pregnancy termination should be included in counseling the patients.

Alternatively, in utero repair of myelomeningocele to stop or slow any progression in damage to the exposed

spinal cord reportedly decreases the incidence of hind-brain herniation and shunt-dependent hydrocephalus.[39] The rationale for the procedure is that closure ante-natally may decrease spinal cord dysplasia and preserve neurologic function by protecting it from potential insults such as amniotic fluid trauma. Although fetal surgery is promising on a theoretical basis, significant complications are associated with in utero repair, including prematurity and lethal pulmonary hypoplasia secondary to oligohydramnios. In addition, the evidence of long-term benefit including improved lower extremity motor function and bladder and bowel continence is at this time unclear.[40,41] To date, no prospective randomized trials comparing the outcomes of the antenatal versus postnatal surgical repair of meningomyelocele have been published. The American College of Obstetrics and Gynecology advised in 2000 that such surgery should be considered experimental until the availability of evidence that the benefits outweigh the risks to both mother and fetus. Currently, there is a multicentered randomized clinical trial under way in the United States in order to compare the outcomes of fetal surgery with postnatal management for spina bifida.[34]

When a meningomyelocele is diagnosed and the patient plans to continue the pregnancy, a multidisciplinary team consisting of a pediatric neurologist, neurosurgeon, obstetrician, and neonatologist assemble to discuss the implications with the family. An actively involved perinatal social worker can provide invaluable support to the family before and after birth. Fetal surveillance is recommended for all ongoing pregnancies with the exception of anencephaly, including serial sonography to assess fetal growth, head size, and severity of ventriculomegaly. Unless maternal or other obstetric indication takes precedence, delivery should occur at term or with documentation of fetal lung maturity.

Labor and Delivery

Postmaturity is common in pregnancies complicated by anencephaly. Cesarean delivery is not indicated for fetal distress, but may be necessary for maternal indications. Humane care is provided to the liveborn anencephalic infant until death. The use of anencephalic newborns as organ donors remains widely debated.[42,43] Pathologic examination of the fetus is important to confirm the diagnosis and to exclude conditions in which anencephaly is part of a genetic syndrome.

The optimal mode of delivery for the fetus with cephalocele is controversial. If a large amount of brain tissue is observed in the sac, and especially if one of the more grave prognostic factors (i.e., microcephaly or associated anomalies) is also present, the parents are counseled that the chance of a good outcome is remote, and cesarean delivery for fetal indications avoided. Decompression of a large sac or associated hydrocephalus may be necessary to allow vaginal delivery. However, cesarean delivery is an option

in those rare instances when a cephalocele is very large and sufficiently solid to cause dystocia. There is no clear objective evidence that cesarean delivery reduces birth trauma and improves neonatal outcome when a cephalocele is present. However, this does not exclude the possibility that trauma during vaginal delivery could, in theory, worsen the prognosis for these children.

Similarly, no conclusive information demonstrates that the optimal route of delivery for the vertex fetus with a meningomyelocele is cesarean. One retrospective clinical study concluded that elective cesarean delivery prior to the onset of labor improved outcome in terms of the functional level of the spinal defect at age 2 years.[44] However, this study contained numerous sources of bias. Multiple subsequent studies, which have sought to eliminate some of the design flaws of the first, could identify no benefit from cesarean delivery.[45–48] A randomized trial to study this question is needed. Until then, in our view, cesarean delivery of a fetus with meningomyelocele remains the first choice.

Care must be taken during delivery to minimize traction on the spine regardless of the route of delivery. If there is an indication for cesarean delivery, a low transverse incision is acceptable if the lower uterine segment is well developed. Otherwise, a vertical incision should be performed. After the head is delivered, the bisacromial diameter is positioned horizontally. Both fetal flanks are grasped and gentle traction applied in an outward direction away from the uterine wall near the meningomyelocele. The assistant retracts the edge of the uterine incision as the body of the infant is delivered (Fig. 18–10).

Postnatal and Prepregnancy

The recurrence risk for any neural tube defect after one affected child may be as high as 3% to 5% in the United

FIGURE 18–10
Fetus with a meningomyelocele is delivered through a low transverse uterine incision. Both fetal flanks are grasped, and gentle traction is applied in an outward direction. Assistant retracts edge of uterine incision as body is delivered. (From Chervenak FA, Duncan C, Ment LR, et al: Perinatal management of myelomeningocele. Obstet Gynecol 1984;63:376.)

States,[49,50] and up to 10% after having two affected offspring. The risk is greater in populations where ONTDs are more common. The recurrence risk is 4% to 5% if one parent is affected, and 25% when the ONTD is part of the Meckel-Gruber syndrome. A cephalocele may also occur as part of other autosomal recessive syndromes.

Randomized, placebo-controlled trials demonstrate that the likelihood of recurrence is reduced by periconceptual administration of folate (4 mg orally daily). This treatment should be offered to all women with a prior affected child. Antenatal ultrasonography should be performed in future pregnancies initially at 12 to 13 weeks in search of a recurrent ONTD.

SUMMARY OF MANAGEMENT OPTIONS
Open Neural Tube Defects: Anencephaly, Cephalocele, and Spina Bifida

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Search for skull defect in cephalocele and associated anomalies in all cases of open neural tube defects (especially hydrocephalus), including magnetic resonance imaging.	III	B	23, 87, 103
Prognosis for cephalocele depends on amount of herniated brain tissue; prognosis for spina bifida is difficult to predict early and depends on level and extent of lesion.	–	GPP	–
Advise karyotype in all cases.	–	GPP	–
Monitor for hydrocephalus.	–	GPP	–
Interdisciplinary approach is needed.	–	GPP	–
Termination may be chosen.	–	GPP	–
Monitor ongoing pregnancies (growth, umbilical artery Doppler recordings, amniotic fluid volume).	–	GPP	–
Fetal surgery for spina bifida should be regarded as experimental at present.	III	B	39, 40, 41
Labor and Delivery			
Deliver by vaginal route for anencephaly and humane neonatal care.	–	GPP	–
Mode of delivery for cephalocele is uncertain; some suggest that method should be determined by prognosis; no evidence suggests that cesarean section is beneficial.	–	GPP	–
Cephalocentesis is performed for encephaloceles if parents wish.	–	GPP	–
Optimal route of delivery is unknown for spina bifida.	III	B	45–48
Great care is needed with delivery of the back, regardless of delivery route.	–	GPP	–
Postnatal and Prepregnancy			
Necropsy is performed for abortuses/stillbirths/neonatal deaths.	–	GPP	–
Karyotype if not already done.	–	GPP	–
Assess for diabetes, teratogens (anticonvulsants, vitamin A).	–	GPP	–

HYDROCEPHALUS

General

Hydrocephalus is defined as ventriculomegaly and macrocephaly associated with increased intracranial pressure.

As such, hydrocephalus is a description and not a disease diagnosis. It results from an abnormal increase in the cerebral ventricular volume compared to brain tissue. There are many causes of hydrocephalus. It may result from abnormal formation of central nervous system structures, as in hydrocephalus inherited along a mendelian pattern

or hydrocephalus associated with a malformation syndrome. Hydrocephalus may result from defects acquired in utero, from infection with subsequent scarring, or inflammation and CSF obstruction, from intraventricular hemorrhage, or from intracranial tumors and mass lesions. Many cases of hydrocephalus cannot currently be assigned to any one specific etiologic category.

In general, there are four ways in which the ventricles grow to an abnormal size (Fig. 18–11):

- Obstruction to outflow (noncommunicating hydrocephalus), usually at a point of narrowing in the system (frequently the aqueduct of Sylvius or the foramina of either Lushka or Magendie)
- Impaired resorption of CSF by the arachnoid granulations (communicating hydrocephalus)
- Overproduction of CSF
- Underdevelopment or destruction of cortical tissue with a relative increase in the size of the ventricles (hydrocephalus ex vacuo)

Obstructive causes are the most common in both fetus and newborn.[51,52] Hydrocephalus is described as isolated when the fetus is otherwise free of anomalies and is not the direct result of the ventricular enlargement or increased intracranial pressure. Meningomyelocele is the most common abnormality associated with hydrocephalus. In the United States, the incidence of congenital hydrocephalus unassociated with a neural tube defect

is 5.8 per 10,000 total births. This is likely an underestimate of the true incidence, as both spontaneous regression and antepartum death occur in some cases.[51]

Diagnosis

A variety of techniques are advocated for the diagnosis of ventriculomegaly. Measurement of the atrium of the lateral ventricles is most common (Fig. 18–12). This method is optimal because the width of the atrium of the lateral ventricle usually remains constant throughout the second and third trimesters despite the fact that there is a decrease in the proportion of the cross-section of the brain occupied by the lateral ventricles as pregnancy advances. Cardoza and associates[53] presented strong evidence that a single measurement of the lateral ventricle atrium accurately differentiates a normal ventricle system from one that is pathologically enlarged.

Evaluation of the choroid plexus can also be useful when ventriculomegaly in hydrocephalus is suspected.[54] The choroid plexus usually fills the posterior portion of the lateral ventricles and appears symmetrical bilaterally, regardless of the orientation of the fetal head. In ventriculomegaly and hydrocephalus, the choroid plexus assumes a dependent position in the enlarged ventricle and appears as a dangling structure (Fig. 18–13). Serial ultrasound examinations are especially important for at-risk pregnancies. The absence of hydrocephalus at one

point early in gestation does not preclude its development later in gestation. Once hydrocephalus is diagnosed as an isolated abnormality, serial scans are important to identify in utero progression. The differential diagnoses for severe hydrocephalus includes alobar holoprosencephaly, hydrancephaly, porencephaly, and arachnoid cyst (Fig. 18–14), which may be distinguished by the criteria listed later in this chapter. Another rare cause of large, intracranial fluid-like collection is an aneurysm of the vein of Galen, characterized by blood flow that can be visualized by color Doppler ultrasonography (Fig. 18–15).

Management Options

Prenatal

Prior to the development of postnatal surgical shunting of the dilated ventricular system, the outlook for the infant with hydrocephalus was generally poor. Although some cases of unoperated obstructive hydrocephalus progressed slowly, or arrested spontaneously, massive head enlargement with blindness and mental retardation were far more common and still occur in the nonindustrialized world.[55]

After the development of postnatal surgical shunting, the prognosis of isolated hydrocephalus improved greatly. Most neonatal deaths are attributable to associated anomalies as well as obstetric trauma from cephalocentesis. Intellectual development is related to the etiology, and not necessarily to the severity of the hydrocephalus.[56,57] The association between the age at initial shunt placement and intellectual development is controversial.[58,59] Infants with associated central nervous system anomalies or secondary hydrocephalus related to other defects such as Dandy-Walker malformation or porencephaly have significantly lower IQs than infants with isolated hydrocephalus.[60,61] In addition, infants with congenital hydrocephalus have somewhat lower overall survival rates compared to infants who develop hydrocephalus in the neonatal period.[62] Recently, a 10-year follow-up study of 129 consecutive children with non–tumor-related hydrocephalus who underwent their first shunt insertion before age 2[63] had an overall mortality rate below 10%. However, motor deficits were found in 60%, visual or auditory deficits in 25%, and epilepsy

in 30%. Intellectual deficits were common and 40% had an IQ below 70. Only 32% of the children had an IQ above 90. Other studies have reported similar long-term intellectual prognosis.[64,65]

Once fetal hydrocephalus is identified, a careful sonographic search for associated fetal anomalies, including meningomyelocele, is mandatory. Because hydrocephalus is among the extracardiac anomalies associated with congenital heart disease, fetal echocardiography should also be performed. Up to 10% have a chromosomal aberration.[66,67] The obstetric management of fetal hydrocephalus reflects the gestational age at diagnosis, the presence of other anomalies, the results of the karyotype, and infectious studies and the views of the parents. If the diagnosis is made prior to fetal viability, the patient may consider pregnancy termination. If the karyotype is normal, and the parents wish to continue the pregnancy, serial ultrasound examinations are performed to identify progressive ventricular enlargement. In some cases, ventriculomegaly may regress in utero.

Although experimental placement of ventriculoamniotic shunts in fetal Rhesus monkeys yielded encouraging results, the experience in human pregnancies has to date been disappointing. A study of 39 fetal ventriculoamniotic shunt placements reported to the International Fetal Surgery Registry in 1993[68] listed 34 survivors: 14 had apparently normal neurodevelopment, and 18 had severe handicaps. The remaining two survivors had varying degrees of neurologic impairment. Children with intact intellectual development were all diagnosed with simple aqueductal stenosis. Of a total of seven deaths, four were directly attributed to the procedure. Many of the operated-on fetuses were misdiagnosed, errors that would be less likely to occur using MRI. Although most fetal medicine practitioners are not placing intrauterine ventriculoamniotic shunts, others believe it is time to revisit the issue.[69]

Labor and Delivery

Serial sonography may detect worsening hydrocephalus. In this situation, delivery should be considered as soon as pulmonary maturity in hopes of minimizing the potential ill effects of progressive ventricular enlargement. There is no clear indication for preterm delivery if the hydrocephalus is rapidly progressive prior to fetal lung maturity because respiratory distress syndrome, which would delay shunt placement, could actually worsen the final outcome. If delivery before fetal lung maturity is elected, maternal corticosteroids should be administered to hasten pulmonary maturity and reduce the risk and severity of respiratory distress syndrome. Fetuses with isolated disease and moderate to severe macrocephaly should be delivered by cesarean section to facilitate the atraumatic delivery of the enlarged fetal head. However, cesarean delivery is not necessary for all cases of fetal hydrocephalus. Attempted vaginal delivery is appropriate when the fetus is in vertex presentation and has only mild macrocephaly.

Fetal cortical mantle thickness correlates poorly with subsequent intelligence. Further, normal intelligence is possible for infants with hydrocephalus who receive optimal neonatal neurosurgical care. In cases of fetal hydrocephalus with associated anomalies that are either incompatible with life or associated with the severest forms

of neurologic dysfunction (e.g., alobar holoprosencephaly, hydrancephaly, or thanatophoric dysplasia with cloverleaf skull), cephalocentesis and subsequent vaginal delivery are an acceptable alternative to cesarean delivery. Cephalocentesis is performed by passing a 14- to 18-gauge needle transabdominally or transvaginally under ultrasound guidance (Fig. 18–16), and removing sufficient cerebrospinal fluid to allow overlapping of the cranial sutures. This is a destructive procedure. In a recent series of three cases reported by Chasen and associates, all fetuses were stillborn with two delivering vaginally and one abdominally through a low transverse uterine incision.[70]

Postnatal and Prepregnancy

Hydrocephalus has diverse etiologies and the identification of its specific cause aids greatly the subsequent genetic counseling. A postmortem examination is essential. Several heritable patterns are recognized. X-linked recessive aqueductal stenosis carries a 1:4 risk of recurrence in future pregnancies, or 1:2 risk for male fetuses. Cerebellar agenesis with hydrocephalus is extremely rare, but also may be X-linked. Hydrocephalus is also associated with a variety of chromosomal abnormalities including triploidy, trisomies 13, 18, and 21, and certain balanced translocations. The risk of recurrence is relatively low for sporadic chromosomal abnormalities but is much higher for balanced translocations.

Additionally, hydrocephalus is associated with several syndromes that manifest dominant inheritance (e.g., achondroplasia and osteogenesis imperfecta).[71] The Dandy-Walker syndrome has been reported in siblings, suggesting the possibility of autosomal recessive inheritance. Several studies suggest an increased risk of uncomplicated hydrocephalus in families with neural tube

FIGURE 18–16
Sonographic guidance of the needle during cephalocentesis.

defects. Lorber and De[72] studied uncomplicated congenital hydrocephalus and found an empiric risk of 4% for a central nervous system malformation and 2% for spina bifida or hydrocephalus in future pregnancies. Other causes of fetal hydrocephalus include prenatal infection (i.e., toxoplasmosis), intracranial tumors or cysts, and vascular malformations. Such causes are unlikely to result in an increased risk of hydrocephalus in future pregnancies.

CRANIOFACIAL DISORDERS OF VENTRAL INDUCTION: THE HOLOPROSENCEPHALY SEQUENCE

General

The prechordal mesoderm, an embryonic connective mass between the undersurface of the neural tube and the oral cavity, is thought to be responsible for both the division of the prosencephalon, or forebrain, and the production of the nasofrontal process. The term holoprosencephaly includes several cerebral abnormalities that share incomplete cleavage of the primitive prosencephalon. Because of the underlying embryologic insult, various midline facial abnormalities are closely associated with holoprosencephaly, although the face can be normal (Fig. 18–17). The incidence of holoprosencephaly approximates 1 in 10,000 live births.[73] Holoprosencephaly is divided into alobar, semilobar, and lobar categories, based on the degree of separation of the cerebral hemispheres (Fig. 18–18). The alobar form is the most severe, with no evidence of cerebral cortical division.

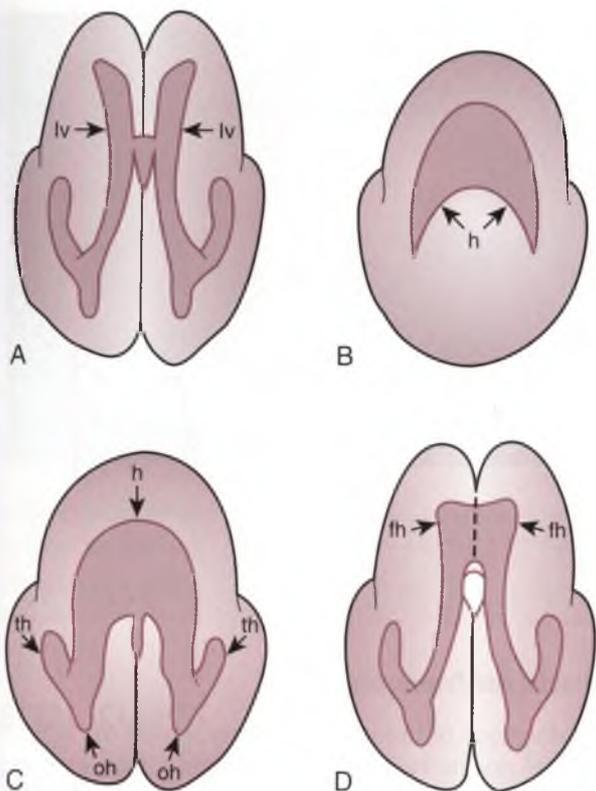

FIGURE 18–18
Schematic representation of the alobar, semilobar, and lobar forms of holoprosencephaly. *A*, Normal brain. Both the cerebral hemispheres and the lateral ventricles are separated. *B*, Alobar holoprosencephaly. The normal division of the cerebral hemispheres is absent, and there is a single ventricular cavity. *C*, Semilobar holoprosencephaly, showing an incomplete separation of the cerebral hemispheres in the occipital area and partial development of the occipital and temporal horns of the lateral ventricles. *D*, Lobar holoprosencephaly. Separation of the cerebral hemispheres and lateral ventricles is nearly complete except for the frontal portions. The frontal horns of the lateral ventricles are usually mildly dilated. (From Pilu G, Romero R, Rizzo N, et al: Criteria for the prenatal diagnosis of holoprosencephaly. Am J Perinatol 1987;4:41–49.)

FIGURE 18–19
Schematic drawings of the facies associated with holoprosencephaly. (From Mahony BS, Hegge FN: The face and neck. In Nyberg DA, Mahony BS, Pretorius DH [eds]: Diagnostic Ultrasound of Fetal Anomalies: Text and Atlas. Chicago, Year Book, 1990, pp 203–261.)

The falx cerebri and the interhemispheric fissure are absent. There is a common ventricle with fused thalami. The semilobar and lobar forms represent a higher degree of brain development with the semilobar having partial separation of the hemispheres. Although there is much variability in the types of defects in the midline cerebral structures (corpus callosum, septum pellucidum, thalamus, etc.), the olfactory tracts and bulbs are usually absent, explaining the older term "arrhinencephaly."

The holoprosencephaly sequence results in the following characteristic facial findings (Fig. 18–19):

- Cyclopia with one median orbit, proboscis from the lower forehead, and absent nose
- Ethmocephaly with proboscis between two narrowly placed orbits and absent nose
- Cebocephaly with hypotelorism and rudimentary nose (single nostril)
- Hypotelorism (decreased intraorbital distance), median cleft lip, and flat nose
- Bilateral cleft lip

Diagnosis

The dictum "the face predicts the brain" is often used to describe holoprosencephaly, as cyclopia, ethmocephaly, cebocephaly, and hypotelorism with midline cleft lip are commonly found in association with this central nervous system anomaly.[74] Sonographic markers include hypotelorism and a single common cerebral ventricle with absent midline echo (Fig. 18–20). The general appearance of the face, the position and configuration of the nose, and the integrity of the upper lip should be observed closely for clues. It may be impossible to differentiate semilobar from lobar holoprosencephaly before birth.

It is not sufficient to diagnose holoprosencephaly based solely on a central fluid collection in the brain, as this may also represent hydranencephaly or a midline porencephalic cyst. Other anatomic aberrations associated with holoprosencephaly detectable by ultrasonography include hydrocephalus, polydactyly, and hydramnios.

Management Options

Prenatal

The prognosis for alobar holoprosencephaly is uniformly poor. Most infants die shortly after birth, and the

FIGURE 18–20

survivors have profound mental retardation.[75] Less is known about the prognosis for lobar and semilobar varieties. A normal life span is reported, but many are severely mentally retarded. Subtle forms of lobar holoprosencephaly with little neurologic abnormality may exist. Karyotyping should be offered because of the association with aneuploidy (especially trisomy 13).

Labor and Delivery

The obstetric management of holoprosencephaly is dependent on gestational age at the time of diagnosis. Many patients opt for pregnancy termination when the diagnosis is made in the first or second trimester. Macrocephaly in the third trimester may obstruct labor, and cephalocentesis should be considered to avoid cesarean delivery. The destructive nature of this procedure must be explained to the parents.

Postnatal and Prepregnancy

The diagnosis of holoprosencephaly signals the need for a careful postmortem examination and a fetal karyotype to guide the management of future pregnancies. A chromosomal anomaly may predict either a recurrence risk less than 1% (as when a trisomy is demonstrated), or a much higher risk if there is a translocation in one of the parents.

Absent a chromosomal abnormality, the reported empiric risk for recurrence ranges from 6% to 14%,[76,77] although some families have a 25% risk associated with autosomal recessive inheritance. Rarely, autosomal dominant inheritance is present, predicting a 50% recurrence rate. A close examination of both parents for minor signs of midline facial abnormalities (e.g., hypotelorism) is essential to rule out this possibility. Last, maternal diabetes should be excluded, as it significantly increases the risk of holoprosencephaly.[78]

FACIAL CLEFTS

General

Cleft lip or palate is the most common congenital facial deformity diagnosed at birth.[79] It results from failure of the nasofrontal prominence to fuse with the maxillary process. Clefts may be complete, incomplete, unilateral or bilateral, symmetrical or asymmetrical. Although more than 100 syndromes are associated with cleft lip or palate, these syndromes probably account for fewer than 10% of cases, as the majority are isolated. A multifactorial etiology is reflected in the varied incidences depending on race, sex, and geographic location. Similar to other lesions with a multifactorial etiology, the empiric recurrence risk increases with the number of previously affected siblings.

Diagnosis

The lower portion of the face must be anterior and clearly visualized in order to demonstrate a facial cleft on antenatal ultrasound (Fig. 18–21). The coronal, sagittal, and transverse planes are used to clearly assess the features of the lower face. Facial clefts may be suspected when either undulating tongue movements, hypertrophied tissue at the edge of the cleft, or hypertelorism is seen on ultrasound. An intact lip does not mean the palate is intact. Transverse sections may reveal a break in the maxillary ridge. Caution is necessary to avoid a false-positive diagnosis from a shadowing artifact produced by the maxillary bones. The availability of three-dimensional ultrasound may facilitate visualization of the precise location and extent of facial clefting.[80,81]

Management Options

It is important to search carefully for other anomalies after a facial cleft is identified. Fetal karyotyping should be offered. The prognosis and management depend on the presence of associated abnormalities and the severity of the defect. If the cleft appears isolated, then the prognosis is excellent. Staged plastic surgical correction is typically offered early in infancy, though the timing of the repairs remains controversial. Prior to surgery, the newborn may experience some difficulty feeding, but this is usually remedied with a specially designed artificial palate. Antenatal diagnosis of a cleft may help the parents prepare for a visually disturbing deformity that is typically correctable and allows the birth to occur with a treatment plan in place.

DANDY-WALKER MALFORMATION

General

The Dandy-Walker malformation is characterized by the complete or partial absence of the cerebellar vermis and an enlarged posterior fossa cyst continuous with the fourth ventricle (Fig. 18–22). Hydrocephalus with ventriculomegaly is often present. Theories on pathogenesis include atresia of the foramina of Lushka and Magendie, and hypoplasia or gross alteration of the cerebellum. In addition to the classic Dandy-Walker malformation, a Dandy-Walker variant indicates a spectrum of anomalies classified by variable hypoplasia of the cerebellar vermis with or without enlargement of the posterior fossa. The Dandy-Walker malformation occurs in approximately 1 in 30,000 births, and is diagnosed in 4% to 12% of all cases of infantile hydrocephalus.[82] There is an increased risk of chromosomal anomalies and mendelian syndromes. In the absence of a genetic syndrome, the recurrence risk is probably about 1% to 5%.[83] The Dandy-Walker malformation occurs with increased frequency in families with a history of polycystic kidney disease and after the birth of a child with another central nervous system abnormality. Autosomal recessive inheritance is documented in some families.

FIGURE 18–22
Suboccipital bregmatic view demonstrating Dandy-Walker cyst (DW) with defect in the cerebellar vermis and its communication with the fourth ventricle.

Diagnosis

Dandy-Walker cyst appears on ultrasound as an echo-spared area in the posterior fossa. The cerebellar vermis, a bright echogenic midline structure caudal to the fourth ventricle, is absent or defective. As a result, the Dandy-Walker cyst is seen communicating with the fourth ventricle. Hydrocephalus usually involves all four ventricles.

Management Options

The prognosis for infants with a Dandy-Walker malformation is quite variable. A relatively recent review of 50 cases of Dandy-Walker malformation and 49 cases of Dandy-Walker variant diagnosed by antenatal ultrasound[84] noted a frequent occurrence of associated anom-

alies and aneploidy. Of fetuses with a classic Dandy-Walker malformation, 85% had other anomalies (32% ventriculomegaly and 38% cardiac defects) and 46% were aneuploid. Of the fetuses with Dandy-Walker variant, 85% had other anomalies (27% ventriculomegaly and 41% cardiac defects) with a 36% aneuploidy rate. Fifty of the 99 women elected pregnancy termination. Of the remaining 49 fetuses, 16 survived the neonatal period with only 8 having a normal pediatric examination at 6 weeks, including 6 with an isolated finding of Dandy-Walker variant. Clearly, the overall prognosis is not good and the presence of other anomalies is associated with the worst prognosis.

Hydrocephalus and associated anomalies are more common in cases diagnosed in utero and the prognosis is less favorable. The option of pregnancy termination should be discussed with the parents. There is an increased risk of chromosomal anomalies and mendelian syndromes associated with the Dandy-Walker malformation, and it occurs at higher frequency in families with a history of polycystic kidney disease and after the birth of a previous child with Dandy-Walker malformation. Autosomal recessive inheritance is documented in some families. In the absence of a clear genetic syndrome, the recurrence risk is between 1% and 5%.[82]

ANEURYSM OF THE VEIN OF GALEN

The cerebral veins may enlarge as a direct result of arterial fistula or adjacent arteriovenous malformation. Aneurysmal dilation of the great vein of Galen from an arteriovenous malformation is well documented. The dilated vein appears on ultrasound as a nonpulsatile, midcerebral tubular structure often seen behind the third ventricle (see Fig 18–15).[85,86] MRI and three-dimensional ultrasonography can be useful adjuncts to definitively diagnose an aneurysm of the vein of Galen antenatally.[87,88] The lesion may be isolated or associated with fetal hydrocephalus or other abnormalities. The increased intracranial blood flow to a low-resistance shunt can cause cardiomegaly and hydrops, and serial studies are indicated to monitor for the development of fetal hydrops. Traditionally, the prognosis for neonates with an aneurysm of the vein of Galen was considered poor, as many die from heart failure.[89] However, recent therapeutic advances may be improving outcome. In one study of 18 cases of antenatally diagnosed vein of Galen aneurysm, the neonatal mortality rate was 25% despite evidence of cardiac deterioration in 94%. All survivors required digoxin therapy. Neurologic development was normal in 67% of the surviving neonates.[90]

HYDRANENCEPHALY

General

Hydranencephaly is characterized by replacement of the cerebral hemispheres with fluid covered by leptomeninges such that no cerebral cortex is present. Only the basal ganglia and remnants of the mesencephalon remain within a normally formed skull above the tentorium cerebelli. The subtentorial structures are usually intact, and the falx cerebri is frequently present. Hydranencephaly is thought to result from a severe destructive insult, most likely bilateral occlusion of the internal carotid arteries.

Diagnosis

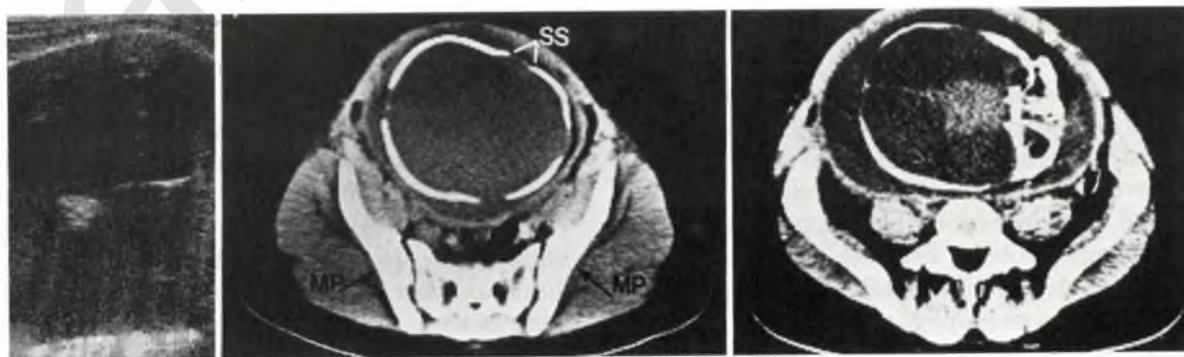
Ultrasonographic findings include a normal cranial vault filled with fluid. The cerebral cortex is absent, but a midline echo, the tentorium cerebelli, and cerebellum may be visible. This disorder is differentiated from hydrocephalus, holoprosencephaly, and porencephaly by the absence of cerebral cortex. In severe hydrocephalus, the thin cortical mantle may be hard to detect sonographically and MRI or less frequently used intrauterine computed tomography scanning may aid the diagnosis (Fig. 18–23).


FIGURE 18–23
In utero computed tomogram showing widening of sutures of fetal calvarium. Skull is filled by homogeneous low-density fluid with no evidence of cortex present. MP, maternal pelvis; SS separated suture. (From Chervanak FA, Berkowitz RL, Romero R, et al: The diagnosis of fetal hydrocephalus. Am J Obstet Gynecol 1983;147:703–716.)

Management Options

Most infants with hydranencephaly die in the first year of life. Survivors are profoundly retarded. Sporadic familial recurrences are reported, but these are the exception. In general, the recurrence risk is negligible. The option for pregnancy termination should be offered to the parents when the diagnosis is firm.

MICROCEPHALY

General

Strictly translated, microcephaly means "small head." The clinical importance of the entity is its association with mental retardation. Some authors classify postnatal microcephaly as a head perimeter smaller than 2 standard deviations (SD) below the mean.[91] Alternatively, a definition of 3 SD below the mean for gender and age may correlate better with mental retardation.[92]

Diagnosis

The postnatal diagnosis of microcephaly is made simply by measuring the neonatal head circumference, but the antenatal diagnosis is more difficult. The head circumference is preferable to the biparietal diameter (BPD), which carries a high false-positive rate because of such normal variants as dolichocephaly. Serial ultrasound examinations are important in suspected cases, as significant microcephaly may not manifest until the third trimester.

Management Options

Prenatal

Because microcephaly is a part of many different malformation syndromes, a careful sonographic search for associated anomalies is mandatory. Cortical mass may be decreased in microcephaly, leading to ventriculomegaly in the absence of an obstructive process. A careful pedigree should be taken and a search made for causes, including possible teratogen exposure, alcohol abuse, and infection. The definitive diagnosis of fetal infection requires an invasive procedure: Amniocentesis and even cordocentesis are often necessary.

The majority of microcephalic children are mentally retarded, many severely so. As a rule, the smaller the head, the worse the prognosis. If microcephaly occurs as part of a genetic syndrome (e.g., Meckel-Gruber syndrome), the outcome is uniformly poor. However, children born with microcephaly may have normal intelligence despite their very small head size.

Labor and Delivery

Vaginal delivery of a microcephalic infant is appropriate. Shoulder dystocia due to incomplete dilation of the cervix by the small fetal head is a rare occurrence.

Postnatal and Prepregnancy

The risk of recurrence for microcephaly depends on the underlying etiology. The search for an etiology should include a physical examination of the infant, a maternal history for teratogenic exposure, a careful family pedigree, chromosomal, microbiologic, and serologic studies, and an autopsy should death occur. Alcohol abuse is a common cause of mental retardation, and often associated with microcephaly. Several patterns of inheritance are described within the subgroup of microcephaly without associated anomalies, which is termed "true" microcephaly. These patterns include autosomal recessive, autosomal dominant with incomplete penetrance, and sporadic patterns of inheritance.

AGENESIS OF THE CORPUS CALLOSUM

General

The corpus callosum is the great commissural plate of nerve fibers interconnecting the cortical hemispheres. It lies at the base of the interhemispheric fissure and curves in the midline, forming the roof of the third ventricle. Agenesis of the corpus callosum can occur as either an isolated anomaly or in association with other anomalies, such as hydrocephalus and holoprosencephaly. It is usually a sporadic occurrence, although it has been associated with various genetic syndromes, chromosomal abnormalities, and prenatal exposure to teratogens such as alcohol.

Diagnosis

Agenesis of the corpus callosum is diagnosed in utero on coronal and midline sagittal views of the fetal head, including the routine transverse planes. Transvaginal ultrasonography improves access to these planes by providing an acoustic window through the anterior fontanelle.

On a midsagittal ultrasound examination, the corpus callosum appears as a hypoechoic structure below the pericallosal artery, where it forms the roof of the cavum septum pellucidum and cavum vergae. (Fig. 18–24). Failure to image it suggests agenesis of the corpus callosum. However, it is quite difficult antenatally to be defin-

itive. The pathognomonic "sunburst lesion" is seen on midsagittal section and represents the radial orientation of the gyri and sulci of the cerebral cortex to the third ventricle (Fig. 18–25). Normally, the gyri and sulci parallel the corpus callosum.[93] As the corpus callosum itself cannot be seen on transverse scan, it is necessary to

FIGURE 18–24

search for the anatomic alterations produced by its absence. These indications include lateral displacement of the bodies of the lateral ventricles, enlargement of the atria and occipital horns producing a characteristic tear-drop shape, and enlargement or upward displacement of the third ventricle (Fig. 18–26).

Management Options

The prognosis for a fetus with agenesis of the corpus callosum is highly variable and depends on the presence of associated defects. Management is based on these underlying anomalies. Agenesis of the corpus callosum has been reported as an incidental autopsy finding in intellectually normal adults[94] and caution should be exercised counseling patients when isolated agenesis of the corpus callosum is suspected. Three-dimensional ultrasonography and MRI may provide additional prognostic information.

INTRACRANIAL HEMORRHAGE AND PORENCEPHALY

General

Bleeding within the head of the newborn is a well-recognized phenomenon. In particular, intraventricular hemorrhage is often associated with prematurity. When severe, it can produce obstructive hydrocephalus and intraparenchymal hemorrhage. On the other hand, the antenatal diagnosis of intracranial hemorrhage is uncommon. In most instances, hydrocephalus is first identified in association with echogenic areas of hemorrhage in the dilated ventricular system. Alloimmune thrombocytopenia may be the underlying cause of antenatally diagnosed intracranial hemorrhage (see Chapter 15).

Porencephaly describes a condition in which a portion of the cerebral cortex is replaced by a cystic cavity and is thought to represent the remains of a severe intrauterine insult. The cavity may communicate with the subarachnoid space or a ventricle (Fig. 18–27). Most cases result from a vascular lesion, either hemorrhagic or embolic. Areas of prior hemorrhage or tissue necrosis resorb, leaving behind porencephalic cysts. In rare cases, an infection or traumatic insult may result in porencephaly.

Diagnosis

Antenatal hemorrhage typically appears as an echogenic mass in the region of the germinal matrix or within the lateral ventricles (Fig. 18–28). Antenatal diagnosed intracranial hemorrhage is predominantly grade 3 or 4, using the established grading system for neonatal intracranial hemorrhage, which classifies grade 1 as isolated periventricular hemorrhage, grade 2 as intraventricular hemorrhage with normal ventricular size, grade 3 as intraventricular hemorrhage with acute ventricular dilation, and grade 4 as intraventricular hemorrhage

with parenchymal involvement.[95] Consequently, these lesions are associated with a high perinatal mortality rate. These cases demonstrate that high-grade intraventricular hemorrhage can occur in the absence of birth trauma.

Porencephalic cysts appear sonographically as solitary or multiple echo-spared areas of variable size and location within the brain. The midline echo is present but may be displaced. Some cortical tissue may be preserved in each cerebral hemisphere. These distinctions help differentiate a large porencephalic cyst from unilateral hydrocephalus, holoprosencephaly, and hydranencephaly.

Although the prognostic validity of the grading system for neonatal intracranial hemorrhage is well estab-

FIGURE 18–27

lished, it has not been extensively evaluated in the antenatal period. Ghi and associates followed 109 cases of antenatally diagnosed intracranial hemorrhage and concluded that intracranial hemorrhage could be accurately identified and categorized by antenatal sonography.[96]

Management Options

When antenatal intracranial hemorrhage is diagnosed in the absence of an identifiable cause, a search for alloimmune thrombocytopenia is warranted. Serologic studies for intrauterine infection, a fetal karyotype for aneuploidy, and a workup for maternal infections including hepatitis and pancreatitis may also be of value.

The prognosis for porencephaly depends on the underlying etiology, location, and volume of tissue loss. The outcome in the majority of reported cases is poor.[97] Fortunately, there is no increased risk of recurrence unless alloimmune thrombocytopenia is diagnosed. Alloimmune thrombocytopenia carries a greater than 75% recurrence risk.[98]

CHOROID PLEXUS CYST

General

Small areas of cystic dilation are seen in the choroid plexus of the lateral ventricles in 1% to 2% of all fetuses (Fig. 18–29). They typically resolve before the end of the second trimester and lack clinical significance. Choroid plexus cysts may be associated with trisomy 18.

However, the great majority of fetuses with trisomy 18 have other structural abnormalities detectable by ultrasonography.

Management Options

A karyotype is recommended for all fetuses with choroid plexus cysts associated with other structural abnormalities. However, the vast majority of isolated choroid

FIGURE 18–29
Transverse section demonstrating a choroid pexus cyst (C).

plexus cysts are clinically insignificant, and the need for genetic evaluation is controversial. A meta-analysis reported that the risk of trisomy 18 associated with an isolated choroid plexus cyst in all women was 1:374.[99] Another large study concluded an isolated choroid plexus cyst increased the midtrimester risk of trisomy 18 enough to justify genetic testing only in women over 35 years old.[100] Other large studies have concluded that isolated choroid plexus cysts in women under 35 years old do not increase the risk of trisomy 18 to a degree that amniocentesis is warranted.[101,102] We believe the presence of a choroid plexus cyst should be disclosed to the patient. However, counseling should take into account the presence of associated anomalies, the age of the patient, and the results of first- and second-trimester screening tests for aneuploidy.

CYSTIC HYGROMA

General

Cystic hygromas are congenital malformations of the lymphatic system (Fig. 18–30). They appear as single or multiloculated, fluid-filled cavities lined by true epithelium. In fetal life, they are associated with a generalized disorder of lymphatic formation. Cystic hygromas may occur as isolated defects or as part of a variety of genetic syndromes (Fig. 18–31).

Diagnosis

Cystic hygromas can be diagnosed reliably by ultrasonography. Their posterolateral location and cystic appearance are characteristic. Larger hygromas are frequently divided by incomplete septa and often have a dense midline septum extending from the fetal neck across the full width of the hygroma (Fig. 18–32). Hydrops is often associated with cystic hygroma, as both may result from a defect in lymphatic formation. The sonographic features that dif-

ferentiate a cystic hygroma from another craniocervical mass (e.g., cephalocele or other neural tube defects, cystic teratoma, or nuchal edema) include an intact skull and spinal column, lack of a solid component to the mass, a constant position of the mass relative to the fetal head, and the separation of cysts by septa.

Management Options

Prenatal

Once a cystic hygroma is detected, a careful search for skin edema, ascites, pleural or pericardial effusions, and cardiac or renal anomalies is indicated. A fetal karyotype is essential and may be performed by chorionic villus sampling in the first trimester or amniocentesis in the second trimester. When there is little fluid and the hygromas are large, the cyst can be aspirated and the karyotype obtained from the contained lymphocytes.

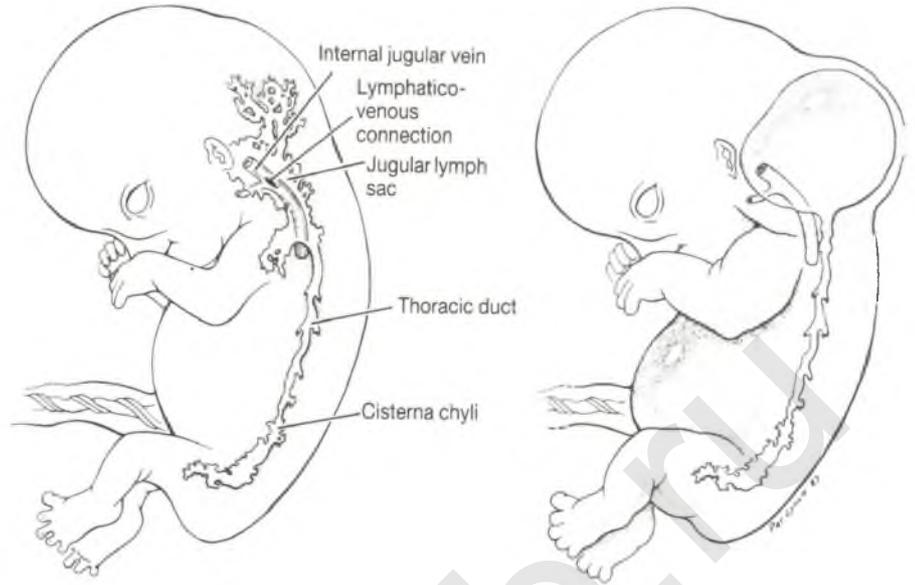
The prognosis and management depend on the underlying cause and any associated anomalies. The outlook is grave if there is hydrops and no treatable cause is identi-


FIGURE 18–30

fied. Isolated cystic hygromas may be surgically corrected postnatally and the prognosis for survival is then good. Some cystic hygroma regress in utero, leaving only a webbed neck. This may account for this physical feature in girls with Turner's syndrome.

Labor and Delivery

There is no evidence that cesarean delivery improves outcome.

Postnatal and Prepregnancy

A careful postmortem examination is recommended, and tissue for cytogenetic studies is obtained whenever there is an unstudied aborted or stillborn fetus. In live births, tissue samples may be taken from fetal membranes or from the newborn itself. Because these fetuses may have chromosomal mosaicism, several tissues should be studied before concluding they are euploid. The content of the postpartum counseling depends on the underlying cause.

CAUDAL REGRESSION SYNDROME

Caudal regression syndrome describes an embryologic malformation leading to structural defects in the caudal region. The severity is quite variable and may include incomplete development of the sacrum and lumbar vertebrae (Fig. 18–33) and disruption of the distal spinal cord, causing neurologic impairment. Caudal regression syndrome is strongly associated with maternal diabetes. Although this disorder was previously considered a severe form of sirenomelia, recent evidence suggests the two defects are pathogenetically unrelated.[70] The etiology of caudal regression syndrome is unknown and most likely heterogeneous.

MAGNETIC RESONANCE IMAGING OF FETAL CENTRAL NERVOUS SYSTEM ANOMALIES

Ultrasonography is currently the primary imaging technique used for antenatal evaluation of fetal CNS anomalies when the ultrasonographic findings are not straightforward. The ability to make definitive diagnoses by ultrasound alone is often restricted by various factors, including reverberative artifacts from the bony calvarium, fetal position, oligohydramnios, and maternal body habitus. In addition, ultrasound often does not have the sensitivity to detect subtle abnormalities of fetal brain development.

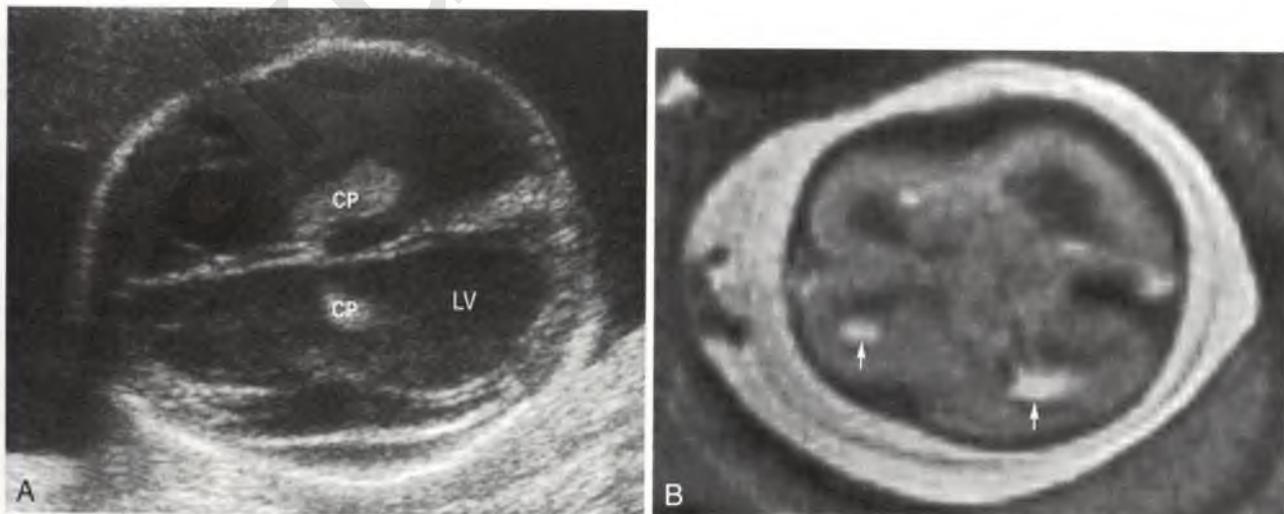
MRI can enhance the diagnostic accuracy of ultrasound for the assessment of fetal brain abnormalities (Figs. 18–34 and 18–35).[87,103] MRI permits acquisition of multiplanar views of the fetal brain, allowing for a detailed evaluation of the CNS anatomy that is not possible using ultrasound alone. Additionally, MRI is not hindered by the same technical limitations of ultrasound, such as low amniotic fluid amount or fetal position. The use of ultrafast MRI techniques permits good quality brain images, even when there is fetal movement.[104,105] To date, there have been no reports of adverse fetal effects from MRI. Baker and associates evaluated children 3 years after prenatal MRI exposure and reported no deleterious effects.[106] The information obtained from the MRI may change management by enhancing the diagnostic accuracy. Sharma and associates recently described a series of pregnant patients with fetal brain abnormalities in whom MRI provided valuable additional information in all cases.[107] Ultrasound remains the standard modality for assessing fetal anatomy. Moreover, prenatal ultrasound allows for reliable detection of fetal brain abnormalities. However, MRI of the fetal CNS is evolving as a useful adjunct for obtaining additional information in cases in which confirmation of a suspected abnormality or further clarification is sought.


FIGURE 18–34

CONCLUSIONS

- Craniospinal and facial abnormalities are among the more commonly detected fetal anomalies at the 20-week scan.
- Detailed ultrasound is required to elucidate the nature of the abnormality and to search for other anomalies.
- MRI may be a useful adjunct in the evaluation process.
- Karyotyping is indicated for many conditions.
- Interdisciplinary counseling is advisable.
- In utero therapeutic interventions are not currently of proven benefit, although clinical investigations are underway.

Fetal Genitourinary Abnormalities

Marc Dommergues / Rodrigo Ruano / Marie-Cécile Aubry

INTRODUCTION

Genitourinary abnormalities consist of a wide spectrum of heterogeneous malformations. Urinary tract dilations and kidney abnormalities are relatively common with a prevalence ranging from 1/250 to 1/1000 deliveries.

The majority of genitourinary abnormalities are detected during routine screening sonography in the absence of any significant clinical or family history. Generally, the sensitivity of antenatal screening depends on the experience of the sonographer and on the timing of the onset of detectable consequences of the abnormality. Antenatal diagnosis of urinary malformations is facilitated by the often conspicuous, transonic image. The diagnosis of a lethal form may become evident with severe oligohydramnios and patent dilation of the urinary tract. In contrast, some urinary tract abnormalities, such as urinary reflux, may remain undetectable in utero. Urinary dilation above an incomplete obstruction may occur in the third trimester only after the urinary volume exceeds the obstructed capacity. These will be missed unless there is a policy of routine third-trimester ultrasound. Renal abnormalities without urinary tract dilation can be detected if examination of the fetal kidneys is included in the screening ultrasound.

In contrast to uronephrologic abnormalities, isolated genital malformations are rare disorders. There is no consensus on whether the structure of the fetal genitalia should be imaged as part of a screening ultrasound examination. Minor abnormalities are virtually impossible to identify, and counseling may be extremely difficult when ambiguous genitalia are identified.

FETAL UROPATHIES

Pathophysiology

Uropathies potentially detectable in utero may be classified according to their pathophysiology:

- Obstruction of the ureteropelvic junction: This abnormality is the most common lesion of the fetal urinary tract. The obstruction may result from compression by an ectopic vessel, or it may occur in the setting of duplication or ectopy.
- Megaureter: True megaureter is the result of a dysfunction at the ureterovesical junction. Spontaneous relief of megaureter with mild hydronephrosis often occurs during the first years of life, whereas major hydronephrosis or a retrovesical ureteral diameter greater than 1 cm tends to resolve slowly and may require surgery.[1,2]
- Ureterocele: This cystic dilation of the distal intravesical ureter arises most often from an abnormal location of the ureteral meatus in the bladder. Ureterocele is often associated with double ureter, in which the ureterocele at the lower ureteric orifice drains the upper pole of the duplicated kidney. The lesion is associated with obstruction, accounting for the dilation of the corresponding ureter and renal pelvis. A large ureterocele can even obstruct the bladder neck, and the disease resembles an infravesical obstruction. Antenatal diagnosis is important to plan postnatal management and to avoid future complications.[3]
- Bladder outlet obstruction: This obstruction usually occurs in the urethra, causing bladder dilation with muscle hypertrophy and hydronephrosis. The kidneys may be dysplastic, resulting in a variable degree of renal failure.[4] The most common cause of bladder outlet obstruction is posterior urethral valves. Urethral atresia is less common, causing lethal lesions with fetal anuria in the early second trimester. In spite of advances in antenatal care, posterior urethral valves may still result in postnatal renal failure.[5]
- Reflux: This common disorder is often suspected antenatally, but is rarely diagnosed definitively. Occasionally, it may be diagnosed based on the dynamic dilation of the upper urinary tract or of the bladder. Dynamic imaging of reflux is sometimes possible. In severe cases, the bladder and ureters appear dilated owing to

a functional increase in urinary outflow. Antenatal diagnosis permits the initiation of prophylactic antibiotic therapy to avoid postnatal urinary infection and subsequent kidney damage. Postnatal surgery may be required for severe forms.[6]

- Prune-belly sequence: This abnormality consists of deficient abdominal wall musculature, bladder distention with renal dysplasia, absence of prostatic tissue, and cryptorchidism.[7] A patent urachus is common. The uropathy usually consists of urethral obstruction and dysfunction resulting in megacystis and bilateral megaureter. Prostatic hypoplasia is common in males. It is rare in females in whom the uropathy and the abdominal wall defect are associated with vaginal atresia, rectovaginal or rectovesical fistula, and bicornuate uterus. The prognosis depends on the amount of functional renal tissue.

The antenatal diagnosis of fetal uropathies is rarely made before the second trimester. An intra-abdominal transonic mass in the first trimester suggests a dilated bladder. It may resolve spontaneously, and follow-up is needed to confirm the diagnosis of fetal urinary tract dilation. Most antenatal diagnoses of urinary tract dilation are made in the second trimester. Third-trimester ultrasound may reveal late onset uropathies. In a substantial number of cases, urinary dilation appears only late in gestation or during postnatal life and will not be amenable to antenatal screening.

Sonographic Assessment of Normal Development of the Fetal Kidneys, Urinary Tract, and Genitalia

The fetal bladder and kidneys are identifiable by 11 to 12 weeks of gestation (Figs. 19–1 and 19–2) when they appear as homogeneous echoes on each side of the spine. Between 18 and 24 weeks' gestation, the medulla becomes hypoechogenic and is distinguishable from the

FIGURE 19–2
Bladder, sagittal view, at 12 weeks.

echogenic renal cortex (Fig. 19–3). The growth of fetal kidneys parallels the fetus and can be evaluated in a quantitative manner.[8-10]

The image of the genital tubercle should be interpreted carefully during the first trimester,[11] though it is possible to identify fetal gender at 12 to 14 weeks in 70% to 90% of cases.[12] In boys, the urethral canal can be seen at 26 to 27 weeks, but it is easier to see in the third trimester (Fig. 19–4). Undescended testes are physiologic until 32 weeks but should be intrascrotal near term. In girls, vulvar structure can be identified as early as 15 weeks and seen clearly by 22 weeks. However, a detailed analysis of a vulva anomaly is not usually feasible until 24 weeks (Fig. 19–5). In the third trimester, the external genitalia are large and easier to analyze.

It is not always possible to identify the uterus, even late in gestation. The fetal sacrum is an indirect but useful marker of the harmonious development of the fetal pelvis. It curves inward progressively during the second trimester (Fig. 19–6). The anal sphincter can also be seen (Fig. 19–7).

Management Options

Once fetal urinary tract dilation is detected, the following issues should be addressed rapidly:

1. The diagnosis should be confirmed.
2. Associated abnormalities should be ruled out, which requires a special expertise in the field of fetal ultrasound.
3. The risk of aneuploidy should be evaluated and weighed against the potential iatrogenic risks of performing an amniocentesis.
4. The risk of developing postnatal respiratory distress (due to severe oligohydramnios leading to pulmonary hypoplasia) should be evaluated.
5. The risk of developing postnatal renal failure should be evaluated.
6. A perinatal management plan should be established in collaboration with a pediatric urologist. The potential need for emergency neonatal surgery should be evaluated in order to plan the site of delivery.

Sonographic Diagnosis of Fetal Urinary Tract Abnormalities

Antenatal diagnosis of fetal urinary tract anomalies is relatively easy based on the identification of transonic images corresponding to the dilated urinary tract. However, it is not always possible to ascertain the mechanism of the uropathy in utero, because the obstructive lesion cannot be imaged directly, and because urinary tract dilations resulting from a vesicoureteral reflux can mimic the dilation of a true obstruction. Nevertheless, it is rarely important to recognize the exact cause of the dilation before birth. A satisfactory surgical repair can be achieved postnatally in most cases, resulting in a good pediatric outcome provided the renal function is not altered and there is no associated malformation.

Apparent Level of Urinary Dilation

Fetal uropathies can be classified by the level of dilation.[13–17] Only the renal pelves are dilated in upper dilations, whereas the ureters are also involved in midlevel dilations. Upper and midlevel dilations are also categorized as unilateral or bilateral, an important prognostic feature because postnatal renal function should be normal in unilateral cases. Dilation of the upper urinary tract may correspond to either ureteropelvic junction obstruction or to ureteropelvic reflux. Similarly, midlevel dilation may be a sonographic feature of vesicoureteral reflux as well as congenital megaureter.

The bladder is involved in low-level dilations, which are usually referred to as low urinary tract obstructions (LUTOs). They comprise mainly the posterior urethral valves. However, a dilated bladder may be the hallmark of major vesicoureteral reflux, which increases the urine output through the bladder. More complex urinary defects, for example, cloacal malformations, may appear as a bladder dilation, and occasionally, as a midlevel dilation associated with minor abnormalities of the fetal

pelvis. Complex pelvic floor malformations are the most common LUTO diagnosed antenatally in females, and posterior urethral valves are the most frequent etiology of LUTO in males.

Upper Urinary Tract Dilation. There is no universally accepted definition and grading of fetal upper urinary tract dilation. Pyelectasis is defined by moderate dilation of the renal pelvis without associated dilated calyces, whereas hydronephrosis refers to kidneys with a variable degree of calyceal dilation.

Pyelectasis. The renal pelvis is measured in the antero-posterior (AP) plane on cross section. However, the upper size limit of a normal fetal renal pelvis remains controversial, partly because there is substantial overlap in renal pelvic sizes between normal fetuses and infants who later prove to have reflux or obstruction. Low thresholds tend to stimulate unnecessary and potentially dangerous intervention, and high threshold values will lead to false-negative conclusions.[18]

Pyelectasis is variously defined in the literature as an AP pelvic diameter exceeding 4 to 6 mm in the second trimester and 8 to 10 mm in the third.[19–25] Depending on the definition, pyelectasis (Figs. 19–8 and 19–9) occurs in 1% to 3 % of pregnancies. In most cases, isolated fetal pyelectasis is physiologic. However, it may correspond to a mild reflux or to an ureteropelvic junction syndrome. The likelihood of pyelectasis being associated with substantial morbidity requiring postnatal surgery increases with the degree of antenatal pelvic dilation.[6,26,27] Fetuses with pyelectasis should be followed serially to confirm the dilation does not increase with advancing gestational age.[18,28]

Postnatal evaluation is required but should not be performed immediately after delivery as the false-negative rate is increased. At-risk neonates should have a renal ultrasound between 1 and 3 weeks of age. There is no consensus on whether and when postnatal ultrasound should be repeated, and on which patients should be offered a retrograde cystogram and when. Whatever the

FIGURE 19–8

FIGURE 19–11
Large unilateral hydronephrosis, transverse view, at 28 weeks.

postnatal strategies for the diagnosis of reflux or for the prevention of urinary tract infections are, the prenatal history should be kept in mind when unexplained symptoms occur postnatally.[29–31] The sensitivity of antenatal ultrasound for the detection of clinically significant reflux remains low,[16,17] and most cases of reflux are discovered after postnatal symptoms.

Hydronephrosis. Hydronephrosis is defined by an AP pelvic size of more than 1.5 cm or calyceal involvement.[32–34] In mild hydronephrosis, the calyces are slightly dilated and retain their shape. With greater upper urinary tract dilation, the calyces become rounded (Fig. 19–10), but the transonic calyceal images are distributed regularly and are connected to the renal pelvis in contrast to the irregular pattern of a multicystic kidney in which the cysts are independent of the pelvis. In severe cases, the calyceal images are no longer identified separate from the pelvis, appearing instead as a large single transonic image (Fig. 19–11). The renal parenchyma is considered thinned when it is less than 3 mm thick. This finding is not always ominous, because large dilations

with thin parenchyma can be associated with a normal renal function. At the parenchymal level, the presence or absence of a corticomedullary differentiation should be noted, as well as the echogenicity of the parenchyma and the presence of cysts. Although subjective,[35–39] the evaluation of the sonographic structure of the renal parenchyma may be a useful predictor of renal function, although it is less sensitive than urinalysis to predict postnatal survival with altered renal function.[40]

Midlevel Dilations. Hydroureter is a dilated ureter that appears as a convoluted transonic image, located between the kidney and the bladder (Figs. 19–12 and 19–13); normally, the ureter is unseen sonographically. Peristaltic activity suggests a megaureter, but a dilated ureter may also result from vesicoureteral reflux.[41]

A ureterocele can cause ureteric dilation. It appears as a round transonic image located inside the bladder and lined by a thin border (Figs. 19–14 and 19–15).

Low-Level Dilation (Low Urinary Tract Obstruction). A dilated bladder that does not empty over the course of the sonographic examination suggests an outlet obstruction.

FIGURE 19–10
Unilateral hydronephrosis with rounded calyces, transverse view, at 22 weeks.

FIGURE 19–12
Dilated ureter, frontal view, at 29 weeks.

FIGURE 19–13
Dilated ureter, transverse view, at 29 weeks.

FIGURE 19–16
Enlarged bladder, frontal view, at 30 weeks. Note thickened bladder wall and infravesical image of the dilated urethra (posterior urethral valves).

The dilated bladder is usually round, but may be larger above the umbilical arteries than below, evoking the shape of the champagne bottle cork. The image of a dilated urethra is rather specific for posterior urethral valves, but is far from constant. At a later stage, bladder outlet obstruction can result in a muscular hypertrophy imaged as a bladder wall thicker than 3 mm (Figs. 19–16 and 19–17). Bladder diverticula may also form. Although posterior urethral valves are the most common cause of bladder dilation in males, other etiologies are possible. Urethral atresia is an almost universally lethal condition and cannot be directly imaged. Rather, it is usually diagnosed at pathologic postmortem examination (Fig. 19–18). Complex genitourinary anomalies should also be carefully sought and ruled out. Keep in mind that a low urinary tract obstruction, including posterior urethral valves, can present as a midlevel or even an upper-level obstruction with bladder enlargement becoming noticeable during subsequent sonographic examinations.

FIGURE 19–20
Bladder exstrophy. Note the abnormal appearance of the anterior abdominal wall, the absence of vesical image, and the low-lying fetal insertion of the umbilical cord, at 25 weeks.

Ascites and Urinoma

Urine may leak into the peritoneal cavity through minor and usually unidentifiable disruptions of the urinary tract wall, causing ascites. Urinous ascites is not specific for a given uropathy and is not necessarily an ominous finding. The urinary origin of the ascites is usually apparent. Similarly, disruption of the urinary tract in the retroperitoneal space may lead to a urinoma (Fig. 19–19), which appears as a transonic image surrounding the kidney and confined within Gerota's facia.[42] Urinomas are usually easy to differentiate from renal masses, lymphangioma, neuroblastoma, mesenteric cyst, and enteric duplications.

Once the antenatal sonographic diagnosis of a fetal uropathy is made, the most clinically relevant question is prognosis. Because virtually any isolated uropathy can be successfully repaired postnatally, the prognosis is based on the presence of additional birth defects and postnatal renal function.

Ruling Out Associated Anomalies Including Karyotyping

The first step in the management of a fetus with a urinary tract abnormality is to rule out extraurinary anomalies by a complete sonographic assessment performed by an experienced practitioner.[43–45] Soft markers suggestive of a chromosomal abnormality should be sought (see later discussion) Complex pelvic malformations should be sought.

Bladder exstrophy is characterized by the absence of a vesical image[46,47] and can sometimes be imaged directly (Fig. 19–20). The antenatal diagnosis on cloacal malformations is based on the association of a variety of relatively minor signs that may appear only in the third trimester.[48–52] Rectal atresia is suggested when the sacrum appears too straight (Fig. 19–21). A urodigestive fistula is suspected when the bowel is dilated with hyperechogenic material (Figs. 19–22 and 19–23). The image of an enlarged duplicated vagina is quite specific of a cloacal malformation[53] but may not appear until the third

FIGURE 19–19
Urinoma, frontal view, at 20 weeks.

FIGURE 19–21
Straightened and shortened sacrum (cloacal abnormality), sagittal view, at 23 weeks.

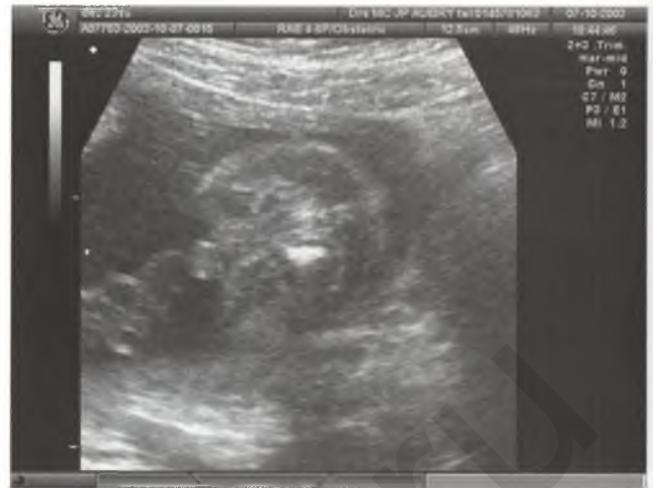
FIGURE 19–22
Hyperechogenic content of the small bowel (urodigestive fistula), transverse view, at 23 weeks.


FIGURE 19–24
Absence of image of the anal margin, tangential view of the perineum, at 23 weeks.

trimester. Though it is possible to image the anal sphincter, this does not rule out the diagnosis of anal atresia (Fig. 19–24). The external genitalia should also be carefully imaged. They may appear as enlarged and fused labia "floating" in the amniotic fluid. Overall, the potential for surgical repair may be difficult to establish when a complex malformation of the pelvic floor is diagnosed in utero, and the procedure should be discussed with an expert pediatric surgeon. Magnetic resonance imaging may be helpful in some instances if the radiographer is comfortable and skilled.

The prune-belly syndrome is another complex malformation in which the prognosis may be difficult to establish. The diagnosis is suspected antenatally when a large bladder (Fig. 19–25) and substantial ureteral dilations (Fig. 19–26) are seen, in contrast to mild hydronephrosis (Fig. 19–27). Undescended testes are common. It is possible to depress the fetal abdomen with a moderate amount of pressure by the ultrasound probe.

FIGURE 19–25
Enlarged bladder at 34 weeks. No infravesical urethral dilation. Normal bladder wall (prune-belly).

FIGURE 19–23
Hyperechogenic content of the small bowel (urodigestive fistula), frontal view, at 23 weeks.

FIGURE 19–26
Oblique view showing bladder, ureter, and kidney (prune-belly), at 34 weeks.

FIGURE 19–27
Mild pyelectasis (prune-belly), parasagittal view, at 34 weeks.

Some less common conditions are even more difficult to diagnose than the prune-belly sequence. For example, a microcolon megacystis syndrome[54,55] is suspected when there is a large bladder and bowel dilation. However, the bowel dilation may only occur late in the third trimester, explaining why this condition is often missed antenatally. It carries a poor postnatal prognosis owing to associated alterations in digestive function.

The second step of the diagnostic workup is to consider a fetal karyotyping. In pilot studies, the incidence of chromosomal abnormalities associated with genitourinary defects was 12%.[56] However, in many uropathies secondary to chromosomal abnormalities, additional extrarenal defects are sonographically detectable, reducing the prevalence of aneuploidy in truly isolated uropathies such as posterior urethral valves or hydronephrosis. Thus, the risk of aneuploidy should be evaluated and weighed against the potential risk of an amniocentesis.[57–60] When at least one soft ultrasound marker is associated with the uropathy, such as a short femur or humerus, a facial abnormality, or a minor anomaly of the fingers or toes, or when an additional malformation is found, the parents should be informed there is a high risk of aneuploidy. When previous aneuploidy screening tests such as nuchal translucency measurement or maternal serum makers yielded "borderline" risks, one should consider the finding of the fetal uropathy as raising the risk above the usual "action line." Unfortunately, large studies that would allow calculation of the likelihood ratio of aneuploidy associated with isolated unilateral hydronephrosis or posterior urethral valves in utero are lacking. Regardless of any attempt at estimating the risk of aneuploidy, some parents may wish to have a karyotype to maximize their opportunities of ruling out associated abnormalities in a baby for whom neonatal surgery and long-term uronephrologic follow-up are likely.

Whether or not pyelectasis is an indication for karyotyping has been a matter of some controversy owing to the high incidence of pyelectasis in normal children. When pyelectasis is associated with another fetal anomaly, even minor, the risk of aneuploidy is increased 10 to 20 times the baseline maternal rate,[61,62] and karyotyping is indicated. In contrast, the risk of aneuploidy is increased by only 1.5 times the baseline maternal rate in cases of isolated pyelectasis. This information should be considered as a part of the sequential screening process for aneuploidy using multiple parameters including maternal age, nuchal translucency measurement, and maternal serum markers (see Chapters 7 and 8).[21–24,60,63–70] The integrated risk of aneuploidy should then be weighed against the risks related with amniocentesis.[58]

Predicting Postnatal Pulmonary Function

Pulmonary hypoplasia (PH) is a disorder of impaired lung growth characterized by diminished size and generational branching and vasculature. Severe oligohydramnios from 16 weeks onward appears to preclude further pulmonary development. In contrast, oligohydramnios after the second trimester is unlikely to result in PH because the crucial canalicular phase of lung development (occurring between 16 and 25 weeks) has largely been completed by this stage. Predicting the likelihood of PH is difficult. Most studies that give predictive data have used cases with preterm premature membrane rupture (PPROM),[71–73] and it is not clear how applicable such data are to cases of olgohydramnios secondary to fetal uropathies. In the case of PPROM additional factors such as preterm delivery and infection contribute to the outcome, and one might speculate that they will worsen the prognosis in contrast to oligohydramnios alone. However, the PPROM data suggest the following:

- If there is a mean vertical pocket of amniotic fluid on ultrasound prior to 26 weeks of greater than 10 mm, PH is very unlikely to occur.[71]
- If the mean vertical pocket of amniotic fluid on ultrasound prior to 26 weeks is less than 10 mm, there is a 90% neonatal mortality rate.[71]
- If the mean vertical pocket of amniotic fluid on ultrasound after 26 weeks is less than 10 mm, PH is very unlikely to occur.[71–73]

Thus, in summary, although absence of severe oligohydramnios before 26 weeks probably means that PH is unlikely, predicting which fetus will develop PH after birth is more difficult. Alternative ultrasound measures, such as chest size, do not appear to produce reliable results.[71,74]

Predicting Postnatal Renal Function

The next goal, once associated abnormalities are ruled out, is to predict postnatal renal function. Unilateral uropathies are associated with a good functional outcome, and it is unnecessary to perform invasive fetal studies to obtain biochemical data from the abnormal

kidney, regardless of its sonographic appearance. Serial examinations are required to ensure that contralateral lesions do not appear later in gestation.

The evaluation of fetal renal function with bilateral renal dilation or low urinary tract obstruction is based mainly on ultrasound and, in select cases, on fetal urine analysis or fetal blood sampling. Ultrasound permits assessment of the parenchyma and the amniotic fluid volume.[14,35,75] Fetal urinalysis assesses the ability of the renal tubule to reabsorb a variety of compounds, including sodium, β_2-microglobulin, calcium, phosphorus, and glucose.[32,45,76–84] The β_2-microglobulin level in the fetal serum is thought to reflect fetal glomerular function.[85–88]

Sonographic features related to terminal renal failure in utero include severe oligohydramnios and abnormal images of the renal parenchyma, such as loss of the normal corticomedullary differentiation, hyperechogenicity, and cortical cysts (see Fig. 19–17). In these instances, fetal urinalysis might confirm renal failure, showing high fetal urinary concentrations of sodium and β_2-microglobulin.[89] On the other hand, the functional prognosis is usually good and fetal urine sampling unnecessary in cases of upper obstruction with normal amniotic fluid volume and normal renal parenchyma throughout pregnancy.

In select cases, the functional prognosis cannot be established sonographically. These cases include fetuses with bilateral lesions and moderately decreased amniotic fluid, and fetuses with mild alterations of the renal parenchyma. Moreover, in cases in which the antenatal diagnosis of posterior urethral valves is almost certain, the relatively high incidence of postnatal renal failure could advocate in favor of fetal urine sampling, even in the absence of any ominous sonographic finding. For such cases, one of the most clinically relevant issues is to identify among the children expected to survive those who are at risk for developing postnatal renal failure from those whose renal function will remain normal after surgical repair. The establishment of prognostic values for any marker is complicated by the fact that renal failure may occur relatively late in life, for instance, during adolescence, which underscores the need for long-term follow-up of children in whom fetal urine analysis was performed in utero. Some studies show that fetuses with a normal urinary sodium but a urinary β_2-microglobulin above the 95th percentile are at increased risk of having a serum creatinine greater than one standard deviation (1 SD) above the mean by 1 year of age.[78] When both compounds are abnormally high, neonatal renal failure is likely. In contrast, a good postnatal outcome is anticipated when both compounds are within the normal range.[78] Others report higher thresholds for fetal urinary β_2-microglobulin to predict a postnatal serum creatinine greater than 2 SD above the mean, thereby increasing specificity.[83] To increase the accuracy of fetal urinalysis, it has been advocated that the apparently less affected kidney be sampled[40] or to repeat vesicocentesis serially as

long as the values continue to improve or until they normalize.[83,90] In our experience, the results of fetal urinalysis should be interpreted with great care, because in the absence of ominous sonographic findings, only very high levels of urinary β_2-microglobulin (i.e., >10 mg/L) are error-proof predictors of renal failure at the age of 10 to 16 years (unpublished data).

Overall Management

GENERAL

Once the prognosis is decided, management options including termination of pregnancy, occasionally fetal therapy, and postnatal care and follow-up should be discussed with the parents. The option of pregnancy termination should be raised whenever there is terminal renal failure or multiple malformations. Fetal intervention is not indicated when there is unilateral disease or an isolated uropathy with normal renal parenchyma and normal renal function. In these instances, postnatal treatment is planned. It is important to refer the couple antenatally to the pediatric urologist who will be in charge of the baby.

IDENTIFICATION OF CONDITIONS REQUIRING EMERGENCY NEONATAL SURGERY

Some isolated uropathies in which postnatal renal function is anticipated to be reasonably good may require emergency postnatal surgery, requiring delivery in a tertiary care center with pediatric surgery facilities. These include posterior urethral valves, obstructive ureterocele, major bilateral hydronephrosis, and more generally cases with late onset oligohydramnios leading to the diagnosis of acute blockage of urinary output.

Fetal Therapy

Fetal therapy for uropathies is considered because although obstruction of the urinary tract may be treated by relatively simple postnatal procedures, they can be associated with severe renal lesions that manifest before birth. The lesions include severe renal dysplasia, severe oligohydramnios, and pulmonary hypoplasia, leading to either perinatal death or end-stage neonatal renal failure. Animal investigation suggested that intrauterine decompression of experimental urinary tract obstruction in the fetal lamb prevented renal dysplasia.[91–94] Unfortunately the positive impact of fetal urinary decompression on chronic renal disease has not been demonstrated in the clinical setting.[95–101]

Lower urinary obstruction in the human fetus has been treated by open fetal surgery, endoscopic ablation of posterior urethral valves, percutaneous vesicoamniotic shunting, or serial vesicocentesis. Some of these techniques can also be applied to upper tract obstruction. Open fetal surgery was abandoned with the development of percutaneous techniques. Endoscopic ablation of the

posterior valves has to date yielded poor perinatal outcomes.[102–104] Serial vesicocentesis was performed as early as the first trimester,[105] but its efficacy remains unclear. Indeed, resolution of first-trimester urinary dilation following percutaneous needling may reflect the natural history rather than the intervention.[106]

Percutaneous ultrasound-guided vesicoamniotic shunting was first reported in the 1980s.[107] Briefly, a cannula is inserted percutaneously through the maternal abdomen under ultrasound guidance and after local analgesia into the dilated fetal bladder or kidney. A double pigtail catheter is inserted through the cannula, with the distal end placed into the dilated urinary tract and the proximal end left in the amniotic cavity. Complications are similar to most "needle"-type procedures and include chorioamnionitis, preterm labor, premature rupture of membranes, or preterm delivery in around 10% of cases.[108,109] Up to half of the shunts are displaced after a few days or weeks. Migration of the amniotic end into the peritoneal cavity can cause urinary ascites, which can be addressed with modest success by placing a peritoneoamniotic shunt.[110] Other complications include an iatrogenic gastroschisis.

A systematic review and meta-analysis published in 2003[111] concluded there is a lack of high-quality evidence to guide clinical practice regarding prenatal bladder drainage.[95,98,112–115] However, in utero drainage may improve survival in severely affected fetuses by improving lung function, but it is achieved at the expense of increasing pediatric morbidity. Long-term follow-up of shunted survivors reveals that some form of chronic renal disease is the rule. Many are ultimately transplanted.

Perform careful examination and assessment of baby after delivery or postmortem examination after perinatal death.	III	B	89

CONCLUSIONS

- Dilations of the urinary tract are common findings at the 20–22 week ultrasound scan with varying prognosis.
- Associated abnormalities should be sought using ultrasound; karyotype should be considered, but the risk of amniocentesis should be weighed against the risk of chromosomal anomaly, taking into account previous screening tests.

- Evaluation of renal function by ultrasound (amniotic fluid volume and renal parenchyma) and, occasionally, fetal urinalysis or fetal blood sampling may help clarify prognosis; renal function is good with unilateral disease.
- In the most severe cases with bilateral disease, the option of pregnancy termination should be considered.
- In continuing pregnancies, perinatal management should be planned with a pediatric surgeon/pediatrician.
- Fetal urinary decompression should be considered with great caution; although it does improve prognosis, parents should be aware that even though it allows survival of a baby, it might carry the price of long-term renal dysfunction.

KIDNEY ABNORMALITIES

General

Fetal renal anomalies include those of number, location, size, and structure. These malformations are primarily renal and usually occur in the absence of a urinary tract defect. Some, such as renal agenesis or multicystic kidney disease, are rather common and easy to diagnose. The diagnosis and antenatal management can be more difficult when renal structural anomalies present as hyperechogenic or enlarged kidneys. The first step after a renal abnormality has been identified is to exclude associated anomalies and, if necessary, offer fetal karyotyping.

The prognosis of isolated unilateral renal abnormalities is uniformly good, whereas bilateral anomalies associated with severe oligohydramnios are lethal. In bilateral cases with normal amniotic fluid, the long-term postnatal morbidity is difficult to predict. Biochemical markers that have been proved predictive of postnatal morbidity in uropathies have not performed well in fetal nephropathies. Our personal experience suggests that neither the fetal urinary electrolytes nor the fetal serum β_2-microglobulin are reliable predictors of postnatal renal function in fetuses with bilaterally enlarged and hyperechogenic kidneys and normal amniotic fluid volume (unpublished data).

Anomalies of Number

Renal agenesis can be unilateral or bilateral. It may result from early degeneration of the ureteric bud, or from a failed interaction between the ureteric bud and the blastema (Figs. 19–28 to 19–31). The corresponding adrenal gland assumes a globoid shape and should not be mistaken for a hypoplastic kidney.[116] Bilateral agenesis is lethal, causing the oligohydramnios sequence (pulmonary hypoplasia, dysmorphic face, and limb deformities).[62,117] In contrast, fetuses with unilateral renal agenesis remain symptom-free during postnatal life in the absence of associated anomalies. Minor genital anomalies such as duplicated/hypoplastic uterus, absent fallopian tube, absent epididymis and vas efferens can be found ipsilateral to unilateral renal agenesis. They cannot be diagnosed in utero and would not alter the prognosis for survival.[118]

FIGURE 19–28
Bilateral renal agenesis, transverse view, at 20 weeks.

Duplication of the kidney is caused by the premature division of the ureteric bud before it connects to the nephrogenic mesoderm (Fig. 19–32). This explains its association with a double or bifid ureter. In the instance of a double ureter, the upper ureter typically enters the bladder more caudally, but may also connect ectopically to the urethra, vagina, seminal vesicle, or the rectum.

FIGURE 19–29

FIGURE 19–30
Unilateral renal agenesis, transverse view, at 22 weeks.

FIGURE 19–32
Renal duplication, frontal view, at 23 weeks.

The upper kidney usually shows some degree of outflow obstruction and parenchymal dysplasia. Therefore, a dilated pelvis or an abnormal structure in a dysplastic part of the kidney with a ureterocele at the connection of the distal ureter to the bladder may be a hallmark finding.[119] The accuracy of antenatal ultrasound for the diagnosis of fetal duplex kidney approximates 75%, based on two main sonographic features: identification of two separate poles in the affected kidney and the presence of a ureterocele.

Supernumerary kidney results from premature branching of the ureteric bud. The supernumerary kidney has its own ureter and blood supply, and frequently has complications such as obstruction or dysplasia.

Abnormalities of Position

Ectopic kidneys are usually displaced caudally. One or both kidneys may be involved, and the shape is abnormal due to malrotation. This condition is asymptomatic pro-

vided the renal parenchyma is well differentiated and free of dysplasia.[120] In crossed renal ectopia, both kidneys are located on the same side of the body and may be fused.

Horseshoe kidney results from the fusion of the kidneys, usually by their lower poles.[121] Fusion of both upper and lower poles produces the ring kidney. When isolated, horseshoe kidneys are usually asymptomatic. However, they are also associated with aneuploidy (trisomy 18, Turner syndrome, triploidy).

Isolated Abnormalities of Size and Structure

Renal hypoplasia is defined as kidney mass smaller than 2 SD below the mean. This condition is diagnosed postnatally except in its most severe form.

Multicystic dysplasia manifests antenatally as kidneys that have lost their normal shape (Figs. 19–33 and 19–34), containing a collection of macrocysts of variable diameter

FIGURE 19–31

(0.5–3 cm or more) that are connected neither to each other nor to the rest of the urinary tract. Some clusters of tubules, rudimentary glomeruli, primitive ducts, and bars of metaplastic cartilage may be irregularly distributed within the loose mesenchyme. It usually occurs in the absence of any obstructive uropathy. Whereas bilateral disease is lethal, unilateral forms have a good prognosis. Spontaneous involution of the multicystic kidney is usual during postnatal life and may on occasion occur in utero. The cyst size is usually constant throughout fetal life, but rarely extremely large cysts may compress the fetal abdomen or cause dystocia and therefore require intrauterine needling. These macrocystic lesions are easy to distinguish from polycystic kidney diseases, which present antenatally as enlarged hyperechoic kidneys. The sonographic pattern of the latter conditions is due to the microscopic cysts that fill the renal parenchyma.[122]

Autosomal recessive polycystic kidney disease is an inherited disorder and is also referred to as infantile polycystic kidney disease. It is characterized by enlarged kidneys that retain their shape. The cut surface has a spongy appearance due to elongated microcysts that have a radial orientation extending from the medulla to the cortical surface. These cysts correspond to dilated collecting ducts.[118] The liver is always involved with portal fibrosis and proliferation of bile ducts.[123,124] Postnatally, the diagnosis is easy to make based on typical anatomic features. The fetopathologic diagnosis, however, may be far more difficult in second trimester fetuses, underscoring the need for referring abnormal kidneys to pathologists familiar with fetal renal development.

Disease expression in utero is variable.[125–129] Some fetuses remain sonographically normal. In this instance, renal enlargement develops during infancy, and renal failure occurs relatively late in the second decade. At the other end of the spectrum, autosomal recessive polycystic kidney disease manifests in the second trimester as a premortem, anuric fetus with absent amniotic fluid and dramatically enlarged, hyperechogenic kidneys with no

corticomedullary differentiation (Figs. 19–35 and 19–36). Intermediate forms are the norm, with a variable combination of renal enlargement and late-onset oligohydramnios.[128] The controlling gene has been mapped.[130]

Autosomal dominant polycystic kidney disease is also referred to as adult polycystic kidney disease because its clinical onset usually occurs in adulthood. This term, however, is misleading because autosomal dominant polycystic disease may manifest early and occasionally quite severely, including during fetal life. Autosomal dominant polycystic kidney is a common cause of enlarged hyperechogenic kidneys in the fetus because of the relatively high frequency of the mutation in the general population.[129,131–133] The diagnosis is easy when renal cysts are present in one of the parents. However, this hint may be lacking either because of the variability of disease expression or because the fetus has a new mutation.

In the adult, the kidneys are enlarged and their surface distorted by bulging macrocysts. During fetal life, however, the cysts are usually very small, producing a sonographic

FIGURE 19–36
Enlarged hyperechogenic kidney (recessive autosomal polycystic kidney disease), parasagittal view, at 36 weeks. Note the absence of corticomedullary differentiation of the renal parenchyma.

pattern of enlarged, hyperechogenic kidneys similar in appearance to that of the recessive disease.[129] In the most severe cases, terminal renal failure occurs in utero. The diagnosis is made post mortem by showing both collecting tubules and nephrogenic cysts. Several mutations can result in disease. Known sites include chromosome 16 (PKD1 locus) and chromosome 4 (PKD2 locus).[134,135]

Transient nephromegaly is a poorly understood condition and can be defined as renal enlargement without any alteration of renal function. These patients may present as fetuses with moderately enlarged kidneys in which corticomedullary differentiation is usually retained. The kidneys may appear slightly hyperechogenic. The amniotic fluid volume remains normal. The sonographic abnormalities tend to regress during infancy, and the children remain symptom-free.[136] The uneventful postnatal course may be the only way to distinguish this condition from a true renal disease, such as polycystic kidney disease, or from less common causes of enlarged fetal kidneys.[129]

Prenatal Management of Isolated Hyperechogenic Kidneys

The counseling of a pregnant woman after sonographic diagnosis of isolated hyperechogenic fetal kidneys is challenging, because providing patients with overly pessimistic information leads to unnecessary pregnancy termination, whereas unrestricted reassurance may be unfair. Fetal sonography usually fails to provide an accurate etiologic diagnosis, and fetal hyperechogenic kidneys can result from a variety of etiologies, including recessive and dominant polycystic kidney disease and transient nephromegaly.[137] Further, there is a wide range of outcomes within each etiologic group. Postnatal series are likely to overlook the most severe cases leading to perinatal death, as well as the mildest ones, which may remain clinically undetectable over a long period.

The outcome can be predicted accurately in the most severe cases, in which terminal renal failure is certain with the discovery of severe oligohydramnios in the second trimester. If the pregnancy is terminated, it is crucial to obtain an accurate etiologic diagnosis and to store fetal DNA, because this information may lead to first-trimester prenatal diagnosis at subsequent pregnancies, should autosomal recessive or dominant polycystic kidney disease be identified. A wrong histopathologic diagnosis might have dramatic consequences in terms of genetic counseling and prenatal diagnosis.

In less severe cases, antenatal counseling should be based on prospective studies with long postnatal follow-up. In our experience[129] of a continuous series of 45 fetuses with bilateral isolated hyperechogenic kidneys, there were 20 with autosomal recessive disease, 8 with autosomal dominant disease, 9 with other renal disorders, and 6 symptom-free survivors without etiologic

diagnosis. There were 19 pregnancy terminations, 5 neonatal deaths, and 19 survivors, of whom 14 had normal renal function, 3 had mild renal failure, and 2 had end-stage renal failure. None of those with severe oligohydramnios and fetal kidneys greater than 4 SD survived ($n = 14$, 10 terminations, 4 neonatal deaths), whereas 13 of 16 with normal amniotic fluid volume and kidneys less than 4 SD survived; 9 were symptom-free with a follow-up of 34 to 132 months.

Rare Etiologies of Fetal Nephropathies

Renal tubular dysgenesis is a rare condition characterized by poorly developed or undeveloped proximal tubules, causing severe oligohydramnios.[138] It is thought due to an abnormality of the renin-angiotensin system because similar renal anomalies are reported after prenatal exposure to angiotensin-converting enzyme inhibitors. This lethal condition is probably inherited in an autosomal recessive disorder and should be recognized at fetal autopsy to provide adequate genetic counseling. Prolonged exposition to indomethacin may also induce renal failure, but probably by a different mechanism.[139]

Nephroblastomatosis is characterized by the presence of nephrogenic rests of metanephric blastema in both kidneys.[140] The kidneys may appear hyperechogenic and are associated with overgrowth syndromes such as Beckwith-Wiedemann syndrome. Affected patients are also at increased risk for developing Wilms' tumor (see Chapter 23).

Renal tumors that present during fetal life are rapidly growing solid heterogeneous masses.[141] They are easy to distinguish from single transonic cysts that can also be recognized in utero but remain asymptomatic postnatally. Mesoblastic nephroma are reported to have a typical "ring" sign on Doppler examination, which consists in an anechoic ring surrounding the tumor with a color Doppler signal.[142]

Fetal Nephropathies with Polyhydramnios

The Finnish type of congenital nephrotic syndrome may present antenatally with hydramnios, placentomegaly, and moderate growth restriction. Modest alterations in the renal parenchyma such as hyperechogenicity are inconstant, making the antenatal diagnosis difficult in the absence of an index case.[143–145] In practice, one should consider performing a biochemical analysis of amniotic fluid in cases of unexplained hydramnios, which may occasionally lead to the diagnosis of fetal proteinuria (high concentration of α-fetoprotein and other proteins). Inconsistently,[146] anomalies of electrolyte or aldosterone concentrations in the amniotic fluid may suggest Bartter's syndrome,[147–150] which is characterized by early-onset hydramnios and mild pyelectasis resulting from the fetal polyuria.

Cystic Kidneys and Multiple Malformation Syndromes

Cystic kidneys are part of several multiple malformation syndromes.[151] The autosomal recessive Meckel-Gruber syndrome is one of the most common and lethal. It is characterized by severe oligohydramnios during the second trimester with markedly enlarged kidneys whose normal structure has been replaced by multiple cysts.[152] Encephalocele and postaxial polydactyly are characteristic of the Meckel-Gruber syndrome but can be difficult to see once severe oligohydramnios has occurred.[153] Severe oligohydramnios and enlarged dysplastic kidneys can also be sonographic features of chromosomal abnormalities such as trisomy 13.

Horseshoe kidney is associated with trisomy 18, Turner syndrome, or triploidy.

The Laurence-Moon-Bardet-Biedl syndrome presents antenatally as hyperechogenic kidneys with polydactyly.

Growth is usually normal during fetal life. In the Beckwith-Wiedemann syndrome the enlarged kidneys are part of a more generalized visceromegaly, occasionally associated with an omphalocele. DiGeorge syndrome may manifest as a heart defect associated with renal abnormalities. Zellweger syndrome appears as renal cortical cysts with cerebral periventricular pseudocysts. Smith-Lemli-Opitz syndrome is considered when dysplastic kidneys are associated with intrauterine growth restriction, abnormal fingers, and ambiguous genitalia.

Dysplastic kidneys are also found in a variety of other syndromes, but usually as a secondary finding (e.g., short rib polydactyly associations). This underscores the need for careful sonographic evaluation when abnormal kidneys are found. Fetal karyotyping is considered when the structure of the kidneys is abnormal (hyperechogenicity, suspected dysplasia). However, isolated multicystic kidneys, renal agenesis, and ectopic kidneys are not associated with an increased risk of aneuploidy.

CONCLUSIONS

- Fetal anomalies can vary in prognosis; the prognosis is generally good for unilateral lesions, poor for bilateral lesions with oligohydramnios, and difficult to predict with bilateral lesions with normal amniotic fluid volume; biochemical testing of urine is not helpful in predicting kidney function.
- Other abnormalities should be excluded; karyotyping will be indicated with specific abnormalities.
- Fetal DNA should be stored when a termination of pregnancy is performed for a suspected genetic renal abnormality, such as polycystic kidney disease.

ABNORMAL GENITALIA

General

Although fetal ultrasound is widely used to determine fetal gender, there is no consensus as to whether the structure of external genitalia should be part of standard screening ultrasound. Major genital abnormalities can have a devastating impact on postnatal life, and genital abnormalities may be the hallmark of a multiple malformation syndrome. Ambiguous genitalia can be a medical emergency in neonates with salt-wasting forms of congenital adrenal hyperplasia. An examination of the fetal genitalia is mandatory whenever a uronephrologic abnormality is found to rule out a complex malformation of the fetal pelvis (see previous section) (Fig. 19–37).

Sonographic Diagnosis

Abnormal fetal genitalia may be identified under different circumstances:

- A specific genetic risk based on family history. This includes 5α-reductase deficiency, androgen insensitivity, and congenital adrenal hyperplasia. However, in a growing number of cases, the molecular mechanism of the disease is established, allowing for first-trimester genetic diagnosis using chorionic villi.
- A discrepancy between the fetal gender established on routine ultrasound and fetal karyotyping.
- Abnormal or ambiguous genitalia found during routine ultrasound, either isolated or as part of a complex anomaly of the fetal pelvis or of a multiple malformation syndrome.

Undescended testis (Fig. 19–38) can be physiologic in the second trimester. Associated abnormalities, including uropathies and the prune-belly syndrome, should be ruled out.

FIGURE 19–38
Unilateral undescended testes at 34 weeks.

The diagnosis of hypospadias is more often made during the third trimester than in the second. Even in experienced hands, the antenatal diagnosis of hypospadias can be impossible because of fetal position or technical limitations, including oligohydramnios. Anterior or middle hypospadias is rarely identified antenatally on ultrasound, although it is usually self-evident on examination of the neonate. Occasionally, the fetal penis is suspected to be shorter than usual, or to have a certain degree of abnormal curvature (Fig. 19–39). The tip of the penis may seem blunt. Ventral deflection of urinary stream can occasionally be seen using color Doppler.[154] Posterior hypospadias may be diagnosed antenatally based on the finding of a bifid scrotum, a short and curved penis, and no urethral canal (Fig. 19–40). The angulated penis located between the two scrotal folds is said to resemble a tulip flower.[155] When associated with undescended testis, posterior hypospadias may be difficult to differentiate from masculinized female genitalia with fused labia and an enlarged clitoris.[156]

Rare conditions identifiable antenatally by ultrasound include distal obstruction of the fetal urethra

FIGURE 19–37
Bifidity of external genitalia in a girl with bladder exstrophy, Tangential view of the perineum, at 25 weeks.

FIGURE 19–39
Short penis, sagittal view at 32 weeks.

FIGURE 19–42
Ambiguous genitalia, showing virilization of an XX fetus (congenital adrenal hyperplasia) at 29 weeks.

(Fig. 19–41), perineal tumors, congenital hernia, and penoscrotal transposition.[157]

Gender discrepancies may be explained by a variety of mechanisms.[158] A discrepancy between the phenotypic fetal gender and fetal karyotype may result from a labeling error of the amniotic fluid sample, a typing error in sonographic or genetic records, or maternal contamination of amniotic fluid cultures. The ultrasound examination should seek to establish whether the external genitalia seem structurally normal or ambiguous. Enlarged adrenal glands in the third trimester are suggestive of adrenal hyperplasia, and result more often in ambiguous virilized female genitalia than in a male phenotype with an abnormal scrotum (Fig. 19–42). The presence of a fetal uterus can occasionally be documented sonographically, but its absence can never be ascertained confidently. Conversely, when abnormal genitalia are first identified by ultrasound, fetal karyotyping is the first step toward an antenatal diagnosis.[156]

Management Options

Parallel to establishing the anatomy of the fetal genitalia, associated abnormalities should be sought. A number of multiple malformation syndromes including Smith-Lemli-Opitz, CHARGE, Prader-Willi, and camptomelic dwarfism, can be associated with genital abnormalities. Complex cloacae malformations should also be sought (see previous section) and may be part of a more complex entity, such as the VATER association or a caudal regression syndrome. Fetuses with bladder exstrophy have abnormal genitalia. A bifid genital tubercle with epispadias may be found in males. The diagnosis is based on the absence of a fetal bladder associated with a low-lying fetal umbilical cord insertion and an abnormal bony pelvis. Cloacal exstrophy can produce bowel abnormalities suggestive of gastroschisis associated with vesical exstrophy.

The results of the fetal karyotype should be interpreted with great care, for the "genetic" gender may not be the "true" gender of the infant. For example, XX males bearing the *SRY* gene are unambiguously boys, and XY fetuses with complete androgen insensitivity present as females. Adrenal hyperplasia may be suspected by ultrasound and confirmed by measuring the amniotic fluid 17-OH progesterone concentration. Counseling after the antenatal diagnosis of an apparently isolated abnormality of external genitalia is challenging and may be devastating for the family. Identifying the mechanism of the anomaly is helpful. Determining the anatomy of the fetal genitalia is crucial to establish the prognosis in terms of the potential for surgical repair. Counseling by a pediatric surgeon and a pediatric endocrinologist having extensive experience of intersex states is warranted to provide the parents with information on postnatal management and gender assignment.

Distal urethral obstruction with dilated penile urethra, at 22 weeks.

SUMMARY OF MANAGEMENT OPTIONS
Abnormal Genitalia

Management Options	Quality of Evidence	Strength of Recommendation	References
Exclude other abnormalities.	–	GPP	–
Karyotype for gender and to exclude other chromosomal abnormalities, but exercise care in assigning gender even after birth.	–	GPP	–
Organize prenatal sonographic follow-up.	–	GPP	–
Interdisciplinary approach: plan perinatal management with pediatric surgeon, pediatric endocrinologist, and geneticist.	–	GPP	–
Delivery is probably best in center where careful examination, assessment, and plans for management can be made after birth.	–	GPP	–

CONCLUSIONS

- Full extent of abnormalities not always clear before birth.
- Careful search for other abnormalities including chromosomal is advisable.
- Interdisciplinary management is manadatory.
- Care needs to be taken with gender assignment.

Fetal Gastrointestinal Abnormalities

Peter Stone

INTRODUCTION

Fetal gastrointestinal and abdominal wall malformations are easily visualized by ultrasound and may be detected either during a second trimester scan for anomalies or by chance during an examination for an unrelated indication, such as the evaluation of poor fetal growth, abnormal amniotic fluid volume (usually hydramnios), or an increased maternal serum α-fetoprotein concentration. The most common gastrointestinal abnormalities detected antenatally are omphalocele, gastroschisis, and diaphragmatic hernia. The other malformations are both less common and less frequently diagnosed by ultrasonography. Upon detection, the abnormality should be managed in consultation with a multidisciplinary team that provides consistent advice and treatment. Team members typically include an obstetrician with expertise in fetal medicine, a neonatal pediatrician, pediatric surgeon, clinical geneticist, and anesthesiologist. The patient should meet before delivery with these people either on an individual basis or as a group as needed.

OMPHALOCELE (EXOMPHALOS)

General

Omphalocele is an extraembryonic hernia caused by the arrest of ventral medial migration of the dermatomyotomes (Fig. 20–1). It is associated with other malformations in 60% of cases. Omphalocele has an annual prevalence of 1:2500 to 1:5000 pregnancies. The annual prevalence is similar to gastroschisis, though recent publication suggests the latter is growing more common.[1] "Physiologic" herniation of abdominal contents into the base of the umbilical cord is normal up until around 11 weeks' gestation (Fig. 20–2) and must be distinguished from an omphalocele.

Diagnosis

An omphalocele contains abdominal contents enclosed in a membrane. The diagnosis is made after 11 weeks when an anterior, extra-abdominal mass is detected upon which the umbilical cord inserts rather than to the anterior abdominal wall (see Fig. 20–1). Defect size and type have some prognostic importance. Although the omphalocele contents are usually enclosed within a membrane, spontaneous rupture does occur. A less common variant is the "giant omphalocele" (Fig. 20–3) in which the abdominal wall defect is massive. Giant defects and those in which the membrane has ruptured are often associated with a small or defective thoracic cage associated with pulmonary hypoplasia and postnatal respiratory complications.[2] There may on rare occasion be difficulty distinguishing a ruptured omphalocele from gastroschisis. Omphalocele is commonly associated with other malformations (Table 20–1) and, like gastroschisis, may be associated with hydramnios. Intrauterine growth restriction is common, and approximately one of six fetuses with omphalocele are chromosomally abnormal. A small omphalocele may be missed on ultrasonography, especially if the fluid volume is reduced and the anterior abdominal wall cannot be clearly delineated. However, the sensitivity of ultrasound detection exceeds 86%.[3]

Both omphalocele and gastroschisis cause a very high maternal serum α-fetoprotein concentration during the second trimester. If an amniotic fluid sample is obtained, it will reveal a faint acetylcholinesterase band and a dense pseudocholinesterase band. This pattern is opposite that of a neural tube defect (see Chapter 18).[4]

Risks

Maternal

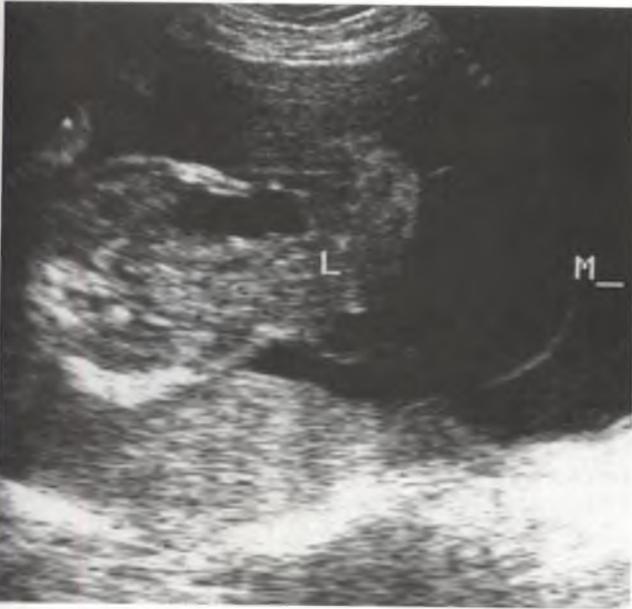
There are few obstetric risks to the mother apart from the rare complication of hydramnios. The recurrence risk reflects the underlying etiology.


FIGURE 20–1
Characteristic ultrasound appearance of omphalocele. Note the membrane (M) surrounding the liver (L) and bowel.

FIGURE 20–3
Ultrasound appearance of a giant omphalocele showing massive amount of extracorporeal tissue and cord insertion.

Fetal and Neonatal

Perinatal risks include those of invasive diagnostic testing, the implications of associated abnormalities, and postnatal surgery that may be complicated when there is extracorporeal liver.

Management Options

Antenatal

The first step is to exclude other abnormalities (found in at least 60% of cases).[5-7] This mandates a detailed ultrasonographic examination, including a fetal echocardiogram (see Chapter 17) and a fetal karyotype. Abnormal cardiac findings occur in 45% of fetuses with omphalocele.[8] The sonographic differentiation between

omphalocele and gastroschisis is important and generally not difficult. The presence of a sac or membrane around the contents with the umbilical cord inserting upon it is pathognomonic. Difficulties arise when the sac has ruptured spontaneously, or when the relationship of the herniated tissue to the umbilical cord insertion is unclear. On occasion, thickened loops of bowel in the fetus with gastroschisis may appear as a covering membrane. The peritoneal membrane can also be difficult to visualize when there is oligohydramnios. In contrast to gastroschisis, extracorporeal liver is common (40%). Fetuses with intracorporeal liver are significantly more likely to have chromosomal abnormalities,[3] as are fetuses with other malformations and with mothers with advanced age. There is probably little prognostic significance of the omphalocele contents if the karyotype is normal, except for a worse prognosis with large defects.

Parental counseling after diagnosis stresses the importance of a fetal karyotype and that the prognosis is generally good if the chromosomes are normal and there are no associated malformations (though not all may be detected before birth). Even with postnatal diagnosis, the survival rate of otherwise normal infants exceeds 75%.[3] Large abdominal wall defects can pose particular problems for both neonatal respiratory management and surgical closure, and these issues should be covered during counseling with the neonatologist and pediatric surgeon. Death of the otherwise normal infant results from prematurity, sepsis, or problems with short gut syndrome, which is more common with gastroschisis than omphalocele. Long-term follow-up of adults with a congenital abdominal wall defect suggests the quality of life is similar to that of the general population, though common problems include disorders of the abdominal wall scar in 37% and functional gastrointestinal disorders in 51%.[9] Parents may benefit from illustrations showing typical defects before and after surgery (Fig. 20–4).

Labor and Delivery

Delivery should occur in a center with a neonatal medical and surgical team in attendance to optimize the transition to ex utero life and the preoperative care. There is no evidence elective cesarean delivery a priori confers any benefit to the fetus or neonate with omphalocele with or without a ruptured sac and irrespective of the contents of the sac.[10] Theoretical concerns for vaginal delivery—namely, visceral trauma, dystocia, and infection—are unsupported. In one series in which the diagnosis was known in only a minority of cases, cesarean delivery made no difference to neonatal outcome.[11] There are untested scenarios in which cesarean delivery might be considered, such as extracorporeal liver when torsion with obstructed cardiac return is a theoretical concern. Neonatal morbidity in all recent series relates to associated anomalies and prematurity. Isolated cases with late morbidity and death relate mostly to complications

FIGURE 20–4
Omphalocele at delivery. Note that the lesion is epigastric and at the site of the umbilical cord insertion.

of bowel obstruction or short bowel syndrome in association with intestinal atresia.[12]

Postnatal

Prevention of heat and fluid loss and infection are the initial goals after delivery while the neonatal evaluation is completed and the surgery planned. These infants are at increased risk of hypothermia owing to the large surface area of exposed viscera. The neonate is immediately lowered into a sterile bag containing warm electrolyte (no warmer than 37.5°C), plasma solution, and antibiotics (e.g., Vi-Drape isolation bag). In emergencies, any sterile bag with warmed normal saline or lactated Ringer's solution and antibiotics will suffice. A suitable solution consists of 1 L lactated Ringer's solution, 500 mL stable plasma protein or similar solution, and 1 million units of penicillin. The bag is tied at the level of the axillae, and care is taken to avoid torsion of viscera (Fig. 20–5).

FIGURE 20–5
Neonate with an omphalocele showing bowel isolation bag tied above defect.

Alternatively, a sterile plastic bag without the fluid may be used. A nasogastric tube is passed to keep the bowel decompressed, and ventilatory support is provided when necessary.

Neonates with associated lethal structural malformations or trisomy 13 or 18 are typically managed nonsurgically. Untreated neonates generally die of dehydration or sepsis. There are two main options: either keep the neonate comfortable and provide supportive care only, or paint the unruptured omphalocele sac with 1% mercurochrome solution. Note that mercurochrome has been reported to be associated with renal failure.

All other infants are managed surgically with operative repair as soon as the general condition is stable. It is difficult to always predict antenatally whether a primary surgical closure is possible. Small defects less than 4 cm in diameter and without extracorporeal liver are almost always closed primarily. Large defects, or those containing liver, may not be closable during the first operation. When primary closure is not feasible, the defect and contents are covered with a Silastic silo sutured to the edge of the defect. Over the following days, the contents of the silo gradually enter the abdominal cavity under the influence of gravity coupled with the silo being compressed daily. Care must be taken to avoid respiratory or circulatory compromise during these maneuvers. Postoperative problems common to all abdominal wall defect repairs include respiratory embarrassment, pulmonary hypertension, small bowel perforation, bowel obstruction, and malrotation. The average neonatal hospital stay after a silo ranges from 3 to 4 weeks. Parenteral nutrition is often necessary for days or weeks postoperatively. It may be 3 months in some cases before satisfactory bowel function is achieved. Weakness of the anterior abdominal wall or a poor cosmetic result after the initial surgery may be corrected in a subsequent plastic surgical revision.

The long-term prognosis for surviving infants is generally very good, and in the absence of associated structural or chromosomal abnormalities, the risk of recurrence in a subsequent pregnancy is extremely low. The main recurrence risk is that for the associated abnormalities, although case reports of a familial recurrence have been recorded.[13]

GASTROSCHISIS

General

Gastroschisis is a paraumbilical defect, usually on the right side of the anterior abdominal wall lateral to the umbilical vessels. Left-sided defects are rare. The annual prevalence of gastroschisis approximates 1:2500 to 1:3000 live births with an equal sex ratio.[5] It would appear that there is an increasing annual prevalence of gastroschisis not entirely explained by increased recognition of the problem. Population-based studies suggest an association with nonsteroidal anti-inflammatory drug use in the first trimester (see later discussion). Gastroschisis is generally considered a developmental accident whereby abnormal regression of usually the right umbilical vein weakens the abdominal wall, which then bursts. However, the precise etiology remains controversial.

Recent studies suggest an association between the ingestion of aspirin and other vasoactive substances.[14,15] These studies provide support for a vascular etiology. Iatrogenic abdominal wall defects have also resulted from placement of a vesicoamniotic shunt for obstructive uropathy. Perhaps the most important reason to distinguish from omphalocele is to emphasize the different incidence of associated abnormalities—less than 10% with gastroschisis compared to more than 60% with omphalocele.

Diagnosis

Antenatal detection is similar to that of omphalocele, either at "routine" ultrasonographic examination (Figs. 20–6, 20–7, and 20–8), because of a raised maternal serum α-fetoprotein, or during ultrasonographic exami-

FIGURE 20–7

nation for hydramnios when associated with intestinal atresia. The sonographic image is one of free-floating loops of bowel typically appearing like a clump of grapes.

Risks

Maternal risks are similar to those for omphalocele, reflecting complications of the anomaly.

Fetal risks are associated with complications of bowel torsion that compromise the vascular supply or obstruction. It has also been theorized that exposure of the intestines to amniotic fluid may contribute to damage to the bowel serosa, though there are other explanations for the so-called "peel."

FIGURE 20–6
Typical appearance of gastroschisis: loops of bowel floating freely in the amniotic fluid (in this case, unusually, liver was also protruding through the defect).

FIGURE 20–8
Ultrasound of gastroschisis showing the cord insertion adjacent to the abdominal wall defect.

Fetal growth restriction may also complicate gastroschisis but is not necessarily secondary to uteroplacental dysfunction.

Neonatal complications include not only difficulty reducing and closing the gastroschisis, but also complications due to atretic segments causing critical shortening of the bowel.

Management Options

Antenatal

Though the risk of associated structural abnormalities is lower than that for omphalocele, a detailed sonographic search by a skilled sonologist remains important. The risk of an abnormal karyotype is <1% and many physicians do not consider a karyotype necessary. One large review included only one case of trisomy 18.[13] The risk of an abnormal karyotype increases if other abnormalities are detected. Associated abnormalities include bowel stenosis or atresia (which are probably complications of the gastroschisis itself) and, less commonly, cleft palate and diaphragmatic hernia. On rare occasions, other viscera are contained within the gastroschisis: liver, uterus, and undescended testes each have been reported.

Serial ultrasonographic examination is recommended to assess fetal growth, amniotic fluid volume, and bowel appearance. However, any appraisal of fetal nutrition based on the abdominal circumference measurement is at best an approximation as any defect will artifactually reduce the circumference. Oligohydramnios may be associated with fetal growth restriction secondary to uteroplacental dysfunction (see Chapters 12 and 13). Polyhydramnios is the only antenatal sonographic finding correlated with severe neonatal bowel complications.[16] The appearance of the bowel and the diameter of the bowel loops are not of prognostic significance.[17,18] Increased echogenicity and apparent thickening of the bowel wall after 28 weeks may represent a fibrinous coating or "peel" covering and binding together loops of bowel. The etiology of the peel and interventions to prevent are debated. There is conflicting evidence for the hypothesis that amniotic fluid components cause a chemical peritonitis. Although there is evidence of intra-amniotic inflammation in human gastroschisis,[19] prolonged intestinal exposure to amniotic fluid does not invariably lead to peel formation.[20] Amnioinfusion or amnioexchange procedures are reported,[21] but there is little evidence of benefit.

An alternative explanation for peel formation is venous and lymphatic obstruction, a hypothesis supported by the observation that the intra-abdominal peritoneum does not always show a peel, although it too is exposed to amniotic fluid. Although the presence of peel can make the surgical closure more difficult, it has little correlation with outcome and resolves quickly after surgical closure (K. Pringle, personal communication). And though

increasing dilation of bowel loops may appear worrisome, it is not an indication for delivery (Fig. 20–9).[22] Perhaps most important, no evidence suggests that early delivery to decrease exposure to amniotic fluid improves outcome. Term delivery at 37 weeks' gestation allows for an earlier, definitive closure of the defect, and shorter times to full oral feedings.[23]

Parental counseling should emphasize the high chance of a good outcome with over 80% survival (and a primary closure rate in the range of 52% to 80%). Prolonged hospitalization with durations of 47 to 75 days is recorded.[24] In the absence of ultrasonographic abnormalities of growth, amniotic fluid volume, umbilical artery Doppler recordings, or heart rate tracing abnormalities, the pregnancy may continue to term. However, close monitoring in the third trimester and especially after 34 weeks is recommended, as there appears to be a fairly high incidence of unexplained intrauterine death after 37 weeks, which may be due to either fetal growth restriction[25] or umbilical cord compression[26] (Fig. 20–10).

Labor and Delivery

Fetuses with a gastroschisis should be delivered at a referral center equipped with the appropriate facilities and staff. Like omphalocele, there is no evidence that cesarean delivery results in improved outcome. Large case series actually report a higher survival rate in fetuses subject to labor. Thus, vaginal delivery should be anticipated in the absence of other indications.

Postnatal

The immediate postnatal management is similar to that for omphalocele, but the preoperative workup and stabi-

FIGURE 20–9
Gastroschisis: dilated loops of bowel. This fetus was delivered vaginally at term and primary abdominal wall closure was achieved.

FIGURE 20–10
Gastroschisis at delivery, unusually containing the liver. Baby was delivered by cesarean section, the indications being a footling breech presentation.

FIGURE 20–11
Abdominal wall closure in gastroschisis. Similar results are usually obtained with or without previous use of a silo.

Primary surgical closure is achieved in 52% to 85% of cases.[18,24] Postoperative ventilation is generally required for about 72 hours, and total parenteral nutrition is often required until oral feeding can commence. The surgical approach favored by the author's unit is a transverse incision at the level of the defect if required. The bowel is carefully examined for atretic segments. Any bowel incision made is closed transversely to minimize the risk of a subsequent stricture, and the abdominal wall defect is closed vertically with the umbilical cord left in place to produce a "normal" umbilicus (Fig. 20–11). When primary closure is not possible, a Silastic silo is created as with omphalocele (Figs. 20–12 and 20–13). Failure to pass stool by 28 days mandates a new search for atresia that will be found in up to 5%.[30]

lization of the newborn should be expedited, as there is no protecting membrane over the bowel. The neonate is immediately placed into the Lehey bag (or even a sterile plastic oven bag) containing the warmed electrolyte and antibiotic solution as described under omphalocele (see earlier discussion and Fig. 20–5). The bag is carefully tied at the axillae so not to kink or rotate the bowel, and a nasogastric tube is passed to keep the bowel decompressed.

Recently, reduction of the gastroschisis has been reported without general anesthesia or endotracheal ventilation.[27,28] The initial studies have been extended to develop selection criteria for safe application of the technique, and the current results reviewed.[29] Proposed contraindications are poor general condition, obvious gut atresia, significant vital organ anomaly, bowel to abdomen disproportion, and "at-risk" bowel circulation. The developments of distress or progressive metabolic acidosis during the procedure are indications to convert to a standard approach. There were two deaths in the original communication, but recent reports describe increased success. Ward reduction of umbilical hernia is also reported.[28] The role of ward reduction in routine management of abdominal wall defects remains to be determined by well-designed trials.[29]

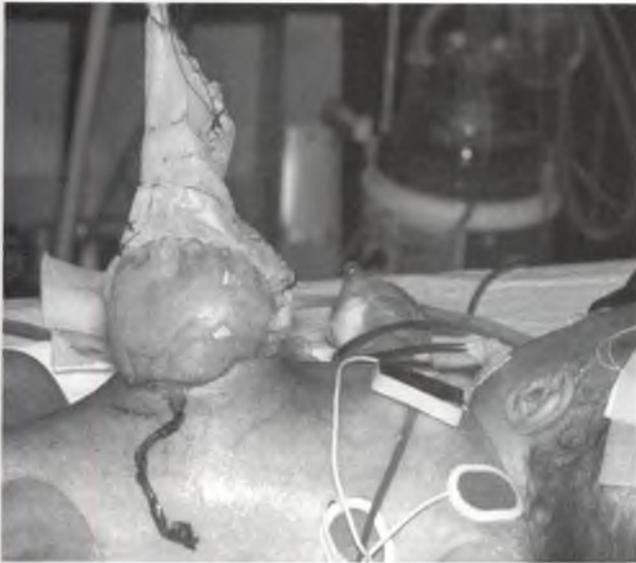
FIGURE 20–12
Silastic silo used to cover bowel.


FIGURE 20–13
The silo is reduced in size over 7 days as its contents are returned to the abdomen.

The mortality rate is between 3% and 10% and reflects prematurity, intestinal ischemia or necrosis, late sepsis, or the effects of other associated abnormalities. Prolonged bowel dysfunction, especially motility disorders or malabsorption, occurs in a small percentage of cases, though short-term complications are very common. Fewer than 25% of neonates have a completely uncomplicated post-surgical course.[31] The few long-term studies of patients with gastroschisis[9,32] suggest that development beyond 5 years of age is normal when the lesion was isolated. Those with bowel atresia or complications requiring bowel resection have a higher frequency of long-term bowel problems or nonspecific abdominal complaints.

The risk of recurrence is very low, although isolated case reports suggest familial recurrence is possible.[33] Fear of recurrence of an abdominal wall defect may dominate the reproductive choices of couples.[34]

Prevent heat and fluid loss and early surgery.	–	GPP	–

CONGENITAL DIAPHRAGMATIC HERNIA

General

Congenital diaphragmatic hernia has several parallels to gastroschisis and omphalocele. Diaphragmatic hernia is a protrusion or herniation of the abdominal contents into the thoracic cavity. Herniation may occur through a posterolateral defect in the pleuroperitoneal canal (the most common is the hernia of the foramen of Bochdalek) (Fig. 20–14), defect in the sternocostal hiatus, a retrosternal or Morgagni hernia, a hiatus hernia, defect in

FIGURE 20–14
Prenatal ultrasound image of a posterior (Bochdalek) diaphragmatic hernia (shown by *arrow*). This was a late diagnosis despite earlier scans, possibly owing to the position of the stomach in the abdomen.

the central tendon of the diaphragm, and through complete eventration of the diaphragm. The reported annual prevalence is 1:3500 live births,[35] but this does not include terminations and stillbirths. Left-sided hernias are more common than right-sided ones. Up to 50% of antenatally diagnosed cases have associated abnormalities,[36] and diaphragmatic hernia is associated with a number of syndromes, including Beckwith-Wiedemann, Pierre Robin, Fryns, and chromosomal defects such as trisomy 13, trisomy 18, and deletion 9p. Lung hypoplasia, central to the poor prognosis of diaphragmatic hernia, may originate during embryogenesis and before the visceral herniation into the thoracic cavity.[37] Postnatally, pulmonary hypoplasia and pulmonary hypertension are often lethal.

Diagnosis

The most common postnatal presentation is cyanosis shortly after clamping the umbilical cord. Other signs include a scaphoid abdomen (Fig. 20–15), a barrel-shaped chest, and dextrocardia. Diaphragmatic hernia is the most common cause of dextrocardia diagnosed in the delivery suite.

The antenatal sonographic diagnosis can be difficult. A multinational study achieved an overall detection rate of 59%. Isolated diaphragmatic hernia was detected in 51% of cases, and in 72% when other malformations were present.[38] Small hernias may be missed by even the most thorough sonologists. A right-sided diaphragmatic hernia is extremely difficult to identify because liver and lung are of similar echogenicity in early pregnancy. As pregnancy advances, the lungs become more echogenic.

FIGURE 20–15
Neonate with congenital diaphragmatic hernia showing scaphoid abdomen.

The hypoechoic line seen on ultrasonography separating the thoracic from the abdominal cavities may appear present but is an unreliable sign for the exclusion of diaphragmatic hernia. The most sensitive sign is an abnormal thoracic location of the heart[39] (Fig. 20–16). Other signs, which are not necessarily prognostic, include hydramnios, visualization of the bowel or stomach at the level of the heart, and absence of the stomach in the abdomen. Hydramnios may result from either impaired swallowing (due to mediastinal compression) or obstruction of the upper gastrointestinal tract.

Several techniques can be used to facilitate the diagnosis of diaphragmatic hernia if there is uncertainty. The instillation of warmed normal saline into the fetal pleural or peritoneal cavities at the time of karyotyping or as a separate procedure is described.[40,41] Color and pulsed Doppler ultrasonography can help delineate the vascular anatomy when there is an echogenic mass in the fetal thorax.[42] Magnetic resonance imaging is especially helpful to confirm the location of the liver.

FIGURE 20–16
Ultrasound image of fetal thorax showing appearances of a diaphragmatic hernia. Note that the heart and stomach are visualized in the same imaging plane.

Management Options

Antenatal

The differential diagnosis of an intrathoracic ultrasonographic abnormality includes several possibilities:

- Diaphragmatic hernia
- Cystic adenomatoid malformation of the lung
- Extralobar sequestration (may be intra-abdominal)
- Bronchial atresia
- Other cystic and solid masses within the mediastinum

It is important to exclude the presence of other structural abnormalities notably in the cardiovascular (e.g., ventricular septal defect, tetralogy of Fallot), gastrointestinal, skeletal, and genitourinary systems because they may profoundly affect the prognosis. A karyotype is indicated. A summary of seven series revealed an overall 18% incidence of aneuploidy, only 2% when the diaphragmatic hernia is isolated, but up to 34% when other abnormalities are present.[43]

The option of pregnancy termination should be discussed with the parents if permissible, especially when other abnormalities are present, as the combination is generally fatal. The prognosis for isolated diaphragmatic hernia has in the past been controversial. Early reports of a less than 20% survival rate reflected a bias of ascertainment. Population-based studies confirm an overall survival rate of approximately 65%.[44] Although some units quote around 80% survival rate should postnatal management take place at a center with extracorporeal membrane oxygenation (ECMO) facilities,[45] others do not.[46] Thus, a definitive statement on the optimal management providing the highest survival rate cannot be made at present.

There is considerable debate on the accuracy of antenatal prediction of postnatal prognosis. The reported association between early diagnosis (<25 weeks) and poor prognosis (mortality rate as high as 58%)[47,48] is supported by recent study.[44] Hydramnios and the location of the fetal stomach do not appear to be prognostic factors,[48] nor do fetal echocardiographic variables in structurally normal hearts.[49] The presence of liver in the chest is a poor prognostic sign[48] and is associated with the triad of hydramnios, mediastinal shift, and intrathoracic stomach. The poor prognosis when liver is present in the chest is consistent with the finding of right-sided diaphragmatic hernia being an independent risk factor for decreased survival.[44] The estimation of lung size or volume has similarly proved difficult to measure reliably and correlate with prognosis. Fetuses with a left-sided hernia uncomplicated by liver herniation have a good prognosis, even in the presence of a low lung-to-heart ratio, which has been reported to be a poor prognostic sign.[50] Magnetic resonance imaging is used to estimate a lung volume.[51] A summary of the factors considered influential on outcome is shown in Table 20–2. None are accepted as completely reliable, as this condition has a spectrum of severity and fatality or morbidity due to varied factors,

including pulmonary hypoplasia, pulmonary hypertension, morphologic and biochemical abnormalities of the lungs, and the longer-term sequelae of treatment.

As diaphragmatic hernia represents a wide spectrum of disease with multifactorial dysfunction as causes of death, some parents may accept this outcome and opt for termination of the pregnancy rather than the uncertainty of continuing with antenatal or postnatal treatments.

Recent experience has clarified the role of fetal surgery. There is no benefit from open fetal surgery for isolated congenital diaphragmatic hernia as the results are worse than conventional management after birth.[47] Investigative fetal treatments under study in some centers include a variety of tracheal occlusive[52] or plugging procedures[47] that prevent the egress of lung fluid with the aim of stimulating lung growth and development. The timing and duration of tracheal occlusion and the use of antenatal corticosteroids in congenital diaphragmatic hernia all require further investigation. Problems include chronic pulmonary dysfunction and direct complications of the procedures. An international trial is currently evaluating the effects of glucocorticoids in antenatally diagnosed congenital diaphragmatic hernia. Until the results of these treatments are fully evaluated, each remains experimental.[53]

Obstetrically, the pregnancy is monitored closely for the development of hydramnios and any of its sequelae. There is limited evidence that the antenatal administration of corticosteroids reduces the severity of lung disease and pulmonary surfactant deficiency.[54,55] Human trials are in progress. It is unknown whether amniotic fluid studies can define groups of fetuses with congenital diaphragmatic hernia most likely to benefit from corticosteroids or indeed postnatal surfactant therapy.

Where the parents elect to continue with the pregnancy, they should meet with a member of the surgical team before delivery who will explain that a period of preoperative stabilization after birth yields better results than immediate surgical repair. Poor ventilatory parameters that fail to improve with preoperative stabilization generally do not improve postoperatively and the prognosis is poor.

Labor and Delivery

There is no a priori indication for cesarean delivery. In the absence of massive hydramnios, labor and delivery

are generally normal. However, these deliveries should be planned and occur at a referral center equipped for all likely complications.

Postnatal

Immediate intubation, ventilation, and paralysis of the newborn facilitate care, as the maintenance of good oxygenation is a good prognostic sign. Typically, the chest radiograph shows a mediastinal shift with abdominal contents in the thorax (Fig. 20–17). Maintenance of the mediastinum in a central position by preventing overdistention of the larger lung is associated with improved postoperative survival.[56] This suggests special care be taken during the resuscitation to avoid causing excessive mediastinal shift or lung overdistention. There is presently insufficient evidence to support either a policy of early (<24 hours) or late (>24 hours) repair after delivery.[57]

Extracorporeal membrane oxygenation (ECMO) is available in some centers for those neonates who cannot be adequately oxygenated using conventional ventilatory techniques. The criteria for ECMO vary among centers, as may the criteria for what constitutes good response. Early reports of ECMO responders (defined as a postductal Po_2 >100 mm Hg) noted a 90% survival rate compared with only 7% in nonresponders. The same series showed a similar high survival rate in those not requiring ECMO.[58] More recent reports support an increased survival rate in ECMO-treated groups, but the magnitude of the improvement is far more modest than first reported,[59] and others suggest similar survival rates are obtainable without ECMO.[46] ECMO complications include intracranial hemorrhage and vascular complications, and the survivors frequently experience long-term problems.[60] The place of

FIGURE 20–18
Diaphragmatic hernia. At surgery, the defect is shown as the contents of the hernia are being removed from the thorax.

ECMO along with other postnatal treatments including surfactant, partial liquid ventilation, pulmonary vasodilators, and lung transplantation remains to be settled.

A diaphragmatic hernia and its repair are illustrated in Figures 20–18 to 20–21.

FIGURE 20–17
Diaphragmatic hernia. Neonatal chest radiograph showing the heart displaced to the right and abdominal contents in the left thorax.

FIGURE 20–19
Diaphragmatic hernia. A large defect after the contents have been removed.

FIGURE 20–20
Diaphragmatic hernia illustrating closure of the defect.

Survivors of postnatal repairs may suffer long-term morbidity secondary to bronchopulmonary dysplasia or other lung degenerative disorders, such as emphysema. However, these problems occur in the minority of affected children. In general, the long-term prognosis is good if the neonate survives beyond surgery.

The recurrence risk is low, except where the defect occurs as part of a genetic syndrome such as Fryns syndrome, which is an autosomal recessive trait including diaphragmatic hernia, dysmorphic facies, and distal digital hypoplasia. A recent case report expanded the phenotype of Fryns syndrome to include microcephaly and midline defects.[61]

BODY STALK ANOMALY/LIMB BODY WALL COMPLEX

General

These rare abdominal wall defects have an annual prevalence of 1:14,000 births. The defect is considered to result from either maldevelopment of the body stalk or a disruption of part of the early amnion rupture sequence,[62] with the characteristic feature of unfused amnion and chorion such that the amnion forms a continuous sheet between the anterior abdominal wall and the placenta.[63]

Diagnosis

It is essential to differentiate a body stalk anomaly from other abdominal wall defects, as the former is incompatible with extrauterine life. Multiple organ system anomalies are present in most cases. Characteristically, there are neural tube and lower limb defects with scoliosis. The viscera of the fetus may appear either attached to the placenta (Fig. 20–22) or entangled with the fetal membranes. The umbilical cord is absent or abnormal.

FIGURE 20–22
Body stalk anomaly showing abnormal fetal spine (*arrow*) and the appearance of the fetus being stuck to the placenta (*double arrows*).

Management Options

Antenatal

The option of pregnancy termination should be offered where legal. Vaginal delivery is the goal.

Postnatal

This defect is lethal. It is thought to be sporadic in occurrence, and thus, the recurrence risk is extremely low.

BLADDER AND CLOACAL EXSTROPHIES

General

Both exstrophies are rare, although bladder exstrophy is more common than cloacal exstrophy. The total annual prevalence approximates 1:200,000 live births, constituting less than 2% of anorectal malformations.[64] The primary defect is believed to be failure of the caudal fold of the anterior abdominal wall to develop. Failure of the urorectal septum to develop leads to a persistent cloaca with failure of the urogenital sinus to separate the bladder from the rectum.

Management Options

Antenatal

The antenatal diagnosis of cloacal exstrophy has been rarely reported. It is typically associated with severe oligohydramnios, probably due to the associated genitourinary abnormalities. The maternal serum α-fetoprotein may be high when associated with either a neural tube defect or an omphalocele. Ultrasound may show a lower than normal abdominal origin of the umbilical cord, with an infraumbilical abdominal wall defect that has a mass herniating through it. The bladder is absent from the normal position, but the pelvis may contain loops of bowel. These anomalies create difficult management issues, including gender assignment in neonates with cloacal exstrophy. The anomalies with these disorders (omphalocele, exstrophy, imperforate anus, and spina bifida) are grouped in the OEIS complex.

Termination of pregnancy is an option where legal in view of the associated genital abnormalities, the difficult surgical repair, and the long-term problems of achieving continence. The clinical management of the pregnancy is otherwise unaltered. The patient should meet with the neonatal surgical team prior to delivery to maximize understanding of the future medical requirements.[65]

Labor and Delivery

There is no a priori reason for cesarean delivery. Standard obstetric management is appropriate with delivery in a unit equipped with neonatal extensive care and surgical facilities.

ESOPHAGEAL ATRESIA WITH OR WITHOUT TRACHEOESOPHAGEAL FISTULA

General

The total annual prevalence of esophageal atresia and tracheoesophageal fistula is about 3:10,000 live births.[66] These abnormalities typically occur together because the esophagus and trachea develop from a common diverticulum of the primitive pharynx. The upper respiratory and gastrointestinal tracts separate between 3 and 5 weeks' gestation. The most common anomaly is esophageal atresia with a distal tracheoesophageal fistula (87% of cases). The variants of tracheoesophageal fistula are illustrated in Figure 20–23. Isolated esophageal atre-sia and isolated tracheoesophageal fistulas account for 8% and 4% of the cases, respectively.

Diagnosis

The most common antenatal presentation is hydramnios associated with preterm labor. Fetal swallowing begins around 16 weeks' gestation, and failure to visualize the stomach after this time is unusual. Failure to visualize the fetal stomach on serial scans from 20 weeks should alert the sonographer to the possibility.[67] The differential diagnosis for the sonographic absence of the stomach includes three possibilities:

- Esophageal atresia
- Congenital diaphragmatic hernia
- Impaired fetal swallowing from "neurologic" causes

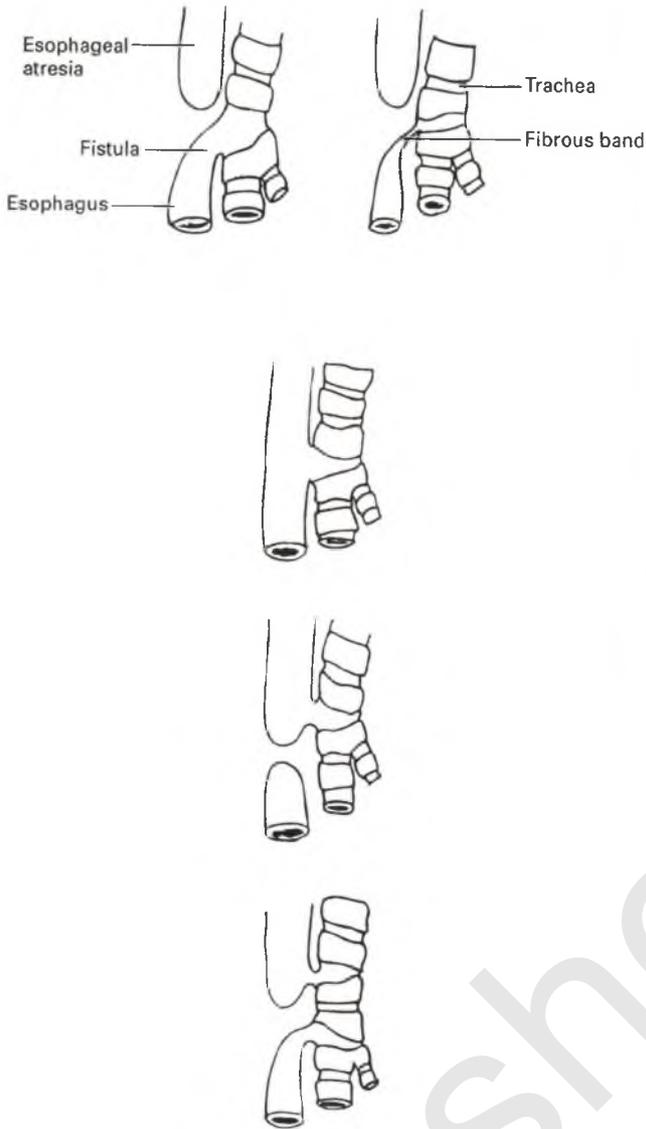
FIGURE 20–24
Esophageal atresia. Scan shows hydramnios and absent stomach in the imaging plane for the abdominal circumference measurement.


FIGURE 20–23
The main types of tracheoesophageal fistula.

The stomach may simply be empty at the time of the scan, but after 20 weeks typically it will fill over the course of the examination. In the absence of other abnormalities, a repeat scan within a few days is warranted. The diagnosis is suspected in all cases of hydramnios (Fig. 20–24), and a targeted ultrasound examination should be part of the management of women with preterm labor (see Chapters 61 and 62). Esophageal atresia with tracheoesophageal fistula allows for the passage of amniotic fluid into the stomach and is not usually associated with either hydramnios or an absent stomach on examination. In point, the diagnosis may not be possible antenatally. A very small stomach in the presence of hydramnios suggests the diagnosis. The positive predictive value of hydramnios and an absent stomach for esophageal atresia approximates 50%.[68] A high number

of fetuses have aneuploidy or other malformations. The prognosis for the fetus with esophageal atresia is markedly worse than for the neonate with esophageal atresia first suspected postnatally.

Occasionally, the proximal esophageal pouch can be imaged in the fetus with esophageal atresia when the stomach is absent. This has been referred to as the pouch sign, and can be seen as early as 23 weeks.[69] A blind pouch in the neck appears to have a worse outcome than a mediastinal pouch.[70] Magnetic resonance imaging has been successfully used when esophageal atresia was suspected but not confirmed on antenatal ultrasound.[71] Failure to demonstrate the stomach necessitates a careful search for other abnormalities including the VATER or VACTERL group of abnormalities. These abnormalities include vertebral, anal, cardiac (especially atrial and ventricular septal defects), renal and limb abnormalities, plus otocephaly, a major malformation of the mandible and temporal bones associated with abnormally placed ears.

Management Options

Antenatal

A karyotype should be obtained to rule out aneuploidy (particularly triploidy or trisomy 18), which is present in over 10% of cases.[72] Esophageal atresia may be part of the DiGeorge sequence identifiable by a characteristic deletion in chromosome 22.[73] More than half of the

fetuses with esophageal atresia in one series had multiple malformations,[72] the VATER syndrome in either its complete or incomplete forms being the most common abnormality in another series.[74] The other cluster of abnormalities sufficiently different from the VATER complex to warrant distinction is the CHARGE association (Table 20–3). These infants usually have some degree of mental retardation. In contrast, the majority of neonates with VATER have normal intelligence (except those associated with either trisomy 18 or 13q deletion syndromes).

When the diagnosis is made before viability, parental counseling should include the influence of any associated abnormalities on neonatal outcome, the possible related problems during the pregnancy (e.g., hydramnios), and the short- and long-term prognosis after surgical repair. The latter has improved dramatically since the first recorded survival in 1939[75] owing to improvements in both surgical technique and neonatal intensive care. The option of pregnancy termination should be offered where legally possible, especially if there are multiple anomalies.

The most common anomaly is esophageal atresia with a distal tracheoesophageal fistula. This is usually managed by thoracotomy with division of the fistula and then end-to-end esophageal anastomosis. In the absence of other abnormalities, survival rates of up to 100% are reported.[75] However, this statistic may not represent the general experience, for a recent review of 176 repairs between 1985 and 1997 noted a perinatal and infant mortality rate of 22%, and a further 21% still had significant morbidity after 2 years of age.[76]

Continuing pregnancies are managed along standard obstetric lines. Hydramnios complicating esophageal atresia may prove to be difficult and is associated with preterm labor. Medical management of hydramnios using indomethacin has appeared to help in certain fetal abnormalities, but the one report with esophageal atresia was unsuccessful.[77] Other adverse fetal effects of indomethacin or cyclooxygenase inhibitors class II generally preclude their use in the third trimester of pregnancy. Therapeutic amniocentesis is an option after antenatal corticosteroids have been given to enhance pulmonary maturity if preterm labor occurs (see Chapters 61 and 62).

Labor and Delivery

Labor and delivery management are not influenced by the malformation.

Postnatal

Awareness of the potential for esophageal atresia in all cases of hydramnios and in any newborn with excessive

oral secretions, particularly if there are breathing difficulties or possibly cyanosis, should lead to the same management as planned for the neonate diagnosed or suspected antenatally. Oral feedings are avoided until the diagnosis is clear to reduce the risk of aspiration pneumonia. Definitive surgery is offered once the infant's condition is stable.

The most important single determinant of outcome is the severity of the associated anomalies followed by ventilator dependence.[76,78–80] Prematurity and low birth weight are generally associated with a good outcome, especially if the birth weight is over 1500 g.[74,81] Immediate surgical complications include anastomotic leaks, tracheal perforation, and chest infection. Late complications are related either to the development of an esophageal stricture with obstruction to solids at the anastomotic site, or respiratory complications including pneumonia, tracheomalacia, and tracheal compression by the upper pouch. Only 10% have respiratory complications beyond the first year and 8% an esophageal stricture. A recent survey of the treatment results for over 370 consecutive neonates over 50 years revealed an 11% mortality rate, and incidences of 13% for tracheomalacia and 33% for gastroesophageal reflux.[82]

The less common types of esophageal atresia with or without fistula (the types producing an airless abdomen either because of blind upper and lower pouches and no fistula, or an atretic fistula) may require more complex surgery, and the prognosis, especially in terms of morbidity, is worse but improving.[76,80] In this group, gastrostomy feeding and delayed anastomotic repair until the child grows are more frequently required.

Although esophageal atresia is said to be a sporadic abnormality, a familial form is described.[83]

ATRESIAS OF THE BOWEL

A wide variety of congenital anomalies can occur in perinates with either gut atresias or stenoses. The specific pattern of anomalies depends on the location of the atresia. For example, cardiac and renal atresias are associated with what may appear to be isolated esophageal atresia or duodenal atresia.[84] Other associations are discussed in the sections on the each abnormality.

DUODENAL ATRESIA

General

Atresia of the duodenum is generally considered to occur around 11 weeks' gestation after an insult to the duodenum, most commonly either just proximal or distal to the ampulla of Vater, causes failure of canalization. Occasionally, vascular accidents or midgut strangulation associated with omphalocele are implicated as causes. The annual prevalence of duodenal atresia approximates 1:6000 live births. Around 30% of cases of isolated duodenal atresia are associated with trisomy 21 or other aneuploidies.

Diagnosis

Hydramnios is common with upper intestinal atresias and implies total obstruction. Half the pregnancies compli-

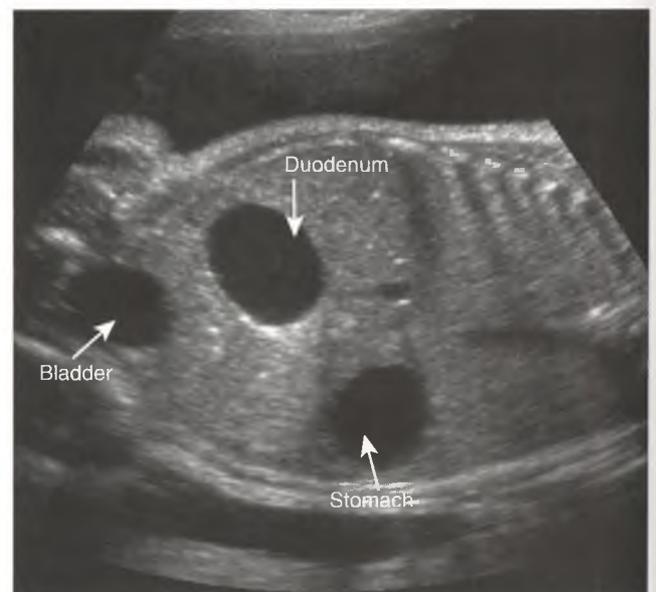
cated by duodenal atresia are associated with hydramnios. The sonographic diagnosis is made by the appearance of a "double bubble" (Fig. 20–25). Generally, this image appears late in the second trimester, but has been suspected as early as 12 weeks[85] and positively detected at 19 weeks.[86] Like all forms of gastrointestinal obstruction,


FIGURE 20–25
Duodenal atresia. Oblique longitudinal ultrasound image of fetal abdomen showing "double bubble" in a fetus with duodenal atresia.

duodenal atresia may not be diagnosable by ultrasonography until the third trimester. This may reflect the production of motilin, the hormone necessary for peristalsis, which begins in the mid to late second trimester. It is important that a true transverse section of the abdomen be obtained and that a connection between the two bubbles is seen (Fig. 20–26). This avoids the potential confusion of an oblique scan of the stomach artificially producing a double bubble, or confusing the stomach and a choledochal cyst with a duodenal atresia. Increased peristaltic waves may be seen during real-time imaging.

Management Options

Antenatal

Associated anomalies are present in over 50%. They include trisomy 21 in 30%, other gastrointestinal malformations in 25%, and cardiac, tracheal and esophageal, renal, hepatobiliary, and pancreatic ductal abnormalities in 48%. Apart from trisomy 21, other chromosomal abnormalities associated with duodenal atresia include abnormalities of chromosome 9. Other gastrointestinal abnormalities include malrotation (28%), annular pancreas (33%), esophageal atresia, imperforate anus, jejunal atresia, duplication of the duodenum, and Meckel's diverticulum.[87] Duodenal atresia may be associated with multiple atresias of the bowel. About half the infants have early onset growth deficiency.

This range of associated anomalies mandates a detailed ultrasonographic examination by experienced personnel for associated structural abnormalities and a karyotype. Fetuses with trisomy 21 have a high risk of cardiac abnormalities. They may also have heart rate abnormali-

ties in labor not necessarily indicative of hypoxia and, in that circumstance, do not require cesarean delivery. Indomethacin (or similar cyclooxygenase inhibitors) has been given in an attempt to treat the hydramnios.[77] Few clinically adverse effects on the fetus are documented when given for a short time before 32 weeks, though a fetal pleural effusion is reported with maternal indomethacin therapy that resolved after stopping of therapy.[88] The main clinical risk is constriction of the ductus arteriosus. Therapeutic amniocentesis after antenatal corticosteroids represents a reasonable therapeutic option (see Chapter 10).

Labor and Delivery

There is no a priori indication for cesarean delivery because of duodenal atresia. As in any situation with gross hydramnios, delivery in a tertiary center is advised, both to manage the potential complications of the hydramnios and for access to neonatal surgical services. Similar to esophageal atresia in which the cause of the hydramnios may be in doubt, passage of a orogastric or nasogastric tube after delivery followed by radiographs of the neonate will help confirm the diagnosis. Because a double bubble is not absolutely diagnostic of duodenal atresia, other possibilities must be excluded after delivery. The differential diagnosis includes annular pancreas, peritoneal bands, and duodenal stenosis.

Postnatal

After delivery, a tube is passed into the stomach and abdominal radiographs taken. The diagnosis can be confirmed at this stage by examination of the gas pattern. The atretic area is excised (Fig. 20–27) when the infant is stable.

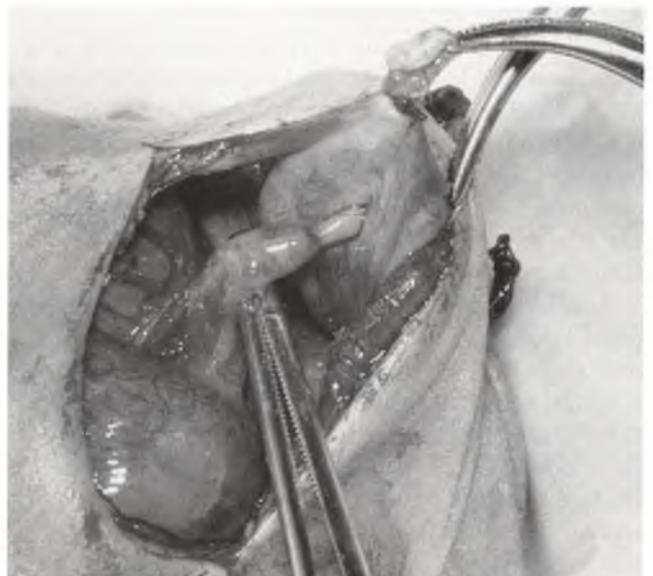
FIGURE 20–26
Duodenal atresia in true transverse section showing communication between stomach and duodenum. Increased amniotic fluid is noted.


FIGURE 20–27
Duodenal atresia. Atretic segment as seen at neonatal surgery (segment above surgical forceps).

The prognosis for this condition, if recognized and isolated, is good, and the recurrence risk is low. Operative mortality rate is up to 4%, with long-term survival rate quoted as 86%. Cardiac lesions are one of the main contributors to long-term morbidity and death.[87]

JEJUNAL AND ILEAL ATRESIA

General

Jejunal and ileal atresia have an annual prevalence approximating 1:5000 live births. They are the second most common forms of neonatal bowel obstruction.[89] These atresias are thought to result from vascular compromise of a bowel segment after organogenesis is complete. Intestinal atresias are categorized according to the degree of occlusion or separation of the bowel on either side of the atretic segment.

Associated anomalies are less common than with duodenal atresia. Five cases of trisomy 21 were reported in one series of 589 perinates with jejunoileal atresia.[90] A special form, the "apple peel" deformity, is an autosomal recessive trait and may have a worse prognosis than the other forms of atresia.[91] Another review noted gastroschisis in 16% of cases, intrauterine volvulus in 27%, and meconium ileus in 11%.[87]

Diagnosis

The sonographic appearance of jejunal atresia is that of multiple distended bowel loops. Hydramnios is more common with upper gastrointestinal obstruction (duodenal and jejunal) than with lower obstructions. The development of ascites or an echogenic mass on scan is a sign of bowel perforation.

Detailed ultrasonographic examination of the wall of cystic or echogenic intra-abdominal structures for peristalsis is important, as it can be associated with bowel perforation and development of a meconium pseudocyst. Other features useful antenatally for diagnosing bowel obstruction are increased peristalsis, failure to detect a normal colon late in gestation, and a disproportionately large abdominal circumference for dates.

Management Options

Antenatal

Jejunal and ileal atresias are usually isolated from other gastrointestinal lesions. It is important to exclude other causes of echolucent structures within the abdomen, such as a urinary tract obstruction. It is suggested that serial measurements of the bowel loop diameter are of value, and tables of bowel diameter are available.[92] However, these measurements correlate with neither the diagnosis of bowel obstruction or prognosis. The appearance of the

bowel is quite variable, particularly in the third trimester, and in our experience, mild bowel dilation is typically associated with a normal outcome (Fig. 20–28). However, a bowel obstruction should be suspected whenever the internal diameter of the small bowel is greater than 7 mm.[93] There is little evidence to support early delivery based on bowel loop diameter.

Labor and Delivery

Fetuses with a presumptive bowel obstruction should be delivered in a center with neonatal surgical facilities. Otherwise, obstetric management is unaltered by the presence of the abnormality. Hydramnios is not an indication for a cesarean delivery.

Postnatal

After delivery, the neonate is evaluated to determine the site of obstruction and the presence of any associated congenital anomalies or meconium peritonitis. The prognosis is very good following repair, with no losses in one series.[89] Even in the group with apple peel deformity, early diagnosis and prolonged parenteral nutrition has resulted in a dramatic improvement in survival.[94]

The risk of recurrence for jejunal and ileal atresia is small except in the group with apple peel syndrome,

FIGURE 20–28

LARGE BOWEL OBSTRUCTION, ANAL ATRESIA, AND IMPERFORATE ANUS

General

Colon atresia is rare and largely confined to the right colon.[89] The annual prevalence of imperforate anus is 1:2500 to 1:5000 live births. In the embryo, the distal colon develops a lumen beginning in the region of the descending colon. Anorectal malformations are complex, and there are several classifications. One is to classify them by the level of the defect and its association with fistula formation.[96] Anal anomalies may be part of multiple malformation syndromes, including the VATER and CHARGE complexes, and cloacal exstrophy and are often associated with spinal and genitourinary defects.[97] At least 25 such syndromes are defined.[98]

Presentation

Large bowel abnormalities are rarely diagnosed antenatally except when part of other multiple malformation syndromes. Apart from mechanical abnormalities such as malrotation or volvulus, other reasons for dilated large bowel or increased echogenicity are meconium ileus, aganglionosis (Hirschsprung's disease), and congenital syphilis. Generally, the ultrasound findings are nonspecific, and the diagnoses of these conditions are made postnatally. The fetal karyotype is generally normal.

MECONIUM ILEUS AND MECONIUM PERITONITIS, HYPERECHOGENIC BOWEL

General

Hyperechogenic bowel, defined sonographically as echogenicity at least equal to the surrounding bone, occurs in 0.1% to 1.8% of pregnancies in the second or third trimesters.[99] It may be transient. Meconium ileus is an obstruction of the lower ileum by thick meconium. Perforation can occur after bowel obstruction secondary to any cause, including meconium ileus producing meconium peritonitis, intestinal atresia, volvulus, and malrotation. These conditions are rare. Meconium ileus is most commonly associated with cystic fibrosis. In contrast, most cases of meconium peritonitis are not (though cystic fibrosis should be considered). Bayesian analysis of risk of prevalence of cystic fibrosis in a fetus with echogenic bowel yields a range of 3.3% to 13% in a mixed North American population.[100] In addition to cystic fibrosis, hyperechogenic bowel is associated with bowel obstruction, viral infection, aneuploidy, and fetal growth restriction. An echogenic mass in the stomach may be swallowed blood, for example, after an abruption or invasive procedure.

Diagnosis

Both meconium ileus and peritonitis have been diagnosed in the second trimester.[101] Meconium ileus presents as either a cluster of bright echoes, or the bowel may appear dilated and echogenic. Hyperechogenic bowel is present when the echogenicity is at least as bright as adjacent bone or liver. This definition overcomes variation in description due to ultrasound machine settings. Distinguishing it from normal, especially late in the third trimester, may be difficult (Fig. 20–29).

FIGURE 20–29
Ultrasound scan showing echogenic bowel (*arrow*) in the third trimester. This fetus had a normal outcome.

Fetal ascites and hydramnios are signs of perforation. A hyperechoic mass or diffuse hyperechoic deposits in the fetal abdomen suggest meconium peritonitis (Fig. 20–30). The thorax may be compressed if there is a volvulus or massive bowel distention.

Management Options

Antenatal

Suspected meconium ileus triggers a search for cystic fibrosis. The parents should be tested and if at least one is a carrier (not all mutations are known), the fetus should be tested either by amniocentesis or cordocentesis. Meconium

FIGURE 20–30
Longitudinal section of fetal abdomen showing massive bowel dilation. The bowel is surrounded by meconium (*arrow*) indicating the development of peritonitis in a fetus with cystic fibrosis. There is gross hydramnios.

ileus affects some 15% of neonates with cystic fibrosis.[102] Meconium peritonitis is a serious condition, and the guidelines for management are dictated by the ultrasonographic appearance. A discrete lesion within the fetal abdomen that appears unchanging and free of ascites or hydramnios does not warrant intervention. However, the presence of ascites, increasing abdominal distention, and hydramnios may warrant preterm delivery if the estimated risks of prematurity do not exceed the potential benefit of early intervention. There are no data to allow clear guidelines to be generated. In this situation, antepartum corticosteroid administration should be considered to hasten pulmonary maturation. Drainage of the ascites, especially if there is lung compression, has been associated with a good outcome, possibly by smoothing the transition to ex utero life. Appropriate study is lacking. Therapeutic amniocentesis is also an option for pronounced hydramnios (see Chapter 13), though indomethacin would be undesirable as a prostacyclin inhibitor. Unexplained death is reported in up to 5% of fetuses with echogenic bowel presenting in the second trimester in the absence of cystic fibrosis, aneuploidy, or infection.[99,103] Death was associated with fetal growth restriction and oligohydramnios.[103]

Labor and Delivery

Expectant management is standard in the absence of perforation, though the neonatal intensive care team should be informed of the possible diagnosis. The management of meconium peritonitis in labor is determined by obstetric factors (e.g., the gestation and the ease of which labor can be induced). There is no information to suggest cesarean delivery a priori benefits the fetus with meconium peritonitis.

Postnatal

Infants with meconium ileus typically become symptomatic within the first 24 to 48 hours of life. Abdominal distention and delayed passage of the meconium plug are characteristic. Vomiting is a relatively late sign. The overall prognosis for the neonate with meconium ileus is determined in part by the success of either the Gastrografin enema or surgery in relieving the obstruction, but mainly by the severity of the cystic fibrosis if present. The prognosis for meconium peritonitis is not good, in part due to prematurity. The recurrence rate is low except when the condition is secondary to cystic fibrosis.

ECHOGENIC ('BRIGHT') LIVER AND HEPATIC CALCIFICATIONS

General

Echogenic ("bright") liver (Fig. 20–31) is an uncommon finding with a number of causes or associations, including liver tumors, congenital viral infection, and vascular congestion.

FIGURE 20–31
Longitudinal scan of fetus showing hyperechoic liver (*crosses*). This fetus had a normal outcome.

FIGURE 20–32
Hepatic calcifications in the fetal liver (*arrows*). Note the shadowing.

Hepatomegaly may occur in hemolytic disease or as part of a visceromegaly syndrome (e.g., Beckwith-Wiedemann syndrome).

Hepatic echogenic areas ("calcifications") may be on the surface or within the parenchyma (Fig. 20–32) or be associated with the vasculature. The cause of this ultrasound finding is not always known, and postnatal scanning does not invariably confirm their presence. Subcapsular calcifications may be seen with meconium peritonitis. Intrahepatic calcification is associated with fetal infection or thromboses.

Management Options

Antenatal

Management is directed toward making a diagnosis. The association of hepatic calcification with congenital viral or toxoplasmosis infection is well documented (see Chapters 27, 30, 31, and 33). Serologic screening is commonly employed to identify women at risk of having an affected child, but assumes one knows which infectious agent to screen for and that a maternal response has occurred. In one review, of 49 at-risk pregnancies for toxoplasmosis, fetal infection was diagnosed in 5. The diagnosis of fetal infection was based on the culture and detection of toxoplasmosis-specific immunoglobulin M (IgM) in blood obtained by cordocentesis. No abnormal fetal liver calcifications were recorded, but both hydrocephalus and intracranial calcifications were seen.[106]

Herpes virus, echovirus, varicella, coxsackie virus, and adenovirus all have similar hepatic manifestations of infection. Hepatitis leading to ascites is not rare. The ultrasonographic appearances are nonspecific, and invasive tests are usually necessary for a definitive diagnosis (see Chapters 27, 30, 31, and 33). In the case of toxoplasmosis, the risk of fetal transmission after proven maternal first-trimester infection is thought to be low (~4%),[107] but a negative result after fetal testing may provide reassurance.

Hepatic tumors including hepatoblastoma and hepatic adenoma[108] have been diagnosed *in utero*. Management involves observation until delivery, though the fetus may develop congestive heart failure as with any large tumor causing arteriovenous shunting.

A detailed search for markers of aneuploidy is indicated because there is an increased risk, but typically aneuploidy is associated with other findings.[109]

Labor and Delivery

Standard obstetric management is generally appropriate.

Postnatal

This care is determined by the likely diagnosis. Delivery in a center with pediatric surgical facilities as well as neonatal intensive care is advisable.

SUMMARY OF MANAGEMENT OPTIONS
Meconium Ileus/Peritonitis/Echogenic Bowel and Liver

Management Options	Quality of Evidence	Strength of Recommendation	References
Antenatal			
Diagnosis is made by ultrasound.	III	B	99,101
Use strict criteria for diagnosis of echogenic bowel/liver ("bone-white").			
For all, consider diagnosis of cystic fibrosis.	III	B	100,102
For echogenic bowel, consider diagnosis of cystic fibrosis, cytomegalovirus or parvovirus, aneuploidy, intestinal obstruction (meconium ileus), intra-amniotic bleeding, and increased risk of placental bleed, intrauterine growth restriction, and fetal death later in pregnancy.	III	B	101,102
Maintain vigilance for hydramnios and/or ascites.	–	GPP	–
No data support drainage or delivery if ascites or hydramnios develops.	–	GPP	–
Provide interdisciplinary counseling.	–	GPP	–
Labor and Delivery			
Timing depends on obstetric factors and/or presence of ascites/hydramnios.	–	GPP	–
Delivery is performed in a tertiary center with full pediatric resources but otherwise normal management.	–	GPP	–
Postnatal			
For meconium ileus and peritonitis, outcome is dependent upon surgical feasibility of repair, associated abnormalities, perforation, and gestation.	III	B	99,103
For echogenic bowel/liver, implement pediatric assessment and management.	–	GPP	–

ECHOLUCENT STRUCTURES WITHIN THE FETAL ABDOMEN

General

Echolucent or "cystic" structures separate from normal bowel or the urinary tract may be identified on ultrasonography. Differential diagnoses include the following possibilities:

- Omental cysts
- Mesenteric cysts
- Cysts of the ovary
- Urachal cysts
- Hepatic cysts
- Choledochal cysts
- Duplication cysts of the bowel
- Retroperitoneal cysts

Management Options

Antenatal

Intra-abdominal cysts are usually a chance finding on ultrasonography. The sonographer should attempt to determine the origin of the structure and exclude other fetal abnormalities. Massive intra-abdominal cysts, especially those detected early in pregnancy, seem to have a poor prognosis, but in many cases they remain unchanged or resolve.[104]

Hepatic cysts may be isolated or associated with adult type polycystic renal disease (see Chapter 19). Choledochal cysts (single or multiple) occur in the right upper quadrant, below the liver, and are intraperitoneal. Similar to most cystic lesions, their significance relates to postnatal management. Untreated, choledochal cysts can lead to biliary cirrhosis and portal hypertension.

The most common hypoechoic intra-abdominal lesion in the female fetus is an ovarian cyst. These cysts are best observed, as most resolve spontaneously over several weeks after delivery.

Labor and Delivery

Obstetric care is unaltered by these abnormalities.

Postnatal

Knowledge of the differential diagnosis is important. The neonate should undergo an ultrasound examination as soon after delivery as feasible. Duplications of the

small and large bowel may rarely communicate with normal bowel lumen. In this instance, the neonate will present with signs of bowel obstruction. Intestinal duplications in association with spinal cord and vertebral body anomalies are reported.[105]

Exclude other fetal abnormalities.	–	GPP	–
Postnatal			
Implement pediatric assessment and management, including early neonatal ultrasonography.	–	GPP	–

CONCLUSIONS

- The fetal gastrointestinal and abdominal wall malformations most commonly identified prenatally are omphalocele, gastroschisis, and diaphragmatic hernia.
- They are detected either after an increased maternal serum α-fetoprotein concentration, at routine second-trimester ultrasound, or by chance in later pregnancy because a problem is detected (especially poor fetal growth or hydramnios).
- Management should involve a multidisciplinary team.
- Exclusion of other abnormalities is a priority for most conditions.
- Delivery should be in a tertiary center with full neonatal medical and surgical facilities.

Fetal Skeletal Abnormalities

David R. Griffin

INTRODUCTION

The sonographic detection of a fetus with a skeletal disorder presents the clinician with challenging diagnostic dilemmas and management options. In some instances, the lethality of the disorder is apparent and a discussion of pregnancy interruption is appropriate. In other instances, the diagnosis, prognosis, and management options are far less evident, and require additional biochemical, genetic, or hematologic investigation. Consultation with a geneticist specializing in dysmorphology may be invaluable.

Women typically present for the prenatal diagnosis of a skeletal abnormality in one of three scenarios:

- A relevant family history
- An abnormality found during routine sonography
- A relevant maternal history—unfavorable intrauterine environment

Heritable Defect in Family

Inheritable skeletal disorders may be autosomal dominant, recessive, or sex-linked. The gene locations for an increasing number of conditions are now known, making antenatal diagnosis possible early in gestation in families at increased risk, often before any skeletal manifestation is evident sonographically. In this chapter, the gene, if known, is placed in parentheses at the heading for the appropriate syndrome. However, disease-related genes are being discovered at an astonishing rate. The reader is advised that the list will inevitably be incomplete by publication. In the remainder of disorders and in new presentations, sonography is the prime method for diagnosis.

Carriers of dominant disorders (Table 21–1) have a 50% offspring risk and are expressed in the heterozygous form. Some show variable expression and may be barely noticeable in a mildly affected individual (e.g., ectrodactyly, Holt-Oram syndrome). Many dominant conditions are new mutations and thus appear sporadically. In these cases, the risk of recurrence is low (about 1%). Recurrence is attributed to gonadal mosaicism in which some of the germ-line cells (but not the somatic cells) of one parent carry the mutation. Recent evidence suggests this may be the mechanism of recurrence in some types of osteogenesis imperfecta.

Recessive disorders (Table 21–2) are manifest in the homozygous form. They occur in the offspring of unaffected heterozygous carriers. The risk of a heterozygous couple having an affected child is 25%; 67% of unaffected children are carriers. Close relatives in the same family are more likely to carry the gene than members of the general population, so consanguineous unions increase the likelihood of two carriers coupling. The risk for a recessive disorder is such (up to 3% for first cousins) that it warrants a detailed ultrasonographic examination of the fetus.

Few X-linked disorders are in this group (X-linked chondrodysplasia punctata).

TABLE 21–1
Dominant Disorders
Achondroplasia
Cleidocranial dysostosis
Holt–Oram syndrome
Isolated polydactyly
Ectrodactyly
Ectrodactyly–ectodermal dysplasia–clefting syndrome
Spondylocostal dysplasia
Hypoglossia–hypodactyly syndrome
Distal dominant arthrogryposis
Dominant hypophosphatasia
Aase syndrome
Blackfan–Diamond syndrome

Roberts syndrome
Jarcho–Levin syndrome
Fanconi pancytopenia syndrome
Thrombocytopenia–absent radius syndrome
Many polysyndactyly syndromes
Many multiple contracture syndromes

Chance Finding During a Routine Ultrasound Examination

The ultrasonographic abnormalities that may lead to the recognition of conditions with limb defects are listed in Table 21–3.

Unfavorable Intrauterine Environment

Factors associated with limb defects include insulin-dependent diabetes mellitus, drugs (e.g., sodium valproate), and oligohydramnios.

TABLE 21-3

Ultrasonographic Abnormalities and Skeletal Defects

	INHERITANCE	INCIDENCE	PROGNOSIS
Short Long Bones: Severe Symmetrical			
Achondrogenesis (types 1 and 2)	AR(1)/S(2)	1:75 000	Lethal
Thanatophoric dysplasia	AD/S	1:30 000	Lethal
Campomelic dysplasia	S	1:150 000	Mainly lethal
Osteogenesis imperfecta type 2	S	1:55 000	A + C: Lethal
			B/3: Often lethal
Hypophosphatasia (AR form)	AR or AD	1:110 000	AR: Lethal
			AD: Mild
Homozygous achondroplasia	AR	Very rare	Lethal
Schneckenbecken dysplasia[1]			
Atelosteogenesis[2]			
Grebe syndrome			
Short Long Bones: Moderate Symmetrical			
Hypochondrogenesis	S	Very rare	Lethal
Jeune thoracic dystrophy	AR	Rare	70% Lethal

ULTRASOUND SCANNING FOR FETAL LIMB ABNORMALITIES

A full examination of a fetus at risk for a skeletal abnormality requires a detailed study of the general fetal anatomy, which can provide important clues to the diagnosis.

Limbs

The long bones are measured in as near to the horizontal scanning plane as possible to avoid shadowing artifact (Fig. 21–1). As a result, the longest measurement of a technically adequate view is the true measurement. It is inappropriate to average limb measurements. The strongest reflections occur from the most proximal bone interface, so that a bone with thickened metaphysis may appear bowed. Hypomineralized long bones reflect less ultrasound at the proximal interface. Thus, they appear less echo-dense across the diaphysis and have reduced acoustic shadow. Minor degrees of hypomineralization are likely to go undetected. Several examples of actual femur length measurements from fetuses with skeletal dysplasia in the author's practice are plotted on the fetal size chart in Figure 21–2.

Head

Hypomineralization

Skull hypomineralization reduces the reflection of ultrasound and increases transmission. The net effect is to reduce both the echogenicity of the skull and the acoustic shadowing of tissues beyond it. The cranial contents are seen more clearly than normal. In severe cases of hypomineralization such as osteogenesis imperfecta types 2a and c, and achondrogenesis type 1, the cerebral hemispheres are almost anechoic, giving the appearance of ventriculomegaly. This is easily excluded by showing the choroid plexus, and the walls of the lateral ventricle antrum are normally situated within the hemisphere (see Fig. 21–6A). The skull bones are soft and can deform when subjected to pressure from the transducer. Hypomineralization may be less obvious in disorders such as hypophosphatasia or osteogenesis imperfecta types 2b and 3.

Skull Shape

The cloverleaf skull is characteristic of some forms of thanatophoric dysplasia. Other unusual skull shapes imply craniosynostosis, which occurs in some short-ribbed polydactyly syndromes.

Face

Cleft lip or palate (see Chapter 18) are features of short-rib polydactyly (SRP) type 2 (Majewski), fibrochondrogenesis, atelosteogenesis, ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome and a number of other dysplasias. Measurement of the intraorbital diameter[6,7] may reveal hypertelorism in some syndromes.

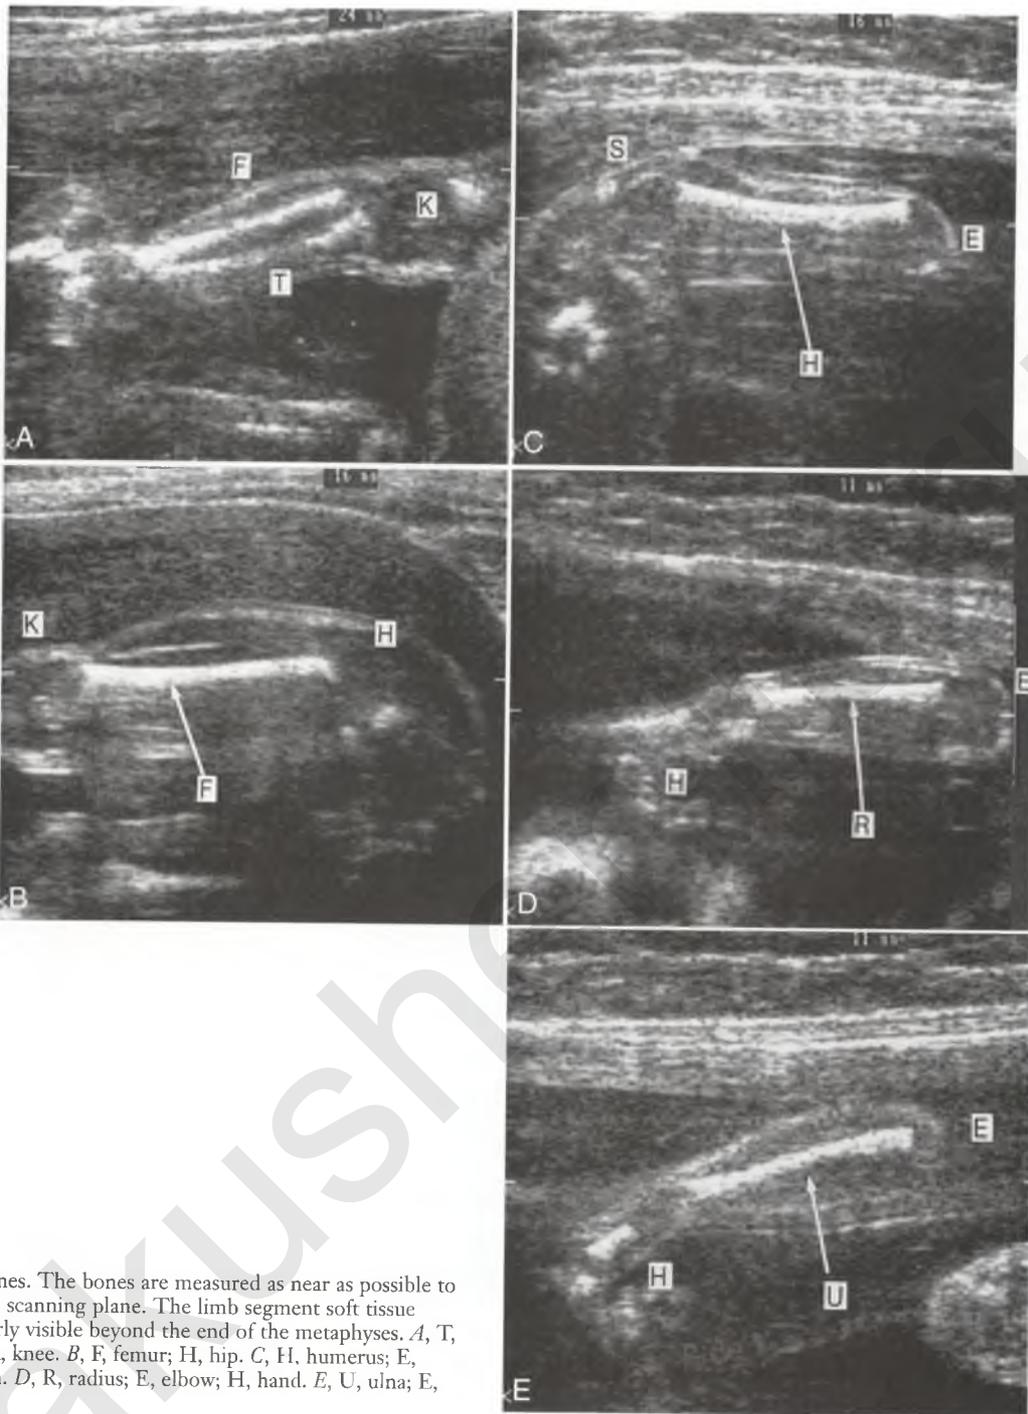
A facial profile in the sagittal plane may show frontal bossing (achondroplasia, thanatophoric dysplasia), a depressed nasal bridge (chondrodysplasia punctata), or micrognathia (campomelic dysplasia). The mandible is measured in the axial plane from the temporomandibular joint to the mental eminence.[8,9]


FIGURE 21–1
Normal long bones. The bones are measured as near as possible to horizontal in the scanning plane. The limb segment soft tissue extremity is clearly visible beyond the end of the metaphyses. *A*, T, tibia; F, fibula; K, knee. *B*, F, femur; H, hip. *C*, H, humerus; E, elbow; S, scapula. *D*, R, radius; E, elbow; H, hand. *E*, U, ulna; E, elbow; H, hand.

Thorax

The ribs may be short, thick, thin, beaded (i.e., fractured), flared, or irregular in shape, arrangement, or number. The thorax may be normal, constricted, short, or long. When constricted, the ratio of heart circumference to thoracic circumference (normally about 1:3)[10] is increased. Normal liver size and abdominal circumference cause the abdominal wall to protrude in the antero-posterior view, giving what is described as a "champagne cork" appearance. Pulmonary hypoplasia secondary to the restricted thorax is the major cause of death in neonates with this feature.

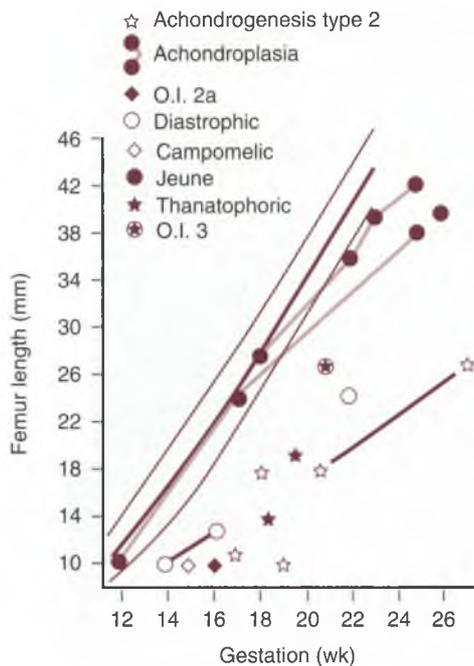
Congenital heart abnormalities can be found in Ellis–van Creveld syndrome (50%), SRP type 2, campomelic dysplasia, Holt-Oram syndrome, thrombocytopenia—absent radius (TAR) syndrome, Noonan's syndrome,


FIGURE 21–2
This diagram shows femur length measurements in many of the skeletal dysplasias described in the text set against a nomogram for femur length against postmenstrual age. (Modified from Griffin DR: Detection of congenital abnormalities of the limbs and face by ultrasound. In Chamberlain G (ed): Modern Antenatal Care of the Fetus. Oxford, Blackwell Scientific Publications, 1990, pp 389–427; Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh, Churchill Livingstone, 1992, pp 257–313.)

Carpenter's syndrome, trisomies, and in fetuses of diabetic women.

Kidneys

Renal abnormalities may be a feature of Jeune thoracic dystrophy, some of the short-ribbed polydactyly syndromes, caudal regression syndrome, and the VACTERL (vertebral, anal, cardiac, tracheoesophageal, renal, and limb abnormalities) association.

TERMINOLOGY

Table 21–4 contains a list of terms employed in the text.

SHORT LONG BONES: SEVERE SYMMETRICAL

The prevalence of skeletal dysplasias is approximately 1:5000 live births and 1:500 stillbirths. The most common (achondroplasia) occurs with a frequency of about 1:20,000.[11]

TABLE 21–4

Terminology of Limb Defects

Acromelia—shortening predominantly of distal segments (hands and feet)
Amelia—absence of a limb
Campomelia—bent limbs
Diaphysis—central part of shaft of long bone
Epiphysis—bone ends with separate centers of ossification; may not be apparent prenatally
Hemimelia—absence or hypoplasia of longitudinal segment (e.g., radius)
Kyphoscoliosis—combination of lateral and convex curvature of the spine
Kyphosis—dorsally convex curvature of spine (as thoracic)
Lordosis—dorsally concave curvature of the spine (as lumbar)
Mesomelia—shortening predominantly in the intermediate long bones (radius/ulna, tibia/fibula)
Metaphysis—more recently developed growing extremities of shaft
Micromelia—severely shortened limb
Phocomelia (seal limb)—absence or hypoplasia of long bones with hands or feet attached to trunk
Platyspondyly—flattening of the vertebral body
Rhizomelia—shortening predominantly in proximal long bones (humerus, femur)
Scoliosis—lateral curvature of the spine

Achondrogenesis

This group of conditions is characterized by severe micromelia and hypomineralization. Fetal hydrops and hydramnios may appear late.

Diagnosis

TYPE 1 (PARENTI-FRACCARO SYNDROME) (5q31-5q34) DTDST

The long bones show extreme micromelia with very poor modeling (e.g., femur length of 10 mm at 19 weeks).[12] The calvarium and vertebral column are severely hypomineralized (Fig. 21–3B).

TYPE 2 (LANGER-SALDINO SYNDROME) (12q13-12q14) COL2AI

The long bones are better modeled than in type 1 but are still extremely short, thick, and straight (Fig. 21–3A). The calvarium is normally ossified, and although hypomineralization of the spine is variable, it can be striking (Fig. 21–3B, C, D).

HYPOCHONDROGENESIS (12q13-12q14) COL2AI

This condition is thought to represent the milder end of the spectrum of the achondrogenesis type 2/spondyloepiphyseal dysplasia group of conditions.[13] Spinal hypomineralization is seen only at the cervical and caudal portions of the spine.

Diagnosis

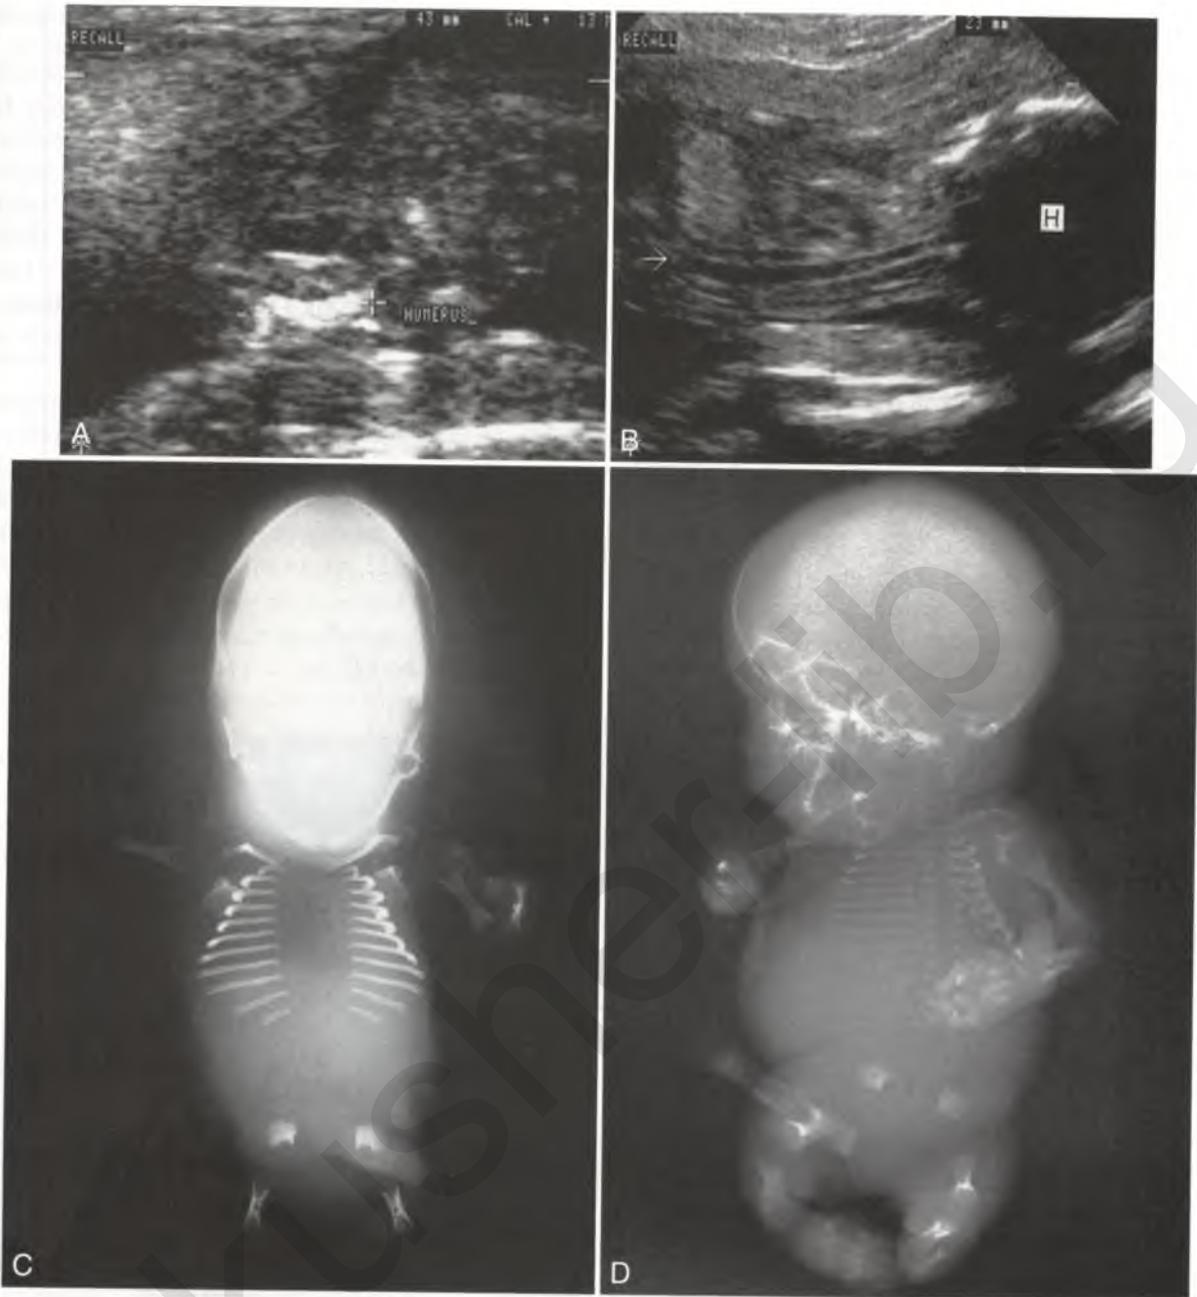
The condition is suspected when moderate long bone shortening (see Fig. 21–3) is associated with a constricted


FIGURE 21–3
Achondrogenesis. *A,* Short (13 mm) humerus of a fetus with achondrogenesis type 2 at 18 weeks. *B,* Sonogram of the trunk and head (H) of the same fetus shown in *A.* The spinal column is shown (*arrow*) as an anechoic cartilaginous column. The skull shows some mineralization. *C,* Radiograph of the fetus in *A* showing total absence of ossification in all elements of the spinal column. The ribs are short and the thorax small. There is little mineralization of the skull. *D,* Postnatal radiograph of a different fetus with achondrogenesis type 2 at a similar gestation to that in *C.* In this case only the vertebral bodies show lack of calcification. Other features are similar to those in *C* with short, straight reasonably modeled long bones showing flared, cupped metaphyses. The ischial bones are unossified and the ilia small and halberd shaped. (*A* and *B* from Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh, Churchill Livingstone, 1992.)

thorax. The bones are straight and show some thickening of the metaphyses.

Risks and Management Options

Achondrogenesis types 1 and 2 and hypochondrogenesis are lethal conditions at or before birth. Termination of pregnancy should be included as an option during counseling. The diagnosis is supported by postnatal radiography and expert pathology. Where possible, it should be confirmed by DNA analysis. The recurrence risk is 1:4 for achondrogenesis type 1. Achondrogenesis and hypochondrogenesis are usually new, dominant mutations.

Thanatophoric Dysplasia (4p16) (*FGFR3*)

Thanatophoric dysplasia is the most common skeletal dysplasia encountered in obstetric practice.

Diagnosis

A definitive diagnosis is possible by 12 to 14 weeks, but is more commonly made at 18 to 20 weeks.[14,15] The femur and other limb-length measurements are well below the third percentile for menstrual age (Fig. 21–2) and display a characteristic thickening of the metaphyses. Measurements from 14 to 21 mm at 18 to 20 weeks to 26 mm at 32 weeks are reported.[16–19] The femurs may appear bowed in some cases and straight in others (Fig. 21–4*B*). The feet and hands are short. The short, splayed fingers are described as a "trident hand." Short stubby ribs produce a markedly small thorax (Fig. 21–4*C*). The cardiothoracic ratio is high (Fig. 21–4*C*), and the characteristic truncal champagne cork appearance is seen in the sagittal plane (Fig. 21–4*D*). Some cases show flattening of the vertebral bodies (platyspondyly) and a short spine. The skull is normally ossified and may be macrocephalic or brachycephalic. Some variants with straight, long bones show the cloverleaf (Fig. 21–4*A*) deformity produced by prominence of the parietal bones. This sign is more evident later in pregnancy. Lateral cerebral ventriculomegaly may occur. The facial profile shows a depressed nasal bridge and frontal bossing. Late in pregnancy, soft tissue folds can often be seen on the arms (the "Michelin man" appearance). Hydramnios is also a later feature.

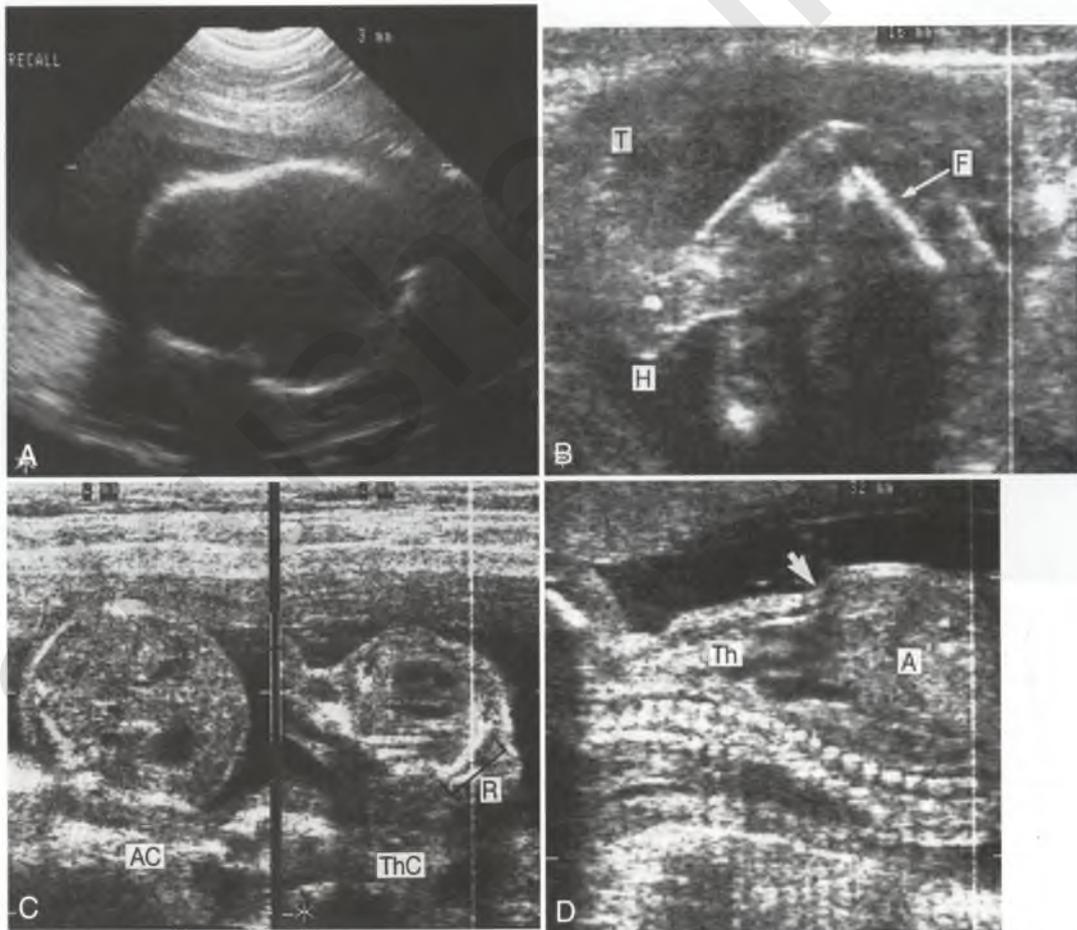
Because the majority of cases result from a mutation at 4p16, it can be useful to test the index case. The recurrence risk is small (<1%), but confirmation by DNA extraction will allow for early prenatal diagnosis and reassurance in subsequent pregnancies, although a careful scan at 12 to 14 weeks could also exclude a recurrence.


FIGURE 21–4

Thanatophoric dysplasia. *A,* Skull of a 20-week fetus showing the clover-leaf deformity. *B,* Lower limb of a fetus of 18 weeks showing short leg and femur (F) of 18 mm. H, heel; T, toes. *C,* Transverse sections of the trunk of the fetus in *B* at the level of the umbilical vein (AC) and the heart (ThC) showing marked reduction of the thoracic circumference and short ribs (R). *D,* Longitudinal anteroposterior sagittal scan of the trunk of the fetus in *B* showing the narrow thorax (Th) and abdomen (A) protruding anteriorly: the "champagne cork" appearance. A normally mineralized spine is posterior.

Risks and Management Options

Thanatophoric dysplasia is lethal and the option of pregnancy termination should be included in the counseling session. Support for the diagnosis by radiography or confirmation by DNA study is essential. Parents should be advised that recurrence risks are low because this is a dominant sporadic condition.

Campomelic Dysplasia (17q24-17q25) (*SOX9*)

Diagnosis

Early diagnosis is possible.[20–25] The characteristic midshaft bowing of the femur should be recognized during a routine ultrasound (Fig. 21–5), although there is considerable variation in presentation.[26] The tibia is short and bowed and the fibula hypoplastic. Marked talipes may cause the whole lower limb to be grossly bowed inward (campomelia). The ribs may be short and the thorax constricted. Brachycephaly, micrognathia, and short clavicles may be detected during a careful skeletal survey. Associated soft tissue anomalies are found in a third of cases and include atrial/ventricular septal defect (ASD/VSD), hydronephrosis, and ventriculomegaly. Hydramnios may occur late in pregnancy. Phenotypic sex reversal in males is common, but is detected only by a karyotype.

FIGURE 21–5
Sonogram of a 15-week fetus with camptomelic dysplasia. Note the short, bent leg (L). Micrognathia is evident in the facial profile. (From Griffin DR: Detection of congenital abnormalities of the limbs and face by ultrasound. In Chamberlain G [ed]: Modern Antenatal Care of the Fetus. Oxford, Blackwell Scientific Publications, 1990, pp 389–427.)

Risks and Management Options

Approximately three-quarters of newborns die during the neonatal period from pulmonary hypoplasia; 90% die by the age of 2 years. The prognosis depends on the severity of associated malformations. Survivors fail to thrive and can show neurologic impairment. The recurrence risk is around 5%; many cases are thought to be the result of a new dominant mutation.[26] The option of pregnancy termination should be offered when the diagnosis is made at a stage in gestation when termination is legal. Support for the diagnosis by pathologic examination and radiography is essential before counseling the parents about the recurrence risk. Antenatal ultrasonographic diagnosis should be offered in subsequent pregnancies.

Osteogenesis Imperfecta

Osteogenesis imperfecta is characterized by poor bone mineralization. Based on the clinical and pathoradiologic findings, it is divided into types 1 through 4; all are due to various mutations in the *COL1A1* gene. The overall incidence approximates to 1:10,000. Types 1 and 4 are probably not amenable to early ultrasound diagnosis, although diagnosis was reported in the second trimester for type 4 and the third trimester for type I. Types 2a, b, c, and type 3 have all been diagnosed before 22 weeks' gestation. Type 2 is usually sporadic, occurring in approximately 1:55,000 live births. Recent evidence suggests that recurrences are due to gonadal mosaicism and the recurrence risks should be quoted as around 5% to 7%. Both types 1 and 4 are autosomal dominant conditions. In type 3, recurrence is reported, and there is the possibility of autosomal recessive inheritance and again, gonadal mosaicism. Recurrence risks after an isolated case are around 7%.

Diagnosis

Osteogenesis imperfecta type 2a is the most common form. It is recognizable early in pregnancy by the characteristic hypomineralization of the skull and long bones with severe micromelia and apparent bowing or crumpling due to multiple fractures.[29-36] The usual bright echo of the skull bones is lost and there is no acoustic shadow (Fig. 21–6A). The orbits may be unusually prominent. The cerebral hemispheres take on a transsonic character. There may appear to be ventriculomegaly, though it can be excluded by identifying the choroid plexus within normal ventricular walls and a normal posterior horn measurement. The head is brachycephalic. It is easily deformed by pressure from the ultrasound transducer even late in pregnancy, yet anatomic details of cerebral structure remain prominent. The long bones are hypoechoic, irregularly bowed, and

crumpled as a result of multiple fractures and callus formation (see Fig. 21–6*B*). The limbs show marked, fixed campomelia and talipes. Other features, such as beading of the ribs and a small thorax, may be recognized. Amniotic fluid abnormalities can occur later in pregnancy. Munoz and associates[36] report the reliable differentiation of osteogenesis imperfecta from other skeletal dysplasias using three criteria: multiple fractures, hypoechoic skull, and femoral length greater than 3 SD below the mean for gestation.

Type 2b shows features intermediate between type 2a and type 3. Type 2c has skeletal features similar to type 2a. Poor cranial ossification has the worst prognosis of this type.

Fetuses with type 2b or 3 rarely have a poorly calcified skull. The femurs may show bowing (Fig. 21–7) or fracture with mild to moderate shortening, but are generally well modeled. Typically, the tibias are bowed but the fibulas are straight.[33,37] Other long bones tend to be around or just less than the fifth percentile.

Type 1 has been diagnosed prenatally[21] but cannot reliably be excluded before viability. The author followed one affected case with normal limb growth and morphology through 24 weeks. However, bowed femurs were apparent at birth and fractures occurred shortly afterward. The clinical presentation and prognosis of types 1 and 4 are quite variable and can show considerable overlap. Expert advice is recommended before counseling. The antenatal diagnosis of type 4 has also

been reported. The features are usually mild, with bowing of the femurs but preservation of limb growth in all other long bones.

Risks and Management Options

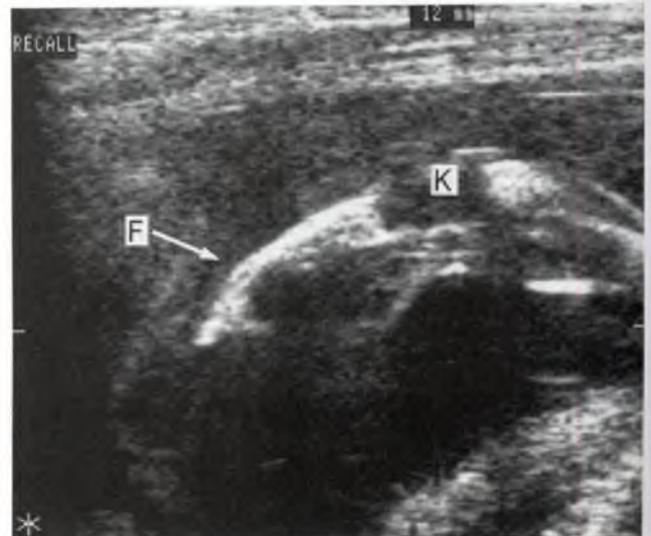
Types 2a and c are lethal. And although type 2b is often lethal, a child may survive to infancy. Children with type


FIGURE 21–7
Osteogenesis imperfecta type 3. Femur (F) with midshaft bowing and poor mineralization. The cartilagenous epiphyses are evident at the knee (K).

3 can survive, but with significant physical handicap due to multiple deforming fractures. Types 1 and 4 overlap and are not often diagnosed during pregnancy.

The option of pregnancy termination should be discussed when the diagnosis of type 2 or 3 osteogenesis imperfecta is made at a time in gestation when it is still legal to act. It has been suggested that abdominal delivery might reduce the risk of either trauma or intracranial hemorrhage. Expert pathologic and radiologic examination is required to distinguish type 3 from 2b, as the genetic implications may be important.

Hypophosphatasia (1p34-1p36)

Bone hypomineralization results from a deficiency of alkaline phosphatase. This heterogeneous group of disorders varies from a lethal condition to milder forms, which become apparent only in childhood. The appearance of the lethal form is similar to that of osteogenesis imperfecta type 2. Although the bones are generally less "crumpled," they may show marked angulation.

Diagnosis

The diagnosis may be based on biochemical, ultrasonographic, or molecular tools, or a combination of the three. There are surprisingly few reports of the antenatal diagnosis of hypophosphatasia.[38,39] If cranial hypomineralization is marked, the skull appears similar to osteogenesis imperfecta type 2 with anechoic calvarium, with prominent intracranial structures and an easily deformed skull. The femurs and humeri are short and may be so bowed at the midshaft that full image and measurement of the shaft are difficult. Dislocations of the knees and elbows can occur.[39] The ribs are thin and may show fractures. The spine may be markedly demineralized, particularly in the area of the neural arch. In a case report of the milder form, the femoral bowing appeared to resolve during pregnancy.[40]

A biochemical diagnosis by measuring alkaline phosphatase (ALP) in amniotic fluid[41] or in cultured amniocytes is unreliable until after 20 weeks. Warren and associates[42] successfully diagnosed the condition in the first trimester of a high risk pregnancy by measuring cellular ALP in a chorion villous sample. Brock and Barron were successful making the diagnosis by measuring liver/bone/kidney (LBK) ALP.[43]

Risks and Management Options

The severe recessive form is lethal, and the option of pregnancy termination should be included in the counseling session. The osseous maldevelopment in the milder, autosomal dominant forms tends to improve with advancing age. The diagnosis must be confirmed by expert radiography and also by biochemical or genetic investigation of the parents. It is unclear whether milder forms should be delivered abdominally to avoid trauma.

Homozygous Achondroplasia

This form occurs only in the offspring of two heterozygous achondroplastic parents. Most fetuses perish in early pregnancy, as the condition is rarely seen among achondroplastic couples.

Diagnosis

The one case report[44] described severe micromelia and a small thorax, similar to thanatophoric dysplasia.

Risks and Management Options

This condition is lethal. The option of pregnancy termination should be included in the counseling session.

SHORT LONG BONES: MODERATE SYMMETRICAL

Jeune Thoracic Dystrophy (Asphyxiating Thoracic Dystrophy)

The severity of this condition and the degree of limb shortening are quite variable. Associated features include renal, hepatic, pancreatic, and pulmonary dysplasia and, occasionally, postaxial polydactyly.

Diagnosis

The reports of prenatal diagnosis of Jeune syndrome are based on the finding of a small thorax in high risk families.[45,46] The chest is reduced in the anteroposterior diameter with consequent protrusion of the anterior abdominal wall. Limb shortening may not be apparent until late in pregnancy (Fig. 21–8). Hydramnios may occur in late pregnancy.

Risks and Management Options

About 70% of live-born children die from respiratory failure during the neonatal period. Survivors are small in stature, and often succumb to respiratory, renal, hepatic, or pancreatic complications in childhood. Intelligence is normal. The option of pregnancy termination should be included in the counseling session if the diagnosis is made in a timely fashion, as the mortality and morbidity rates are high. This autosomal recessive disorder has a 25% recurrence risk.

Short-ribbed Polydactyly Syndromes (SRPS)

The main subdivisions of these conditions are characterized as follows:

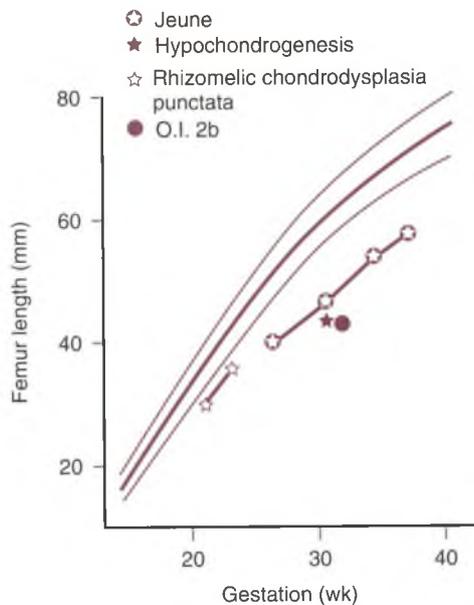
• Type 1 (Saldino-Noonan syndrome) is associated with micromelia characterized by distinct, pointed ends to long bones, and associated urogenital and anorectal anomalies.


FIGURE 21–8
Diagram showing growth of the femur in a fetus with prenatal diagnosis (and postnatal confirmation) of Jeune thoracic dystophy against nomogram of fetal growth against postmenstrual age. Single measurements are also shown for fetuses with hypochondrogenesis and osteogenesis imperfecta type 2b.

- Type 2 (Majewski syndrome) is characterized by median cleft lip/palate and disproportionately short, ovoid tibiae. The differential diagnosis prenatally includes the orofacial digital syndrome (OFD) type 4.

Both syndromes can be associated with abnormalities of other organ systems. Fetal hydrops is common and may be a consequence of a cardiovascular anomaly. Phenotypic sex reversal (to apparent female) is a common finding and requires a karyotype for confirmation.

Diagnosis

Prenatal diagnosis is based on the identification of a small, narrow thorax with short ribs, short limbs, and polydactyly (Fig. 21–9) plus, occasionally, other distinguishing features. A number of other uncommon SRPSs have been described.

Risks and Management Options

SRPSs are lethal secondary to respiratory failure. The option of termination of pregnancy, if legal, should be included in the counseling session. These autosomal recessive disorders have a 25% recurrence risk.

Ellis–van Creveld Syndrome (Chondroectodermal Dysplasia) (4p16)

Diagnosis

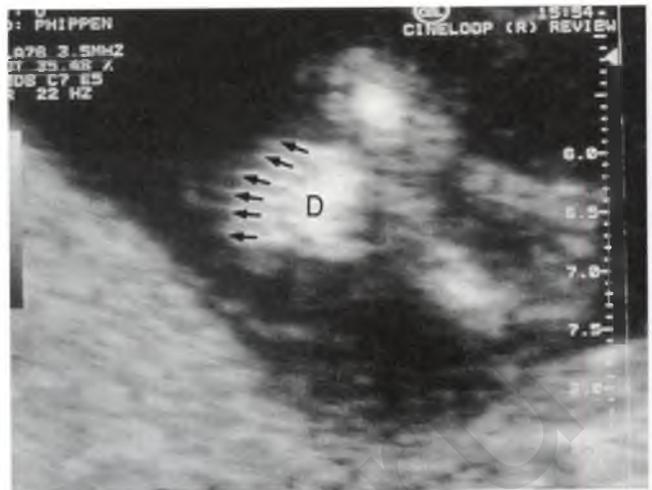
Limb shortening is more pronounced in the forearm and lower leg (mesomelic) than in the remaining long bones. Polydactyly (hands more commonly than feet) is com-


FIGURE 21–9
Scan of the foot of a fetus with short-rib polydactyly syndrome showing six digits (arrowed, D). (With thanks to Mr. P. Smith.)

mon.[47] The diagnosis should be considered when these findings are present in association with a small thorax.[48] A fetal echocardiogram is indicated, as half of these fetuses have congenital heart disease, typically an ASD.

Risks and Management Options

One-third of affected children succumb during infancy. Survivors have normal intelligence, but a final height of 3.5 to 5 ft (105–150 cm). The inheritance is autosomal recessive with a 25% chance of recurrence. DNA should be stored so that early, antenatal diagnosis can be offered in subsequent pregnancies. The option of pregnancy termination should be discussed if abortion is a legal option. Obstetric management of a continuing pregnancy is unaltered. Neonatal echocardiography is advisable.

Diastrophic Dysplasia (5q21-5q34) DTST

This condition has a variable presentation.

Diagnosis

Antenatal diagnosis is possible in severe cases based on the combination of rhizomelic limb shortening and bowing in association with the hitchhiker thumb and talipes (Fig. 21–10).[49–51] Other features may include micrognathia and cleft palate. It may be difficult to exclude the diagnosis before viability in milder cases of high risk families, as the degree of limb shortening can be minimal. Identification of normal thumbs is helpful in excluding the diagnosis.

Risks and Management Options

Diastrophic dysplasia is an autosomal recessive disorder with a 25% risk of recurrence. DNA should be stored so that early antenatal diagnosis can be offered in subsequent pregnancies. A significant number of newborns die

FIGURE 21–10
Scan of the hand (H) of a fetus with diastrophic dysplasia showing proximal displacement and abduction of the thumb (T) (the "hitchhiker" thumb). Femur length measurement from this fetus at 22 weeks is shown in Figure 21–2. F, forearm.

from respiratory failure and pneumonia. No specific measures are needed before birth in continuing pregnancies. Survivors have normal intellect, but suffer significant and progressive physical handicap coupled with limited mobility secondary to the kyphoscoliosis and arthropathy. They require considerable mobility and physiotherapy support. Surgical release of contractures is possible, but of limited value. In light of the disease severity, the option of pregnancy termination should be discussed when the diagnosis is made.

Chondrodysplasia Punctata

For this heterogeneous group of conditions definitive diagnosis can be impossible before birth, and indeed frequently after birth as well. Among the many forms the three most common are X-linked dominant (Conradi-Hunermann disease), X-linked recessive, and rhizomelic.

Diagnosis

X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA (Xp11) (EBP)

This mildest form is seen only in females, as the heterozygous male form is lethal. Antenatal diagnosis is reported in high risk cases[52-54] when epiphyseal stippling and mild limb shortening was detected.

X-LINKED RECESSIVE FORM (Xp22) (ARSE)

The author has seen two cases diagnosed during the second trimester of high risk pregnancies. Affected males have generalized but moderate shortening of the long bones with epiphyseal echogenicities, particularly in the femurs. In each case, there was extensive, paravertebral epiphyseal stippling and a flat face with nasal depression. In one instance, echogenicities were seen in the larynx. This disorder also may be seen in association

with cytogenetic deletions of the X chromosome, in which case it may also be associated with intellectual impairment.[55] Heterozygous female carriers are clinically normal, but tend to be slightly shorter than noncarrier relatives.

RHIZOMELIC FORM (6q22-6q24) (DHAPAT)

Individuals with rhizomelic chondrodysplasia punctata have rhizomelic shortening that is more pronounced in the humerus compared to other long bones. They may show sigmoid bowing. The characteristic feature on an ultrasound examination is stippled epiphyses.[52] There may also be stippling around the pelvic bones, the trachea, and larynx. Fixed flexion deformities of the limbs can be seen, more pronounced in the arm than the leg (Fig. 21–11). Cultured amniocytes and fibroblasts have low dihydroxyacetone phosphate transferase activity (DHAPT).[53]

Risks and Management Options

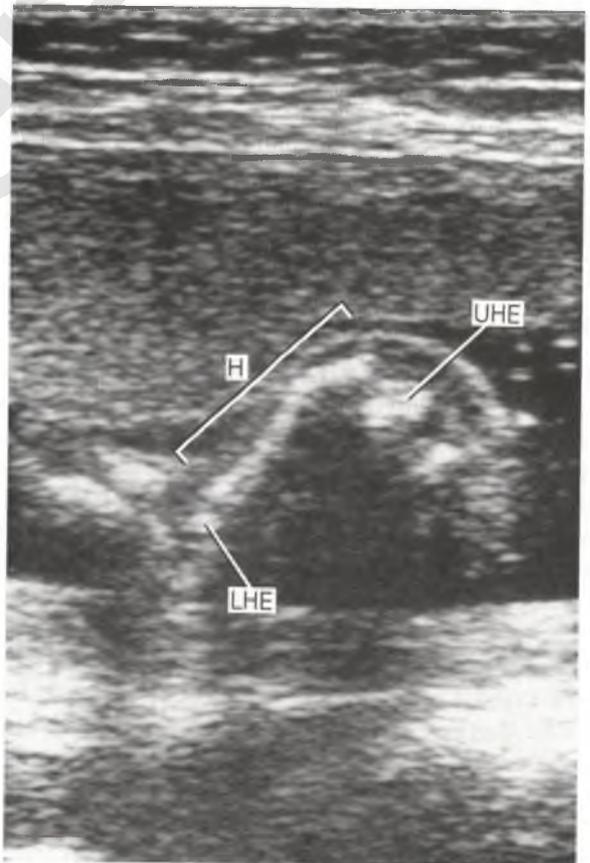
Many newborns with the rhizomelic chondrodysplasia punctata die from respiratory failure. Survivors fail to thrive and develop microcephaly associated with severely


FIGURE 21–11
Scan of the arm and shoulder of a 21-week fetus with rhizomelic chondrodysplasia punctata. The humerus (H) is short (25 mm) and bowed. At both the upper (UHE) and lower (LHE) humeral epiphyses there are echogenic accumulations representing disorganized calcification. Movement of the upper limb was limited during examination.

retarded neurologic development. Survival beyond the first year is unusual; the longest reported survival is 5 years. Measurements of DHAPT activity in amniocytes or chromosome/molecular analysis are helpful adjuncts to the ultrasonographic diagnosis. The option of pregnancy interruption should be discussed.

Kniest Dysplasia (12q13-12q14) (COL2AI)

Diagnosis

Kniest dysplasia is characterized by moderately short, dumbbell-shaped long bones with metaphyseal flaring, restricted joint mobility, platyspondyly with vertebral clefts, and a flat face with depressed nasal bridge. Although the limbs are noticeably short at birth, antenatal diagnosis has been reported only once.[56] In this instance, the features were not evident at 16 weeks but were apparent at 31 weeks. In an unpublished case, the author noted features of metaphyseal flaring, micrognathia, mild frontal bossing, small chest, and talipes in a low risk pregnancy at 22 weeks. The diagnosis of Kniest dysplasia was made after interruption of the pregnancy.

Risks and Management Options

Affected children may survive with normal intelligence but are short (106–145 cm) and have limited mobility and severe orthopedic disabilities. Ophthalmic complications and deafness may occur in childhood.

Spondyloepiphyseal Dysplasia Congenita (12q13-12q14) (COL2AI)

Diagnosis

At the mild end of the hypochondrogenesis spectrum, the antenatal sonographic findings of spondyloepiphyseal dysplasia congenital was reported only once. There was moderate shortening of the femur at 16+ weeks followed by more marked rhizomelic shortening at 27 weeks.[57] No other distinguishing features were evident, and a definitive diagnosis was not made. The disorder is characterized by deficient ossification of the spine, pubis, talus, and calcaneum, and delayed appearance of the lower femoral and upper tibial epiphyses. Vertebrae show marked platyspondyly with ovoid vertebral bodies, the thorax is narrow and bell-shaped, and the long bones are moderately short. Cleft palate may also occur.

Risks and Management Options

This disorder is compatible with prolonged survival. Myopia and retinal detachment occur in about half the survivors. Hypotonic muscle weakness and restricted joint mobility reduce overall mobility, and the spinal deformities cause progressive kyphoscoliosis.

Heterozygous Achondroplasia (4p16) FGFR3

Achondroplasia is well recognized by the general population. Affected individuals have markedly short stature but normal intelligence and are generally well integrated members of society.

Diagnosis

The characteristic features are not usually evident until after 24 weeks' gestation, when the long bone shortening manifests[38,58] (see Fig. 21–2). Achondroplasia is characterized by predominantly acromesomelic limb shortening with stubby abducted fingers (trident hand). Typical facial features include a wide, prominent forehead (frontal bossing), depressed nasal bridge, hypertelorism, and a wide mandible. Thoracic dimensions may be reduced, but usually not enough to cause respiratory embarrassment. The spine is short and shows marked lumbar lordosis. Macrocrania and hydrocephalus can occur. The diagnosis can be confirmed by DNA analyses because the majority result from a single base substitution in the FGFR3 gene.[59]

Risks and Management Options

Life expectancy and intellectual performance are good. Hydrocephaly secondary to partial obstruction of the restricted foramen magnum is usually mild and nonprogressive; surgical treatment is usually not needed. Progressive neurologic problems can result from spinal cord compression secondary to progressive narrowing of the interpedicular distance, particularly in the lumbar spine as the degree of lordosis increases. Corrective orthopedic surgery may be required to correct the spinal deformities and bowed legs.

Affected women usually require cesarean section because of a contracted pelvis. Cephalopelvic disproportion may also occur during the delivery of an affected fetus to a normal woman if the macrocephaly is marked. The recurrence risk for two unaffected parents is low, as achondroplasia usually results from a new mutation.

SHORT LONG BONES: ASYMMETRICAL

Isolated Limb Reductions

This heterogeneous group comprises disorders with asymmetrical reduction in limbs or portions of limbs.

Risks and Management Options

The majority of isolated limb reductions are nongenetic, but some may occur as part of a genetic syndrome or chromosomal abnormality.[60] Because of these associations, a detailed ultrasonographic examination is essential to exclude other markers. Karyotyping is recommended. The prognosis is generally good in the absence of associated physical or chromosomal abnormalities. Advances in

prosthetics and orthopedics are such that much can be done to restore function and appearance of the reduced limbs. Parents should be encouraged to discuss these possibilities with appropriate professionals. There are, however, some specific syndromes associated with isolated or asymmetrical limb reductions.

Roberts' Syndrome (Pseudothalidomide Syndrome)

Diagnosis

Typically, all four limbs (tetraphocomelia) are affected, similar to the teratogenic effects of thalidomide. Median facial clefting, microcephaly, joint flexion deformities, talipes, syndactyly, and extremely short or missing fingers and toes are accompanying features. Other associated anomalies include hydrocephaly, encephalocele, and renal abnormalities such as polycystic or horseshoe kidneys. A similar condition of hypoglossia-hypodactyly syndrome involves asymmetrical limb reductions associated with micrognathia and microglossia. Facial clefting is uncommon in the latter. The two syndromes can be distinguished in utero by cytogenetic studies. In many cases of Roberts syndrome, premature separation of the centromeres produces a characteristic phenomenon of chromosome "puffing."

Risks and Management Options

Affected individuals have a high perinatal mortality rate (70%–80%) and severe growth restriction. Survivors are often profoundly mentally retarded. The option of pregnancy termination should be discussed. Survivors with hypoglossia-hypodactyly syndrome generally have satisfactory intellectual development, and the level of handicap depends on the severity of limb anomalies.

Femoral Hypoplasia: Unusual Faces Syndrome

This condition appears more common in the progeny of diabetic women. Cleft palate and micrognathia are associated with varying degrees of hypoplasia/aplasia of the femur. The tibia and fibula may be hypoplastic. Humeral reduction with a flexion deformity at the elbow can also be seen. Other associated abnormalities include vertebral anomalies of the lower spine, pelvic anomalies, and urogenital anomalies. The main differential diagnosis is caudal regression syndrome, but this syndrome is not associated with the facial dysmorphisms or humeral reduction. Most individuals have normal intelligence and are ambulatory.[5]

Femur-Fibula-Ulna Syndrome

This syndrome is characterized by femoral and fibula hypoplasia/aplasia and varying degrees of paraxial ulna hemimelia. It has been diagnosed antenatally.[61]

Holt-Oram Syndrome (12q21)–(TXB5)

Diagnosis

The cardinal features of Holt-Oram syndrome are congenital heart disease (usually ASD or VSD) associated with various upper limb and limb girdle reductions. The limb reductions are typically more severe in females and twice as common on the left than the right.[5,62,63] Abnormalities in the hand and forearm include aplastic, hypoplastic or triphalangeal (finger-like) thumb, syndactyly, and hypoplasia of the radius, ulna, humerus, clavicles, scapula, or sternum. This is a dominant condition and affected individuals have a 50% offspring risk. There is no consistent pattern, and expression is variable.

Risks and Management Options

Management options depend on the severity of the cardiac malformation and the skeletal deformities.

Thrombocytopenia–Absent Radius Syndrome

The skeletal manifestations of TAR syndrome are variable bilateral radial aplasia/hypoplasia sometimes associated with humeral or ulna reduction or bowing. The femurs can be affected, and cardiac anomalies are relatively common. Thrombocytopenia is a marker of an underlying hematopoietic abnormality. Antenatal diagnosis is based on both the sonographic findings and documentation of fetal thrombocytopenia in a blood sample obtained by cordocentesis. This is an autosomal recessive disorder with a 25% recurrence rate.

Cleidocranial Dysostosis (6p21)

Diagnosis

The characteristic findings of cleidocranial dysostosis are hypoplastic clavicles (Fig. 21–12A,B).[64] However, the clavicle is not generally included in routine prenatal surveys of the fetus. Further, they may be shadowed by the chin, arms, or scapulas. De novo presentations are frequently missed. Mild femoral shortening and a hypomineralized cranium with wide fontanelles may also be evident.

Risks and Management Options

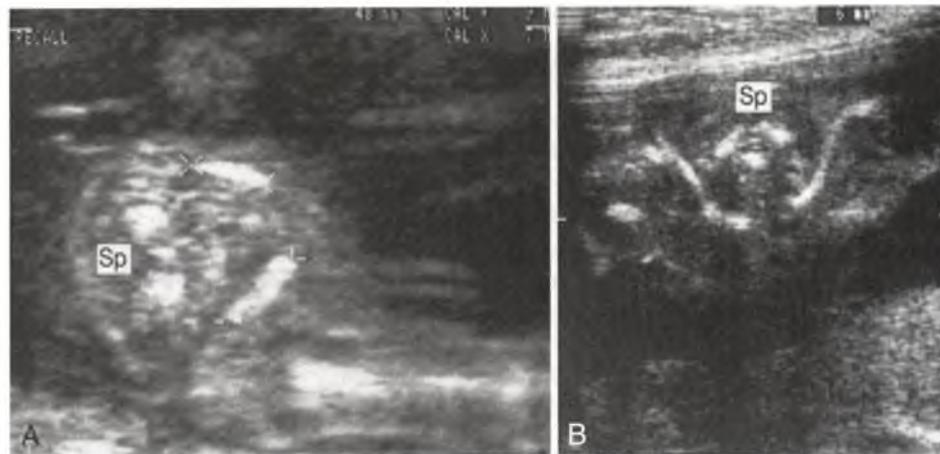
Individuals with cleidocranial dysostosis are generally short. They may have respiratory difficulties in infancy if the thorax is restricted. Dental and hearing problems can present in later childhood. However, the absent or hypoplastic clavicles do not cause significant handicap, and intelligence is unimpaired. Poor skull ossification tends to improve with age. Affected mothers may require cesarean section because of a small pelvis.


FIGURE 21–12
Cleidocranial dysostosis. *A*, Transverse scan of the clavicles of the fetus of a mother with cleidocranial dysostosis. The clavicles are short, thick, and straight. *B*, Similar posteroanterior scan of the clavicles of a normal 22-week fetus. Note the sigmoid form of the clavicle. Sp, spine.

CHROMOSOMAL ABNORMALITIES

Forearm reduction deformities can occur in fetuses with chromosomal abnormalities including 13q, trisomies 8, 13, and 18, triploidy and others.[60]

Polydactyly/Syndactyly

These conditions frequently coexist. The polydactyly can be either preaxial (on the radial side of the hand or medial side of the foot, including bifid thumb or great toe) or postaxial (on the ulnar side of the hand or lateral side of the foot). Polydactyly is associated with numerous genetic and chromosomal syndromes (Table 21–5). Isolated polydactyly can be inherited as an autosomal dominant trait with variable penetrance. The incidence of polydactyly is higher among some ethnic groups (e.g., Afro-Caribbean).

The syndactyly may be either osseous (fusion of the bones) or cutaneous (fusion of the digits by soft tissue). Some syndromes featuring syndactyly are listed in Table 21–6. Many are common to those with polydactyly.

Ectrodactyly

Ectrodactyly (split hand) is a variant of syndactyly in which the hands resemble a "lobster claw" (Fig. 21–13). It may occur either as an isolated phenomenon, or as part of several syndromes,[60] the most common of which is the ectrodactyly ectodermal dysplasia clefting (EEC) syndrome. Isolated ectrodactyly and EEC syndrome are both inherited as autosomal dominant traits with a 50% risk of recurrence.

Diagnosis

Isolated ectrodactyly may affect one or more limbs and has extremely variable penetrance. Parents of an affected child may show only minimal changes in the skin

TABLE 21–5

Syndromes Associated with Polydactyly

SYNDROME	ASSOCIATED FEATURES
Anocerebrodigital	CHD, renal agenesis, growth deficiency, anal atresia
Bloom	Growth deficiency, syndactyly
Carpenter	Craniosynostosis (acrocephaly)
C-trigonocephaly	Synostosis metopic suture, palate
Egger	Cerebellar anomalies (see Joubert)
Ellis–van Creveld	Mesomelic dysplasia (see above)
Fanconi pancytopenia	Forearm reductions (see above)
Fitch (Oto-palato-digital type 2)	Cleft palate, micrognathia, joint contractures, camptodactyly
Fuhrman	Polysyndactyly, fibula aplasia/hypoplasia, bowed femora
Golabi–Rosen	Prenatal macrosomia, extra ribs
Goltz	Syndactyly
Grebe	Short limbs (see above)
Greig cephalopolysyndactyly	Macrocephaly
Hydrolethalus	Hydrocephaly, micrognathia, CHD CL/CP (similar to Meckel's)
Jeune thoracic dystrophy	Short limbs, small thorax (see above)
Kaufman–McKusick	CHD, anal/vaginal atresia, urethral stenosis, intestinal malrotation
Klippel–Trenaunay–Weber	Asymmetrical limb hypertrophy, syndactyly, oligodactyly
Meckel–Grüber	Encephalocoele, polycystic kidney or liver, microcephaly, CP
Mohr (Orofacial-digital type 2)	Median CL/CP
(Orofacial-digital type 1)	Median CL/CP, porencephalic cysts
Robinow-Sorauf ACPS	Acrocephaly, bifid great toe
Sakati-Nyhan ACPS	Acrocephaly, CHD, short limbs, dysplastic ears
Trisomy 13, 3p-, dup(17q)	

Only those associated features which might be amenable to prenatal diagnosis have been included. For further details refer to Winter et al.[60] CHD, Congenital heart disease; CL, cleft lip; CP, cleft palate.

TABLE 21–6

Syndromes Associated with Syndactyly

SYNDROME	ASSOCIATED FEATURES
Ablepharon-macrostomia (McCarthy)	Camptodactyly, cutaneous webs
Acrofacial dysostosis (Miller)	As Treacher Collins syndrome, postaxial defects
Acrocephalosyndactyly (Apert)	Coronal synostosis with brachycephaly, severe osseous syndactyly, CL/CP
(Pfeiffer)	2–3 Syndactyly, acrocephaly
Amniotic reduction	Oligohydramnios, CL/CP, limb reductions, abdominal wall defects (see text)
C-Trigonocephaly	As polydactyly
Carpenter	As polydactyly
Cenani-Lenz	Severe mesomelic limb hypoplasia. Complete syndactyly, radioulnar synostosis and severe hypoplasia
Cryptophthalmos	Renal agenesis, hypospadias
Ectrodactyly-ectodermal dysplasia-clefting	CL/CP, "split" hands and feet (see below)
Fitch	As polydactyly
Fuhrmann	As polydactyly
Greig	As polydactyly
Goltz	As polydactyly
Golabi–Rosen	As polydactyly
Hypoglossia–hypodactyly	Limb reductions, micrognathia (see Roberts syndrome)
Klippel–Trenauny–Weber	As polydactyly
Lenz–Majewski	Growth retardation
Moebius	Micrognathia, CL/CP, radial defects
Nager	
Neu–Laxova	Microcephaly, flexion deformities, agenesis corpus callosum
Oculodental-digital	4–5 syndactyly
Orofaciodigital (type I)	Median CL, CP, polydactyly, asymmetrical syndactyly, porencephalic cysts
Otopalatodigital	CP, "tree frog" hands and feet (clinodactyly of peripheral digits)
Popliteal pterygium (severe, lethal AR form)	Popliteal webs, CL/CP, microcephaly
Poland sequence	Hypoplasia of fingers or hand
Roberts	As polydactyly
Robinow–Sorauf	As polydactyly
TAR	Radial aplasia (see above)
Triploidy	Growth retardation, large placenta, umbilical hernia, talipes, micrognathia, CHD, hydrocephaly, holoprosencephaly, renal dysplasia, hydronephrosis
Yunis–Varon	Cleidocranial dysostosis + micrognathia, absent thumbs distal aphalangia

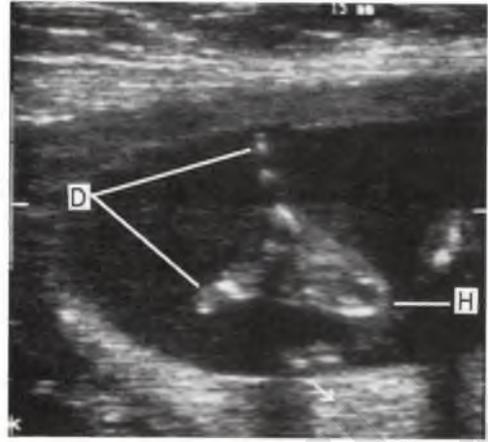
creases.[65] Although an antenatal diagnosis is possible in most severe cases, it may not be possible with mildly affected cases. In the EEC syndrome, ectrodactyly is associated with cleft lip or palate and skin, hair, and teeth dysplasia. Renal defects may also be present.


FIGURE 21–13
Scan of a fetal foot showing ectrodactyly. H, heel; D, digits. Reproduced with permission from Griffin (2). Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA (eds): Prenatal Diagnosis and Screening. Edinburgh, Churchill Livingstone, 1992, pp 257–313.

Risks and Management Options

Individuals with EEC syndrome have normal intelligence and can generally adapt to their deformities to lead productive lives. The facial clefting can be surgically corrected, as can some of the orthopedic deformities. Dentures and wigs may be of value, and it is important to assure lacrimal duct drainage from an early stage to prevent corneal scarring.

POSITIONAL DEFORMITIES

Positional deformities are found in several settings:

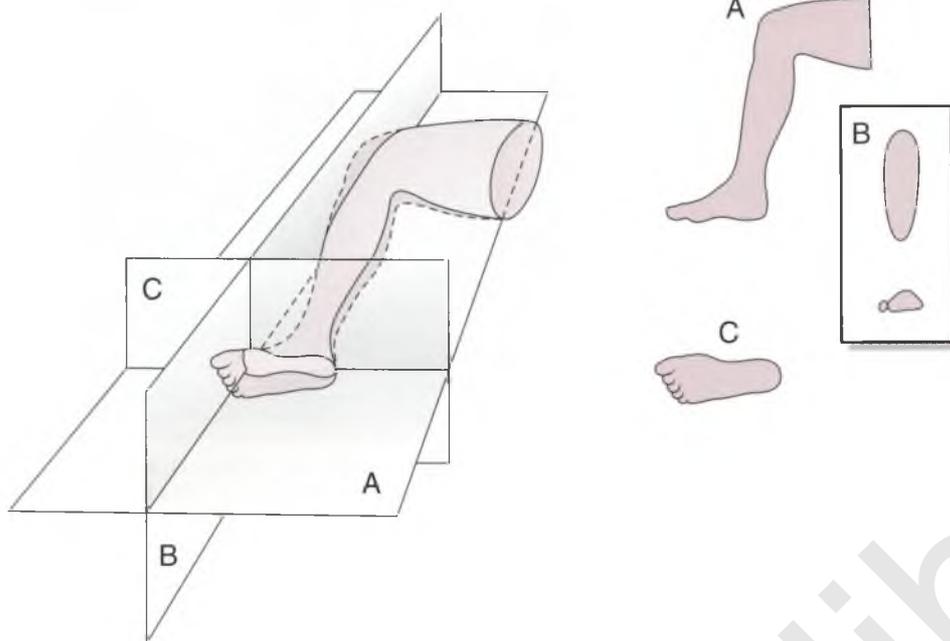
- In response to adverse intrauterine pressures (oligohydramnios, amniotic bands, or tumors)
- Diastrophic dysplasia
- Rhizomelic chondrodysplasia punctata
- Chromosomal disorders
- Generalized neuromuscular deficiencies
- As specific isolated phenomena

The deformities are generally ones of flexion, but extension and bizarre combinations can be seen in the legs.

Talipes

The most common positional deformity is talipes equinovarus, in which the foot is adducted and plantar inverted so that the sole points medially. In the equinovalgus (calcaneovalgus) deformity, the heel is elevated and the foot is plantar everted. Talipes occurs as an isolated phenomenon in about 1:1200 births with varying degrees of severity, or as a marker for chromosomal abnormalities or a number of genetic syndromes.

Diagnosis

Positional deformities of the feet are best sought in the sagittal and coronal scanning planes (Fig. 21–14). When


severe talipes equinovarus is present, the plantar view of the foot is seen in continuity with the leg in sagittal section (Fig. 21–15). Because of the many associated syndromes, a careful search for other abnormalities is mandatory before counseling. The combination of talipes with polyhydramnios raises the suspicion of congenital myotonic dystrophy. The mother should be examined for evidence of mild disease.

Risks and Management Options

Isolated talipes is usually amenable to orthopedic correction. Karyotyping is recommended if other markers of aneuploidy or risk factors are present, as talipes is a marker of chromosomal anomalies. Management depends on the severity of any associated structural defects and the karyotype.

Rocker-bottom Feet

The typical appearance of rocker-bottom feet, usually caused by a vertical talus, is a posteriorly prominent heel and convexity of the normally concave contour of the plantar arch (Fig. 21–16). Rocker-bottom feet are associated with trisomy 18, 18q syndrome, trisomy 13, and Pena-Shokeir type 2 syndrome. Its finding requires a diligent search for other abnormalities. Karyotyping is indicated if other abnormalities are present.

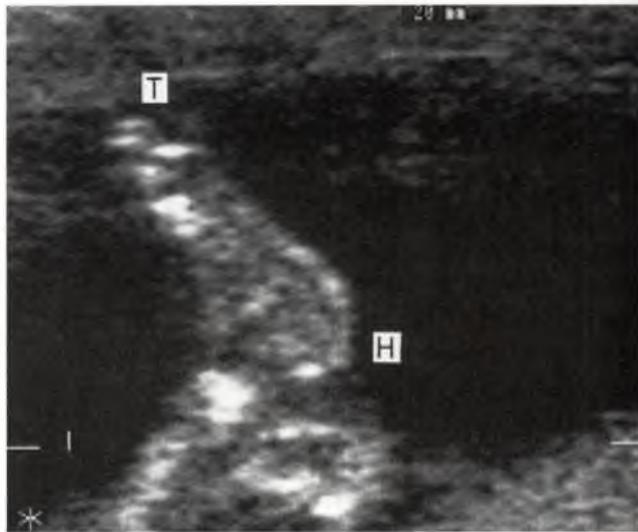
FIGURE 21–15
Positional deformities. Longitudinal sonogram of the leg showing the lower end of the femur, knee (K), tibia/fibula and foot with talipes. The plantar view of the foot would not normally be seen in this plane.


FIGURE 21–16
Rocker-bottom foot. Sagittal scan of the foot of a fetus with confirmed trisomy 18 showing prominent heel (H) and loss of the plantar arch. T, toe.

MULTIPLE JOINT CONTRACTURES

This heterogeneous group of disorders is characterized by multiple flexion deformities of the limbs, hands, and feet, resulting in fixed immobile limbs, sometimes with cutaneous webbing (pterygia) at joint flexures. The causes include the following:

- Central nervous system disease (55%)
- Peripheral neuromuscular disorder (8%)
- Connective tissue disease (11%)
- Miscellaneous skeletal or other abnormality (19%)[66]

Oligohydramnios is present in 7%.[66] Increased nuchal translucency in the first trimester and fetal hydrops in the second trimester are reported.[67,68] Deficient swallowing and fetal breathing may result in hydramnios and pulmonary hypoplasia. Within the spectrum of disease, the more severe forms, commonly designated arthrogryposis multiplex congenita, include congenital muscular dystrophy, lethal multiple pterygium syndrome, and Pena-Shokeir type 1 syndrome. Table 21–7 lists these and other syndromes with varying degrees of contractures that are potentially amenable to antenatal diagnosis.

Risks and Management Options

The more severe forms are associated with thoracic constriction, hydrops, and multiple deformities. Congenital muscular dystrophy, lethal multiple pterygium syndrome, and Pena-Shokeir type 1 syndrome are lethal or seriously handicapping. The choice of abortion should be discussed if it is a legal option. A definitive antenatal diagnosis of other syndromes may not be possible except in high risk families where detection or exclusion of relevant features is possible. Discussion with a geneticist prior to counseling is useful when there is uncertainty. The deformities can be severe enough to produce dystocia or trauma in continuing pregnancies with a vaginal delivery.

SPINAL DEFORMITIES

These deformities can occur as a consequence of neural tube defects, hemivertebrae, dysplasia or agenesis of the vertebrae, or asymmetrical muscle action (severe abdominal wall defects). Neural tube defects and abdominal wall defects are reviewed in Chapters 18 and 20.

Hemivertebrae

Hemivertebrae occur when one of the pair of chondrification centers that normally combine to form the vertebral body fails to appear. Only half of the vertebral body devel-

TABLE 21-7

Syndromes Featuring Positional Deformities

SYNDROME	FEATURES
Aase-Smith-hydrocephalus-CP-joint contractures	CP, Dandy-Walker malformation (very variable presentation)
Amyoplasia	Multiple contractures with medial arm rotation (waiter's tip)
Bowed-Conradi	Like trisomy 18, rocker-bottom feet, micrognathia, camptodactyly
C-trigonocephaly	(see Polydactyly)
Cerebroarthrodigital	Digital hypoplasia, hydrocephalus microcephaly
Christian adducted thumbs	Craniosynostosis, micrognathia, CP adducted thumbs
Congenital myotonic dystrophy	More common with affected mother
Distal arthrogryposis	Camptodactyly of hands, talipes
Freeman–Sheldon	Ulnar deviation of hands, talipes
Marden–Walker	Camptodactyly, CHD, occ. CP
Multiple pterygium (Lethal type)	Severe webbing, cystic hygroma, hydrops, pulmonary and cardiac hypoplasia, CP
Neu–Laxova	(see Syndactyly)
Pena–Shokeir type I	Growth deficiency, pulmonary hypoplasia, camptodactyly, talipes
Syndesmoplastic dwarfism	No details
X-linked arthrogryposis	

Adapted from Winter RM, Knowles SAS, Bieber FR, Baraitser Mm: The malformed Fetus and Stillborth: A Diagnostic Approach. Chichester, John Wiley, 1988, pp 166–182.

ops, and the result is lateral angulation of the spine (scoliosis). Hemivertebrae may be isolated or associated with cardiac, renal, radial, or digital anomalies, tracheoesophageal fistula, and anal atresia in the VACTERL association, or as a part of numerous other genetic syndromes.

Diagnosis

Hemivertebrae are recognized sonographically by spinal scoliosis and asymmetry in the vertebral echoes (Fig. 21–17). A careful search for associated abnormalities is essential. Hydramnios may be the only clue to tracheoesophageal atresia. A karyotype is indicated if other anomalies are seen, as a similar spectrum of deformities may be found in trisomy 18 and 13q syndromes.

Risks and Management Options

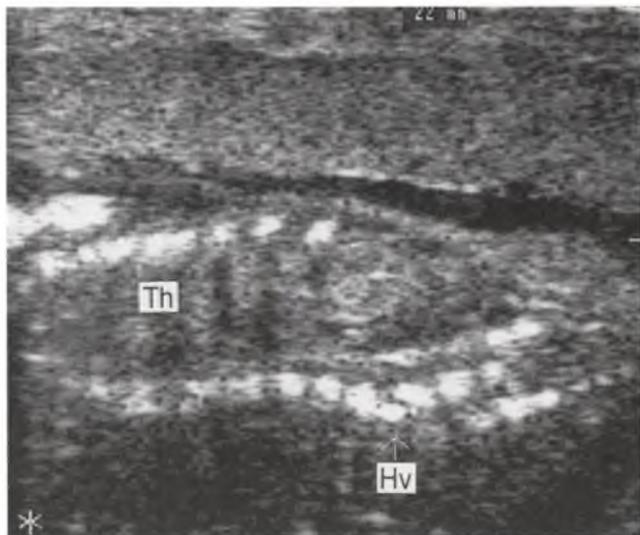
These options depend on the presence and severity of associated anomalies. The parents should meet with an orthopedic specialist to discuss the postnatal management including surgical correction of the spinal defor-


FIGURE 21–17
Longitudinal scan of the vertebral bodies of one of twin fetuses showing a midlumbar hemivertebra (HV). The spinal canal showed no evidence of narrowing on scan. Spinal deformity was minimal at birth. Th, thorax.

mity. Individuals with VACTERL association generally have normal intellectual potential.

Jarcho-Levin Syndrome

This autosomal recessive disorder is most common in the Puerto Rican population.

Diagnosis

The Jarcho-Levin syndrome is characterized by a grossly disorganized axial skeleton and thorax (Fig. 21–18). The spine may be missing or fused, and the hemivertebrae and ribs are frequently reduced in number with posterior fusion and anterior flaring (the "crab chest" deformity). Visceral and urogenital anomalies along with diaphragmatic hernia are also reported.[69,70]

Risks and Management Options

The majority of individuals with this condition die in the neonatal period or during early infancy as a result of respiratory insufficiency. The option of pregnancy termination should be discussed.

HYDROPS (See also Chapter 25)

Fetal hydrops may be a feature of the most severe forms of the following:

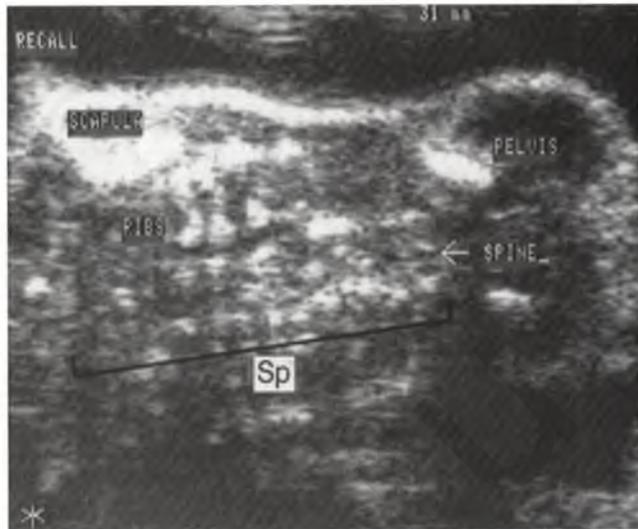
- Achondrogenesis types 1
- Short-rib polydactyly syndromes
- Multiple contracture syndromes (including Pena-Shokeir syndrome type 1)
- Noonan's syndrome


FIGURE 21–18
Longitudinal coronal scan of the trunk of a fetus with Jarcho-Levin syndrome. The ribs are thick and irregular and the spinal components (Sp) grossly disorganized. (From Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh, Churchill Livingstone, 1992, pp 257–313.)

- Chromosomal abnormalities (Down syndrome, Turner's syndrome)

A karyotype is indicated.

HYDRAMNIOS (See also Chapter 13)

Many limb reduction deformities are associated with hydramnios and include the following:

- Achondrogenesis
- Asphyxiating thoracic dystrophy
- Chondrodysplasia punctata
- Dyssegmental dysplasia
- Roberts' syndrome
- VACTERL association
- Congenital myotonic dystrophy

Hydramnios generally presents late in pregnancy and may not be apparent at the time of a routine second trimester scan. As pregnancies complicated by diabetes mellitus may also develop hydramnios, spinal and lower limb deformities should also be sought.

UNFAVORABLE INTRAUTERINE ENVIRONMENT

Diabetes Mellitus

Patients with diabetes mellitus predating pregnancy have an 8% to 12% risk of fetal malformation (see Chapter 45). Skeletal malformations associated with diabetes mellitus

include the caudal regression syndrome and femoral hypoplasia-unusual faces syndrome (discussed earlier).

Caudal Regression Syndrome

This syndrome is highly variable in severity and location of the malformation.

Diagnosis

The typical lesion is agenesis of the lower spine (Fig. 21–19) and may be associated with lower limb reductions or deformities including fusion of the legs (sirenomelia) (Fig. 21–20). Urogenital and anorectal organs of similar caudal origin are frequently malformed or atretic. Radial reduction and esophageal atresia may also occur similar to VACTERL. A single umbilical artery is usual.

Risks and Management Options

Survival and prognosis depend on the severity of the lesions. Minor degrees of sacral agenesis are compatible with normal life, whereas severe defects may cause considerable handicap or may be incompatible with life (e.g., renal agenesis). Karyotyping is recommended, as similar deformities may be associated with chromosomal abnormalities. The option of pregnancy termination, where it is legal, should be discussed in severe cases.

Early Amnion Rupture Sequence

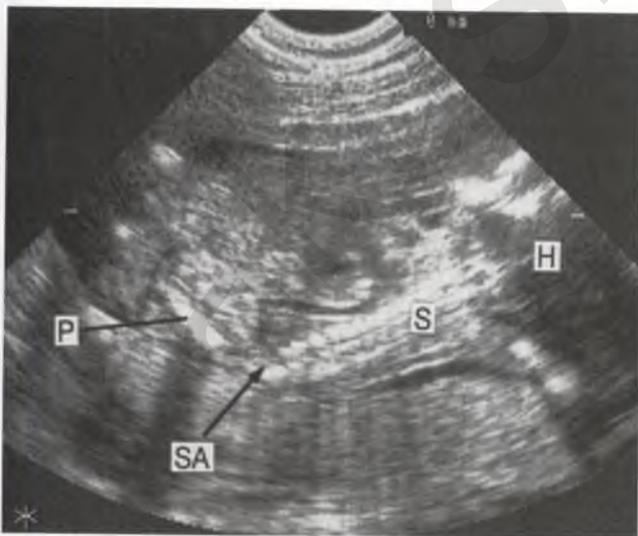
This bizarre and sporadic group of disorders (1:2000 births) consists of asymmetrical anatomic disruptions associated in many cases with adherent bands or sheets of amnion. The current consensus view is that the defor-


FIGURE 21–20
Sonogram of the lower "limb" of an 18-week fetus diagnosed as sirenomelia. The single femur arose from the midpelvis and the broadened lower metaphysis articulated with two bones, presumed to be the tibias.

mities are secondary to early amnion rupture, the severity and site of the lesion being related to the stage of organogenesis at which rupture occurs. Vascular occlusion during organogenesis may be responsible for some of these anomalies. The abnormalities may not necessarily be associated with continued oligohydramnios.

Diagnosis

The diagnosis of early amnion rupture sequence is considered when transverse reduction defects or multiple asymmetrical disruptions are discovered. Manifestations include anencephaly, asymmetrical encephalocele, facial clefts and disruptions, abdominal wall defects (usually gastroschisis), and limb deformities, constrictions, or transverse reductions. Such malformations are reported after amniocentesis and chorionic villous sampling (CVS) before the 10th postmenstrual week.[71,72] Amniotic bands may be attached to deformed structures. In known cases of early amnion rupture or continued bleeding during the first trimester, such deformities should be excluded by a detailed second trimester ultrasonographic examination. Visualization may be difficult, if not impossible, when there is oligohydramnios. Amnioinfusion can be used to improve visualization.[73] The physician must bear in mind that amniotic band-like structures (synechiae) are commonly observed during routine sonographic examination. There is no evidence they cause deformities unless they are attached to the fetus, occasionally in a tourniquet fashion, or restrict mobility.

Risks and Management Options

These options depend on the severity of lesions. In instances of continuing severe oligohydramnios, preterm delivery and pulmonary hypoplasia threaten survival. The

FIGURE 21–19
Caudal regression sequence. Longitudinal sagittal scan of the trunk and spine of a fetus with agenesis of the lumbosacral spine (S). The spine terminates at the lower thoracic region (SA). The pelvis (P) is present. H, head. (From Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh, Churchill Livingstone, 1992, pp 257–313.)

option of pregnancy termination should be discussed in nonviable or severely disrupted cases if abortion is legal. Karyotyping is indicated when deformities are seen.

Drugs in Early Pregnancy

Most drugs undergo extensive animal testing for evidence of teratogenicity before their release for human consumption. A detailed fetal scan is recommended for any pregnant individual who has ingested a significant medication during the first trimester. Some drugs specifically implicated in limb teratogenesis are thalidomide (whose distribution is now tightly controlled), coumadin, phenytoin, sodium valproate, alcohol, cytotoxic drugs, and lithium. The interested reader should consult a more extensive source.[74,75]

CONCLUSIONS

- Skeletal defects can be extremely difficult malformations to diagnose sonographically with accuracy.
- A multidisciplinary approach is essential.
- During the initial stages of diagnosis, the complex fetal deformities should be discussed with a geneticist who has a specific interest in dysmorphology.
- Thereafter, the diagnosis may be refined by further sonographic examination, karyotyping (if not already performed), biochemical, molecular biologic, or other ancillary test.
- Parents often find it useful to speak with relevant specialists who have experience with the disorder before deciding on further management.
- All relevant professionals who may encounter the mother during her pregnancy and labor should be informed of the diagnostic findings and their significance (if known).
- If the condition is lethal, the fetus or newborn should be photographed and xeroradiographed (mammography radiographs give excellent definition). Skin, blood, or placental samples should be obtained for karyotype/DNA analysis. When possible, the fetus should be examined by a perinatal pathologist. A pediatric radiologist should examine radiographs.
- It is only when all information has been gathered that the final consultation with the parents is arranged with the obstetrician, geneticist, or both. The parents are then informed of the recurrence risks in future pregnancies, and the offspring risks for their existing children or other family members. Management plans for antenatal diagnosis in a future pregnancy can then be discussed.

SUMMARY OF MANAGEMENT OPTIONS
Skeletal Abnormalities

Management Options	Quality of Evidence	Grade of Recommendation	References
Prepregnancy			
Ensure accuracy of diagnosis before counselling	–	GPP	–
Counseling (possibly interdisciplinary) about recurrence risks and prenatal diagnostic options	–	GPP	–
Prenatal			
Careful ultrasonography by experienced sonographer, including general examination of fetus for other anomalies	–	GPP	–
Consider a karyotype or other additional tests if other anomalies or suspicion of genetic condition with DNA probe	–	GPP	–
Interdisciplinary discussion before counselling parents (differential diagnosis rather than definitive diagnosis may be all that is possible)	–	GPP	–
Ongoing review of sonographic findings if pregnancy continues (further features may develop allowing definitive diagnosis)	–	GPP	–
Psychological support of parents	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS
Skeletal Abnormalities *(Continued)*

Management Options	Quality of Evidence	Grade of Recommendation	References
Labor and Delivery			
Consider pregnancy termination with severe and/or lethal anomalies	–	GPP	–
Psychological support of parents	–	GPP	–
Caesarean section for normal obstetric indications though severe forms of arthrogryposis may only deliver safely with caesarean section	–	GPP	–
Postnatal			
If lethal, encourage postmortem by experienced perinatal pathologist	–	GPP	–
Detailed postnatal examination including radiography	–	GPP	–
Tissue for karyotyping and other tests if not performed prenatally	–	GPP	–
Ensure accuracy of diagnosis before counseling	–	GPP	–
Counselling (possibly interdisciplinary) about recurrence risks and future prenatal diagnostic options	–	GPP	–

Fetal Thyroid and Adrenal Disease

Stephen Robson

FETAL THYROID DISEASE

Fetal Thyroid Function

The embryonic thyroid is derived from the endoderm of the buccal cavity. The gland enlarges and migrates to the lower neck by the seventh week of embryonic development. Thyroid hormone synthesis begins at 10 to 12 weeks, but appreciable amounts are only released from 14 to 16 weeks onward.[1,2] Prior to that time, all thyroid hormone comes from the mother. Thyroxine (T_4) concentrations increase thereafter, reaching adult values by term (total T_4 100–150 nmol/L, free T_4 15-25 pmol/L).[3] Thyroxine is converted locally to the active metabolite, triiodothyronine (T_3), by deiodinase enzymes. Free T_3 levels increase gradually, particularly after 28 weeks, but remain below adult values. Thyroid-stimulating hormone (TSH) is low until 15 to 18 weeks' gestation, and then increases to around 8 mU/L by term.[3] The fetal pituitary is capable of responding to thyrotropin-releasing hormone (TRH) after 20 weeks, but is relatively insensitive to negative feedback from T_3 and T_4 until late in the second trimester.

The placenta is freely permeable to iodide substrates, TRH, thionanides, and TSH receptor immunoglobulins, but is impermeable to TSH. Significant transfer of T_3 and T_4 occurs and is controlled by the action of placental deiodinase enzymes. Differential expression of deiodinases maintains a suitable maternal-fetal gradient.[2] The placenta also produces several peptides (including hCG) capable of stimulating the maternal thyroid. As a result, maternal free T_4 (FT_4) concentrations increase during early pregnancy.

Thyroid hormones are essential for optimal growth and development of the central nervous system (CNS), lung, gut, and liver and the regulation of carbohydrate, lipid, and protein metabolism. It is likely that several factors, including deiodinase activity and thyroid hormone receptor expression, maintain adequate local concentrations of thyroid hormone at different times during gesta-tion (reviewed by Chan and Rovet[2]). Neural requirements for thyroid hormone vary across gestation. Because the maternal thyroid is the fetus' primary source of thyroid hormone in the first half of pregnancy, it can be anticipated that neurodevelopmental abnormalities associated with maternal thyroid disease reflect damage to different neural structures (e.g., brainstem) than those resulting from defective fetal gland development that impact development later in gestation and in the neonatal period (e.g., cortex, hippocampus, and cerebellum). Thus, the specific types of deficit reflect the timing and duration of thyroid hormone insufficiency, with prenatal hypothyroidism contributing to visual-spatial deficits, perinatal hypothyroidism to fine motor weakness, and hypothyroidism slightly later in infancy to memory and language deficits.[2,4]

Fetal Hyperthyroidism

Etiology (Table 22–1)

Fetal or neonatal hyperthyroidism affects less than 1 in 5000 pregnancies.[5] The disorder is almost invariably secondary to maternal autoimmune thyroid disorders, principally Graves' disease or less commonly Hashimoto's thyroiditis. Graves' disease complicates between 1 in 500 and 1 in 1700 pregnancies and is responsible for over 90% of cases of maternal hyperthyroidism.[6–7] Here, maternal IgG antibodies to the TSH receptor cross the placenta and stimulate the fetal thyroid. Transplacental passage of these thyroid-stimulating immunoglobulins (TSI) may also occur in euthyroid mothers who have undergone partial or complete thyroidectomy. Thyrotoxicosis occurs in 2% to 10% of neonates born to women with a history of Graves' disease, of which half require therapy.[7,9–11] Maternal Hashimoto's thyroiditis usually has no adverse effect on the fetal thyroid, even though antithyroid antibodies may be found in the newborn due to transplacental passage. Thyroid hormone concentrations are also

TSH, thyroid-stimulating hormone.

increased in fetuses with anemia secondary to red blood cell alloimmunization.[12]

Presentation and Diagnosis

Fetal hyperthyroidism should be suspected in any woman with a history of active or treated Graves' disease or clinical features suggestive of hyperthyroidism. Most hyperthyroid fetuses are asymptomatic. Fetal tachycardia is the most common symptom, being much more common than growth restriction.[13]

MATERNAL THYROID FUNCTION AND ANTIBODY TESTS

Decreased TSH and increased FT_4 concentrations are diagnostic of maternal hyperthyroidism. However, maternal thyroid function does not predict fetal thyroid function. The value of measuring TSH-receptor immunoglobulins is controversial, and a variety of assays exist. Many studies report TSH binding inhibitory Ig (TBII) activity, measured by radioreceptor assay (elevated values >15%).[10,14] Assays are also available for both stimulating (TSI) and blocking (TBI) immunoglobulins.[14] TSI can be measured by immunoassay or more commonly by a biologic assay based on the release of cAMP by purified IgG from thyroid cell cultures (elevated values greater than 130% or greater than 1.3 index units [IU]).[13–15] Some 20% of women with Graves' disease have TSH-receptor immunoglobulins. Kung and Jones[15] reported a change from stimulatory to blocking Ig activity during pregnancy in Graves' disease; median levels of TSI fell from 280% in the first trimester to 130% at term while TBI increased from 16% to 43%. They postulate that this change contributes to the remission of Graves' disease during pregnancy.

The risk of fetal hyperthyroidism correlates with maternal TSI and TBII levels.[7,10,11] In one recent study, a TSI of 5 IU or more correctly predicted neonatal hyperthyroidism with a sensitivity of 100%, specificity of 76%, positive predictive value of 40%, and negative predictive value of 100%.[13] The risk of neonatal hyperthyroidism is very small if both TSI and TBII are negative and increases to 42% when both tests are positive.[9] Guidelines for the measurement of TSH-receptor immunoglobulins in pregnancy are suggested by the European Thyroid Association[11] (Table 22–2).

FETAL IMAGING

Ultrasound assessment of the thyroid may be of some value in at-risk fetuses. Very large goiters can be associated with esophageal/tracheal compression and hydramnios, and are reported to cause malpresentation or mechanical obstruction in labor owing to hyperextension of the neck.[16] The sonographic differential diagnosis of an anterior neck mass includes hygroma, teratoma, hamartoma, and hemangioma. Subtler degrees of thyroid enlargement are difficult to diagnose and require the measurement of thyroid size in a transverse section of the fetal neck. Reference ranges for midthyroid width and

TABLE 22–2

Guidelines for Measurement of TSH-Receptor Immunoglobulins in Pregnancy

1. **A euthyroid pregnant woman without medication, but who has previously received antithyroid drugs for Graves' disease**: the risk for fetal and neonatal hyperthyroidism is negligible. Measurements of TSH-receptor immunoglobulins are not necessary.
2. **A euthyroid pregnant women (with or without thyroid hormone substitution therapy) who has previously received radioiodine therapy or undergone thyroid surgery for Graves' disease**: the risk of fetal and neonatal hyperthyroidism reflects the level of TSH-receptor immunoglobulins in the mother. Immunoglobulins* should be measured early in pregnancy:
    If absent or low, no further special evaluation is recommended.
    If high,† the fetus should be followed carefully for signs of hyperthyroidism. Immunoglobulins should be measured again in the last trimester to evaluate the risk of neonatal hyperthyroidism.
3. **A pregnant women who takes antithyroid drugs for Graves' disease to keep thyroid function normal**: TSH-receptor immunoglobulins should be measured in the last trimester:
    If absent or low, neonatal hyperthyroidism is unlikely.
    If high,† evaluation for neonatal hyperthyroidism is needed (clinical evaluation and thyroid function tests on cord blood and again after 4–7 days).

</td></tr>
</table>

*The generally available and technically simple assays measuring TSH-receptor immunoglobulins by competitive inhibition (not indicating whether the immunoglobulins are stimulating the thyroid) predicted nearly all cases of neonatal hyperthyroidism.
†In Europe a widely used method is TRAK (Brahms, Berlin, Germany). With this method levels >40 U/L are considered high enough to indicate risk of neonatal hyperthyroidism.
Source: Laurberg P, Nygaard B, Glinoer D, et al: Guidelines for TSH-receptor antibody measurements in pregnancy; results of an evidence-based symposium organized by the European Thyroid Association. Eur J Endocrinol 1998;139:584–586.

circumference are illustrated in Figure 22–1.[17] Other sonographic features of hyperthyroidism include fetal tachycardia, intrauterine growth restriction (IUGR), and hydrops fetalis.[13,16] Of six cases of fetal or neonatal thyrotoxicosis reported by Peleg and associates,[13] five had tachycardia, one of which was IUGR, and one had hydrops. Thyroid measurements were not made.
