Serial fetal ultrasonography is generally recommended in women with hyperthyroidism.[18] Assessment of fetal heart rate, fetal growth, and thyroid size every 4 to 6 weeks is reasonable although more frequent scans may be prudent in women with high TSI. A recent study by Cohen and associates[19] suggests this approach does allow early detection of enlarged fetal thyroid (Fig. 22–2). Magnetic resonance imaging (MRI) has also been used to assess fetal thyroid size with a diffuse goiter showing homogeneously elevated signal on T_1-weighted images.[20] It remains to be determined whether MRI is more sensitive than ultrasound.

FETAL THYROID FUNCTION TESTS

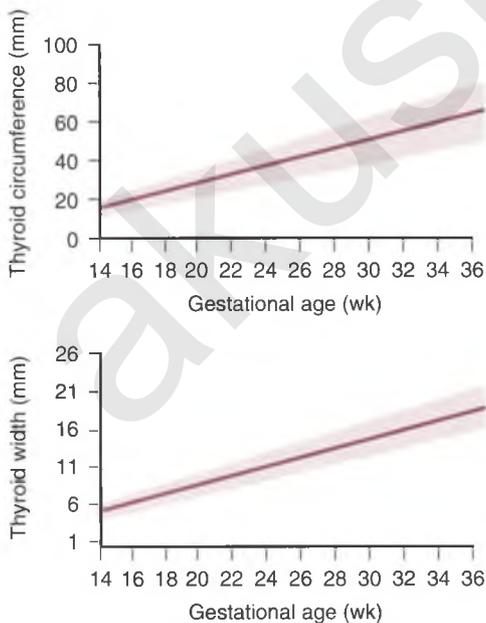
Amniotic fluid thyroid hormone concentrations do not reliably predict fetal thyroid status.[21] Fetal blood sampling is the only method of directly assessing thyroid function.[3] TSH concentrations are low in fetal hyperthyroidism.[16] Cordocentesis is clearly justified in women with Graves' disease when there is evidence of fetal involvement (goiter, tachycardia, IUGR). Unclear is the role of cordocentesis in women with high TSI, in the abscence of other fetal ultrasonographic abnormalities.[7] In a series of nine women with Graves' disease undergo-


FIGURE 22–2
Sagittal scan of fetal neck at 24 weeks' gestation in woman with Graves' disease on propylthiouracil 1050 mg/week (FT_4 18.4 pmol/L, TSH 0 mU/mL). Arrow indicates enlarged fetal thyroid. (From Cohen O, Pinhas-Hamiel O, Sivan E, et al: Serial in utero ultrasonographic measurements of the fetal thyroid: A new complementary tool in the management of maternal hyperthyroidism in pregnancy. Prenat Diagn 2003;23:740–742.)

ing cordocentesis, three of four fetuses with sonographic evidence of fetal involvement had abnormal thyroid function (one hyperthyroid and two hypothyroid) while only one of nine with "high" TSI (defined as bioassay levels of >160% or immunoassay levels >10 U/L) was hyperthyroid. This experience, though, is by no means uniform. Kilpatrick offered criteria for cordocentesis, which seem reasonable[22] (Table 22–3) if one assumes that either fetal hyperthyroidism or hypothyroidism (secondary to maternal antithyroid drug treatment) reliably results in sonographic abnormalities, or that fetal hypothyroidism will be compensated for by maternal transfer of hormone, and fetal hyperthyroidism not detectable by ultrasound has no morbidity. The evidence supporting these assumptions is weak.

Risks

Perinatal risks of fetal hyperthyroidism include IUGR, hydrops, hydramnios, preterm delivery, and malpresentation. Overt neonatal thyrotoxicosis is associated with tachycardia, tachypnea, flushing, difficulty in feeding,

FIGURE 22–1
Ultrasound measurements of fetal thyroid circumference and width. Data are mean and 95% confidence limits based on 193 normal fetuses. (From Achiron R, Rotstein Z, Lipitz S, et al: The development of the foetal thyroid: In utero ultrasonographic measurements. Clin Endocrinol 1998;48:259–264.)

TSH, thyroid-stimulating hormone; TSI, thyroid-stimulating immunoglobulin.

hyperirritability, and poor weight gain. There may be associated jaundice, hepatosplenomegaly, and a bleeding tendency due to thrombocytopenia and low prothrombin levels.[1] The half-life of antithyroid drugs in the neonate is shorter than the maternal immunoglobulin, and therefore, symptoms of neonatal thyrotoxicosis may not present until 5 to 10 days of age.

Early studies of perinatal thyrotoxicosis reported mortality rates up to 50%,[23] but more recent studies incorporating current standards of maternal and fetal surveillance suggest the risks are lower. In severely affected babies, mortality rate may still be as high as 25% due to cardiac arrhythmia or high output failure.[1] Autopsy findings include wasting, visceromegaly, pulmonary hypertension, and generalized adenopathy. Long-term sequelae include craniosynostosis and neurodevelopmental impairment.[24]

FETAL RISKS OF MATERNAL AND FETAL HYPERTHYROIDISM

The prognosis for mother and fetus is excellent for women who either become pregnant while their thyrotoxicosis is under control or in whom the condition is diagnosed and treated early.[6] However, untreated or poorly controlled maternal hyperthyroidism is associated with serious maternal and fetal sequelae. Most studies report increased early pregnancy loss[6] that may be partly explained by an increased incidence of structural and chromosomal abnormalities.[10,25] Heart failure occurs in up to 60% of untreated mothers and is often precipitated by an obstetric event (e.g., hemorrhage, sepsis, or hypertension).[26]

Maternal hyperthyroidism is associated with increased risks of IUGR and preeclampsia.[27–29] In one large study, the odds ratios (95% confidence intervals) in uncontrolled women were 9.2 (5.4–15.6) and 4.7 (1.1–19.7), respectively. Preterm delivery occurred in 33% (OR 16.5 [2.1–130]) while IUGR was present in 12% (OR 2.2 [0.4–11.5]).[28] Interestingly, the risk of IUGR was also doubled (OR 2.4 [1.4–4.1]) in women controlled during pregnancy (i.e., hyperthyroid at presentation but euthyroid at delivery). As a result, perinatal mortality rates as high as 37% are reported for uncontrolled maternal thyrotoxicosis, although more recent studies indicate much lower rates.[27–29] Thyrotoxicosis for 30 weeks or more of pregnancy, Graves' disease for 10 years or longer, onset of Graves' disease before 20 years of age, or a high TBII at delivery (>30%) are each associated with an increased risk of IUGR.[10] It is likely that the adverse outcomes associated with maternal Graves' disease reflect a combination of maternal and fetal hyperthyroidism.

Management Options (See also Chapter 46)

MATERNAL THIONAMIDE THERAPY

Treatment of fetal and maternal hyperthyroidism involves the use of antithyroid therapy. Effective treatment of maternal hyperthyroidism is associated with improved maternal and fetal outcomes.[10,19,28] Therapy ideally should be initiated before pregnancy. Women who remain euthyroid throughout gestation are not at increased risk of preeclampsia, preterm delivery, or IUGR.[28] However, neonatal complications are higher than in control subjects when euthyroidism is achieved only at the end of pregnancy.[28]

The thionamides inhibit the synthesis of thyroid hormone by preventing iodination of the tyrosine molecule. Propylthiouracil (PTU) and methimazole are widely used in the United States. Carbimazole, which is metabolized to methimazole, is popular in other countries. PTU has the advantage of crossing the placenta more slowly than carbimazole and methimazole.[30] Further, carbimazole and methimazole use are both associated with fetal scalp defects (aplasia cutis).[31] However, the incidence of major congenital malformations is comparable in offspring of women taking PTU and methimazole (2% to 3%),[32] and there is no evidence the use of PTU reduces the incidence of neonatal hyperthyroidism.[33] Umbilical cord FT_4 is low in 6% to 7% and TSH is elevated in 14% to 21% of women on thionamides.[33]

Carbimazole and methimazole are readily excreted in breast milk, achieving a milk-plasma ratio approaching unity. In contrast, PTU, which is highly bound by plasma proteins, is poorly excreted, with concentrations in milk approximating 10% of maternal serum.[34] Thus, PTU is the drug of choice in breastfeeding mothers and should be taken just after breastfeeding, allowing a 3- to 4-hour interval before feeding again.

In newly diagnosed cases of maternal hyperthyroidism, the initial dose of PTU is usually 150 mg every 8 hours. The equivalent dose of carbimazole is 20 mg twice daily. Clinical and biochemical improvement is usually evident after 2 to 4 weeks, although the fetal response may take longer. The dose should be halved once the maternal symptoms have improved and thyroid function is within normal range. Further reductions are possible because of the tendency of Graves' disease to ameliorate during the third trimester, and it is usually possible to reach a maintenance dose of 150 mg/day or less of PTU (or 15 mg/day or less of carbimazole). Side effects include nausea, arthralgia, skin rash, metallic taste, and fever. Leukopenia, agranulocytosis, and hepatitis can also occur. It is important to recognize that maternal euthyroidism does not mean the fetus is euthyroid.

Combined blocking-replacement regimens have been advocated, but there is no evidence they reduce the risk of fetal hypothyroidism, presumably because transplacental passage of T_4 is limited, and the maternal requirement for thionamides may increase.[35]

SURGERY

Subtotal thyroidectomy can successfully be performed during pregnancy. Maternal thyrotoxicosis must be adequately controlled preoperatively, which is most rapidly achieved with beta-blocking agents and iodide. Surgical

complications include hemorrhage, recurrent laryngeal nerve palsy, hypoparathyroidism, and hypothyroidism. Although the incidence of complications is low in experienced hands, surgery is usually reserved for women who are allergic to antithyroid drugs or when adequate biochemical control cannot be attained with medical therapy. The optimal time for surgery is during the second trimester. Radioiodine is contraindicated in pregnancy, particularly after the 12th week of gestation when the fetal thyroid is able to concentrate iodine.[6] Inadvertent administration of ^{131}I in the first trimester causes perinatal hypothyroidism in 3%.[36]

MONITORING THIONAMIDE TREATMENT

Once control is achieved, the aim of therapy is to keep the mother and fetus euthyroid using the minimum amount of thionamide. Maternal thyroid function should be monitored every 4 weeks, aiming to keep the FT_4 at the upper end of the normal range. Although there is a correlation between maternal and umbilical cord FT_4 levels, normal maternal FT_4 levels do not preclude fetal hypothyroidism.[25] If the mother remains euthyroid despite a small dose of PTU (50–100 mg) or methimazole (5–10 mg), therapy should be discontinued. This may be possible in up to 30% of patients after 32 weeks.[6]

The effects of thionamides on fetal thyroid function are sometimes unpredictable and dose-independent. Correlation between maternal and fetal thyroid function is poor and in one series of 11 consecutive pregnancies, six fetuses were hyperthyroid and five were hypothyroid

when the mother was euthyroid on stable drug therapy (Weiner C, personal communication). Accurate differentiation of thionamide-induced hypothyroidism from TSI-induced hyperthyroidism requires measurement of fetal FT_4 and TSH. Measurement of fetal thyroid function has also been used to modify the dose of thionamide.[37]

Fetal heart rate alone is unreliable for the detection of thyroid dysfunction; thionamide-induced hypothyroidism and TSI-induced hyperthyroidism may both occur in the absence of tachycardia.[7,38] In contrast, serial measurement of the fetal thyroid may allow early detection of thyroid dysfunction.[19,37] Cohen and associates[19] measured the thyroid in 20 women with Graves' disease on PTU (1050 mg/wk). Thyroid width and circumference were above the 95% percentiles in five fetuses; in three the thyroid size decreased concurrently with a decrease in maternal thionamide dosage and all were euthyroid at birth. In two fetuses, thyroid size was unaffected by a decrement in maternal PTU dose and both had thyrotoxicosis at birth. However, the variability of fetal thyroid measurements is unknown. This point is important because the absolute change in fetal thyroid size after a reduction in PTU was small. It remains to be determined whether serial ultrasound measurements can replace cordocentesis for monitoring thionamide dosage. Until these findings are confirmed in larger series, fetal thyroid status should be determined by cordocentesis when there is evidence of thyroid dysfunction, and umbilical cord blood obtained at birth for FT_4 and TSH levels. It is helpful to screen for TSI if these have not been measured previously.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Hyperthyroidism

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Consider measurement of TSH-receptor immunoglobulins (TBII and TSI) in women with known autoimmune thyroid disease.	–	GPP	–
Check maternal thyroid function tests (TSH and FT_4) and optimize thionamide therapy.	III	B	28
Consider changing to propylthiouracil in preference to carbimazole/methimazole.	IIb	B	30
Prenatal			
Monitor maternal thyroid function tests every 4–6 weeks; aim to keep FT_4 at the upper end of the normal range on the minimum dose of thionamide.	–	GPP	–
Measure TSH-receptor immunoglobulins in women with Graves' disease who have previously received radioiodine therapy or undergone thyroid surgery or are taking antithyroid drugs to keep thyroid function normal.	III	B	11

Fetal Hyperthyroidism *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal *(Continued)*			
Sonographic fetal surveillance every 4–6 weeks (more frequently in women with high thyroid-stimulating immunoglobulins) after 24 weeks looking for:	III	B	28
Goiter			
Cardiac hypertrophy			
Fetal tachycardia			
Growth restriction			
Hydrops			
Oligohydramnios			
Polyhydramnios			
Measure fetal thyroid function (TSH and FT_4) by fetal blood sampling if persistent tachycardia or goiter (poor correlation between maternal and fetal thyroid function tests) is found.	IV	C	38
If fetal hyperthyroidism is confirmed, adjust maternal thionamide dose to optimize maternal control.	III	B	29
Consider maternal beta-blockers if fetal tachycardia persists.	IV	C	108
Fetal thyroid assessment can be followed with color Doppler showing reduced vascularization under appropriate therapy.	IV	C	107
Postnatal			
Measure FT_4 and TSH in cord blood and at 7 days of age, and manage appropriately.	–	GPP	–
Give propylthiouracil if breastfeeding; Ensure that medication is taken immediately after feeding.	IIa	B	34

FETAL HYPOTHYROIDISM

Etiology (Table 22–1)

Congenital hypothyroidism occurs once in every 2500 to 4000 live births in nonendemic areas.[39,40] The condition can be permanent or transient. The most common cause of permanent hypothyroidism is thyroid dysgenesis, accounting for 80% to 90% of cases.[18] This term includes thyroid aplasia (40%), thyroid hypoplasia (20%), and ectopic thyroid (40%). Most cases are sporadic, nonfamilial embryologic defects, although familial cases are reported.[41]

Inborn defects of thyroid hormone synthesis and secretion (dyshormonogenesis) include iodine transport defects, organification defects, iodotyrosine deiodinase deficiency, and thyroglobulin abnormalities, all of which are inherited as autosomal recessive traits. Affected fetuses can develop large goiters. Thyroid dyshormonogenesis occurs in 1 in 40,000 births.[41]

Hypothalamic-pituitary disorders are associated with major and minor midline defects, including holoprosencephaly and septo-optic dysplasia, or with autosomal recessive genetic defects, including Pit-1 deficiency.

These disorders, together with mutations in the TSH receptor and thyroid hormone resistance (due to mutations in the thyroid hormone receptor), have a prevalence of 1 in 60,000 to 1 in 100,000 births.[41]

TSH receptor immunoglobulins are responsible for about 2% of congenital hypothyroidism.[42] Reduced T_4 levels are transient and are more likely to be found in infants of women with high TBI levels.[43,44] Inadequate treatment of maternal Graves' disease is also associated with central congenital hypothyroidism (estimated prevalence 1/35,000).[45] The neonates have low FT_4 but variable TSH levels; TRH testing indicates pituitary dysfunction. It is suggested that a hyperthyroid fetal environment impairs maturation of the fetal hypothalamic-pituitary-thyroid axis.[45] The common thyroid autoantibodies (thyroperoxidase and antithyroglobulin), present in women with Hashimoto's thyroiditis, have little or no effect on fetal thyroid function.

Transient hypothyroidism may follow maternal administration of antithyroid drugs. In the series of 18 cases of maternal Graves' disease treated with PTU, Nachum and associates[7] observed that 4 (22%) developed fetal hypothyroidism, even with doses as low as 50

to 100 mg/day.[7] Hypothyroidism is also reported after maternal use of amiodarone and lithium, and after excessive maternal iodide intake. Inadvertent administration of radioiodine after 12 weeks' gestation invariably results in permanent fetal hypothyroidism.

All preterm infants have a fall in FT_4 during the first 2 weeks of life with a recovery to expected values by the third or fourth week.[46] Levels of FT_4 approximate 50% of those in utero, with around one-third of preterm neonates having T_4 levels greater than 3 SD below the term neonatal mean.[46] Acutely ill infants may also have lower levels of FT_4 and FT_3 due to decreased peripheral conversion. Hypoxic IUGR fetuses also have low FT_4 and FT_3 levels associated with a slightly elevated in TSH.[47] The contribution of early thyroid hormone deficiency to neurodevelopmental delay in these children is unclear.

Worldwide iodine deficiency is the most common cause of combined maternal-fetal hypothyroidism. Iodine deficiency leads to deficient thyroid hormone production, TSH hypersecretion and increased iodide trapping with goiter and a raised $T_3:T_4$ ratio. Such compensatory mechanisms can result in euthyroidism with goiter or varying degrees of goitrous hypothyroidism.[1] The problem is still common in some areas of Europe, Scandinavia, and the Middle East. In Zaire, where iodine intake is below 25 µg/day (recommended intake 200 µg/day), the frequency of fetal hypothyroidism, as evidenced by an elevated TSH at birth, is as high as 25%.[48]

In some areas of severe iodine deficiency, infants are born with endemic or neurologic cretinism characterized by severe mental retardation, deafness, squint, pyramidal signs, and extrapyramidal signs. These infants are euthyroid but frequently have a goiter. In other areas, notably Africa, the infants have hypothyroid cretinism with grossly impaired thyroid function, dwarfism, and delayed sexual maturation, but rarely a goiter. Variations in dietary ingestion of goitrogens, which inhibit thyroid function, and coexistent selenium deficiency are thought to account for the different phenotypes.[49]

Presentation and Diagnosis

Fetal hypothyroidism is usually unrecognized. The condition may be suspected because of a maternal history of thyroid disease or antithyroid medication. Features include IUGR, goiter, and reduced fetal movements. An abnormal fetal heart rate may occur, with both bradycardia and tachycardia reported.[8] In severe cases, there may be delayed skeletal development, congenital heart block, and cardiomegaly.[50] Malformations are reported in 8% of infants with hypothyroidism; 28% of these malformations are cardiac abnormalities.[51]

The classic neonatal features of congenital hypothyroidism are constipation, lethargy, poor feeding, and respiratory problems. Physical signs include macroglossia, dry mottled skin, "cretinoid" facies, abnormal cry, prolonged jaundice, enlarged fontanels, umbilical hernia, and mental retardation. Depending on the cause and severity, clinical features may be apparent for several weeks or months after birth.

MATERNAL THYROID FUNCTION AND IMMUNOGLOBULIN TESTS

Most women with known hypothyroidism have a history of thyroid disease that was either treated surgically or by radioiodine, and will be on thyroxine replacement. Women presenting with features of hypothyroidism in pregnancy (malaise, cold intolerance, dry skin, myalgia, excessive weight gain) often have discontinued or reduced their thyroxine intake. However, the symptoms may be subtle and a goiter may not be palpable. An elevated TSH and a reduced FT_4 confirm the diagnosis of maternal hypothyroidism. Women with Graves' disease previously treated with radioiodine or surgery should have their TSH-receptor immunoglobulins measured early in pregnancy[11] (Table 22–2).

FETAL ULTRASONOGRAPHY

Hypothyroidism is suspected if there is IUGR, reduced fetal movements, or an abnormal fetal heart rate. Unfortunately, and analogous to the sonographic findings associated with hyperthyroidism, none of these features are very sensitive.[7] Ultrasonic evidence of a fetal goiter suggests severe thyroid dysfunction. However, the majority of cases reflect sporadic, embryologic malformations not detectable by ultrasound. Serial ultrasound screening may detect a large goiter when there is a family history of congenital hypothyroidism due to a defect in thyroid hormone synthesis or metabolism.

FETAL THYROID FUNCTION TESTS

Definitive antenatal diagnosis requires fetal blood sampling and confirmation of an elevated TSH and low FT_4. Reported values of TSH in fetuses with goiter have ranged from 25 to 1640 mU/L,[52,53] but the development of a goiter or hydramnios does not closely correlate with the degree of fetal hypothyroidism.[7,53] In many countries, all newborns are screened for congenital hypothyroidism by the measurement of TSH on a blood spot.

Risks

In instances of congenital hypothyroidism, fetal thyroid hormone supply is deficient to varying degrees in utero and during early infancy. Transplacental passage of maternal thyroid hormones, along with compensatory deiodinase activity, ensure thyroid hormone sufficiency during the first half of pregnancy. However, the fetal contribution is reduced or totally lacking in the second half of gestation, and hypothyroxinemia persists until the diagnosis is made and treatment takes effect. As a result, children with congenital hypothyroidism manifest neuropsychological deficits with a mean IQ that is significantly lower than in control subjects, even with optimal neonatal thyroxine supplementation.[54] Infants with severe congenital hypothyroidism, particularly those with absent thyroid glands, or who show ultrasonographic or serum

evidence of hypothyroidism in utero, have lower IQ scores than those with less severe hypothyroidism.[55-57] Perinatal hypothyroidism appears particularly to contribute to visual-spatial and fine motor weakness.[2] Disparity in performance is evident into adolescence.[2] The majority of athyrotic infants manifest systemic signs such as delayed skeletal maturation.[2]

FETAL RISKS OF MATERNAL HYPOTHYROIDISM (See also Chapter 46)

In iodine-sufficient areas, overt maternal hypothyroidism occurs in 5 to 10 per 1000 pregnancies[2,58] and is usually due to Hashimoto's thyroiditis or previous thyroid surgery. Subclinical hypothyroidism (normal FT_4 but elevated TSH) is reported in up to 2.5% of pregnancies,[59,60] and in areas of endemic iodine deficiency the incidence is even higher. Although thyroid hormone levels return to normal within 10 weeks in two-thirds of cases,[59] damage to the fetal CNS may already have occurred.

The rate of miscarriage is increased approximately twofold in women with overt hypothyroidism. This risk appears related more to the presence of circulating thyroid antibodies than thyroid function.[58] Recent reports do not reveal an increased rate of congenital anomalies.[58] Gestational hypertension, preeclampsia, and placental abruption are purportedly more common leading to an increased rate of preterm delivery.[60,61-63] Stillbirth rates range from 4% to 13%,[61,62] and severe maternal hypothyroidism in early pregnancy was in one study associated with a 56% rate of intrapartum cesarean section for fetal distress.[64] The risk appears related to the deficiency as the rate of adverse outcome improves with early therapy.[64]

Infants born to women who remain hypothyroid throughout pregnancy are at increased risk of neurologic impairment. Man and associates[65] initially reported that the mean IQ at 7 years of age was 13 points lower in children born to women who were hypothyroid during pregnancy compared to those born to women who were euthyroid on T_4 replacement. Several subsequent studies (reviewed by Chan and Rovet[2]) have reported on the effects of maternal hypothyroidism on offspring neurodevelopment. Klein and associates[66] initially measured maternal TSH levels at 15 to 18 weeks' gestation (from frozen samples obtained for Down syndrome screening) and found 2.5% had elevated TSH levels (≥6 mU/L), of which 12% (6 of 49) also had low FT_4 levels. Children of mothers who were hypothyroid scored lower than control subjects on all 15 of the neuropsychological tests and attained an average IQ that was 4 points below control subjects.[67] Children of untreated women performed less well than children of biochemically hypothyroid women who received T_4 treatment (albeit inadequate) during pregnancy.[67] The severity of maternal hypothyroidism, as assessed by TSH concentration, correlates with offspring IQ; in mothers with TSH concentrations below the 98th, 98th to 99.85th, and above the 99.85th percentiles, mean IQ at 8 years of age was reported to be 107, 102, and 97 respectively with the percentage of children with IQ above 1 SD below the control mean being 15%, 21%, and

50%.[68] The children of euthyroid women with increased thyroperoxidase autoantibodies are reported to have lower IQs than children of antibody-negative women.[69]

Evidence is accumulating that the key factor influencing neuropsychological development of the fetus is first trimester hypothyroxinemia, whether or not TSH is increased.[70] This is a consequence of decreased availability of maternal T_4 to the developing brain, its only source during the first trimester. Normal maternal T_3 concentrations do not appear to prevent the potential damage of a low supply of T_4, although they may prevent an increase in TSH (and detection of the hypothyroxinemia if only TSH is measured).[70] Pop and associates[71] reported recently that children of women with a FT_4 below the 10th percentile and a normal TSH (0.15–2.0 mIU/L) at 12 weeks' gestation had delayed mental and motor function (mean deficit of 8–10 points on Bayley scales of infant development) at 2 years of age compared to control subjects (FT_4 between 50th and 90th percentiles). However, the children had a lower risk of later impairment when FT_4 concentrations increased during pregnancy (at 24 and 32 weeks) in women hypothyroxinemic during early gestation.

As the body of information grows concerning the detrimental and long-term effects of maternal hypothyroidism on the fetus, many authorities have advocated screening all women as early as possible in pregnancy.[70] However, it is not certain whether FT_4 or TSH should be used, what cutoff point to adopt, nor what treatment should be instituted for screen positive women.[2] Ultimately the value of screening and treating mildly hypothyroid women in nonendemic areas can only be addressed in large trials with adequate follow-up.

Management Options

FETAL THERAPY

Fetal therapy is indicated in cases with confirmed fetal hypothyroidism because of the risk of neurologic damage. Direct fetal therapy is necessary because relatively little T_4 crosses the placenta, and the amount of T_4 needed to treat the fetus adequately would cause maternal hyperthyroidism. Van Herle and associates[72] reported fortnightly fetal intramuscular T_4 injections because the mother received radioiodine early in pregnancy. The fetus was severely hypothyroid at birth.

Weiner and associates[73] reported the first use of intra-amniotic T_4 in the treatment of fetal goiter. Subsequent reports confirm the effectiveness of this mode of administration with reduction in goiter size, resolution of hydramnios, and improvement in fetal thyroid function.[7,37,52] A weekly dose of 250 μg appears to be effective. This is consistent with the neonatal T_4 requirement of 10 μg/day and animal data suggesting that 90% of T_4 administered intra-amniotically is absorbed within 24 hours.[74] Whether this is the optimal dose and frequency is unclear, and larger doses (500–600 μg) given every 14 days may be as effective.[7,53] Fetal therapy should be started as early as possible once the diagnosis of fetal hypothyroidism is made.

In 2002 Agrawal and associates[75] reported the use of intra-amniotic T_3 (60–120 µg) and T_4 (150 µg) in a hypothyroid fetus with goiter and symptomatic hydramnios. They reasoned the more rapid onset of action of T_3 (4–8 hours) and its more potent effects compared to T_4, make it more suitable for "acute" management. However, more frequent intra-amniotic injections are needed because of its shorter half-life (1–2 days) compared to T_4 (6–7 days). Further research is needed to determine the value of combined therapy.

Repeat fetal blood sampling 1 to 2 weeks after starting therapy is justified to confirm that TSH and FT_4 have returned to normal.[37,76] Repeat sampling is particularly important if there is worsening of the fetal condition, failure of the goiter to resolve, or the development of hydramnios.[18,76] In women with Graves' disease and fetal hypothyroidism, assessing the fetal response to a reduction in maternal antithyroid therapy may be appropriate before considering direct fetal therapy.[7]

A possible noninvasive alternative to treat fetal hypothyroidism is maternal administration of 3'-triiodothyroacetic acid (Triac), a T_3-derived analogue that binds to thyroid hormone receptors with higher affinity than T_3. Triac crosses the placenta[77] and was used with apparent success to reduce TSH concentrations and goiter size in fetal hypothyroidism secondary to PTU therapy[53,77] and to reduce TSH concentrations in a fetus affected by a mutation in thyroid hormone receptor beta gene leading to resistance to thyroid hormones.[78] In both case reports, Triac was increased from a starting dose of 2.1 mg/day to 2.8 mg/day[53] and 3.5 mg/day,[78] respectively, in an attempt to normalize fetal TSH levels. Further experience is needed before this therapy can be recommended as a safe alternative to invasive therapy.

MATERNAL THERAPY (See also Chapter 46)

Most women with hypothyroidism already take T_4 prior to pregnancy. Adequate T_4 replacement eliminates or reduces the risk of an adverse pregnancy outcome. The serum FT_4 level should be kept at the upper normal range, necessitating increased T_4 in up to 75% of patients, usually during the first trimester.[79] Average T_4 requirements are increased by 25 to 100 µg/day during pregnancy.[79,80] However, the maternal dose should not be increased without objective proof of need. Maternal TSH and FT_4 should be measured at booking for prenatal care, at 16 to 20 weeks, and at 28 to 32 weeks (although it has been suggested that repeat testing is not necessary unless clinically indicated[81]). Ferrous sulfate reduces thyroxine absorption and ingestion of these drugs should be separated by at least 2 hours. After pregnancy, thyroxine is reduced to the prepregnancy dose. It is safe for women taking T_4 to breastfeed.

In cases of severe iodine deficiency, supplementation during pregnancy prevents the occurrence of hypothyroid cretinism and neonatal hypothyroidism, increases birth weight, reduces the chances of neonatal death, and improves developmental quotients.[48] Iodine can be given in the form of iodized salt, potassium iodide drips, or iodized oil.

NEONATAL THERAPY

Infants confirmed after screening to be hypothyroid should immediately be started on replacement thyroxine (10–15 µg/kg orally once daily). The dose is adjusted after 4 weeks according to the clinical response and serum T_4.[1] TSH often remains high in the presence of adequate replacement and normal T_4 levels. Therefore, TSH levels are not a useful guide to treatment.[1] Serum T_4 should be rechecked, and the dose of thyroxine adjusted, at 3 months, 6 months, and annually thereafter. The response to treatment varies with the etiology; athyrotic infants take longer to normalize their thyroid function and probably should be monitored more frequently in early life.[82]

Much attention has focused on the starting dose of thyroxine. One nonrandomized study indicated higher full scale and verbal IQ results at 7 to 8 years on the standard dose compared with lower doses, but treatment in the higher dose group was begun earlier.[83] In a recent study from Norway, young adults (mean age 20 years) with congenital hypothyroidism had lower scores than their sibling controls on intellectual, motor, and school-associated tests.[84] The initial thyroxine dose predicted their verbal IQ scores. Several studies investigated the value of higher starting doses of thyroxine on outcome, but the evidence currently for an effect on cognitive development, growth, or behavior is too weak to justify recommending a high or standard dose regimen.[85]

FETAL ADRENAL DISEASE

Fetal Adrenal Function

The adrenal cortex arises from the mesoderm of the mesonephros during the fifth week of embryonic development. The cells that form the medulla are derived from adjacent neural crest cells and come to be encapsulated by the fetal cortex, which rapidly increases in size from the end of the second trimester to occupy 80% of the adrenal cortex by term. The adult (or definitive) cortex, also derived from mesenchymal cells, forms a thin outer layer.

All adrenal steroids are formed from cholesterol (Fig. 22–3). In the zona fasciculate of the definitive cortex, steroid precursors are used to synthesize cortisol under the influence of 17α-hydroxylase. Fetal cortisol concentrations rise, particularly toward term, stimulating the maturation of several enzyme systems in the lungs and gastrointestinal tract. Glucocorticoid synthesis is under the control of pituitary adrenocorticotropic hormone (ACTH). Both hypothalamic corticotropin-releasing hormone (CRH) and AVP stimulate the release of ACTH, which is cleaved from a large prohormone pro-opiomelanocortin (POMC) containing the sequences of several other peptide hormones. 17α-Hydroxylase is inactive in the zona glomerulosa, and precursors are used to synthesize aldosterone under the control of the renin-angiotensin system. Adrenal androgen production is insignificant during fetal life.

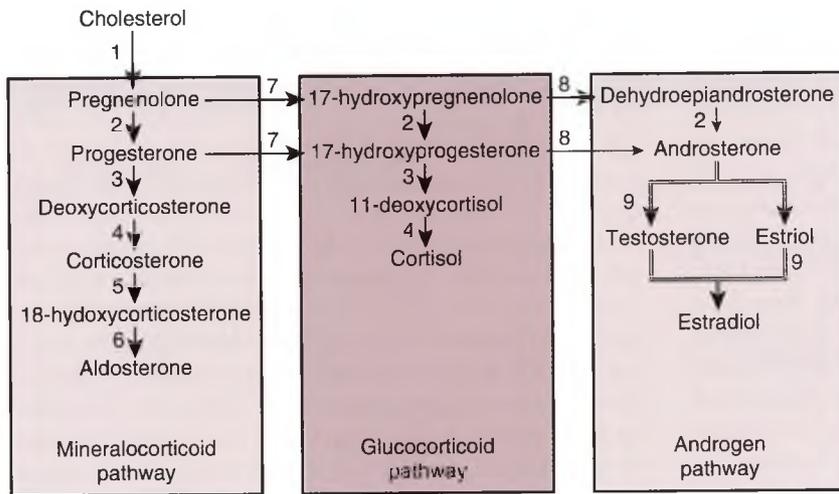
The fetal adrenal gland provides precursors for maternal estrogen production. The cortex contains inactivated 3β-hydroxysteroid dehydrogenase. Therefore, pregnenolone is converted primarily into dehydroepiandrosterone sulfate (DHEAS), which appears in the fetal circulation from 8 weeks. DHEAS is hydroxylated in other fetal tissues, particularly the liver, to 16-hydroxy-DHEAS,


FIGURE 22–3
Pathways of adrenal hormone synthesis. Major pathways are indicated by thick arrows, minor ones by thin arrows. Extra-adrenal conversion of sex steroids is denoted by double arrows. Numbers indicate enzymatic steps as follows: 1, Cholesterol side chain cleaving system; 2, 3β-hydroxysteroid dehydrogenase; 3, 21-hydroxylase; 4, 11β-hydroxylase; 5, 18-hydroxylase; 6, 18-dehydrogenase; 7, 17α-hydroxylase; 8, 17,20-lyase; 9, 17β-hydroxysteroid dehydrogenase.

which then passes to the placenta, where it is converted into androstenedione and subsequently to estrogens.

CONGENITAL ADRENAL HYPERPLASIA

Etiology

Congenital adrenal hyperplasia (CAH) refers to a group of autosomal recessive disorders of adrenal steroidogenesis. The disorder may result from a defect in any of the five enzymes required to synthesize cortisol from cholesterol.

21-HYDROXYLASE (P450C21) DEFICIENCY

In 90% to 95% of cases, CAH is due to deficiency of 21-hydroxylase (21-OH), resulting in a blockade of the conversion of 17-hydroxyprogesterone into 11-deoxycortisol (see Fig. 22–3). Reduced synthesis of cortisol leads to increased ACTH and shunting of precursors into the pathways of androgen synthesis. A spectrum of phenotypes occurs: a severe form with a concurrent defect in aldosterone synthesis (salt-wasting type) and a simple virilizing form with apparently normal aldosterone synthesis. These two forms are responsible for classic CAH, which has a prevalence of approximately 1 in 15,000 whites.[86] There is also a mild, nonclassic form that may be asymptomatic or associated with signs of androgen excess.

Mutations in the *CYP21* (*CYP21A2*) gene, located in the polymorphic HLA histocompatibility complex on chromosome 6p21.3, along with a pseudogene, *CYP21P* (*CYP21A1P*), are responsible for CAH. The high degree of nucleotide sequence identity (98%) between *CYP21* and *CYP21P* permits two types of recombination events: (1) unequal crossing-over during meiosis, which results in complete deletions or duplications of *CYP21*, and (2) gene conversion events that transfer deleterious mutations present in the pseudogene to *CYP21*. Deletions generally account for 20% to 25% of classic 21-OH alleles; small deletions and point mutations make up the

rest.[86,87] There are correlations between genotype and phenotype. Mutations that totally ablate enzyme activity are associated with the salt-wasting form, and those that produce enzymes with 1% to 2% normal activity, permitting adequate aldosterone synthesis, lead to simple virilizing disease. A third group of mutations produce enzymes retaining 20% to 60% normal activity and are responsible for the nonclassic form.[86]

OTHER FORMS

11β-Hydroxylase (P450$_c$11) deficiency accounts for 5% to 8% of CAH. 11-Deoxycortisol is not converted into cortisol, shunting precursors along the pathway for androgen synthesis. The enzymatic defect also leads to an accumulation of deoxycorticosterone within the aldosterone pathway. A mild, nonclassic form is also described. Two copies of the 11β-hydroxylase gene are present on chromosome 11q, and several mutations are known.[88] Deficiencies of 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, and cholesterol side chain cleavage enzyme account for less than 1% of CAH cases. Mild or partial defects may occur more frequently.[88]

Presentation and Diagnosis

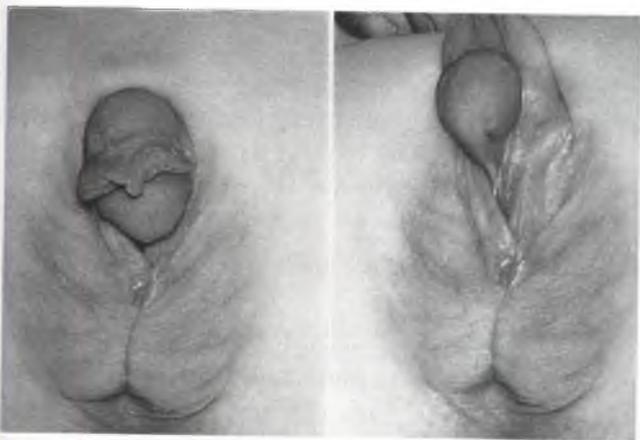
Around 75% of patients with classic 21-OH deficiency have the salt-wasting form and can present in the early neonatal period with hyponatremic dehydration and shock.[86] Female fetuses with classic 21-OH deficiency are exposed to excess androgens from the seventh week of gestation onward, leading to virilization of the external genitalia ranging from clitoral hypertrophy to complete phallus formation and fusion of the labia (Fig. 22–4), causing erroneous assignment of gender. Affected males have normal external genitalia. Postnatally, androgen excess may manifest as progressive virilizing changes and accelerated growth and development. In the nonclassic form, virilizing symptoms appear postnatally. Females affected with 11β-hydroxylase deficiency also have


FIGURE 22–4
Severe virilization in two untreated female infants with
21-hydroxylase deficiency. There is almost complete formation
of a phallus and scrotum.

ambiguous genitalia at birth. The excess deoxycorticos-
terone generally leads to hypertension and hypokalemia.
Virilization of female fetuses is much less marked in
3β-hydroxysteroid dehydrogenase deficiency and in the
other two forms, the male is incompletely masculinized.[88]

The diagnosis of 21-OH deficiency is confirmed by
the measurement of neonatal plasma 17α-hydroxypro-
gesterone (17-OHP), which typically exceeds 10,000
ng/dL (300 nmol/L). Classic 21-OH deficiency is more
common than phenylketonuria, and neonatal screening
of blood spots is routine in many countries in view of the
risks from salt wasting and late diagnosis.[89] Screening in
the United Kingdom is generally considered uneconom-
ical.[1] In 11β-hydroxylase deficiency, plasma deoxycorti-
costerone is elevated. The profile of urinary steroids by
gas chromatography and mass spectrometry provides a
definitive diagnosis.

Risks

Affected children require lifetime glucocorticoid replace-
ment therapy (10–15 mg/m²/day in three divided doses).
Appropriate replacement will suppress androgen levels
and allow normal growth, skeletal maturation, and
puberty.[1] Mineralocorticoid replacement (fludrocorti-
sone 0.1–0.2 mg daily) is necessary in salt-losing forms.
The majority of female infants born with virilized geni-
talia require corrective surgery. Half require more than
one operation. Clitoral reduction is best undertaken
before 6 months of age, but the timing of vaginal recon-
structive surgery is controversial. It was often delayed in
the past until after puberty, but more recently, single-
stage surgery at 2 to 6 months has been advocated.[90] In
addition to progressive virilization, high androgens affect
the hypothalamic-pituitary-gonadal axis in both sexes,
leading to subfertility. Follow-up studies of adult females
with CAH diagnosed in infancy or early childhood sug-
gest that one-third are hirsute, and their ovulation rate is
less than 50%.[91] After reconstructive surgery, about 75%
have an adequate vaginal introitus; and in this group,

pregnancy rates approximate 60%.[91] Early treatment
with glucocorticoids improves fertility. It is suggested
that prenatal exposure to excess androgens affects subse-
quent sexual behavior in adolescent and adult females.[92]

Management Options

PRENATAL DIAGNOSIS

All affected families should be offered genetic counsel-
ing. Ideally, this should be accomplished prior to concep-
tion. Subsequent offspring have a 1 in 4 chance of being
affected and a 1 in 8 chance of being a virilized female.
Prenatal diagnosis was initially accomplished by measur-
ing 17-OHP in amniotic fluid, but is now mostly
replaced by direct DNA analysis of the *CYP21* gene.
Mutations can be identified in 95% of families by
Southern blot analysis and selective amplification of the
CYP21B gene by PCR followed by allele-specific
hybridization with oligonucleotide probes for a panel of
common *CYP21B* mutations.[93,94] The most common
mutation (33–52%) is on intron 2.[87,93] In some families,
direct DNA analysis provides limited information
because of gene conversion or rearrangement between
CYP21 and *CYP21P* genes. In this instance, linkage
analysis using informative marker loci (microsatellites)
provides more comprehensive information.[95] Molecular
diagnosis is possible for some families with other forms
of CAH. Otherwise, antenatal diagnosis is dependent on
the measurement of steroids in the amniotic fluid.[96]

MATERNAL DEXAMETHASONE THERAPY

The fetal adrenal gland can be pharmacologically sup-
pressed by maternal administration of dexamethasone.
Synthetic fluorinated steroids are poor substrates for pla-
cental 11β-hydroxysteroid dehydrogenase and readily
cross the placenta to the fetus, suppressing ACTH.
Because the external genitalia begin to differentiate
around 7 weeks' gestation, dexamethasone (20 μg/kg
prepregnancy weight per day given in three divided
doses) should be begun before this time. Compared to
their previously affected sisters, treated females have
decreased virilization; 25%-50% require no genital sur-
gery, and the extent of genital surgery for those who
require it is reduced.[87,93,97] However, therapeutic failures
occur[98] (Fig. 22–5), and although some failures are
attributed to the late initiation or early cessation of ther-
apy, noncompliance, or suboptimal dosing, there is no
obvious explanation in others. The extent of virilization
varies among affected females in the same family, even
without treatment.[99]

Dexamethasone is discontinued if the fetus is male or
an unaffected female (i.e., in seven of eight pregnancies
initially treated). The success of therapy is monitored by
the measurement of maternal urine estriol and amniotic
fluid 17-OHP, though the interpretation can be diffi-
cult[100] and increasing the dose of dexamethasone can lead
to side effects. Excessive weight gain, cutaneous striae,
edema, hirsutism, and mood fluctuations are most com-

FIGURE 22–5
Partial virilization in a female infant with 21-hydroxylase deficiency treated prenatally with dexamethasone from 8 weeks' gestation. There is clitoromegaly with posterior labial fusion.

mon.[87,93] Hypertension and gestational diabetes develop in 15% and 8% of women, respectively.[87] Overall, side effects necessitate a reduction in the dexamethasone dose in up to 25% of women.[97] It is also reported that the dose of dexamethasone can be reduced later in pregnancy (to 5 μg/kg/day) and still maintain fetal and maternal adrenal suppression, as evidenced by urinary estriol and cortisol metabolites. The efficacy of this regimen in preventing virilization remains to be determined.[101]

Although the long-term safety of prenatal treatment remains uncertain, it is encouraging that no teratogenic effects are reported in fetuses treated to term with dexamethasone.[87] The administration of low doses of glucocorticoids to children has been reported to delay growth and cause diabetes and hypertension. Follow-up studies of prenatally treated CAH children suggest that growth and development are normal. However, the numbers are small and the duration of follow-up limited.[87,97] Concerns remain about the long-term implications of antenatal therapy with respect to hypertension and psychosexual/behavioral development. One small study suggested that although dexamethasone-treated children have cognitive abilities comparable to unexposed children, they have more behavior problems at 2 to 3 years of age.[102] Although antenatal dexamethasone appears justified, it is important to inform parents that the long-term safety and outcome of this therapy is not established.

DETERMINATION OF FETAL SEX

Fetal sex can be determined by ultrasound from 11 weeks' gestation, though a reliable assignment is not possible until 12 to 13 weeks[103] and a phenotypic male fetus can be a virilized female. Thus, ultrasound is of limited value in the management of an at-risk fetus, other than possibly for monitoring the success of prenatal therapy.[104]

Of far greater value is the determination of fetal sex from cell-free DNA in maternal blood. Using real-time PCR, the Y-chromosome-specific SRY sequence can be amplified from the plasma of women carrying a male fetus.[105] Rijnders and associates[106] reported detection of SRY as early as 5 weeks' gestation with correct fetal sex determined by 10 weeks in 13 of 13 cases. This group recently reported the largest experience of prenatal sexing using cell-free fetal DNA. The PCR result was negative in all 29 female fetuses using a protocol of duplicate DNA isolation from 2 mL of maternal plasma. In 35 of 36 male fetuses, SRY was amplified in both DNA isolations (positive predictive value 100%), and in one instance, only one SRY amplification was positive (negative predictive value 96.7%). Early fetal sexing avoids unnecessary dexamethasone treatment and invasive antenatal diagnosis when the fetus is male. Because clinical experience of prenatal sexing using fetal DNA is still limited in CAH, the optimal testing protocol remains to be determined. Rijnders and associates[105] suggest starting dexamethasone and weekly plasma SRY testing from 5 weeks' gestation. The dexamethasone can then be stopped if the SRY PCR is positive in two separate samples and male sex subsequently confirmed on ultrasound examination. When the SRY PCR is negative, testing should be repeated weekly until 10 weeks with a diagnostic CVS at 11 weeks. Dexamethasone can then be discontinued in unaffected females (and undetected males).

SUMMARY OF MANAGEMENT OPTIONS			
Congenital Adrenal Hyperplasia			
Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Identify genetic mutation and feasibility of prenatal diagnosis by direct DNA analysis and linkage analysis.	III	B	93,94,95

SUMMARY OF MANAGEMENT OPTIONS
Congenital Adrenal Hyperplasia *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy *(Continued)*			
Counsel families regarding risks and options for prenatal diagnosis and treatment.	–	GPP	–
Prenatal			
Start maternal dexamethasone (20 μg/kg/day in three divided doses) once pregnancy is confirmed.	III	B	87,93,97
Weekly maternal blood sampling for fetal sexing using PCR amplification of Y-chromosome-specific SRY sequence.	IIa	B	105,106
If PCR amplification not available or negative, chorionic villus sampling is done at 11 weeks for karyotype and DNA analysis.	III	B	93,94,95
For noninformative affected families (no molecular diagnosis possible), diagnosis is by amniotic fluid steroid levels.	IV	C	96
For male fetus or unaffected female fetus stop maternal dexamethasone.	IIb	B	87,93,97,105
In affected female fetus continue dexamethasone.	II	B	87,93,97,105
Measure maternal serum estriol levels every 6–8 weeks to confirm compliance and adrenal suppression.	IIa	B	100
Ultrasonographic assessment of external genitalia: if there is evidence of virilization, measure amniotic fluid for 17-hydroxyprogesterone and androstenedione, and if elevated, increase the dose of dexamethasone.	III	B	87
Monitor for maternal side effects (hyperglycemia, hypertension, edema, and excessive weight gain) and, if necessary, reduce dose of dexamethasone.	III	B	87,93,97
Postnatal			
Examine child carefully after birth for evidence of virilization and salt-wasting disease.	IV	C	86,89
Corticosteroid/mineralocorticoid replacement are considered.	IV	C	86,89
Long-term developmental follow-up is required.	III	B	91

CONCLUSIONS

FETAL HYPERTHYROIDISM

- Suspected in at-risk women from ultrasound features (especially fetal heart rate), but diagnosis depends on fetal blood sampling.
- Treatment involves optimizing maternal thionamide therapy; maternal beta blockers are given if fetal thyrotoxicosis persists.
- Neonatal evaluation and management plan are important.

FETAL HYPOTHYROIDISM

- Key management is to optimize maternal thyroxine replacement.
- Fetal disease may be suspected with ultrasound, but diagnosis depends on fetal blood sampling.
- Treatment for affected fetuses is intra-amniotic thyroxine.
- Neonatal evaluation and management plan are important.

CONGENITAL ADRENAL HYPERPLASIA

- Maternal dexamethasone therapy is begun as soon as pregnancy is diagnosed in at-risk pregnancies.
- Establish gender and molecular diagnosis if the patient is female.
- Continue dexamethasone therapy in affected females.
- Neonatal evaluation, management plan, and long-term follow-up are important.

Fetal Tumors

Joseph Biggio/Katharine Wenstrom

INTRODUCTION AND GENERAL APPROACH

Although fetal tumors are an uncommon, the use of sonography has made antenatal detection possible. Once a fetal neoplasm is identified or suspected, the physician and the family must formulate a management strategy based on the presumptive diagnosis and the prognosis for the specific lesion. An understanding of the sonographic appearance of specific lesions, the differential diagnosis, available treatment modalities, and overall prognosis is critical in providing families with accurate information at a time when difficult decisions may be required. A multidisciplinary team, with representatives from maternal-fetal medicine, neonatology, pediatric hematology-oncology, and pediatric surgery, provides an excellent source of information for the parents and allows for an integrated approach that minimizes maternal risk while maximizing fetal benefit.

The prevalence of fetal tumors is difficult to pinpoint because of imprecision defining what was a congenital tumor prior to the near universal application of ultrasonography. Historically, studies included only those tumors apparent at birth or diagnosed within the first 2 to 3 months of life.[1] Further, tumors found in stillbirths and nonmalignant tumors may not have been reported to cancer registries. A 30-year population study in the United Kingdom from 1960 to 1989 reported an incidence of 7.2 congenital tumors, both benign and malignant, per 100,000 live births. The incidence of malignancy in neonates is estimated at 36.5 per million live births.[2]

Although the histology of congenital tumors is similar to that in older children, the incidence, presentation, degree of differentiation, and biologic behavior frequently differ.[3] Teratomas and neuroblastomas are the most common solid tumors reported, but the behavior of these lesions in fetuses and neonates is markedly different from that observed in older children.[1,3,4] The prevalences of these and other neoplasms are listed in Table 23–1.

Prior to antenatal ultrasound, the first sign of a fetal tumor was often polyhydramnios due either to neurologic or mechanical interference with fetal swallowing. Frequently, the diagnosis was made in the perinatal period after dystocia, fetal hemorrhage, tumor rupture, or fetal hydrops. Modern ultrasonography and the availability of magnetic resonance imaging (MRI) now allow for a thorough antenatal investigation of suspected fetal masses. Harrison and Adzick[5] observed the natural history of several tumor types and found that in some cases the fetus tolerates the mass, while in others the fetus cannot and develops hydrops. Imaging does not provide a histologic diagnosis, but even if a biopsy were taken antenatally, the prognosis might still be obscure because the histologic appearance of malignancy in the fetus or neonate often reflects the immaturity of the patient and not tumor biology.[4] Moreover, even histologically benign lesions can cause fetal or neonatal death if the tumor mass disrupts other vital structures.[6] The location of the mass and the ability to predict the potential for impingement on vital structures is critical in assessing prognosis.

TABLE 23–1

Most Common Perinatal Tumors*

TUMOR TYPE	NUMBER	PERCENTAGE OF TOTAL
Teratoma	113	37%
Neuroblastoma	51	17%
Soft tissue	52	17%
Brain	20	6.6%
Renal	16	5.3%
Hepatic	13	4.3%

*Compiled from three large series of 302 tumors (Isaacs, 1985[4]; Werb et al., 1992[3]; Parkes et al., 1994[1]).

SUMMARY OF MANAGEMENT OPTIONS			
Fetal Tumors—General			
Management Options	Quality of Evidence	Strength of Recommendation	References
Uterine size greater than dates, hydramnios, and fetal hydrops are common presenting signs.	III	B	2–5
Diagnosis is most commonly made by ultrasonography, although adjunctive studies such as MRI may be helpful in some cases.	III	B	2–5
The possibility of genetic syndromes and associated malformations/deformations should be considered.	III	B	2–5
Multidisciplinary counseling and coordination of care with a team of specialty consultants are important in optimizing outcome for the neonate.	–	GPP	–
The development of hydrops is a poor prognostic sign.	III	B	2–5
If preterm delivery is contemplated, maternal steroids should be administered.	Ia	A	235

INTRACRANIAL TUMORS

Congenital brain tumors are extremely rare, with an estimated prevalence of 14 per 1 million live births.[2] Approximately 10% of all tumors diagnosed in the perinatal period arise in the brain.[7,8] While congenital tumors account for only 0.5% to 1% of all brain tumors diagnosed during childhood, they cause 5% to 20% of perinatal deaths due to neoplasms.[1,2,4,7–9]

There are several distinct differences between perinatal brain tumors and those occurring in older children. First, primary intracranial tumors in older children are mainly infratentorial (located in the cerebellum and brainstem), whereas the majority of those in the fetus and neonate are supratentorial.[4,7,8,10–12] Second, the initial clinical presenting sign in perinatal brain tumors is macrocephaly due to the tumor mass, hydrocephaly, or hemorrhage, with resulting dystocia and stillbirth. The lack of fusion of the calvaria and the patent fontanels permit expansion of the skull without increased intracranial pressure.[8,10] In contrast, older children develop signs of increased intracranial pressure, such as vomiting and focal neurologic changes. Third, intracranial teratomas are the most frequent intracranial neoplasms in the perinatal period, but they are highly unusual in older children. Finally, some tumor types behave differently in the perinatal period. For example, medulloblastoma is more aggressive in the perinatal period, while choroid plexus papilloma is more benign.[8] Discovery of a brain tumor in the perinatal period requires a careful search for additional defects, as 12% of congenital brain tumors result from a familial cancer syndrome.[8,13]

Teratomas

Teratomas are the most common congenital brain tumors, accounting for 26% to 50% of congenital intracranial masses.[8,10] They are thought to arise from any of several midline locations within the central nervous system, including the pineal gland, the hypothalamus, the suprasellar area, and the cerebral hemispheres. However, teratomas often become so large as to preclude determination of the exact site of origin.[8] Rapidly growing tumors have been reported to erode through the orbit, oral cavity, and skull, resulting in spontaneous rupture of the scalp and skull during delivery.[14,15]

Teratomas tend to appear as large cystic areas with solid components that frequently replace much of the normal brain architecture. Histologically, mature elements from all three germ layers are identified typically along with immature neuroglial components; these can easily give the impression of malignancy owing to their hypercellularity, high mitotic rate, and nuclear atypia.[8]

Diagnosis

Intracranial teratomas may present in a number of ways. Elevated midtrimester maternal serum α-fetoprotein (AFP) is reported in association with a fetal intracranial teratoma,[16] and some teratomas are seen on the midtrimester ultrasound examination. However, there are reports of normal ultrasound examinations and normal maternal serum AFP in pregnancies later found to be complicated by a massive fetal teratoma.[17] The most common presentation is rapid uterine growth. Macro-

cephaly, hydrocephaly, and an intracranial mass of mixed echogenicity with solid and cystic components are identifiable sonographically.[8,15,17] On occasion, there may be areas of calcification. The tumor mass can cause distortion or destruction of the normal intracranial architecture. Hydramnios occurs in 15% to 20% of cases.[8]

The differential diagnosis includes other intracranial neoplasms, hydrocephaly, hydranencephaly, porencephaly, holoprosencephaly, and encephalocele. Sonographic detection of a complex intracranial mass with the loss of normal intracranial architecture is highly suggestive of teratoma, but in cases in which the diagnosis is uncertain, MRI can be helpful (Fig. 23–1).

Risks

The frequent occurrence of uterine enlargement and hydramnios increases the risk of maternal respiratory compromise and preterm labor. In rare cases, the fetus may develop hydrops due to high-output cardiac failure secondary to arteriovenous shunting within the tumor,[18] which increases the maternal risk of preeclampsia (the "Mirror syndrome"). Perhaps the most significant maternal risk is dystocia due to macrocrania, and in most cases, cesarean section is required or cephalocentesis is necessary for vaginal delivery.[15,17,19] Although in some cases, a low transverse incision may be adequate, delivery of a breech fetus with macrocrania often requires a vertical uterine incision to minimize the risk of a broad ligament laceration. Regardless of the mode of delivery, the massive uterine distention markedly increases the risk of postpartum hemorrhage.

Management Options

The prognosis for a fetus with an intracranial teratoma is dismal. Most infants diagnosed antenatally are stillborn or die in the immediate perinatal period.[8,15,17,19] Although one case report described prolonged survival following tumor resection on the first day of life, that infant had severe motor and mental retardation.[17] Given the bleak prognosis, the patient should be counseled regarding her risks and the expected outcome, and the option of pregnancy termination offered. In ongoing pregnancies, the primary goal is to minimize maternal morbidity. Women who present in preterm labor should not be treated with tocolytic agents, as they do not improve the fetal prognosis and expose the mother to additional risk. Every effort should be made to avoid cesarean delivery, and cephalocentesis may be required to facilitate decompression of an enlarged fetal head and allow vaginal delivery.[15]

Other Intracranial Tumors

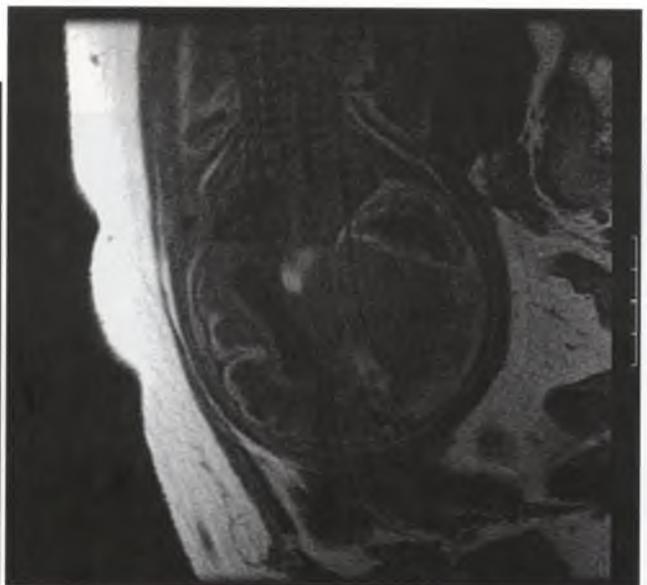
Neuroepithelial tumors predominate the miscellaneous group of other intracranial tumors. The most common types include astrocytomas, medulloblastomas, choroid plexus papillomas, and gliomas. Although less common, mesenchymal tumors such as meningioma and craniopharyngioma are also reported in the perinatal period.[8] These tumors are usually sporadic, and frequently are isolated. Some intracranial masses are associated with genetic syndromes such as neurofibromatosis or tuberous sclerosis. Neurofibromas and cortical tubers are reported on


FIGURE 23–1
A large intracranial mass with solid and cystic components, as well as calcification, was noted in this fetus at 28 weeks' gestation. The mass measured approximately 5 × 3 × 7 cm and caused compression of the ventricular system and development of ventriculomegaly. A fetal MRI was obtained to better define the extent of the lesion. The mass appeared to be arising from the base of the brain and was associated with disruption of normal architecture.

antenatal ultrasound[20–22] and, in the setting of a family history of these disorders, suggest an affected fetus. Both neurofibromatosis and tuberous sclerosis can also be the result of a new mutation, especially in cases of advanced paternal age. Hyperechoic areas with marked vascularity on Doppler interrogation suggest an AV malformation. Although the leptomeningeal angiomatosis associated with Sturge-Weber syndrome may appear hyperechoic, other vascular malformations,[23] such as a vein of Galen aneurysm, may appear as a hypoechoic, cystic structure until Doppler mapping is performed[24] (Fig. 23–2). A rare tumor, hypothalamic hamartoma, is closely associated with Pallister-Hall syndrome; identification of a tumor in the region of the hypothalamus should therefore prompt a search for associated anomalies including polydactyly, cardiac defects, and renal defects.[25,26]

Diagnosis

Although it is not possible to render a histologic diagnosis based on imaging studies alone, several of the more frequent intracranial neoplasms have a characteristic appearance that aids identification. The differential diagnosis for an intracranial mass includes neoplastic lesions, vascular malformations, parenchymal or intraventricular bleeding, and infarction.[27] Astrocytomas, the most common neuroglial tumor of the perinatal period, typically present as an intracranial mass associated with macrocrania. These tumors display a wide spectrum of cellular differentiation. The most poorly differentiated tumors (glioblastoma multiforme) generally appear as unilateral, echogenic, rapidly growing, solid masses that cause either a shift or destruction of the normal intracranial architecture and contralateral hydrocephalus.[8,9,28] Enlargement of the tumor over a short interval suggests hemorrhage, which occurs more frequently in the perinatal period

FIGURE 23–2
A cystic, anechoic mass in the area of the brainstem was identified at 22 weeks in this fetus. Using Doppler interrogation, the lesion was identified as a vein of Galen aneurysm.

than in childhood.[10] Medulloblastomas, a primitive cerebellar neuroendocrine tumor (PNET), are highly aggressive neoplasms that originate from the cerebellar vermis and grow into the fourth ventricle and cerebellar hemispheres, giving rise to the typical ultrasound findings of an echogenic cerebellar mass, hydrocephaly, and macrocrania.[8] Metastasis via the cerebrospinal fluid or vascular route occurs in up to 18%.

Choroid plexus papillomas are histologically benign tumors in the ventricles composed of mature epithelial cells. They account for 5% of perinatal brain tumors.[7] Most commonly, choroid plexus papillomas appear sonographically as a nodular space-occupying lesion arising from the lateral ventricle, although third and fourth ventricle lesions are reported.[7,29,30] Tumor growth results in massive production of cerebrospinal fluid and severe dilation of the ventricular system.[7] These tumors have a more favorable prognosis than other intracranial neoplasms.

Although craniopharyngiomas are a relatively common tumor of childhood, they are rarely discovered perinatally. The most frequent ultrasound findings are hydramnios, a large, cystic, calcified mass in the suprasellar region, and macrocephaly. These tumors may grow quite large, replacing much of the normal brain tissue. The prognosis is poor.[7]

Neoplasms involving nearly all other intracranial tissues (e.g., meningiomas and ependymomas) are reported in the perinatal period as well, but their occurrence is less frequent.[7]

Several distinctive genetic syndromes can present with intracranial masses on the antenatal ultrasound. As noted, tuberous sclerosis is associated with multiple discrete echodense nodules in the cerebral cortex or ventricles. This finding or a family history of this disorder requires a careful search for other lesions, especially in the heart. Hypothalamic hamartomas are rare solid, echogenic tumors associated with Pallister-Hall syndrome. Other anomalies associated with this syndrome include holoprosencephaly, hydrocephaly, polydactyly, palatal abnormalities, renal and cardiac malformations, and imperforate anus. Identification of a tumor in the hypothalamic area mandates a search for these other defects.[26] Although typically not associated with antenatal cortical findings, rare patients with severe neurofibromatosis have diffuse tumor nodules throughout the entire CNS. The occurrence of multiple tumor nodules should prompt consideration of this disorder, especially if the family history is suggestive.[31]

Risks

The maternal risks are similar to those of a fetal intracranial teratoma (discussed previously). The propensity for the development of hydrocephaly and macrocrania predisposes to dystocia. The presence of hydramnios increases the risk of postpartum hemorrhage. The identification of an intracranial mass associated with a familial tumor syndrome (e.g., medulloblastoma and Gorlin

syndrome or cerebellar hemangioblastoma and von Hippel–Lindau syndrome) suggests an increased risk of malignancy in family members.

Management Options

Because teratomas overall tend to destroy normal intracranial architecture, the prognosis is universally poor. The prediction of prognosis is more difficult with other intracranial neoplasms. Choroid plexus papillomas have a more favorable prognosis than most intracranial neoplasms, with a survival rate of 73%.[7] The prognosis for astrocytomas is highly dependent on the degree of cellular differentiation but overall is poor, with only 37% survival rate. Neonates with glioblastomas or anaplastic astrocytomas have a survival rate of only 14%.[7] Medulloblastomas have a propensity to spread throughout the CNS and bloodstream, and therefore have an extremely poor prognosis with less than 10% survival rate.[7] Intracranial lesions characteristic of phakomatoses, neurofibromatosis (NF), or tuberous sclerosis are in general not predictive of the severity of disease, and their presence alone cannot be used to make predictions on long-term outcomes.

Parents should be counseled on the full differential diagnosis of the intracranial mass, and the likely prognosis discussed. Because the ultrasound examination may not completely define the extent of the lesion, MRI can provide additional information to refine the counseling.[32] Many new MRI units are capable of rapid image acquisition, eliminating the need for fetal immobilization with a paralytic agent. In general, large or rapidly growing tumors that result in distortion of normal anatomy or massive hydrocephaly with macrocrania are more likely than not to be lethal. In these cases, the option of pregnancy termination should be offered, and cesarean section should be avoided wherever feasible.

SUMMARY OF MANAGEMENT OPTIONS			
Intracranial Tumors			
Management Options	Quality of Evidence	Strength of Recommendation	References
Intracranial Teratoma			
Supratentorial location and macrocephaly are common. Teratomas are the most common type of lesion; they cause destruction of normal brain tissue and have a dismal prognosis. Prognosis is variable for other tumor types.	III	B	8,10
MRI may be useful in evaluation of nature and extent of lesions.	III	B	32
Exercise vigilance for maternal respiratory compromise, preterm labor, premature rupture of membranes, and abruption in the presence of hydramnios, preeclampsia, or hydrops.	–	GPP	–
Counsel about poor prognosis. Most reported cases have been lethal. Consider termination.	III	B	8,15,17,19
Ongoing pregnancies should be managed with the goal of reducing maternal morbidity.	–	GPP	–
Cesarean delivery or cephalocentesis may be required if macrocephaly develops.	III	B	8,15,17,19
Other Intracranial Tumors			
Manage as for teratoma.	–	GPP	–
MRI may be helpful to further delineate intracranial anatomy.	III	B	32
Fetal prognosis is difficult to estimate. Large tumors associated with hydrocephalus or hemorrhage are likely to be lethal. Some tumors, however, have a fairly good prognosis. The prognosis of tumors associated with genetic syndromes depends on the syndrome itself.	III	B	7–10
Practical options for pregnancy are termination or continuation with vigilance for maternal respiratory compromise, preterm labor, premature rupture of membranes, and abruption in the presence of hydramnios, preeclampsia, or hydrops.	–	GPP	–
Cesarean section may be necessary, if macrocrania is found.	–	GPP	–

FACIAL TUMORS

Facial tumors most commonly involve the orbits, the paranasal sinuses, the tongue, the nasopharynx, and the oropharynx. Teratomas are the most frequent tumor type, but mesenchymal tumors are also encountered.

Orbital Tumors

The antenatal diagnosis of an orbital tumor is infrequent. The differential diagnosis includes a number of non-neoplastic entities such as encephalocele, vascular malformation, orbital cyst, and lesions of the conjunctiva, eyelid, and lacrimal apparatus. In addition, conditions that cause structurally shallow orbits, such as craniosynostosis, can cause proptosis and give the appearance sonographically of an orbital mass.

Diagnosis

An orbital teratoma presents as a unilateral mass arising within the orbit that both displaces the globe and enlarges the bony orbit. The globe may have degenerative changes and appear small because of compression by the tumor mass. As with other teratomas, both solid and cystic components are present, but there is no evidence of communication between cystic areas of the orbital tumor and the intracranial cavity.[33] These tumors occur twice as often in females and are more common on the left side.[34]

Retinoblastomas are the most frequent intraorbital tumors of childhood and usually present as intraocular tumors. Only rarely are these tumors large enough to visualize on an antenatal sonogram. However, giant congenital retinoblastomas protruding from the orbit are reported and can present as an exophytic, solid mass that may compress and destroy the normal ocular structures.[35]

Tumors arising within the ocular apparatus are also reported antenatally. Medulloepithelioma, a malignant tumor arising from the ciliary body, has an exophytic appearance and mixed cystic-solid composition that may mimic the appearance of a teratoma.[36] Massive retrobulbar orbital cysts, with subsequent orbital compression and microphthalmia, have also been diagnosed antenatally.[37]

In addition to intraocular tumors, epibulbar tumors can present as orbital masses. The most common epibulbar tumor is an epibulbar dermoid, a cystic lesion that contains pilosebaceous epithelial elements. Epibulbar dermoids are associated with Goldenhar syndrome and should raise the index of suspicion for this disorder.[38] Epibulbar vascular malformations are also reported.

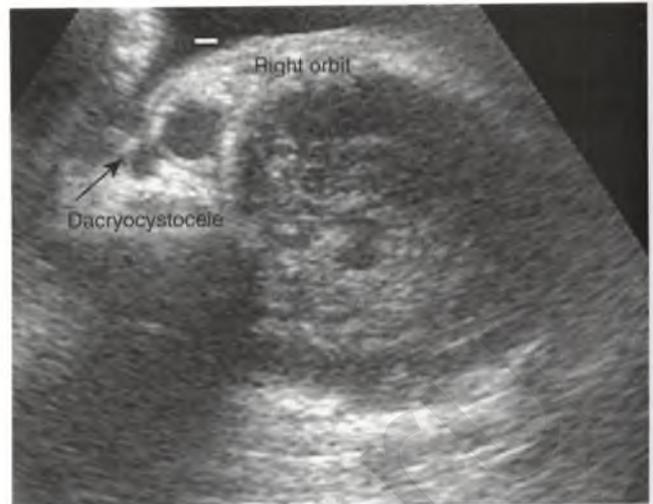
Dacryocystocele secondary to obstruction of the lacrimal duct is reported antenatally; it has a characteristic cystic appearance and is located along the inferomedial border of the fetal orbit[39] (Fig. 23-3).


FIGURE 23–3
A cystic area between the nasal bone and the right orbit was identified on ultrasound in the midtrimester. The differential diagnosis included encephalocele, epibulbar dermoid, and dacryocystocele. At birth, the overlying skin had a bluish tinge characteristic of a dacryocystocele.

Risks

Orbital tumors are unlikely to result in a pregnancy complication or increased maternal risk. The degree of fetal risk depends on the nature of the lesion, as even some benign lesions can compromise future visual potential. Retinoblastomas diagnosed during the perinatal period are commonly due to a hereditary germline mutation in the retinoblastoma gene (a tumor suppressor gene) or a deletion of chromosome 13q; these mutations predispose to the development of other malignancies in addition to retinoblastoma.[40]

Management Options

The tumor type and size and degree of impingement on surrounding structures determine the prognosis of orbital tumors. In general, orbital teratomas have a favorable prognosis; even large lesions that require enucleation of the ipsilateral eye tend to have mature elements and an exceedingly low recurrence rate.[33,34] The prognosis for malignant orbital tumors such as retinoblastoma depends on the degree of spread outside the globe, and the presence of any associated anomalies or a chromosome disorder. A karyotype is indicated once the diagnosis of retinoblastoma is suspected.[35] In addition, parents should be counseled regarding the potential for postnatal treatment. Epibulbar tumors and abnormalities of the lacrimal apparatus have a favorable prognosis for survival and normal vision.[38,39] The management of pregnancy is unaltered, and cesarean delivery is reserved for the usual obstetric indications unless the lesion is large and exophytic and likely to cause dystocia or hemorrhage.

Nasal and Oral Tumors

Tumors of the nasal and oral cavities are rare and are most often teratomas.

Diagnosis

Teratomas of the nasopharynx and oropharynx originate from the sphenoid bone, the hard or soft palate, the jaw, or the tongue, and on ultrasound they typically appear as complex heterogeneous masses that protrude from the fetal mouth.[41–46] A subset of oropharyngeal teratomas are highly organized in appearance with recognizable organs suggestive of a parasitic twin; these tumors carry the special appellation of epignathus.[42,47] The location of these tumors can prevent fusion of the palatal shelves, resulting in a cleft palate, and up to 9% of cases are associated with other organ system anomalies.[41] The size and location of these tumors may cause hydramnios by occluding the pharynx or impeding fetal swallowing.[41,42,44,45] The maternal serum AFP was elevated in several cases.[41–44,46]

Other facial tumors in the nasal and oral regions are reported. There is one antenatal description of a nasal hemangiopericytoma, a rare tumor derived from the contractile cells of the capillary walls found in nasal tissues around the nasal cartilage and anterior skull base. The mass presented as an enlarging vascular mass visible on ultrasound examination.[48] Mesenchymal tumors of the paranasal sinuses are reported, as are granular cell tumors of the gingiva.[49,50] Leiomyoma of the tongue was reported in the neonatal period, and should be included in the differential diagnosis of oropharyngeal masses along with teratomas, hemangiomas, ectopic thyroid, and mesenchymal sarcoma.[51]

Risks

The majority of nasopharyngeal and oropharyngeal teratomas obstruct the oral cavity, interfere with fetal swallowing, and cause hydramnios.[41,42,44] Hydramnios increases the maternal risk of preterm labor, respiratory compromise, and postpartum hemorrhage. For fetuses with large teratomas, there is a significant risk of malposition of the fetal head and dystocia leading to cesarean section.[44]

Although these tumors may be massive in size at birth, most are benign and have a low risk of recurrence after appropriate surgical resection.[41,44] The greatest risk to the fetus is respiratory distress resulting from an inability to establish a patent airway. Arteriovenous shunting through the teratoma's large vascular bed is rare but reported with pharyngeal teratomas; shunting can lead to placentomegaly, high-output cardiac failure, and fetal hydrops with a maternal risk of Mirror syndrome.[44]

Management Options

A large tumor mass within the nasopharynx or oropharynx can impede normal gas exchange, and in some cases, tumor may extend into the trachea so that even if an oral airway is attainable, respiration is still impaired. In the case of large pharyngeal masses, especially if hydramnios is present, delivery coordination with a team including an anesthesiologist, neonatologist, and pediatric surgical specialist may prove lifesaving. The ex utero intrapartum treatment (EXIT) procedure, described and refined by a number of physicians since the early 1990s, allows either endotracheal intubation or tracheostomy to be performed while the placental and umbilical cord circulation is maintained.[42,47,52–54] General anesthesia is used to maximize uterine relaxation and fetal anesthesia, a hysterotomy is performed, and the fetus is partially delivered to the level of the shoulders to provide access to the fetal neck. Endotracheal intubation can then be attempted, either with a laryngoscope or fiberoptic endoscope; if unsuccessful, tracheostomy can be performed while the infant remains on placental support.[42,47,52–54] Some advocate having extracorporeal membrane oxygenation equipment in the operating suite in cases in which the tumor might distort the normal anatomic landmarks.[54,55] Fetoplacental circulation has been maintained for more than 50 minutes after delivery of the fetal head and shoulders, during which time fetal oxygen saturation is easily monitored with reflectance pulse oximetry.[52,53,56]

A substantial number of women will present in preterm labor associated with hydramnios. The presence of these tumors is not a contraindication to either therapeutic amniocentesis or tocolysis, as most of these infants have a favorable long-term prognosis if they survive the perinatal period and initial surgical resection. Prematurity is not a contraindication to the EXIT procedure.[52,53]

Greatest risk to the fetus is severe respiratory compromise at delivery. Coordination of delivery with appropriate specialists can significantly improve the outcome. If tracheal occlusion is anticipated, delivery should be by cesarean section in cooperation with pediatric and surgical consultants to assure prompt intubation, tracheostomy, or tracheoplasty. In some perinates, an ex utero intrapartum tracheoplasty (EXIT procedure) may be required. Some advocate ECMO (extracorporeal membrane oxygenation) to be available at the same time in theater.	III	B	42,47,52–54

NECK TUMORS

Masses in the fetal neck can be divided into those occurring anteriorly or posteriorly. The differential diagnosis depends on the location of the mass. Anteriorly, the most common diagnoses are goiter, thyroid/thyroglossal duct cyst, teratoma, nonseptated cystic hygroma, and branchial cleft cyst.[57] Posteriorly, the differential diagnosis includes nuchal edema, cystic hygroma, meningomyelocele, and rarely teratoma.[58] Structures in the anterior neck are usually small and barely discernible on antenatal ultrasound, so abnormalities involving the thyroid are often readily apparent. Most thyroid masses are solid and represent a goiter often associated with maternal Graves' disease and fetal thyrotoxicosis[57] (Fig. 23–4). The fetal neck is usually in a neutral position and freely mobile; any deviation, such as hyperextension, should prompt an investigation of possible etiologies because of the propensity for airway obstruction.[57] Nonseptated cystic hygromas are small cystic masses located in the antero-

FIGURE 23–4
A large goiter identified in a fetus exposed to propylthiouracil for treatment of maternal Graves' disease.

lateral region of the fetal neck (Fig. 23–5). In contrast to posterior hygromas, they have no clear association with lymphatic abnormalities, and there is controversy regarding their association with anomalies and aneuploidy.[57] One report, however, documents an increased risk of aneuploidy and cardiovascular anomalies with both anterior and posterior hygromas.[59]

Teratoma

Although cervical teratomas are the most common fetal neck tumor, only about 5% of all teratomas are located in the fetal neck.[60,61] Extragonadal teratomas are believed to develop during early gestation when all three germ layers are in close approximation.[62] Historically, a distinction has been made between cervical and thyroid teratomas, depending on the presence or absence of thyroid tissue in the tumor and the presence of a normal thyroid gland, but this distinction is arbitrary.[63] These tumors can achieve a massive size prior to birth and significantly distort the anatomy in the neck, face and even thorax, but only rarely have malignant components or metastatic foci been reported.[64-69] When present, neuroglial cells are the most commonly identified immature elements.

Diagnosis

As with teratomas in other locations, derivatives of all three germ layers are present, and on antenatal ultrasound the lesion has a characteristic appearance with large solid and cystic areas extending from the anterior surface of the neck[64–69] (Fig. 23–6). Calcification within the mass occurs in 40% to 50%.[57,65,69] Although maternal serum AFP is not routinely helpful in diagnosis, those with endodermal sinus derivatives may produce AFP. Hydramnios complicates 25% to 55% of cases, especially those with large tumors causing esophageal and tracheal occlusion, and may provide a clue to the extent of the lesion.[57,64,69]

Risks

As with pharyngeal tumors, the risk of hydramnios increases the maternal risk of preterm labor, respiratory compromise, and postpartum hemorrhage. The most substantial neonatal risk is respiratory distress due to an inability to obtain an airway, leading to hypoxia and resultant neurologic injury.[66] The overall survival rate with modern surgical care is 85% to 95%, even with large tumors. However, the most important prognostic factor is the ability to accomplish a complete surgical

FIGURE 23–5
A large anterior cystic hygroma was identified as an isolated defect in this fetus. The lesion resolved as gestation progressed.

resection of the tumor,[66,69] which may not be possible in all cases owing to the involvement of vital structures. Although antenatal ultrasound can readily detect and identify these masses, a fetal MRI may allow better definition of involved structures. This information could be important for counseling and delivery management.[69,70]

Management Options

The size of the tumor and the resulting hyperextension of the fetal neck frequently cause dystocia and necessitate cesarean delivery. Because of the potential for airway complications, an EXIT procedure should be anticipated, and the delivery coordinated with a multidisciplinary team as described for pharyngeal tumors. Surgical resection is usually performed as soon after birth as possible to avoid loss of a previously secure airway. Although an operative mortality rate of 10% to 15% was reported in the past, more recent series note exceedingly low mortality rates.[65,66] The risk of morbidity due to operative injury to the thyroid and parathyroid glands, the neck vessels, and the recurrent laryngeal nerve remains significant, but an excellent functional and cosmetic result can be expected in 70% of cases.[66]

Cystic Hygroma

Cystic hygromas are malformations of the lymphatic system that appear as either single or multiloculated, fluid-filled, membranous cysts often in the occipitocervical area. The hygroma may be small, simple, and transient or may be large, multiseptated, and persistent. These lesions result from the jugular lymphatic obstruction sequence, in which either the normal communication between the jugular lymphatic sacs and the jugular veins fails to form by 40 days' gestation, or there is an overall lymphatic hypoplasia.[71,72] If the lymph sacs eventually connect with the venous system or an alternative route of lymphatic drainage develops, the cystic hygroma can spontaneously resolve. However, stigmata, such as low posterior hairline and neck-webbing, may persist.[71]

Diagnosis

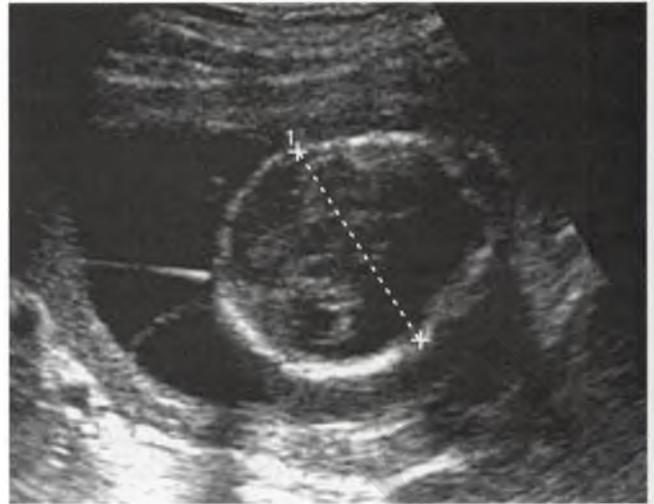
Ultrasound allows ready diagnosis of cystic hygroma. Their location in the posterolateral portion of the neck and their cystic appearance are considered characteristic, but they must be distinguished from other potential abnormalities in this region. The differential diagnosis includes encephalocele, meningomyelocele, and the rare posterior teratoma[58,71] (Fig. 23–7). Nuchal translucency or edema may represent the most mildly affected end of the spectrum of the lymphatic obstruction sequence. It can be distinguished from a cystic hygroma by examining for a more subtle and continuous distribution of subcutaneous fluid (usually less than 10 mm in thickness) versus a larger and usually multiseptated process in cystic hygromas.[58] Cystic hygroma is associated with either an


FIGURE 23–7

A multiseptated cystic hygroma was identified in this fetus at 17 weeks' gestation. The hygroma extended from the occiput to the level of the thoracic spine.

elevated maternal serum AFP or a multiple marker maternal serum test indicating an increased risk of trisomy 21, usually as the result of elevated human chorionic gonadotropin (hCG).[73,74] Other anomalies may be detected in part because of the association with fetal aneuploidy. Associated cardiac anomalies, particularly aortic coarctation and hypoplastic left ventricle, may occur as the enlarged thoracic duct impinges on the developing heart.[75] The development of hydramnios or hydrops may reflect fetal cardiac decompensation which lowers the chances for resolution or survival.[71]

Risks

Between 50% and 75% of fetuses with cystic hygromas are aneuploid; Turner syndrome (45,X and variants) accounts for 75% of the aneuploidies.[71,76] The remainder are autosomal trisomies, especially chromosomes 13, 18, and 21.[77] Noonan syndrome, multiple pterygium syndrome, and the Klippel-Feil sequence are each associated with cystic hygroma, as are abnormalities related to environmental exposures such as fetal alcohol syndrome.[71,77] Associated congenital heart defects are relatively common, as already noted.[77,78] Hydrops occurs in 50% to 90% of fetuses with cystic hygroma, and is associated with an exceedingly low survival rate.[77,79,80] Dysmorphic changes or structural abnormalities in adjacent organs may occur as the result of pressure from lymphatic dilation that alters normal morphogenesis. Dilated lymph sacs cause elevation, protrusion, and angulation of the ear, redundant skin in the nuchal region, and altered patterns of hair growth. Dilated lymphatic channels near the heart increase the resistance to blood flow through the ascending aorta, leading to left-sided hypoplastic cardiac lesions encountered with cystic hygromas.[75,77,78]

Management Options

Once a cystic hygroma is identified, a thorough anatomic survey including fetal echocardiography should be performed and a karyotype determination offered. Counseling and pregnancy management are guided by the presence of other malformations and the fetal karyotype. Because the prognosis for a fetus with a large, persistent cystic hygroma and hydrops is dismal, the option of preg-nancy termination should be offered. If the hygroma decreases in size or resolves, the overall prognosis is more favorable. In general, nonseptated cystic hygromas are more likely to resolve than septated lesions (98% versus 44%) and have a higher survival rate (94% versus 12%).[80] Fetuses with persistent cystic hygromas should be scanned periodically for hydrops. Cesarean section should be avoided once a fetus with a cystic hygroma develops hydrops because of the poor prognosis.

THORACIC TUMORS

Primary tumors of the fetal lung are rare, and most diag-noses are made during the neonatal period.[81] Primary pulmonary tumors reported in the perinatal period include pulmonary blastoma, fibrosarcoma, myofibro-matosis, and hemangiomas. Metastatic lesions, especially from hepatoblastoma, neuroblastoma, or Wilms' tumor, are more frequently encountered.[82] Other mass lesions detected within the lung fields during the perinatal period include vascular malformations, congenital lobar emphysema, and bronchogenic cysts.[83]

Mediastinal and thoracic wall masses are also reported. The differential diagnosis of a mediastinal mass includes bronchogenic cyst, neurenteric cyst, esophageal duplica-tion cyst, diaphragmatic hernia, pericardial cyst, lym-phangioma, teratoma, and neuroblastoma.[84] Chest wall masses include hemangiomas, lymphangiomas, and mes-enchymal tumors.

Diagnosis

Bronchogenic cysts result from abnormal budding of the bronchial tree between weeks 4 and 8 of gestation and usually lack a normal connection to the tracheobronchial tree.[85,86] Bronchogenic cysts typically appear sonograph-ically as fluid-filled cystic areas located either within the pulmonary fields or the mediastinum, most commonly in

the subcarinal area. The antenatal detection of a chest wall mesenchymal hamartoma is reported. The lesion had a heterogenous sonographic appearance and filled the right hemithorax.[87] With metastatic lesions, the primary tumor is often identifiable in another organ system. Approximately 15% of neuroblastomas (see later discussion) are located in either the thoracic cavity or mediastinum. On ultrasound, the lesions can appear either solid with calcification or cystic, which is more common, making the diagnosis problematic.[88–91] Thoracic neuroblastomas tend to be diagnosed at an earlier stage than their intra-abdominal counterparts, and therefore have a better prognosis. Chylothorax attributed to compression of pulmonary lymphatics by a mediastinal tumor is also reported.[88] Lymphangiomas can occur in either the anterior or posterior mediastinum.

Vascular malformations in the pulmonary tree may be part of a genetic syndrome that is associated with multiple hemangiomas such as Osler-Weber-Rendu syndrome. They appear similar to other vascular malformations, displaying hyperechogenicity on routine ultrasound with marked vascularity on Doppler interrogation.

Risks

Regardless of its etiology, any lesion that creates a mass effect within the fetal thorax has the potential to alter pulmonary development and cause hydrops by deviating the mediastinum and obstructing cardiac return. An intrathoracic mass can not only affect the ipsilateral lung by direct compression, but if large enough to cause a mediastinal shift, it may compress the contralateral lung.[92] Compression of the trachea and esophagus can cause hydramnios independent of cardiac function,[93] and hydramnios increases the risk of preterm labor. The ultimate prognosis for the infant depends on the nature of the tumor, its resectability, the degree of lung involvement, and the extent to which pulmonary development is impeded by the mass effect. One study concludes that hydramnios and mediastinal shift are poor prognostic indicators.[94]

Management Options

The progressive growth of a bronchogenic cyst can lead to hydrops as well as bronchial abnormalities.[85,86] Percutaneous drainage via repeated thoracentesis or thoracoamniotic shunt placement is reported.[95,96] The shunt will relieve hydrops only if secondary to mediastinal shift. It is unclear whether a shunt improves outcome in the absence of hydrops. MRI may assist the evaluation of large or atypical chest masses.[97] Because of the potential for respiratory compromise, fetuses with thoracic lesions should be delivered at a center prepared for appropriate fetal resuscitation and support.

TUMOR-LIKE CONDITIONS OF THE LUNG

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is a developmental anomaly of the lung consisting of abnormal tertiary bronchioles. Most lesions are unilateral, but up to 15% have bilateral components.[98] These bronchioles display either hamartomatous changes, or an arrest in embryologic development with the formation of cystic lesions of various sizes.[93,98] They usually communicate with the bronchial tree. The blood supply for a CCAM derives from the pulmonary circulation.

Diagnosis

CCAM lesions are classified by their histologic appearance: type 1 lesions account for more than 50% and are composed of a small number of large cysts; type 2 lesions make up 40% and are composed of multiple small cysts; and type 3 lesions are microcystic, homogenous, solid-appearing masses[99] (Fig. 23–8). Recently, Adzick and associates proposed a simplified approach based on the antenatal sonographic findings. Macrocystic lesions contain single or multiple cysts that are at least 5 mm in diameter, whereas microcystic lesions have cysts less than 5 mm in diameter and appear more solid and echodense.[92,100] The differential diagnosis reflects whether there is a predominant cystic or solid component. For cystic lesions, the differential diagnosis includes diaphragmatic hernia, bronchogenic or enteric cysts, bronchial atresia, neuroblastoma, anterior meningomyelocele, and teratoma. While diaphragmatic hernia and neuroblastoma remain in the differential diagnosis for solid lesions, the most difficult distinction is often between a microcystic type 3 lesion and bron-

FIGURE 23–8
A type 2 CCAM was identified in this fetus. Although there was evidence of mediastinal shift and mild cardiac deviation, the CCAM decreased in size during gestation, and the fetus was asymptomatic at birth.

chopulmonary sequestration. Demonstration that the blood supply comes from the aorta is consistent with sequestration and excludes a diagnosis of CCAM.[76,92] Fetal MRI can provide additional anatomic detail to assist in achieving a definitive diagnosis, especially distinguishing CCAM from diaphragmatic hernia—two lesions often confused on ultrasound alone.[101,102]

Risks

The antenatal natural history of CCAM is variable, and the prognosis is guided by the size and type of the mass, the progression or regression of the mass, and the presence of cardiac axis deviation, hydrops, and associated anomalies. Although initial reports suggested that solid lesions have a worse prognosis than cystic lesions, more recent study suggests the overall size of the mass is more important than the composition of the mass.[76] However, the different composition may reflect a difference in cellular growth and thereby may influence lesion size. Large lesions that cause cardiac deviation and compression of the great vessels, esophagus, or trachea, leading to hydrops and hydramnios, clearly have a worse prognosis. Without antenatal intervention, the development of hydrops is a harbinger of fetal demise.[92,103] In addition, large lesions may cause compression of normal lung tissue and produce pulmonary hypoplasia. Up to 40% of fetuses develop hydrops, and up to 70% develop hydramnios. Crombleholme and colleagues described a technique for measuring the size of the CCAM that generates a volume ratio and then applied the ratio to predict the likelihood of hydrops developing.[103] Approximately 15% of CCAM lesions shrink in utero with resolution of any mediastinal shift. Although many of these lesions appear sonographically to involute or "disappear," this appearance may be due in part to changes in tissue echo texture, as postnatal radiographic or antenatal MRI studies confirm the persistence of at least some lesions.[92,97,102] In the absence of hydrops, more than 90% survive with most lesions resectable postnatally.[92,98]

Although 26% of fetuses had associated anomalies in Stocker's original report, a more recent series observed that only 2% of fetuses with CCAM had associated anomalies.[92,104] This raises questions regarding the diagnostic accuracy of the original series. The women whose fetuses develop hydrops or hydramnios are at increased risk for preterm delivery, Mirror syndrome, postpartum hemorrhage, and respiratory compromise.

Management Options

A complete anatomic survey is required to rule out associated malformations, determine the size and type of lesion, and detect any cardiac deviation or evidence of hydrops. Karyotype determination should be offered especially if there are associated structural malformations; otherwise, the yield is low. If multiple anomalies are detected or hydrops is identified, the family should be counseled regarding the poor prognosis and the option of pregnancy termination offered. In ongoing pregnancies, serial ultrasound studies to identify evolving hydramnios or signs of hydrops are indicated. Corticosteroids for pulmonary maturation followed by delivery are options after consultation with neonatal, pediatric surgery, and maternal-fetal medicine specialists should hydrops develop at a gestation when survival is possible. The delivery of any viable fetus with a persistent thoracic mass should occur at a tertiary center prepared for potential neonatal respiratory compromise.

The management of a pregnancy in which the fetus either develops hydrops at previable gestational age or whose large lesion is compressing the ipsilateral lung and therefore increasing the risk of pulmonary hypoplasia is more problematic. In fetuses with hydrops, the mortality rate is 100% with expectant management, so novel fetal therapy might be warranted. In a number of reports, decompression of large dominant cyst by thoracentesis or thoracoamniotic shunt placement has successfully reversed the mediastinal shift, pulmonary compression, and hydrops; survival rates of 80% to 90% after such a procedure are reported.[92,95,103] The initial procedure should be thoracentesis with cyst drainage, for in some cases the cyst resolves completely.[103] If the fluid rapidly reaccumulates, shunt placement can be considered (see Chapters 10 and 25). The utility of shunts is limited by occlusion or dislodgment, which occurs in up to 29% of cases.[105]

Thoracoamniotic shunt placement is ineffective for the treatment of multicystic and solid lesions. When these lesions are large and associated with hydrops, antenatal fetal surgery is an option. Adzick and associates described the outcomes of 13 hydropic fetuses with CCAM who underwent antenatal resection of an abnormal pulmonary lobe at 21 to 29 weeks' gestation.[92] Eight (62%) survived. Crombleholme and associates reported only two of seven (29%) similar fetuses surviving antenatal surgery.[103] Fetal surgery is limited to a few centers worldwide and is associated with considerable risks including chorioamnionitis, preterm premature rupture of the membranes, preterm labor, postoperative infection, pulmonary edema, and anesthetic complications, as well as an unstable uterine scar with the need for cesarean delivery in all subsequent pregnancies. As surgical techniques and the ability to identify fetuses at highest risk improve, the survival rate will likely improve.

Bronchopulmonary Sequestration

Bronchopulmonary sequestration is an isolated mass of lung tissue that lacks communication with the tracheobronchial tree and derives its blood supply from the systemic circulation, usually from the aorta or a major branch. The lesion is thought to result from a

supernumerary lung bud that arose caudal to the normal lung bud and migrated with the esophagus.[93,106] Lesions that develop early in embryogenesis are surrounded by the adjacent lung tissue and covered by the same pleura. These are termed intralobar sequestrations. In contrast, those that develop later grow separately from the lung and become covered by their own pleura. These are termed extralobar sequestrations. The lesions are typically unilateral, with left-sided lesions being twice as common as right-sided. Although intralobar lesions typically involve the lower lobe of the lung, extralobar regions may be found between the lower lobe and the diaphragm, within the diaphragm, in the mediastinum, or below the diaphragm. Intralobar lesions are more common than extralobar in infants and children, but extralobar lesions predominate in the fetus and neonate.[107–110]

Diagnosis

Bronchopulmonary sequestration appears sonographically as a solid, highly echogenic, homogenous mass. Confirmation of a systemic vascular supply using color-flow Doppler is diagnostic.[111] It can be very difficult to distinguish a sequestration from a microcystic CCAM if the vascular supply cannot be identified. It is usually not possible to determine sonographically whether an intrathoracic sequestration is intralobar or extralobar. The differential diagnosis of an intrathoracic sequestration includes microcystic CCAM, diaphragmatic hernia, teratoma, and neuroblastoma. For extralobar lesions, the differential diagnosis includes neuroblastoma and renal tumors. Although it is usually possible to sonographically demonstrate the well-demarcated boundaries of sequestrations, an MRI can in some cases help to identify other conditions that can present with a solid echogenic mass in the lower thorax such as diaphragmatic hernia with liver herniation.[97]

Risks

The prognosis for bronchopulmonary sequestration is variable, although large sequestrations can cause pulmonary compression, mediastinal shift, and hydrops. The presence of hydrops is the most important prognostic sign. In one series published in the early 1990s, only 36% of fetuses survived, and all fetuses with hydrops (35% of all cases) died. The incidence of hydramnios was 80% and isolated pleural effusion 70%.[107] A more recent experience of 39 continuing pregnancies with bronchopulmonary sequestration reported 100% survival of nonhydropic fetuses.[92] Only four fetuses developed hydrops and the only death occurred in the one fetus not treated antenatally.[92] Significantly, 72% of sequestrations regressed or resolved spontaneously and were asympto-

matic at birth.[92] Postnatal imaging revealed residual evidence of the lesions. Regression appears more common with extralobar sequestration, possibly because the separate pleural investment allows torsion on its vascular pedicle.[112, 113] Intra-abdominal extralobar bronchopulmonary sequestration is rarely associated with hydrops and has a better prognosis than intrathoracic lesions.

Even in the absence of a significant mediastinal shift, fetuses with bronchopulmonary sequestration may develop hydrothorax. This phenomenon is more common with extralobar lesions, possibly as the result of lymphatic and venous obstruction due to torsion.[107] The pressure gradient between the systemic artery and pulmonary vein and the resultant left-to-left shunting has been postulated as an explanation with intralobar lesions.[114]

Associated anomalies of the foregut are reported with bronchopulmonary sequestration, and reflect the embryologic derivation of this lesion from an abnormal outpouching of the foregut. These associated anomalies include tracheoesophageal fistula, esophageal duplication, diaphragmatic hernia, funnel chest, and cardiac defects. Additional malformations occur more commonly with extralobar lesions (58%) than with intralobar lesions (14%).[115–117]

Management Options

Once the diagnosis of bronchopulmonary sequestration is suspected, a complete anatomic survey to search for other anomalies and rule out any signs of incipient hydrops is required. Although the majority of intrathoracic lesions will regress to some degree, the possibility of hydrops justifies serial ultrasound examinations. If the lesion is large and associated with either hydrothorax or hydrops, antenatal therapy may be considered, given the otherwise dismal prognosis. Weekly thoracentesis and thoracoamniotic shunt placement are reported to effectively treat hydrops and pleural effusion when there is a mediastinal shift, but do not address the underlying lesion. Any fetus that fails to respond to these therapies, or has hydrops due to a large lesion without a significant pleural effusion, can be considered a candidate for in utero resection of the lesion. The maternal risks of such intervention should be carefully weighed against the potential fetal benefit.[92,93,106,118–120]

Isolated intra-abdominal bronchopulmonary sequestrations have a better prognosis than intrathoracic masses because these lesions do not cause pulmonary compression and hypoplasia. Like those above the diaphragm, regression occurs. Hydramnios may occur secondary to esophageal or gastric compression preventing fetal swallowing. All fetuses with bronchopulmonary sequestration should be delivered at a tertiary center equipped for appropriate resuscitative and treatment measures.

CARDIAC TUMORS

Primary cardiac tumors are rare, with a reported frequency of 2.7 per 10,000 infants and young children; the prevalence in utero is unknown.[121] Cardiac rhabdomyoma is the most common cardiac tumor detected in infancy, comprising 62% of cases, followed by teratoma in 21%, fibroma in 13%, and only rarely hemangioma, myxoma, or sarcoma.[122-124]

Diagnosis

Rhabdomyoma is thought to be a hamartoma and not a true neoplasm. It can be solitary or multiple, and located within any of the cardiac chambers or the myocardial wall (Fig. 23–9). The sonographic appearance of rhabdomyoma is of a discrete echogenic mass, but whether the mass is mobile or fixed depends on the location.[125,126] Rhabdomyomas can be isolated, but they are

FIGURE 23–9
A cardiac lesion consistent with a rhabdomyoma was identified in this fetus at 24 weeks' gestation. The mass continued to grow during gestation, and at birth occupied most of the left ventricle. Several smaller lesions were noted in the myocardial wall on postnatal echocardiogram. Clinical examination revealed findings consistent with tuberous sclerosis.

more frequently found in association with tuberous sclerosis. Fifty-one percent to 86% of neonates born with cardiac rhabdomyomas will subsequently be diagnosed with tuberous sclerosis. Conversely, these lesions may be found in 50% to 60% of patients with tuberous sclerosis.[125,127,128] The tumors associated with tuberous sclerosis are typically multiple and range in size from 3 to 25 mm.[125] The differential diagnosis includes fibroma, myxoma, and sarcoma, although these lesions are less common in the fetus.

Pericardial teratomas appear sonographically similar to teratomas in other locations—a complex echogenic mass with cystic and solid components and occasional calcifications.[129] These tumors are located outside the heart, attach to the base of the heart and great vessels via a broad stalk, and are usually on the right. In nearly all cases, a pericardial effusion is present that assists in narrowing a differential diagnosis that includes mediastinal teratoma, extralobar bronchopulmonary sequestration, and CCAM. Pericardial effusion rarely occurs in isolation with the later conditions.

Risks

All cardiac tumors are space-occupying with the potential to cause hemodynamic compromise and hydrops due to obstruction of normal blood flow through either the cardiac chambers or the great vessels. This risk depends on the number, size, and location of the tumors.[122] The prognosis for fetuses with a cardiac tumor and hydrops is dismal. Pediatric patients with intramural tumors are at increased risk for cardiac arrhythmias such as ventricular tachycardia and Wolff-Parkinson-White syndrome. The tumor (especially rhabdomyomas, which have embryonal components and conductive capability) is believed to

act as an accessory conduction pathway.[125,126,130,131] Whether fetuses have a similar risk is unstudied. Cardiac tumors are also associated with several genetic syndromes including Beckwith-Wiedemann syndrome, tuberous sclerosis, Gorlin (basal cell nevus) syndrome, and neurofibromatosis. A detailed sonographic anatomic survey by an expert should be performed to search for these stigmata.

Tuberous sclerosis is an autosomal dominant disorder, though approximately two thirds result from new mutations. Most mutations are in the *tuberin* or *hamartin* genes on chromosomes 16 or 9, respectively. Commercial testing for these mutations is not currently available, but consultation with a geneticist is recommended because a mutation can be identified in some families and commercial testing may become available in the future. Although the disorder has 95% penetrance, there is markedly variable expressivity, and evaluation by a geneticist can help confirm or refute the diagnosis. If a cardiac rhabdomyoma is identified or suspected, a professional familiar with the disease diagnostic criteria should carefully evaluate both parents and the fetus's siblings. Children diagnosed with tuberous sclerosis are at risk for mental retardation and seizures, but it is not possible to predict mental function accurately based on either the antenatal findings or the family history. It is suggested that children with cortical tubers or subependymal nodules are more likely to have unremitting seizures and severe mental retardation. Fetal MRI has been used to identify these findings which may not be visible on ultrasound.[132,133]

Management Options

The fetus with a cardiac mass should undergo serial sonographic examinations in search of either developing hydrops or an arrhythmia. If hydrops develops at a gestational age when survival is expected, the administration of antenatal corticosteroids followed by delivery should be considered. Should hydrops develop prior to viability, the option of pregnancy termination may be offered. Absent hydrops, the prognosis for the fetus with a cardiac mass is favorable, and the pregnancy should be managed expectantly. Delivery should be planned at a tertiary center capable of providing pediatric cardiac surgical intervention in the immediate perinatal period if necessary. Intrauterine pericardiocentesis is reported to relieve cardiac tamponade with a successful outcome of pregnancy in a fetus with pericardial teratoma and a pericardial effusion.[134,135] The majority of cardiac rhabdomyomas spontaneously regress after birth.[125,126,131] For this reason, intervention is considered only in the presence of hemodynamic compromise. All true cardiac tumors should be evaluated postnatally and surgical resection planned. Although malignant components have only rarely been identified in pericardial teratomas, all become symptomatic eventually, thus justifying surgical therapy.[129,136,137]

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Tumors

Management Options	Quality of Evidence	Strength of Recommendation	References
Determine the tumor type and likely diagnosis; search for US markers of syndromes.	–	GPP	–
Because the most common fetal cardiac tumor is rhabdomyoma, the diagnosis of tuberous sclerosis must be strongly considered. Linkage studies may help to confirm a familial case, but no genetic test is available to diagnose cases due to a new mutation. Counseling is difficult. Fetal MRI may detect brain abnormalities that are not visible by ultrasonography. Referral to a geneticist for counseling is suggested.	III	B	132, 133
Serial sonographic surveillance is warranted to rule out hydrops and arrhythmias; in the absence of hydrops, prognosis is favorable, often with spontaneous regression.	III	B	122
If hydrops develops, timing affects response:			
Hydrops before fetal viability should prompt counseling and consideration of pregnancy termination.	–	GPP	–
If pericardial effusion with tamponade develops, pericardiocentesis is necessary.	III	B	134, 135
Preterm delivery with maternal steroids is indicated if early signs of hydrops and gestational age is acceptable.	–	GPP	–
Tumors can resolve after birth; surgery is indicated for those that persist with hemodynamic compromise.	III	B	125, 126

US, ultrasound.

ADRENAL TUMORS: NEUROBLASTOMA

Neuroblastoma is the most common malignant congenital tumor, with a prevalence of 0.6 to 2.0 per 100,000 live births. It originates from the neural crest cells that migrate along each side of the spine and give rise to the adrenal medulla and the sympathetic ganglia. Although tumor can begin anywhere along this path, the most common location is intra-abdominal, involving the adrenal gland. Other locations include the neck, thorax, and pelvis.[138] More than 90% of antenatally diagnosed neuroblastomas are adrenal in origin.[139]

Normal adrenal development can be difficult to distinguish in the fetus from neuroblastoma. Neuroblasts normally mature in the fetus to form ganglion cells referred to as neuroblastoma in situ, with a prevalence of 1 in 250 at term. The development of a clinical neuroblastoma represents a defect in the cellular maturation and differentiation. This defect is thought to be temporary in some cases and accounts for the 15% to 20% rate of spontaneous regression.[140]

Diagnosis

The sonographic appearance of adrenal neuroblastoma is variable, ranging from cystic with a thick-walled complex to solid with hyperechogenicity and foci of calcification.[89,139–142] Approximately 40% to 50% of antenatally diagnosed neuroblastomas have a cystic appearance, which may represent a stage of involution.[139] Doppler flow mapping may aid the diagnosis, as the nest of tumor cells is highly vascular, and the pulsatile flow observed in such tumors is suggestive of neovascularization.[143] Other lesions in the differential diagnosis include adrenal hemorrhage, renal mass, and intra-abdominal extralobar pulmonary sequestration. Adrenal hemorrhage is rare antenatally, and the neonatal diagnosis is frequently prompted by hemorrhage into nests of tumor cells.[89,140] Antenatal adrenal hemorrhage is also reported with Beckwith-Wiedemann syndrome, which is characterized by omphalocele and macroglossia.

Metastases occur frequently in utero and can be visualized with sonography. Hepatic metastases are most common, seen in up to 25% of fetuses with near total replacement of the hepatic parenchyma reported in some instances.[139,140] Other sites of metastasis include the retroperitoneal lymph nodes, bone marrow, umbilical cord, and skin. Although nearly 90% of children with neuroblastoma have elevated urinary levels of vanillylmandelic acid (VMA) or homovanillic acid (HVA), only 30% to 35% of prenatally diagnosed cases have elevated urinary levels when measured postnatally. Although the

measurement of maternal urinary VMA or HVA has prompted diagnosis in a few instances, the yield is relatively low.[139]

Hydramnios or fetal hydrops is reported in association with neuroblastoma, and may be the findings that prompt the initial sonographic examination at which time the diagnosis is made. The precise mechanism is unknown, but possibilities include fetal anemia due to bone marrow infiltration, fetal arrhythmia due to catecholamine excess, placental vascular obstruction due to tumor metastases, and vena caval obstruction due to tumor compression.[138-140] In rare cases, the presenting complaints are maternal signs of catecholamine excess such as hypertension, coagulopathy, renal abnormality, or hepatic abnormality.[144,145] Several genetic disorders associated with abnormalities of neural crest derivatives—Beckwith-Wiedemann syndrome, DiGeorge syndrome, and CHARGE association—are associated with neuroblastoma. In addition, a familial form of neuroblastoma is described. Thus, a prior affected child should prompt antenatal screening of subsequent pregnancies.[82,146]

Risks

The prognosis for the fetus depends on tumor stage and the clinical manifestations of the disease. Although the survival rate in children older than 1 year at diagnosis is only 10% to 20%, the survival rate in neonates is greater than 90%.[89,138-140] The presence of fetal hydrops is strongly correlated with advanced disease and markedly increases the risk of the mother developing preeclampsia. In a series of 21 fetuses with an antenatal diagnosis of neuroblastoma collected from the literature, three fetuses developed hydrops. All had advanced stage disease, and all three mothers had preeclampsia. Two of the three died antenatally.[140]

The prognosis for a fetus with either stage I or stage IV tumors (metastases involving liver, skin, or bone marrow) is excellent with survival rates of 90% or better after resection of the primary lesion. The high survival rate reflects the tendency for these tumors to undergo spontaneous regression.[89,139] The prognosis for stages II and III disease is poor, but fortunately they are rare.

Tumor hemorrhage and rupture during labor are reported, but their occurrence is rare. Because dystocia can develop when the fetus has massive hepatomegaly, the abdominal circumference should be regularly monitored by ultrasound in fetuses with metastatic disease; cesarean section is an option should the abdominal circumference be markedly enlarged.[138,147–149]

Management Options

Most women whose fetus has neuroblastoma are relatively asymptomatic. Serial ultrasound examinations are indicated to assess tumor size, amniotic fluid volume, and fetal growth, and to seek evidence of developing hydrops. Careful surveillance for evidence of maternal hypertension is critical. In the setting of fetal hydrops, the decision to deliver is based on the gestation and the potential for survival. In fetuses younger than 32 weeks' gestation, antenatal corticosteroids may be administered to enhance pulmonary maturity prior to delivery. If maternal symptoms of preeclampsia develop, delivery should be seriously considered regardless of gestation. Any fetus suspected of having a neuroblastoma should be delivered at a tertiary center where the appropriate support staff is readily available. The appropriately grown fetus without evidence of fetal or maternal compromise may be delivered vaginally at term.

SUMMARY OF MANAGEMENT OPTIONS Neuroblastoma			
Management Options	Quality of Evidence	Strength of Recommendation	References
Evaluate for hydramnios, hydrops, maternal clinical features (hypertension/preeclampsia, hydramnios, abdominal distention); measurement of maternal urinary catecholamines may help confirm diagnosis.	III	B	140
Delivery may be the only effective treatment. The decision to deliver must include consideration of gestational age, the likelihood of fetal viability, and the maternal condition; use steroids if preterm.	—	GPP	—
Neuroblastomas have a high propensity for metastasis but a high rate of spontaneous regression postnatally.	III	B	139
Take serial measurements of fetal abdominal circumference: a very large renal mass may cause dystocia, necessitating cesarean delivery.	IV	C	138
Prognosis is based on tumor stage. Most cases of fetal neuroblastoma are stage I. Prognosis is generally good.	III	B	139

RENAL TUMORS

Although renal tumors in the neonate are rare, accounting for only 5% of all perinatal tumors, renal masses account for 70% of all abdominal masses in the perinatal period.[150] The majority of these masses are hydronephrotic or multicystic dysplastic kidneys.[4,150] Despite their low frequency, renal tumors are often identified antenatally because of the relative ease with which the kidneys are visualized sonographically. The most common renal tumors are congenital mesoblastic nephroma (renal hamartoma) and Wilms' tumor (nephroblastoma).

Diagnosis

Congenital mesoblastic nephroma is a benign renal lesion composed of spindle cell mesenchymal elements that grow between intact nephrons and replace normal renal parenchymal.[151] It is the most common renal tumor in neonates and is distinguished from Wilms' tumor by its benign clinical behavior.[4] Sonographically, these lesions usually appear as a solid mass without a distinct capsule. However, occasional cystic changes, nodular densities, or diffuse enlargement of one kidney are reported.[138] A fundal height larger than expected for dates may be the finding that initiates further evaluation, as the majority of the antenatal cases reported were associated with hydramnios.[3,4,151] The mechanism of the hydramnios is unclear, but increased renal blood flow, impaired renal concentrating ability, and impaired gastrointestinal motility due to a mass effect are all implicated.[138] The differential diagnosis includes hydronephrosis and multicystic dysplastic kidney (which can usually be excluded because of their predominantly cystic nature), Wilms' tumor, and metastasis from hepatic and adrenal gland malignancies. Wilms' tumor often cannot be distinguished from mesoblastic nephroma antenatally; a histologic examination may be required for diagnosis.[4,138,152] These tumors are isolated findings without associated anomalies.

Wilms' tumor appears sonographically very similar to congenital mesoblastic nephroma, except a distinct capsule may be identifiable. This tumor is believed to be derived from the metanephric blastema, which is the embryonic precursor of nephrons and the renal interstitium.[4] It typically is unilateral (95%) and does not cross the midline.[152] Associated congenital anomalies are common, and Wilms' tumor is described as a component of several genetic syndromes or associations, including WAGR (Wilms' tumor, aniridia, genitourinary malformations, and mental retardation) syndrome due to an 11p13deletion, and VATER (vertebral malformations, imperforate anus, tracheoesophageal fistula, limb abnormalities, and renal abnormalities) association.[153] It is also associated with several over-growth syndromes including Beckwith-Wiedemann syndrome, Sotos (cerebral gigantism) syndrome, Perlman (nephromegaly, hydramnios, macrosomia, cardiac defects, and diaphragmatic hernia) syndrome, and Simpson-Golabi-Behmel (coarse facies, cardiac defects, islet cell hyperplasia, vertebral abnormalities, and vestigial tail) syndrome.[154,155] A sonographic suspicion of nephromegaly or the family history for any of these disorders requires a detailed sonographic examination and careful postnatal surveillance for the development of an obvious tumor mass (if not already present). Fewer than 1% of Wilms' tumor cases are familial with autosomal dominant inheritance. However, 20% of familial cases are bilateral, compared to only 3% of sporadic cases, thus warranting a thorough postnatal evaluation of both kidneys.[156]

Risks

Congenital mesoblastic nephroma is commonly associated with hydramnios. High renin levels are reported and hyper-reninism may precipitate fetal hypertension and rarely hydrops. Other potential causes of hydrops include obstruction of the portacaval circulation, arteriovenous shunting through the tumor, and hemorrhage into the tumor with resulting fetal anemia.[3,138,151] The prognosis for an affected fetus depends on the identity of the mass and the presence of hydrops or associated anomalies. Simple nephrectomy is usually curative with an isolated congenital mesoblastic nephroma. Fetuses with associated anomalies should be carefully evaluated to determine if the constellation of findings represents a defined genetic syndrome. An amniocentesis for karyotype may be warranted. The prognosis for Wilms' tumor depends on the stage of disease at diagnosis. Survival after surgery and adjuvant therapy is greater than 90% when disease is confined to the area of the kidney, as is usual for prenatally diagnosed tumors.[155] The prognosis for the hydropic fetus is more guarded.

Management Options

Because the majority of solid renal tumors are congenital mesoblastic nephromas with a benign clinical course, pregnancy should be allowed to go to term. Periodic sonographic examinations are indicated to monitor fetal growth and amniotic fluid volume and to rule out any signs of developing hydrops. Delivery should be contemplated if hydrops develops at a gestation when survival is expected. Before 32 weeks antenatal corticosteroids should be considered prior to delivery.[138] Dystocia is reported in cases with large renal masses. Cesarean section may be considered if the abdominal circumference is markedly enlarged.

HEPATIC TUMORS

Primary liver tumors are rare in the fetus. Embryologically, the liver is derived from endodermal and mesodermal anlagen and is the potential site for a wide spectrum of neoplasms and other lesions that mimic neoplastic processes.[157] The most frequently identified lesions in the perinatal period are hemangioendothelioma, hemangioma, mesenchymal hamartoma, and hepatoblastoma. The differential diagnosis for hepatic mass lesions includes these lesions as well as metastatic lesions and polycystic liver disease.

Diagnosis

Hemangioendothelioma and hemangioma are vascular tumors derived from endothelial cells forming vascular channels. A hemangioendothelioma has focal or diffuse hypercellular areas, whereas a hemangioma contains flat, inconspicuous endothelium with dilated vascular spaces.[157] Hemangioendothelioma is the most common hepatic vascular lesion in the perinate, but hemangioma is the most common vascular lesion in all age groups. These lesions have a variable sonographic image, appearing hypoechogenic, hyperechogenic, or mixed, depending on the degree of fibrosis, hypercellularity, and the degree of involution.[138] Hepatomegaly and multifocal lesions are seen. Doppler study of the lesion provides confirmation of its vascular nature. Large vascular spaces within the mass are frequently seen with hemangioendotheliomas, and dominant feeding or draining vessels may also be identifiable.[158] Hydramnios is reported, and may be due to either arteriovenous shunting or gastrointestinal tract compression. Midtrimester maternal serum AFP levels are frequently elevated.[158]

Mesenchymal hamartomas are composed of connective tissue stroma, serous cysts, bile ducts, hepatocytes, and angiomatous components.[4,159] These lesions typically have a complex sonographic appearance, with irregular solid and cystic components that can become enlarged and calcified.[160] Hepatoblastoma is the most common hepatic malignancy in the first year of life when 50% to 60% of all hepatoblastomas present. Although hepatoblastoma is believed to develop in utero, fewer than 10% of tumors are detectable antenatally.[4] Sonographically, these lesions are solid-appearing with occasional calcifications. Approximately two thirds involve only one liver lobe, though occasionally only diffuse hepatic enlargement causing abdominal distention may be seen.[161] Although approximately 80% to 90% of childhood or adult patients with hepatoblastoma have an elevated AFP level, the maternal serum AFP levels are not apparently useful for a fetal diagnosis.[4,161]

Risks

Although hemangioendothelioma and hemangioma are benign tumors, they are associated with life-threatening perinatal complications such as hydrops secondary to high-output congestive heart failure and arteriovenous shunting, a consumptive coagulopathy due to platelet sequestration (Kasabach-Merritt syndrome), or hemoperitoneum from intrapartum hepatic rupture. Cutaneous hemangiomas and hemangiomas in other sites, such as the eye, are reported in 40% to 45% of children with hemangioendothelioma.[157,158] There also appears to be an association between hemangioendothelioma and placental chorioangioma, the latter often associated with hydramnios and hydrops.[162] Although the majority of lesions regress and involute during early infancy, the size of the lesion and the degree of arteriovenous shunting will determine the antenatal risk of complications such as hydramnios, hydrops, and preterm delivery. The prognosis for the fetus that remains free of hemodynamic compromise is excellent; the prognosis is poor if hydrops develops.[163]

Rapid growth of mesenchymal hamartomas characterized by enlargement of the cystic components is common and increases the risk of hydrops. Of 13 antenatally diagnosed cases in the literature, 5 were complicated by hydrops or maternal preeclampsia, necessitating delivery; the perinatal mortality rate was approximately 25%.[160] Intrauterine drainage of the cystic lesions has not proved beneficial because drainage into the abdominal or amniotic cavity does not decrease fluid production and may actually precipitate hemodynamic compromise. Further, most cysts are multiloculated and not amenable to a single drainage procedure. In the asymptomatic fetus delivered near term, the prognosis is favorable after surgical resection. Owing to a propensity for spontaneous regression, some pediatric surgeons recommend a conservative, observational strategy.[160]

Hepatoblastoma is a locally invasive tumor that can on occasion metastasize to the lung, brain, adrenal gland, and placenta. Large tumors are associated with hydramnios and hydrops due to a combination of factors including gastrointestinal obstruction, anemia from tumor hemorrhage, compression of the hepatic vasculature and inferior vena cava, and possibly decreased colloid oncotic pressure secondary to altered hepatic synthetic capabilities.[161] Hepatoblastoma, as well as adrenocortical and Wilms' tumors, can occur in association with Beckwith-Wiedemann syndrome; 1% of patients with this syndrome develop hepatoblastoma.[157] Other anomalies associated with hepatoblastoma include hemihypertrophy in 2% to 3%,[157] trisomy 18, Schinzel-Giedion syndrome (congenital heart defects, midface retraction, hypertrichosis, and embryonal malignancies), trisomy 21, and genitourinary abnormalities.[138] There are few reports of antenatally diagnosed hepatoblastoma, and the prognosis for these lesions is uncertain, but it appears dismal in the setting of hydrops.[161,164,165] Complete surgical resection is possible in 40% to 75% of patients, and the survival rate in this group is 60%. The prognosis is poor if complete resection is not possible due to infiltrative disease or metastatic lesions.[4,166]

Management Options

Once a hepatic mass is identified, serial sonographic studies are indicated to monitor fetal status, tumor size, and amniotic fluid volume. Although the ideal mode of delivery is unclear, there are case reports of intrapartum rupture of large hepatic masses with subsequent fetal death.[138,164] It seems reasonable to consider cesarean delivery in cases of marked hepatic enlargement leading to abdominal distention. However, the risks of operative delivery need to be carefully considered in the context of the fetal prognosis. If the fetus has no signs of decompensation, delivery occurs at term. The role of intratumor injection of corticosteroids is uncertain.[235]

INTRA-ABDOMINAL CYSTS

Although these cysts are not strictly tumors, the identification of a cyst or cysts in the fetal abdomen raises concern. A wide variety of cystic masses are detectable in the fetal abdomen including ovarian, mesenteric, urachal, choledochal, renal, hepatic, and splenic cysts. Enteric duplication, bowel obstruction, and meconium pseudocyst may also present as cystic lesions.[167] The location, size, and appearance of the cyst usually suggest the diagnosis.

Ovarian cysts are common. Approximately 95% are unilateral, and the majority are benign, functional cysts that occur in response to maternal hormones and resolve spontaneously after delivery. Sonographically, an ovarian cyst appears as a regular, hypoechoic structure in the lower abdomen. Septations or solid components may be seen if torsion or hemorrhage has occurred. Rarely, a cyst may become so large as to impinge on other organs, cause ovarian torsion and subsequent infarction, or result in dystocia. Ultrasound-guided in utero aspiration of large cysts is reported and may reduce these risks.[168,169]

Choledochal cysts represent a dilation of the common bile duct arising from either a weakness in the wall of the bile duct, or from a developmental anomaly and distal obstruction elsewhere in the biliary tree, especially at the junction of the pancreatic and common bile ducts.[170] These cysts have a prevalence of 1 in 2 million live births, and occur more frequently in females and Asians.[171,172] Sonographically, it appears as a simple, anechoic cyst in the upper abdomen, usually medial to the fetal gallbladder. Occasionally, a tubular structure is seen at the junction of the right and left hepatic ducts or the cystic and common bile ducts (Fig. 23–10). This lesion is not associated with an increased rate of either fetal or maternal complications.[173] However, the patency of the biliary tree must be evaluated in the neonate as it is impossible to distinguish biliary atresia from a choledochal cyst on ultrasound.[170,174,175] All infants with these lesions require surgical treatment and reconstructive surgery of the biliary connections. However, the long-term prognosis with appropriate surgical treatment is excellent.

Solitary cysts are occasionally identified in the hepatic parenchyma. These lesions are usually small and unilocular. Embryologically, they are thought reflect interruptions in the development of the intrahepatic biliary tree, and frequently resolve spontaneously.[167]

Bowel atresia or stenosis may produce cystic dilation of bowel segments proximal to the obstruction. Megacystis-microcolon-intestinal hypoperistalsis syndrome, an autosomal recessive disorder associated with vacuolation and degeneration of the smooth muscle in the bowel and bladder walls, may present as multiple cystic structures in the abdomen that represent dilated segments of proximal small intestine and bladder. No specific antenatal intervention is required. However, hydramnios may develop

FIGURE 23–10
A choledochal cyst was identified in this fetus at 20 weeks' gestation. The cyst was located in the common bile duct.

depending on the degree and level of obstruction. A pediatric surgical evaluation should be obtained after birth prior to the initiation of enteral feeding should bowel atresia be suspected.

Mesenteric and omental cysts represent the benign proliferation of ectopic lymphatic ducts that lack communication with normal lymphatic channels. They occur most commonly in the small bowel mesentery, but can occur anywhere in the gastrointestinal tract. Most of these lesions are asymptomatic antenatally and do not require specific intervention, although there is one report of an enteric cyst associated with hydrops (cause and effect unlikely).[176] Postnatally, enlarging lesions may cause partial bowel obstruction, but the prognosis following surgical resection is excellent.[177] Enteric duplication cysts have a similar sonographic appearance and can only be distinguished postnatally.

Most cysts do not require intrauterine intervention.			
Delivery should be in a tertiary center because neonatal surgery may be required.	–	GPP	–

SACROCOCCYGEAL TERATOMA

Sacrococcygeal teratoma (SCT) is one of the most common tumors of the perinatal period with a prevalence of 1 in 35,000 to 40,000 live births. It is four to nine times more common in females than males.[60,138,178–181] Like teratomas in other locations, these tumors contain elements derived from all three germ cell layers. Sacrococcygeal tumors are believed to arise from either Hansen's node or from ectopic primordial germ cells.[179–181] The majority of sacrococcygeal teratomas diagnosed perinatally are benign, but malignant degeneration reportedly complicates up to 10%, especially when there is a delay in resection or when the tumor is not entirely resected.[179–181] Lesions with foci of immature cells are described in 10% to 15% of cases.[182,183]

The American Academy of Pediatrics (AAP) has adopted a staging system for sacrococcygeal teratomas that grades the involvement of intrapelvic structures and hence the complications associated with surgical resection.[184] Type I tumors, the most common type, are predominantly external and protrude from the perineal region with minimal, if any, presacral component. Type II lesions are primarily external, but have a significant intrapelvic portion, whereas type III lesions are primarily intrapelvic with a small external component. Type IV tumors are completely presacral with no external component.

Diagnosis

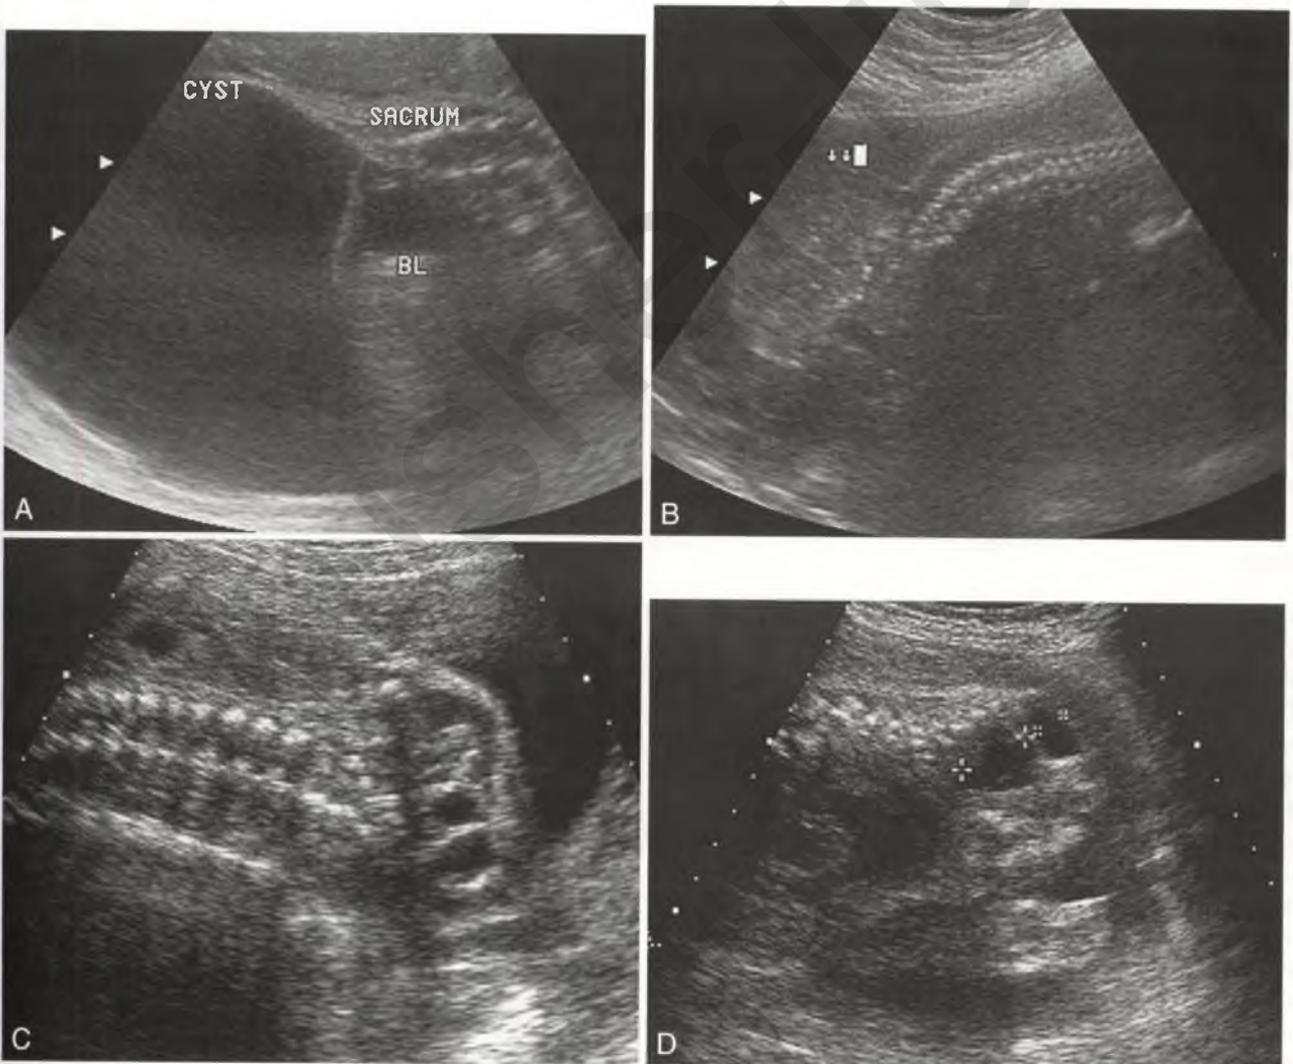
Teratomas have a similar gross appearance regardless of their site of origin, and are generally well circumscribed without direct invasion of adjacent tissues. The most common appearance is that of a complex mass, although predominantly solid or cystic masses are also described. The most common location is caudal and dorsal in close proximity to the coccyx[180] (Fig. 23–11). Teratomas with


FIGURE 23–11
Different types of sacrococcygeal teratomas. *A,* Type 1 lesion—the tumor is entirely extrapelvic; this tumor is predominantly cystic. *B,* Type 1 lesion—although the tumor is entirely extrapelvic, it is more solid appearing. *C,* Type 2 lesion—the predominant portion of the tumor is extrapelvic, but intrapelvic portions are visible. *D,* Type 4 lesion—the tumor appears to be located entirely within the fetal pelvis with no external component evident.

a significant intrapelvic component can compress the urinary and gastrointestinal tracts. Fluid-filled anechoic areas may be visualized proximal to the obstruction. Immature teratomas tend to have a more solid than cystic appearance.[60] Doppler interrogation of the tumor confirms the highly vascular nature. The feeding vessels have blood flow velocities similar to the descending aorta and may have a diameter similar to the external iliac arteries.[185] The middle sacral artery and branches of the internal iliac artery are usually the main sources of blood and, because of the augmented blood flow, are often easily identified antenatally.[181,186,187] The differential diagnosis includes meningomyelocele, hemangioma, lipoma, and other rare soft tissue tumors. A lumbosacral meningomyelocele is differentiated from teratoma based on the presence of spinal dysraphism and intracranial changes that are typically absent with sacral teratoma. Hydramnios, placentomegaly, and fetal hydrops are associated with sacrococcygeal teratomas containing arteriovenous malformations.[179,185]

The incidence of associated anomalies is uncertain, and ranges in the literature from 0% to 35%.[3,178,184,188,189] Certainly, a detailed anatomic survey with special focus on skeletal/vertebral anomalies is obligatory. Defects in the area of the tumor, such as distal sacral agenesis, rectovaginal fistula, and imperforate anus, are reported and likely related to tumor growth during gestation.[189] Aneuploidy has not been reported with sacrococcygeal teratoma, and amniocentesis for a karyotype is not usually indicated.[138] Maternal serum AFP levels may be elevated, especially in those tumors with foci of endodermal sinus tumor. The amniotic fluid AFP and acetylcholinesterase levels may also be elevated.[190–192] MRI can aid ascertainment of intrapelvic involvement. This information is useful in both counseling the parents and planning surgical resection.[193,194]

Risks

The prognosis for antenatally diagnosed SCT differs from that of postnatally diagnosed lesions, with estimates of mortality rate ranging from 12% to 68%.[178,185,195–197] The main causes of perinatal death are hydrops, intrapartum trauma, and postnatally either difficulties with resection or hemorrhage secondary to tumor vascularity.[179] Hydrops may result from the inability of the heart to adequately perfuse the fetus, placenta, and tumor. An arterial steal syndrome often develops if the tumor contains arteriovenous malformations and blood is preferentially shunted to the tumor. The fetus may develop high-output failure due to limited cardiac pumping ability and anemia secondary to sequestration of blood volume in the tumor.[181,185] Because larger tumors require greater blood flow, fetuses with large, vascular, and especially solid tumors are more likely to develop hydrops[179,183,185] compared to those with predominantly cystic lesions associated with low blood flow.[182] The

mortality rate is greater than 90% if hydrops develops.[178,179,185,197–199]

Other predictors of poor outcome include a second trimester diagnosis and delivery before 34 weeks' gestation.[179] The risk of preterm delivery correlates with the size of the tumor and the presence of hydramnios, both of which increase uterine distention.[182] In a compilation of 104 cases from the literature, Brace and associates noted that survival increased from 25% for fetuses delivered before 34 weeks' gestation to 88% for those born after 34 weeks' gestation. Survival was half as high when the diagnosis was made prior to 30 weeks' gestation (41% versus 84%).[179] Not only are large tumors associated with an increased risk of hydramnios, hydrops, and prematurity, but they are also associated with an increased risk of dystocia, intrapartum injury, hemorrhage, or rupture, regardless of the mode of delivery.[178–180,183]

The most important variable affecting long-term outcome is the adequacy of tumor removal.[60] The presence of a substantial presacral component is associated with a worse prognosis because of the complexity involved with resection. Optimal treatment consists of an en bloc removal of the tumor and coccyx, but with extensive presacral involvement, this cannot always be accomplished. Although both mature and immature teratomas are equally resectable, there is a greater risk of intraoperative hemorrhage with an immature teratoma, reflecting its increased vascularity. The identification of frankly malignant elements, especially endodermal sinus or embryonal cell tissue, markedly worsens the prognosis. If the primary tumor is not completely resected, there is an increased risk for recurrence, often with malignant components.[60]

Management Options

Counseling should be provided at the time of diagnosis when the evaluation including MRI is complete. If the tumor is identified at an early gestational age or is associated with hydrops, the option of termination of pregnancy should be offered. Serial antenatal sonographic examinations are indicated to assess fetal well-being and to evaluate tumor growth. If hydramnios develops, amnioreduction may improve maternal symptoms and delay the onset of preterm delivery. If preterm labor develops, tocolysis can be attempted. The efficacy of magnesium as a tocolytic is at best unclear, and in this setting coexistent hydramnios may intensify maternal side effects. Indomethacin may worsen the fetal cardiovascular function by reducing renal free water clearance and premature closure of the ductus arteriosus. A calcium-channel antagonist such as nifedipine may be a superior alternative. In the fetus without evidence of cardiac decompensation, delivery is planned at or near term in a tertiary center. If signs of fetal cardiac decompensation develop after 30 weeks, corticosteroids should be administered to improve postnatal pulmonary function and delivery effected. The optimal management for the

fetus with hydrops at earlier gestational ages is unclear, but the prognosis for these fetuses is dismal.

Operative intervention to interrupt the vascular shunt in fetuses with hydrops, who are otherwise preterminal, has been attempted. Open fetal surgery with in utero debulking or complete resection of the tumor was reported in eight cases, with three long-term survivors.[200,201] Other techniques have been investigated to avoid the maternal morbidity associated with fetal surgery. Radiofrequency ablation via a percutaneously placed electrode was reported in four fetuses; two died after the procedure due to intratumor hemorrhage. The hydrops reversed in the two surviving fetuses, but both were found at birth to have large areas of soft tissue necrosis requiring reconstructive surgery.[186] Further refinement is needed.

Because of the risk of intrapartum traumatic injury, rupture, and hemorrhage, cesarean delivery prior to the onset of active labor is recommended for fetuses with a SCT greater than 5 to 10 cm in diameter.[178–180,182,183] A large vertical uterine incision is required to minimize delivery

trauma which may trigger massive hemorrhage. Type O negative blood should be immediately available for the neonate. It has been suggested that a vaginal delivery may be considered if the tumor is smaller than 5 cm, with an emergent cesarean delivery should any evidence of fetal hemodynamic compromise develop.[180,187] Percutaneous aspiration of a large, predominantly cystic teratoma to facilitate vaginal delivery is reported.[202] Regardless of the mode of delivery, successful management requires the multidisciplinary efforts of maternal-fetal medicine specialists, neonatologists, anesthesiologists, and pediatric surgeons.

Neonates who are stable and have no complications of prematurity will typically undergo surgical resection within the first few days of life. Although in some, surgical trauma to the sacral and pelvic nerves results in urologic or bowel dysfunction, most neonates have excellent functional and cosmetic outcomes.[181–183] The long-term prognosis is determined by the extent of intrapelvic involvement and the ability to completely resect the tumor mass.

LIMB TUMORS

Limb masses are usually either soft tissue tumors (such as fibrous connective tissue tumors, lipomas), skeletal muscle tumors, or tumor-like conditions such as vascular or lymphatic anomalies or hamartomas.

Diagnosis

Soft tissue tumors are often identified at birth or during neonatal life, but rarely reported in the fetus. In the neonate, most soft tissue limb tumors are described as a palpable mass in fascia, muscle, or subcutaneous tissue, or

a smooth, solid, asymmetrical enlargement of a digit or extremity.[4] Hemangiomas are the most common tumors diagnosed in the neonate, and although they may first appear in the late fetal period, they are rarely identified before birth.[203]

Infantile fibromatosis is a benign neoplasm of fibrous tissue that occurs in fascia, muscle, or periosteum. This lesion is a type of proliferative fibroblastic disorder difficult to distinguish from low-grade fibrosarcoma, and although locally aggressive and subject to recurrence, is not associated with metastases.[4] Digital fibromas are among the most common of these lesions, and are typically found on the medial side of digits.[203]

Fibrosarcoma and rhabdomyosarcoma are the two most common malignant soft tissue tumors. Fibrosarcoma is usually cured by local resection, but rhabdomyosarcoma has a propensity for early metastasis and has, therefore, a less favorable prognosis.[204,205]

Congenital lymphangiomas appear sonographically as multicystic masses with anechoic cyst cavities and often result in hypertrophy of the affected extremity. Because of an association with fetal aneuploidy, especially Turner syndrome, a fetal karyotype determination should be offered when a lymphangioma is suspected antenatally.[206]

Klippel-Trenaunay syndrome is a rare congenital syndrome with generalized mesodermal abnormalities including macular vascular nevus, skeletal and soft tissue hypertrophy, and venous varicosities due to abnormal small vessels.[207] Unilateral leg hypertrophy is the most frequent finding on ultrasound, but any extremity may be involved, as may an entire half of the body including the head and brain.[208,209] The finding of a complex mass in the subcutaneous tissue in the presence of hypertrophy of a limb or other body part is highly suggestive of Klippel-Trenaunay syndrome.[210] Proteus syndrome shares several features with Klippel-Trenaunay syndrome, including asymmetrical focal overgrowth, hemihypertrophy, and subcutaneous vascular abnormalities, but is distinguished by the presence of warty pigmented nevi and lipoid visceral tumors.[211] This distinction between the two conditions may not be antenatally possible if limb hypertrophy is the main clinical finding. Both syndromes have a variable prognosis.[211,212]

Risks

These tumors are unlikely to cause maternal symptoms, but vascular tumors are associated with an increased risk of fetal cardiac decompensation. Kasabach-Merritt syndrome, a consumptive coagulopathy due to intralesional clotting and platelet sequestration, occurs in superficial vascular malformations, and can be life-threatening. It is reported in the neonatal period.[207]

Management Options

Close antenatal sonographic monitoring is warranted once a lesion is suspected, not only to identify early signs of fetal compromise, but also to monitor the size of the affected area. A markedly enlarged extremity or body wall can lead to dystocia; cesarean delivery may be necessary.

Obstetric care is usually unaffected, though occasionally cesarean section may be necessary to avoid dystocia.	–	GPP	–

PLACENTAL AND UMBILICAL CORD TUMORS

Tumors of the umbilical cord and placenta are rare. Most masses identified in these structures are vascular malformations or hematomas. Although the majority of lesions are asymptomatic, some can have significant impact on pregnancy outcome.

Diagnosis

Chorioangioma is the most common benign tumor of the placenta, and is thought to be either an angioma or hamartoma derived from primitive chorionic mesenchyme.[213,214] Small lesions are found in up to 1% of placentas examined pathologically, and larger lesions are much less common. Tumors ranging in size from a few millimeters to more than 10 cm have been reported.[213]

The sonographic appearance of a chorioangioma is that of a solid or complex mass on the fetal surface of the placenta (Fig. 23–12). Doppler interrogation will confirm the highly vascular nature of the mass and is typically required to distinguish these lesions from a placental or subchorionic hematoma.[213–216] The maternal serum AFP levels may also be elevated.[213,216]

Although exceedingly rare, placental teratomas are reported.[217–219] As with other teratomas, the cystic and solid components appear sonographically as a complex mass.

Other solid masses identified in placental tissue include metastases from fetal and maternal primary tumors, especially melanoma.[220,221] Although antenatal identification of such lesions has yet to be described, they should be considered in the differential diagnosis of solid placental masses when the clinical scenario warrants.

The most commonly identified umbilical cord masses are hematomas, true cysts, and pseudocysts. An umbilical cord hematoma appears sonographically as a cylindrical solid mass occluding the umbilical vein. Doppler studies may reveal turbulent flow in the area of the hematoma. True cysts in the umbilical cord are remnants of the omphalomesenteric duct or allantois, and are usually located near the fetal end of the umbilical cord (Fig. 23–13). Pseudocysts are more common, and represent localized degeneration and edema of Wharton's jelly. Although they can occur anywhere along the umbilical cord, they are usually near the fetal end.[222,223] The differentiation between pseudocysts and true cysts cannot be made on sonographic findings alone. Hemangiomas of the umbilical cord and varicosities of the umbilical vein are also seen antenatally, as are teratomas. Masses located at the fetal cord insertion site must be distinguished from omphalocele.[224–227]

FIGURE 23–13
An isolated umbilical cord cyst was identified near the fetal end of the umbilical cord in this fetus. Doppler studies confirmed normal blood flow in the umbilical vessels.

Risks

If a chorioangioma is 4 cm or larger, the risk of hydramnios, and its attendant risks of preterm delivery and maternal morbidity, is at least 30%.[213] Large chorioangiomas contain significant arteriovenous shunts and are associated with an increased risk of high-output fetal cardiac failure due to sequestration of blood within the tumor. The prognosis is poor if the fetus develops hydrops.[213,214] The development of fetal hydrops increases the risk of the mother developing Mirror syndrome.[228] Chorioangioma of the placenta is often associated with cutaneous and visceral hemangiomas in the fetus.

Any umbilical cord mass that obstructs blood flow to the fetus can lead to heart failure and hydrops. Large umbilical cord hemangiomas may be associated with sequestration or shunting leading to hydrops. True cysts of the umbilical cord are associated with other anomalies including omphalocele, patent urachus, hydronephrosis, and mesenteric duct cysts.[223] Pseudocysts of the umbilical cord are also associated with multiple anomalies including omphalocele, hemangioma, and chromosome abnormalities, especially trisomy 18 (identified in two of seven fetuses with umbilical cord cysts in one study).[223] These conditions are thought to impair local fluid transport in the umbilical cord leading to edema and myxoid degeneration of Wharton's jelly.[223]

Management Options

Once a placental lesion is identified, close antenatal surveillance is essential to follow fetal well-being and observe for any evidence of cardiac decompensation. Delivery should be considered if fetal hydrops occurs after 32 weeks. At earlier gestational ages, antenatal

FIGURE 23–12
A large chorioangioma was diagnosed at 22 weeks' gestation. The tumor continued to grow over the next several weeks and the fetus developed severe hydramnios. Intractable preterm labor occurred at 29 weeks.

corticosteroids should be administered and any further management individualized. Fetal intrauterine transfusion has been performed in several cases of fetal cardiac decompensation due to chorioangioma as a temporizing measure.[229,230] Large chorioangiomas are associated with a perinatal mortality rate of 40%, and interventions attempted to decrease the arteriovenous shunting include fetoscopic coagulation, alcohol injection, and microcoil embolization of feeding vessels.[231–234] Only alcohol injection met with reported success[232,233]; more investigation is needed.

If an umbilical vein hematoma is identified, careful antenatal surveillance is required to demonstrate regression of the lesion. If the hematoma appears to be growing, delivery may be required to prevent complete occlusion of venous flow. The identification of a cystic structure in the umbilical cord should prompt a detailed anatomic survey of the fetus. Although the true incidence of chromosome abnormalities in the presence of a cystic cord lesion is unknown, karyotype analysis should be offered, especially if other anomalies are present.

Role of transfusion or sclerosing/occlusive therapies when hydrops develops is uncertain.	IV	C	229, 231, 233

CONCLUSIONS

- Fetal tumors are uncommon but important causes of pregnancy pathology.
- Antenatal diagnosis creates the opportunity to alter antenatal care and optimize delivery.
- Interdisciplinary (obstetric, fetal medicine, pediatric surgery and medicine) management in a tertiary center is advisable.
- For each case, an individualized approach is required covering:
      surveillance in pregnancy
      intervention (if necessary) in pregnancy
      timing and method of delivery
      immediate neonatal care
      definitive management of tumor

Liesbeth Lewi / Jan Deprest

INTRODUCTION

In the developed world, the incidence of multiple births has increased dramatically over the past few decades from 1/100 to about 1/60 to 1/70 deliveries, with a 40% increase in twinning rates and a three- to fourfold rise in higher-order multiple births. This rise in multiple births is largely attributable to the increased application of assisted reproductive techniques (ART), although advanced maternal age accounts for a slight increase in spontaneously conceived multiplets.[1]

In twins, about 30% are identical, or monozygotic, and 70% are fraternal, or dizygotic (Fig. 24–1). Monozygotic twins result from the fertilization of a single egg followed by early cleavage into two halves, which develop further separately. Monozygotic twins may be dichorionic diamniotic, monochorionic diamniotic, monochorionic monoamniotic, and even conjoined, depending on the time between fertilization and cleavage. The longer the time span, the more structures the fetuses will have in common. In terms of the presence of separate placentas for each twin, the time period around the third day is important. In 30% of monochorionic twins, cleavage occurs before the third day after fertilization, leading to a separate placenta for each twin (dichorionic); twins that have their own placentas are always in separate amniotic sacs and by definition diamniotic. However, in 70% of monozygotic twins, cleavage occurs after the third day, resulting in a single placenta for two fetuses (monochorionic). Rarely, cleavage takes place after the ninth day, resulting in monoamniotic, monochorionic twins. Finally, splitting after the 12th day results in conjoined twins. Dizygotic twins result from the fertilization of two different eggs, and by definition each twin has its own placenta and amniotic sac (dichorionic diamniotic) with some exceptional reports on dizygotic monochorionic twins due to fusion of two separate blastocysts, confirming the rule.[2,3] The incidence of dizygotic twins

related to polyovulation has a hereditary component and also varies with ethnic group (up to five times higher in certain parts of Africa and half as high in parts of Asia), advanced maternal age (2% at 35 years), increasing parity (2% after four pregnancies), and method of conception. In contrast, the incidence of monozygotic twins is fairly constant throughout the world at 3 to 4 per 1000 births.[4] After assisted reproductive technology (ART), the overall majority of twins are dizygotic (85%), yet 15% are monozygotic.[1] Actually, ART increases the risk of monozygotic twinning fourfold, with about 1/50 of all conceptions being monozygotic compared with 3 to 4 per 1000 of natural conceptions. Several mechanisms have been put forward to explain why these techniques predispose to embryo cleavage, such as hardening of the zona pellucida with ovulation induction, extended culture and blastocyst transfer with in vitro fertilization, micromanipulations of the zona pellucida with intracytoplasmic sperm injection (ICSI) as well as assisted hatching.[5] As for triplets and higher-order multiplets, the overall majority now result from ART and are therefore usually polyzygotic and polychorionic/ polyamniotic. Nevertheless, 5% to 10% of multiple pregnancies after ART[6] and up to 50% of naturally conceived higher-order multiplets contain a monochorionic pair.[7]

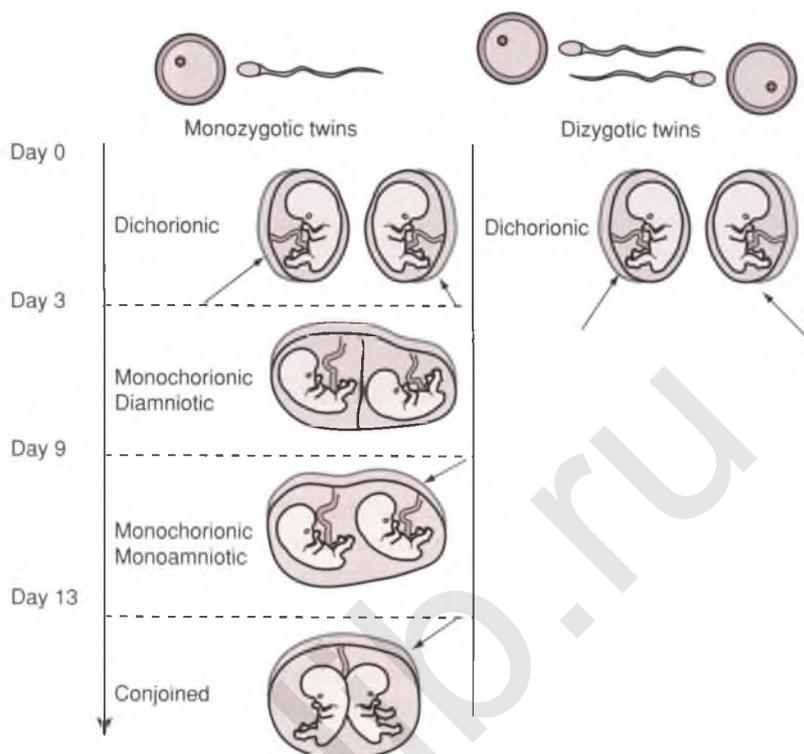
Multiplets have a more complicated in utero stay compared to singletons, with higher incidences of growth restriction, congenital anomalies, and intrauterine demise; monozygotic twins are at higher risk for complications than dizygotic twins.[8] However, at closer look, it is chorionicity rather than zygosity that determines outcome.[9] The increased morbidity and mortality rates in monochorionic twins is primarily related to the angioarchitecture of the monochorionic placenta with its almost ever-present (96%) vascular anastomoses (Fig. 24–2),[10] which are virtually absent in dichorionic twin pregnancies. These vascular anastomoses are unpredictable and randomly distributed and can cause significant blood


FIGURE 24–1

Tienen, Belgium.)

volume shifts between the fetuses, leading to unique complications such as twin-to-twin transfusion syndrome, twin reversed arterial perfusion, and acute fetal transfusion after single intrauterine death.[11] Important to some selected situations, the shared circulation precludes the injection of potassium chloride for selective feticide

into the target fetus' circulation. Furthermore, this single placenta, originally designed to support one fetus, has to care for two or more fetuses and is often not equally divided, explaining the increased incidence of poor growth in monochorionic compared to dichorionic multiplets. Consequently, the perinatal mortality rate in monochorionic twins is nearly twice as high as in dichorionic twins (2.8% versus 1.6%) and four times as high as in singletons (2.8 versus 0.7%). However, perinatal statistics underestimate the problem because the highest fetal loss rate is prior to viability. As such, monochorionic twins have a sixfold higher fetal loss rate (12%) between 10 and 24 weeks compared to dichorionic twins and singletons (2%), which is largely attributable to complications of the twin-to-twin transfusion syndrome.[12] Also, there is a direct relationship between the timing of embryo cleavage and the risk of adverse outcome, with monoamniotic and conjoined twins having the highest complication rates. Not only do multiplets pose more problems, management issues are also complicated by the fact that two or more fetuses have to be taken into account. This concern especially applies to monochorionic multiplets, in whom the well-being of one fetus crucially depends on that of the other, as their fates are invariably linked by the vascular anastomoses in the shared placenta.

Correct determination of chorionicity is therefore of vital importance to identify this high-risk group, for which increased monitoring may improve outcome. Moreover, it is essential for genetic counseling and for the management of discordant anomalies, fetal compromise, and intrauterine death of one twin. Determination of chorionicity is highly accurate when performed prior

FIGURE 24–2
Three-dimensional reconstruction of a CT-angiogram of a monochorionic placenta at term, showing an equal distribution of the placental mass and a large arterioarterial and venovenous superficial anastomosis (*arrows*) (see Color Plate 27). (In collaboration with M. Cannie, UZ Leuven, Belgium.)

to 14 weeks' gestation (100% sensitivity and 99% specificity).[13,14] At these early stages in pregnancy, the amniotic membrane is still separated from the chorion. Chorionicity determination is therefore simply a matter of counting the layers that separate the twins (Fig. 24-3). If there are two thin layers (two amniotic sacs) and two thick separate chorionic plates or one fused chorion (beyond 9 weeks) that forms a lambda at insertion on the placenta, then they are dichorionic diamniotic twins. However, if there are only two thin layers (two amniotic sacs) inserting as a T on the placental disk, then they are monochorionic diamniotic twins. Later on in pregnancy because of close apposition of the amnion and chorion and regression of the chorion laeve, it becomes far more difficult and often not possible at all to determine whether same-sex twins do or do not share a common placenta. Only examination of the placenta after birth will then give a definite answer. Therefore, failure to determine chorionicity in multiple pregnancies undergoing first-trimester scanning is considered substandard care. In contrast to chorionicity, it is not possible to determine zygosity of dichorionic same-sex twins on ultrasound

scan: about 8 out of 10 will be dizygotic, but still 2 out of 10 will be monozygotic. Only genetic examination (DNA fingerprinting) can then determine zygosity, which prenatally would require an amniocentesis of both sacs, or cordocentesis of both umbilical cords. After birth, zygosity of same-sex dichorionic twins can be determined from umbilical cord blood.

POOR GROWTH

General

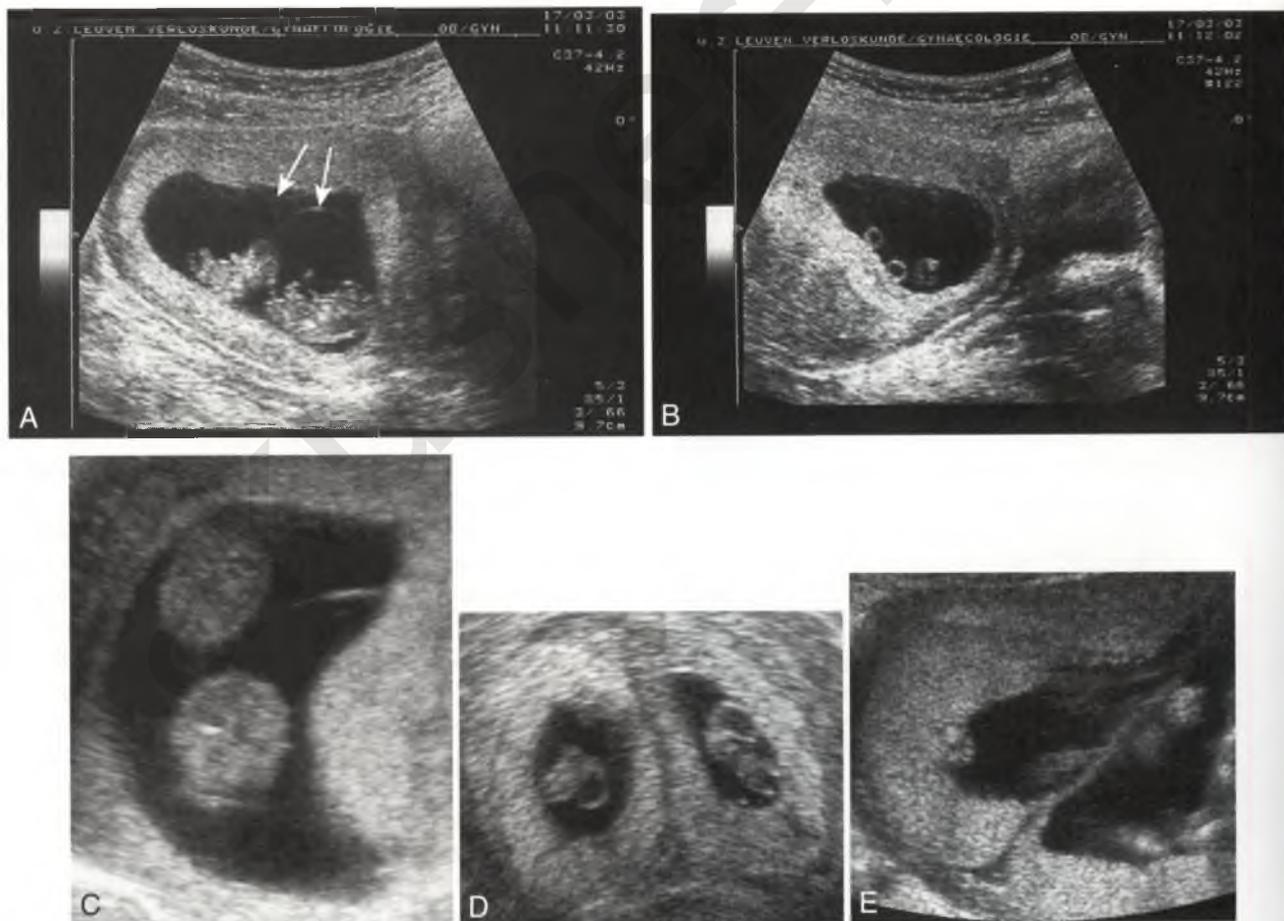
Multiplets are particularly prone to abnormal intrauterine growth, as the human uterus appears less capable of adequately nurturing more than one fetus to term.[15] Consequently, the percentage of small-for-gestational-age (SGA) babies (birth weight <10th percentile of singleton nomograms) is about 27% in twins[16] and 46% in triplets.[17] Growth curves for twins and triplets are similar to those of singletons up to 28 weeks' gestation, when the growth velocity of multiplets begins to fall. In twins


FIGURE 24-3

and triplets the average birth weight crosses the 10th percentile for singletons after 38 and 35 weeks' gestation, respectively,[15] when the majority of twins and triplets actually have already delivered.[18] Some authors consider this growth restriction physiologic and therefore advocate for the use of twin[16] or triplet[17] specific nomograms. However, twins who are SGA according to singleton standards are at equal risk of perinatal death compared to SGA singletons.[19] Thus, the concept that being small is "normal" for twins creates a false sense of security with possible deleterious consequences in this high risk population. Because the impact of size on outcome is similar for singletons and multiplets, singleton growth charts should be used for the clinical management of twin pregnancies.

Accurate pregnancy dating and knowledge of the chorionicity are essential, and both are most reliably determined in the first trimester.[13,14] Two methods are used to describe growth in multiplets: the growth of each individual fetus and the difference (Δ) in sonographic estimated fetal weight (ΔEFW) between the individual fetuses (discordant growth). A fetus is considered SGA when both the abdominal circumference and EFW are below the 10th percentile. The EFW prediction is as accurate in twins as it is in singletons.[20] The chance of both fetuses being SGA is twice as high in monochorionic (17%) as in dichorionic (8%) twins, revealing that a single placenta is less efficient for two fetuses. The rate of delivery before 32 weeks is also greater in monochorionic twin gestations in great part because of the risks of twin-to-twin transfusion syndrome (TTTS). We currently scan monochorionic twins fortnightly for growth and amniotic fluid volume, whereas dichorionic twins are scanned on a monthly basis.

The degree of discordant growth, expressed in percentages, is determined as $(A - B) \times 100/A$, where A is the weight of the heavier fetus and B is the weight of the lighter fetus. Severe growth discordancy is usually defined as a weight difference of 25% or more. It occurs in about 12% of twins[12] and 34% of triplets[21] and more commonly affects primiparous women.[22] The most accurate parameter to detect growth discordance is to compare the abdominal circumferences: a difference of more than 20 mm after 24 weeks has a positive predictive value of 83% for a birth weight difference of greater than 20% (Fig. 24–4).[23] In each pair of discordant twins, the heavier twin is usually appropriate for gestional age (AGA), whereas the lighter twin eventually becomes growth restricted.[24]

Although severe growth discordancy complicates monochorionic (11.3%) as often as dichorionic (12.1%) twins,[12] the growth pattern and underlying pathophysiology are probably different. The onset of discordant growth in monochorionic twins is unpredictable and may present early as well as late in pregnancy, whereas in dichorionic twins, discordancy usually becomes apparent only later in pregnancy.[24] Monochorionic twins are by definition monozygotic and thus have the same genetic growth potential. Occasionally, unequal allocation of

FIGURE 24–4
Ultrasound image illustrating the difference in abdominal circumference in a monochorionic twin pair with discordant growth at midgestation.

blastomeres may alter the growth potential of some monochorionic twins and account for very early discordant growth.[25]

Three factors seem to influence growth in monochorionic twins: the division of the single placenta between the fetuses, the vascular anastomoses,[26] and the effectiveness of invasion of each placental portion into the spiral arteries. These factors determine the magnitude of venous return upon which the fetus depends for its oxygen and nutritional supply. Although it remains impossible to adequately assess the venous return and functional placental territory for each individual twin antenatally, the umbilical cord insertion site provides a good estimate.[27] Placental studies reveal that the combination of a velamentous and normal cord insertion is three times more common in monochorionic than in dichorionic twins (18% and 6%, respectively). Additionally, nearly half of these monochorionic twins have a birth weight discordancy of 20% or more.[28] The site of the umbilical cord insertion can be determined sonographically between 18 and 20 weeks' gestation (Fig. 24–5)[29] and identifies a group of monochorionic twins at high risk for discordant growth. Vascular anastomoses also influence fetal growth in monochorionic twins. As such, an unbalanced net arteriovenous transfusion toward the twin with the smaller placental share may be advantageous to that smaller twin. This so-called "rescue" transfusion could explain the absence of discordant growth in some monochorionic twins with gross unequal placental sharing.[10] Finally, growth in monochorionic twins may be determined by suboptimal implantation of the placental portion of the smaller twin, as suggested by the increased resistance of the blood flow in the spiral arteries of the smaller twin's portion of the placenta.[30]

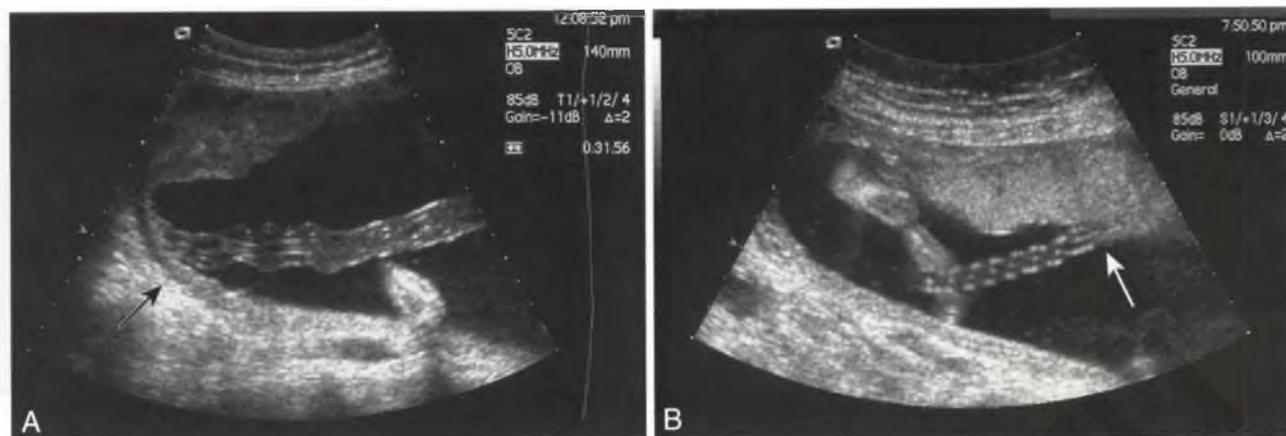
Dichorionic twins are dizygotic in about 90% of cases, and therefore a different genetic growth potential may account for discordant growth; one twin may be "normal" SGA, whereas the other may be "normal" AGA. Additionally, each twin has its own placenta without vascular anastomoses connecting the separate fetoplacental


FIGURE 24–5
Ultrasound image of umbilical cord insertion at midgestation. *A*, Velamentous cord. *B*, Nonvelamentous cord inserting in the placenta.

circulations. Suboptimal trophoblastic invasion of placenta of the smaller twin may also account for growth restriction via similar mechanisms as in singletons.[31] Furthermore, growth discordance in dichorionic twins has been found to be greater when the placentas are fused compared to those with separate placentas.[32]

Several investigators have addressed the use of uterine artery Doppler velocimetry at 18 to 24 weeks of gestation to predict intrauterine growth restriction (IUGR) in twin pregnancies,[33,34] demonstrating a disappointing sensitivity of 10%. Mean uterine artery resistance is lower in twin compared to singleton pregnancies, probably because of a larger placental implantation area. Additionally, the normally implanted portion of the placenta supplying the AGA twin may attenuate the hemodynamic effects of suboptimal implantation of the portion of the placenta supplying the SGA twin.[35]

Fetal Risks

Fetal risks associated with IUGR for multiplets are similar to singletons (see Chapter 12) and include intrauterine fetal death (IUFD) and neurologic morbidity due to chronic oxygen and nutrient deprivation. Erythropoietin levels are elevated in SGA compared to AGA twins, and in twins with discordant growth, in the lighter of twins compared with the heavier.[36] Likewise, nucleated red blood cells tend to be higher in the lighter twin compared with the larger; the difference increasing with greater discordancy.[37] These findings further support the concept that poor growth in twins is not "physiologic" but indicative of chronic fetal hypoxia. SGA dichorionic twins have similar risks of perinatal death compared to singletons, whereas the perinatal mortality rate for SGA monochorionic twins is twice as high.[19]

Growth discordancy (birth weight difference ≥25%) as well as being SGA confers an increased risk for adverse perinatal outcome. Although most discordant pairs contain one or two SGA infants,[38] discordant pairs in which both are AGA still face elevated risks compared with nondiscordant pairs[39]; twins who are both SGA and discordant have the highest risks.[40] The same applies for triplets with higher degrees of discordancy associated with increasing rates of IUFD in the smaller and middle-sized fetuses.[41]

Growth discordant monochorionic twins are at higher risk of adverse outcome than growth discordant dichorionic twins.[42] Unfortunately, most of the data reported on discordant growth in monochorionic twins are a mixture of pregnancies with twin-to-twin transfusion syndrome (TTTS) and isolated discordant growth. Although TTTS is frequently associated with discordant growth, its distinction from isolated discordant growth is essential and based on the sonographic absence of hydramnios (deepest vertical pocket ≥8 cm prior to 20 weeks, ≥10 cm after 20 weeks) in the AGA twin in cases with discordant growth (Fig. 24–6). Whereas TTTS is extensively studied, little is known of the outcome of discordant growth in monochorionic twins. Large population-based studies indicate that the risk for IUFD for growth discordant same-sex twins (30% monochorionic and 70% dichorionic) is increased compared to growth discordant different-sex twins (100% dichorionic). In same-sex twins, both the lighter and heavier twins are at risk of IUFD with a threshold of discordancy of 10% and 20%, respectively. This is in contrast to different-sex twins, in which only the lighter twin is at risk of IUFD, provided the discordancy is at least 20%.[40] Small case series (*N* = 47)[43,44] of discordant growth (≥20%) without TTTS in

---

DIFFERENCE BETWEEN TTTS AND DISCORDANT GROWTH

TTTS	Discordant growth
• Hydramnios (DVP > 8 cm) in sac recipient	• Normal amniotic fluid (DVP < 8 cm) in appropriately grown fetus
• "Stuck twin" = donor	• "Stuck twin" = growth restricted fetus

FIGURE 24–6
Differential diagnosis of twin-to-twin transfusion syndrome and discordant growth. DVP, deepest vertical pocket.

monochorionic twins report an IUFD rate of about 25% in the lighter twin, with concomitant or subsequent IUFD of the larger twin occurring in 25%, or 6% overall. In a series of discordant dichorionic twins (N = 29) managed expectantly until 32 weeks, the IUFD rate of the smaller twin was 35%, with the larger twins surviving in all cases.[45]

After birth, twins with IUGR and discordant growth face increased risks of neonatal morbidity and death.[46,47] In discordant pairs, the lighter twin more frequently has a low 5-minute Apgar score and is at higher risk of neonatal death, whereas the heavier twin has more respiratory difficulties when delivered between 33 and 36 weeks.[39] The fear of an IUFD may prompt obstetric intervention, adding the complications of iatrogenic prematurity to the inherent complications of multiple gestation.[48] Clearly, any decision for iatrogenic preterm delivery to prevent IUFD must be weighed against the risks of death and handicap for each twin as determined by gestational age and EFW.

Finally, IUGR is associated with increased risks of cerebral palsy (CP).[49] Likewise, twins with discordant growth are at increased risk of neurodevelopmental morbidity and CP compared with nondiscordant twins. However, this increased risk may also be determined by their lower birth weight or their earlier delivery rather than the discordancy itself.[50] Nonetheless, in a recent series of preterm twin pregnancies (GA between 24 and 34 weeks), the CP rate was 19% in growth discordant monochorionic twins (N = 20) compared with 5% in dichorionic twins (N = 13). This incidence was actually higher than the 4% CP rate in the report's survivors of TTTS (N = 15)[51] and suggests that monochorionic twins with discordant growth are at especially high risk for adverse outcome. IUFD of one twin is a strong predictor of CP in the survivor, with population-based studies indicating a risk of CP of 30 per 1000 infant survivors of different-sex twins and as high as 106 per 1000 infant survivors in same-sex twins.[52] In the Adegbite series,[51] there were four instances of IUFD associated with discordant growth; three neonates survived and all had cerebral palsy.

Management Options

Similar to singletons, the goals of management are to prevent IUFD and long-term neurologic damage due to poor oxygen and nutritional supply. This discussion is, however, restricted to twins, as twins are far more common than triplets. Nevertheless, growth problems are more frequent and occur earlier in higher-order multiplets, and the management issues are comparable to those of twins. Because of the different pathophysiology and prognosis, the management of IUGR in monochorionic and dichorionic twins is discussed separately. A small paragraph is also dedicated to the management of those twin pregnancies in which the opportunity for adequate

chorionicity determination in the first trimester was missed.

Dichorionic Twins

Dichorionic twins are conceptually singletons who happen to occupy the same womb at the same time. Therefore, the diagnostic workup and follow-up are comparable to that of an IUGR in a singleton pregnancy (see Chapter 12).

ANTENATAL DIAGNOSIS

In instances of severe early-onset IUGR, it is important to exclude aneuploidy, structural anomalies, and congenital infection because these fetuses will not usually benefit from the intense antenatal surveillance and iatrogenic early delivery. Study of amniotic fluid and Doppler studies can help to differentiate the growth-restricted fetus from the constitutionally or abnormal SGA fetus.

FETAL SURVEILLANCE

Methods of fetal surveillance for IUGR in dichorionic twins include a combination of fetal growth and amniotic fluid assessment, nonstress test, biophysical profile score, and Doppler velocimetry. Similar to singletons, uteroplacental dysfunction is associated with a sequence of Doppler and fetal biophysical profile changes, suggesting progressive deterioration and hypoxia.

TREATMENT

The risk of IUFD with expectant management must be balanced against the risks of iatrogenic prematurity. When both twins are growth restricted to a similar degree (which is rare), the risks are similar for both. However, the most common scenario is discordant growth with one growth-restricted twin. The Doppler changes that allow the reliable identification of fetal hypoxemia are discussed in Chapters 11 and 12. Early delivery to rescue the hypoxemic twin may expose the AGA twin to the risks of prematurity. Therefore, it may be preferable in dichorionic twins with early-onset severe discordant growth to delay delivery until the risk of death and handicap due to iatrogenic prematurity are minimal for the AGA twin, irrespective of the condition of the SGA twin. Such an expectant management until 32 weeks or when EFW of the AGA twin was more than 1500 g resulted in a 35% rate of IUFD in the SGA twin but no deaths or handicaps in the AGA co-twins in one series.[45] The timing of any intervention depends on the clarity of the diagnosis in the SGA twin and the chances of survival and handicap for each fetus, and the initiation of intensive fetal surveillance must be planned accordingly. The efficacy of antenatal corticosteroid therapy to enhance maturation is insufficiently examined in twins. However, the available information suggests it is reasonable to administer corticosteroid agents to women whose pregnancies are complicated by discordant twins when-

ever early delivery is contemplated. Testing of fetal lung maturity can also be performed if there is a likelihood of a mature study. It is generally recommended in twins to sample both sacs, especially before 32 weeks.[53]

Monochorionic Twins

Monochorionic twins have an identical genetic constitution and share a single placenta, with their circulations connected through vascular communications in the placenta. Therefore, the management of IUGR in monochorionic twin pregnancies poses some unique challenges.

ANTENATAL DIAGNOSIS

The need to exclude aneuploidy, discordant structural anomalies, and congenital infection also applies to monochorionic twins. Monochorionic twins can be discordant for most common human aneuploidies.[25,54,55] Both amniotic sacs must be sampled in order to diagnose these rare heterokaryotypic monochorionic twins. Additionally, structural anomalies are more common in monochorionic twins[56] and usually only affect one fetus.[57] On the other hand, congenital infection typically affects both twins, although the degree of severity may vary. It is equally important to distinguish discordant growth from TTTS by the absence of hydramnios in the sac of the AGA twin in cases of discordant growth.

FETAL SURVEILLANCE

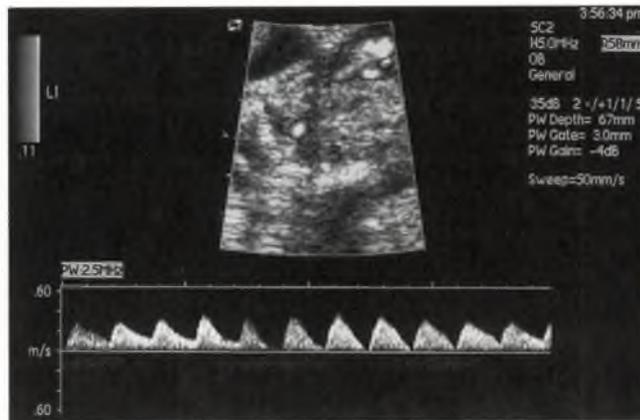
It is unclear as to what the best method is to monitor fetal well-being in growth-restricted monochorionic twins. Doppler velocimetry of the umbilical artery may not have the same prognostic value in monochorionic twins as it has in singletons and dichorionic twin gestations. Umbilical artery waveforms reflect downstream vascular resistance, which in monochorionic twins is determined not only by the adequacy of spiral artery invasion, but also by the direction and shunting across the vascular anastomoses. Large arterioarterial anastomoses can influence umbilical artery waveforms, leading to intermittent absent end-diastolic or even reversed flow.[58] This phenomenon occurs typically in the SGA twin of a monochorionic pair with severe growth discordance (Fig. 24–7).[59,60] IUFD may occur unexpectedly in these fetuses, without additional signs of deterioration of either the Doppler flow profile or the biophysical profile score (unpublished observations), as these large arterioarterial anastomoses may facilitate acute exsanguination or other hemodynamic aberrations. On the other hand, the SGA twin in some cases of discordant growth may have absent end-diastolic flow from early in pregnancy onward for up to 13 weeks, without any adverse effect on fetal survival.[10] Whether brain sparing and venous Doppler velocimetry are better means to assess fetal well-being in monochorionic twins remains to be determined. One recent study observed evidence of brain sparing in 70% of growth-restricted monochorionic twins, but its influence on out-


FIGURE 24–7
Doppler pattern of intermittent absent end-diastolic flow as typically seen in the smaller twin of a monochorionic pair with discordant growth (see Color Plate 28).

come was not reported. Clearly, the potential role of Doppler velocimetry in growth-restricted monochorionic twins requires additional study. In the meantime, the biophysical profile score (including the nonstress test) seems the best method available.

TREATMENT

In monochorionic twins, the management is complicated by the almost obligatory presence of a shared circulation. In dichorionic twins, single IUFD (sIUFD) is associated with perinatal death or handicap of the surviving twin in 5% to 10% and is largely due to extreme preterm delivery. In contrast, sIUFD in monochorionic twins leads to double IUFD in 10% to 25% and antenatal cerebral lesions in 25% to 45% of surviving co-twins. This extra morbidity and mortality is due to a combination of pressure instability as the first twin dies and acute exsanguination in the fetoplacental unit of the dead twin, all in addition to the effects of extreme preterm delivery.[61,62] Expectant management irrespective of the condition of the SGA fetus until 32 weeks is therefore not appropriate in monochorionic twins. Possible management options for severe, early discordant growth in monochorionic twins are expectant management with timely delivery, selective feticide by umbilical cord occlusion, or selective coagulation of the vascular anastomoses. The problems with expectant management are that IUFD may occur before viability, is difficult to predict, and may have major consequences. IUFD is especially dramatic once a viable stage of gestation has been reached. As a result, some advocate elective delivery of all monochorionic twins with a growth discordance of more than 25% at 32 weeks after the administration of maternal corticosteroids or at the latest after confirmation of fetal lung maturity.

Umbilical cord occlusion may be considered prior to viability when there are signs of imminent fetal death. The rationale for cord occlusion is that it may protect the surviving twin better against the adverse effects of

spontaneous demise. However, a major drawback is that the maximum survival rate is 50%. Further, it is not always clear which signs predict impending IUFD in monochorionic twins, and it may be that the risks of co-twin death and neurologic damage are less with sIUFD of the SGA twin because of the smaller fetoplacental unit.

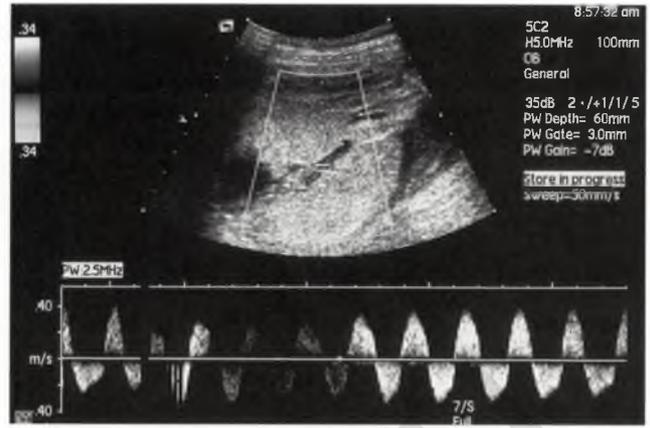
Selective photocoagulation of the vascular anastomoses performed before 26 weeks' gestation also seeks to protect the AGA twin against the adverse effect of IUFD of the SGA twin by "unlinking" the two fetal circulations and transforming the monochorionic placenta into a "functional" dichorionic placenta. However, a small case series comparing treated and expectantly managed cases series did not show any significant difference in survival or neurologic morbidity rates.[44,63] Several explanations for this apparent lack of benefit are possible. First, selective coagulation is technically more challenging for discordant growth than for TTTS owing to the absence of hydramnios. Second, unequal sharing is frequently the reason for discordant growth, and coagulation of the vascular anastomoses may diminish the already critical placental reserve of the SGA twin further. Third, circulatory instability may have already damaged the AGA twin. And finally, the natural history of monochorionic twins needs to be better understood because an overactive management plan may risk the loss of pregnancies that would have reached viability without IUFD of the SGA fetus. Clearly, management of these high risk pregnancies should be individualized after input from the parents, fetal medicine specialists, neonatologist, and obstetricians.


FIGURE 24–8
Characteristic bidirectional Doppler pattern in an arterioarterial anastomosis, which confirms monochorionicity. (see Color Plate 29)

Twins of Unknown Chorionicity

Determining chorionicity in same-sex twins with discordant growth in the second trimester can be challenging. Oligohydramnios with the intertwin membrane plastered around the SGA twin makes assessment of membrane thickness or the presence or absence of a lambda sign especially unreliable. It is estimated that just 3 out of 10 same-sex twins are monochorionic. In these instances, the detection of an arterioarterial anastomosis with its characteristic bidirectional waveform (Fig. 24–8) confirms monochorionicity with 100% reliability.[64] Also, DNA determination of zygosity by amniocentesis will rule out monochorionicity if dizygosity is confirmed.[65] In cases of persistent doubt, it is prudent to manage the pregnancy as a monochorionic twin gestation.

SUMMARY OF MANAGEMENT OPTIONS
Poor Fetal Growth in Twin Pregnancies

Management Options	Quality of Evidence	Strength of Recommendation	References
Dichorionic Twins			
Exclude aneuploidy, structural anomalies, and congenital infection.	—	GPP	—
Determine when to intervene upon signs of fetal distress of the SGA (small for gestational age) twin and plan fetal surveillance accordingly.	See Chapters 11 and 12		
In severe early discordant growth, it may be preferable not to intervene to maximize the chances of the AGA (appropriate for gestational age) twin at the expense of spontaneous demise of the SGA twin.	III	B	45
Fetal surveillance is usually done by a combination of fetal growth assessment, biophysical profile scoring, and Doppler velocimetry.	See Chapters 11 and 12		
Consider administration of corticosteroids and fetal lung maturity testing whenever early delivery is contemplated.	III	B	53

Poor Fetal Growth in Twin Pregnancies (*Continued*)

Management Options	Quality of Evidence	Strength of Recommendation	References
Monochorionic Twins			
Exclude aneuploidy, structural anomalies, congenital infection, and TTTS (twin-to-twin transfusion syndrome).	IIa	B	54–56
Consider referral to a tertiary care center.	–	GPP	–
If spontaneous demise is presumed imminent and in the previable period, selective feticide by cord occlusion may protect the AGA twin better against the side effects of spontaneous demise.	IV	C	63
Consider elective preterm delivery at 32 weeks for cases with a growth difference of ≥25% after administration of corticosteriods or at the latest when lung maturity has been established.	–	GPP	–
Nonstress testing and biophysical profile score are currently the best methods to ascertain fetal well-being, although IUFD can occur unexpectedly, despite normal biophysical profile scoring.	III	B	58–60
Assess for TTTS.	–	GPP	–
Twins of Unknown Chorionicity			
Consider DNA fingerprinting to exclude monochorionicity.	III	B	65
Check for arterioarterial anastomoses to confirm monochorionicity.	III	B	64
If chorionicity remains unconfirmed, manage as monochorionic twins.	–	GPP	–

MONOAMNIOTIC TWINS

General

Splitting of the inner cell mass after day 9 after fertilization results in monochorionic monoamniotic twins. These twins share not only their placenta but also their amniotic sac. Monoamniotic twins are rare, occurring in 1 in 10,000 pregnancies and, as such, constitute 5% of monochorionic twins.[66] The umbilical cords insert usually close to each other midplacenta with multiple deep and superficial large-caliber (8–12 mm) anastomoses connecting the placental stem vessels of the twins (Fig. 24–9).[67]

The diagnosis of monoamniotic twin gestation is reliably made in the early first trimester by the presence of a single yolk sac,[68] one amniotic cavity containing two fetal poles, and a single placenta. Cord entanglement is diagnostic of monoamniotic twins and often already demonstrable in the first trimester by imaging two heart rates on pulsed Doppler in an entangled mass of umbilical cord vessels (Fig. 24–10).[69,70] Current ultrasound technology with sharper resolution usually permits the distinction between diamniotic and monoamniotic monochorionic twins. On occasion, transvaginal scanning at high frequencies will help confirm or refute any dividing membrane. "The stuck twin phenomenon" is regularly mistaken for a monoamniotic twin pregnancy because of the difficulty of seeing the dividing membrane. However, the fixed position of the stuck twin rules it out because in a monoamniotic gestation both fetuses move freely about.

Fetal Risks

Monoamniotic twins are at increased risk of congenital malformation and sudden IUFD. Although rare, conjoined twins must be excluded. Conjoined twins arise when the embryonic disk incompletely divides beyond the 12th day of fertilization and have an estimated incidence of 1 in 50,000 pregnancies. The diagnosis is possible as early as the first trimester by the close and fixed apposition of the fetal bodies with fusion of the skin lines at some point (Fig. 24–11).[71] IUFD occurs in 60% of conjoined twins, and of those that are live born, the majority die as a result of severe anomalies or as a consequence of surgery.[72] Except for conjoined twinning, congenital malformations occur in 38% to 50% monoamniotic twins, usually affecting only one twin.[66,73] At least one third of the perinatal deaths in monoamniotic twins are caused by congenital malformations.[74] Late embryonic splitting and hemodynamic imbalances due to the large and multiple anastomoses may account for the extremely high prevalence.

FIGURE 24–9
A, Macroscopic image of large-diameter anastomoses and side-to-side insertion of the umbilical cords as typically seen in a monoamniotic twin pregnancy (see Color Plate 30). *B*, Rx angiography where injection of the umbilical vessels of one twin was sufficient to visualize the placental vascularization of both twins due to the presence of a large arterioarterial and venovenous anastomosis. Furthermore, about half of the placenta consisted of shared cotyledons.

In structurally normal monoamniotic twins, sudden IUFD is the most important cause of death. Recent series report rates of 2.4%[75] to 10%[74] with careful fetal surveillance and early delivery compared to previously quoted risks of 30% to 70%.[76,77] However, most pregnancies included in these series were diagnosed in the second trimester, and the IUFD rate is likely to be higher when cases diagnosed in the first trimester would be included.[66] Umbilical cord entanglement was long considered the only reason for the high mortality rate, but almost all monoamniotic twins have entangled cords at birth (Fig. 24–12) and usually from early in gestation. "Acute" TTTS may be an important con-

tributing factor, perhaps triggered by cord compression. Acute hemodynamic imbalances across the large-caliber anastomoses may also explain the 70% rate of double IUFDs in monoamniotic twins[67] compared to 25% in diamniotic twins.[61] Indeed, chronic TTTS is only rarely reported in monoamniotic twins, probably

FIGURE 24–11

because volume shifts through the large-caliber anastomoses are not tolerated for long periods and are more likely to lead to sudden IUFD typically of both twins. The deaths usually occur within a short period of each other. However, cord entanglement may still cause IUFD[78] or asphyxia later in gestation if the co-twin survives.[79]

Management Options

The cornerstone of management is a detailed anomaly scan at 16 to 18 weeks to rule out associated anomalies, followed by scans every fortnight for growth and amniotic fluid volume, intense antenatal surveillance from 26 to 28 weeks onward, and timely delivery. It is the authors' opinion that delivery should be planned for 32 weeks or at the latest when lung maturity is established. However, others note extremely low loss rates after 32 weeks, possibly because there is little room for fetal movement.[80] Selective feticide for discordant anomalies in monoamniotic twins can be accomplished by fetoscopic/ultrasound-guided coagulation and laser transsection of the umbilical cord (Fig. 24–13). The procedure is technically more challenging than in diamniotic twins because of cord entanglement. An accessory port for fetoscopy may facilitate cord transsection and to a lesser degree helps to identify the correct cord, albeit with an unknown additional risk of preterm premature rupture of membranes (PPROM) when compared to single port procedures.

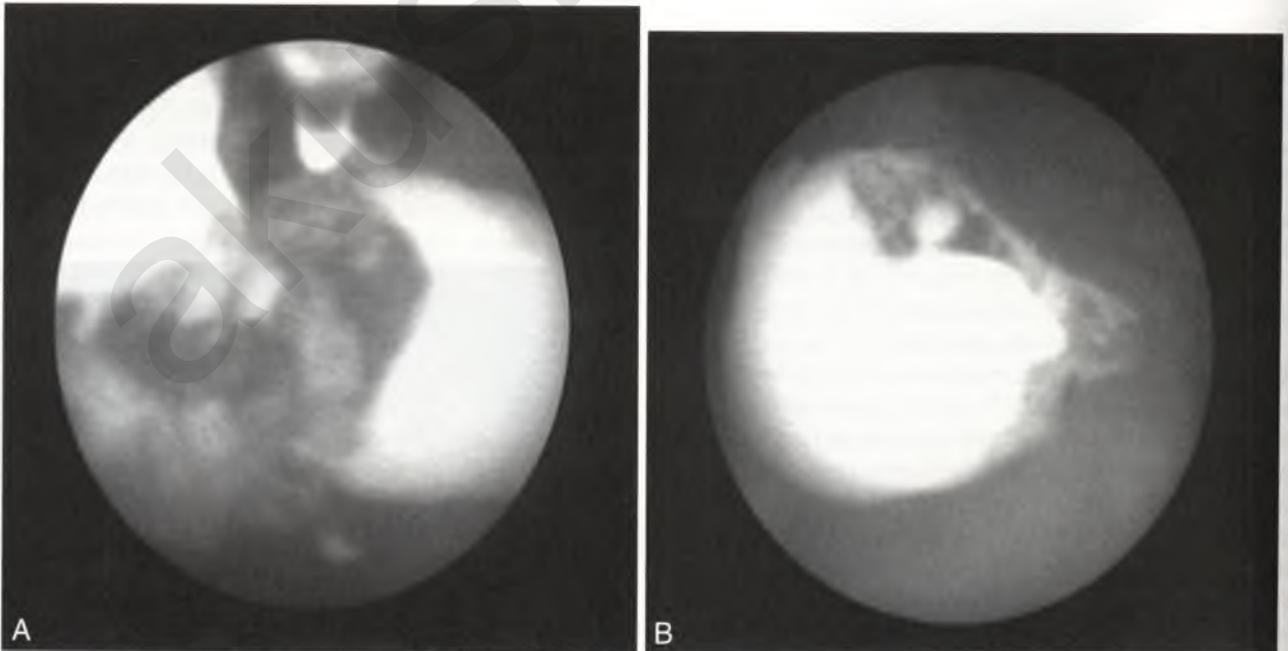
Although IUFD in monoamniotic twins may be sudden and unpredictable, careful antenatal surveillance and early elective delivery appear to improve perinatal survival rate to about 90%.[75] However, the best way to manage these cases is simply not known. Generally, it is agreed that intense fetal surveillance should be started from 26 to 28 weeks onward, with regular nonstress testing and ultrasound scans for biophysical profile score, Doppler, and growth checks. The recommended


FIGURE 24–13

frequency is disputed, and in the literature nonstress testing varies from twice-weekly to several times daily. The high frequency of nonstress testing is justified by the suddenness of the events, but fetal death in between remains possible. Some advocate weekly ultrasound examinations with a biophysical profile score, yet these fetuses are likely lost because of acute events, and not because of chronic hypoxemia. Abnormal umbilical artery Doppler flow waveforms such as diastolic notch[81] or absent/reversed end-diastolic flow are reported to indicate cord compression. But similar to monochorionic twins in general, the predictive value of abnormal umbilical artery Doppler velocimetry may be different compared to singletons and, like biophysical profile scoring,

requires additional validation.[82] The need for hospitalization is likewise controversial, and this decision should be individualized based on the results of the ultrasound scan and antenatal testing.[83] Sulindac was suggested as a "safe" means of medical amnioreduction in monoamniotic twins.[84] Yet, because acute transfusion seems to be an important cofactor, IUFD can still occur after 32 weeks[85] despite sulindac.[66] For these reasons, we advocate delivery at 32 weeks when feasible. Even though cases of successful vaginal delivery are reported, cesarean delivery is the preferred mode of delivery to avoid cord entanglement and inadvertent clamping of the cord of the second twin, which may be tightly around the neck of the first.[86]

IN UTERO DEATH OF ONE FETUS

General

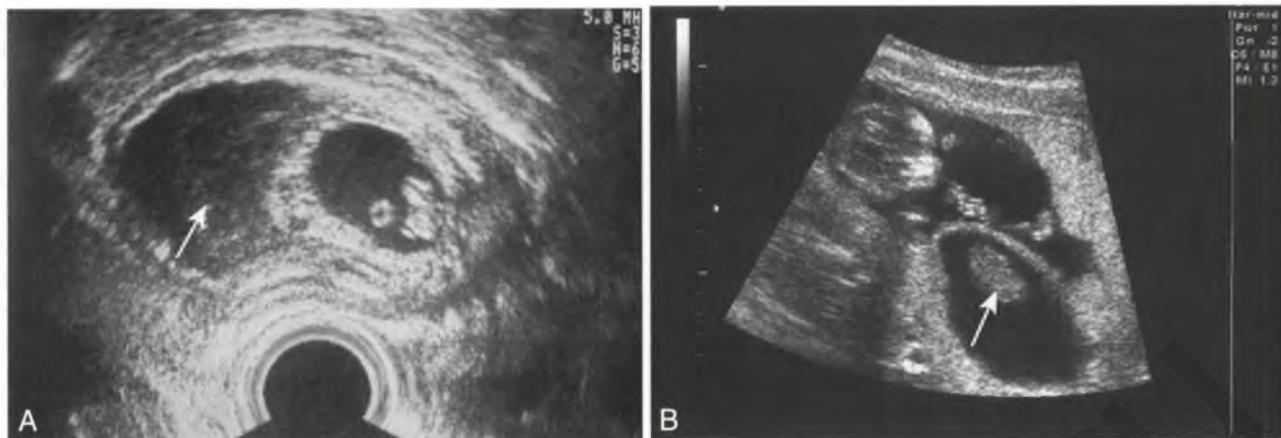
Fetuses of multifetal pregnancies are more likely to die in utero than singletons.[87] Not unexpectedly, the risk grows with an increasing number of fetuses.[88] The rate of sIUFD in twins or higher-order multiplets is difficult to ascertain during the first trimester, as the loss may occur before the diagnosis of either a multifetal pregnancy or sIUFD is made. Also, the "vanishing embryo syndrome" may go unrecognized or may be wrongly diagnosed as a retromembranous blood collection (Fig. 24–14). The diagnosis of sIUFD should be made when fetal remnants are clearly identified or when a later ultrasound examination demonstrates the IUFD or disappearance of a previously known fetus. The risk of sIUFD in twin pregnancies resulting from in vitro fertilization (IVF), which are regularly followed throughout the first trimester, is maternal age–dependent and ranges from 10% to 20% with most cases occurring prior to 12 weeks.[89] These figures are currently the best estimates available for first-trimester sIUFD in dichorionic twins, as about 90% of IVF pregnancies are dichorionic.[90] In a general population scanned between 10 and 14 weeks of gestation, the prevalence of sIUFD is reportedly 4% in dichorionic twins and less than 1% in monochorionic twin pregnancies (compared with 2% in singletons), with double IUFD in 1.6% of dichorionic and 2% of monochorionic twin pregnancies.[91] Thus, double IUFD appears more common than sIUFD in monochorionic twins. Gross unequal placental sharing or hemodynamic imbalances in


FIGURE 24–14
A, Ultrasound image of a retromembranous blood collection (*arrow*) in a singleton pregnancy, which must be differentiated from (*B*) "vanishing twin syndrome" in which felt remnants (*arrow*) can be clearly identified.

monochorionic twins may cause sIUFD, with the connected fetal circulations leading to double IUFD. Also, chromosomal abnormalities or an adverse maternal factor (infection, teratogens) will usually affect both fetuses similarly. In contrast, sIUFD in dichorionic twins is twice as common than double IUFD and may be explained by either a discordant chromosomal or structural anomaly or suboptimal placentation. Because each fetus has a separate fetoplacental circulation, sIUFD will not cause co-twin death per se. About 10% of dichorionic twins are monozygotic and therefore concordant for chromosomal anomalies. Double IUFD in dichorionic twins may also occur because of exposure to the same adverse maternal factor.

From 10 to 14 weeks onward, sIUFD occurs in about 2% of dichorionic but 4% of monochorionic twin pregnancies, and double IUFD occurs in 0.2% of dichorionic and in at least 6% of monochorionic twins. This extra fetal loss of monochorionic twins occurs before 24 weeks and is largely attributable to complications of the connected fetoplacental circulations.[12] Toward the end of gestation, the risk of IUFD in twins increases from 1/3333 at 33 weeks to 1/313 at 36 weeks and 1/69 beyond 39 weeks. IUFD rates of twins at 37 to 38 weeks equal those of postterm singleton pregnancies, and elective delivery at 37 to 38 completed weeks may be justified when uncomplicated twin pregnancies reach that milestone.[92] Data on the risk of IUFD toward term according to chorionicity are currently not available.

Fetal Risks

The prognosis of sIUFD for the surviving fetus depends first and foremost on chorionicity. To a lesser degree, outcome is determined by the gestational age of sIUFD. There is little evidence regarding the implications of sIUFD in the first trimester. Nonetheless, it seems most likely that sIUFD in a monochorionic twin pregnancy leads to either double IUFD or miscarriage. Rarely, the surviving co-twin may prevent "vanishing" of the dead twin by reversed perfusion along the vascular anastomoses—a twin reversed arterial perfusion (TRAP) sequence.[93] Color Doppler should be used to exclude TRAP whenever sIUFD occurs in a monochorionic twin pregnancy, and if there is any doubt, follow-up scans should be arranged. It is also hypothesized that unrecognized, early sIUFD in a monochorionic twin pregnancy may explain some cases of cerebral palsy and certain congenital anomalies such as renal agenesis and intestinal atresias in birth singletons, attributable to agonal hemodynamic events.[94] The outcome of sIUFD in the first trimester in dichorionic twins is usually favorable, although the rate of preterm delivery and subsequent miscarriage may be increased especially if the sIUFD occurs toward the end of the first trimester. In the case series of sIUFD diagnosed between 10 and 14 weeks, 18% (3/16) of dichorionic twins subsequently miscarried.[91]

sIUFD in dichorionic twins during the second to third trimester is associated with either death or handicap in 5% to 10% of survivors, presumably in great part secondary to extreme prematurity, though no doubt in some instances an adverse maternal event may cause demise of one twin but only damage the survivor. Conversely, in monochorionic twins, sIUFD results in a double IUFD in 10% to 25%, and cerebral damage in 25% to 45% due in part to acute TTTS plus the risks of extreme prematurity.[61,62] In dichorionic twins, survival is inversely related to the gestational age of the sIUFD, with infant survival rates improving from 71%, when the sIUFD occurs between 20 and 24 weeks, to 98% for sIUFD occurring beyond 37 weeks.[88] The reported rate of cerebral palsy (CP) after sIUFD in dichorionic twins is 30 per 1000 infant survivors with prematurity being the leading factor in this excess risk compared with 1 per 1000 in singletons.[52,95] In monochorionic twins, the influence of

gestational age of sIUFD on outcome is less clear. It seems early sIUFD is more often associated with death of the co-twin. But, if the co-twin survives, severe morbidity is less common. In contrast, a late sIUFD more frequently results in the delivery of a live-born infant who is neurologically damaged.[62,96] Specific CP rates are not available for sIUFD in monochorionic twins. However, the CP rate in same-sex twins (30% monochorionic and 70% dichorionic) after sIUFD is 106 per 1000 survivors, which is about three times higher than different-sex twins (100% dichorionic).[52] In addition, most of the twins in the same-sex group with CP had monochorionic placentation.[95] Cerebral damage is often detectable sonographically but does not usually become apparent until weeks after the insult. Prenatal magnetic resonance imaging (MRI) may detect brain lesions earlier and with better definition.[97,98] Sonographic evidence of brain injury includes porencephaly, multicystic encephalomalacia, ventriculomegaly, cerebral atrophy, and cerebellar or cerebral infarcts. Less frequently reported complications include renal cortical necrosis, small bowel atresia, aplasia cutis, and limb infarction. Originally, thromboembolic phenomena with passage of thromboplastin from the dead to the living twin were thought to be responsible for these lesions.[99] A variety of studies have failed to find any such evidence, though perimortal circulatory instability and acute exsanguination are well documented.[100] Reversed perfusion of the dead twin has been demonstrated by Doppler interrogation of the chorionic plate vessels,[101] and fetal blood sampling within 24 hours of sIUFD has consistently revealed decreased hematocrits in survivors with normal coagulation profiles.[102] Further, fetoscopy within 3 hours of the demise of a donor twin has documented reversal of the transfusion with a plethoric donor and anemic recipient.[103] Outcome of the survivor may not only depend on the gestational age at sIUFD but also on the type and direction of vascular anastomoses and the fetoplacental mass of the demised twin. The presence of superficial arterioarterial anastomoses is associated with higher rates of death and neurologic damage.[61] However, significant anemia and co-twin death may occur, even in the absence of arterioarterial anastomoses.[96] The outcome of sIUFD associated with TTTS treated by amniodrainage does not differ from sIUFD unassociated with TTTS, and the risk of sIUFD is similar for donors and recipients. It was suggested that the risk of co-twin death and neurologic damage is lower with sIUFD of the donor compared with sIUFD of the recipient, because transfusion is more likely to be directed toward the recipient.[61] However, other small series show similar incidences of anemia and adverse outcome in surviving recipients and donors.[96,104] And even though TTTS treatment by laser coagulation of the vascular anastomoses more frequently results in sIUFD than amniodrainage, it consistently leads less often to a double IUFD.[105] Significantly, anemia in the survivor is rare in the event of sIUFD after laser[106] and

the neurologic morbidity[107] less than after amniodrainage.[106,108] These findings provide further support for the concept that the vascular anastomoses are responsible for most of the adverse outcomes associated with sIUFD in monochorionic twins.

Management Options

Again, knowledge of chorionicity is fundamental to the management of sIUFD in multiple pregnancies. Because of the different pathophysiology and prognosis, management of sIUFD in monochorionic and dichorionic twins is discussed separately. Not to complicate matters unnecessarily, the discussion will be restricted to twins. Although sIUFD is more common in higher-order multiplets and management issues are more complex, they are based largely on the same principles as in twins. A small paragraph is dedicated to issues that are relevant to both groups of twins.

Dichorionic Twins

The main risks of sIUFD in dichorionic twins are miscarriage and severe preterm delivery. Therefore, conservative management is advocated with regular ultrasound scans to check growth and well-being of the survivor. Admittedly, parental anxiety may be an important factor in persuading the obstetrician to intervene, and these complex emotional responses should be adequately addressed.[109]

Monochorionic Twins

The main risks of sIUFD in monochorionic twins are death and ischemic brain lesions secondary to acute TTTS. Depending upon gestational age, there are additional risks of miscarriage or severe preterm delivery. It is presumed that death and especially ischemic brain damage in the survivor occurs during or soon after the death of its co-twin. Therefore, a pre-emptive preterm delivery is inappropriate once a sIUFD has been diagnosed, as this would only worsen the outcome of the surviving twin by adding the complications of prematurity. Further, a long death-to-delivery interval is associated with a better outcome compared to a short death-to-delivery interval, further supporting the benefit of conservative management.[62] Monochorionic twin pregnancies with a sIUFD should be managed in a tertiary referral center with sufficient neonatal support. Also, regular detailed (transvaginal if vertex) ultrasound examinations of the fetal brain are indicated to detect brain injury. Unlike hemorrhage, ischemic brain lesions are difficult to visualize in the early phase, and MRI scan may aid early detection.[97,98] Fetal blood sampling shortly after sIUFD may have prognostic value, as all nonanemic fetuses in one study had a good outcome and did not develop any brain injury.[96] Middle cerebral artery Doppler velocimetry is effective in predicting fetal anemia after sIUFD in cases

complicated by TTTS and obviates the need of cordo-centesis (Fig. 24–15). There is insufficient evidence a res-cue intrauterine transfusion improves outcome. Whereas it may prevent co-twin death, it may not prevent brain injury.[96,104] As such, intrauterine transfusion may increase the survival of severely handicapped infants. Additional multicenter studies are necessary to determine whether rescue transfusion improves the outcome of survivors after sIUFD in monochorionic twins.

After birth, a thorough neonatal evaluation should be performed to detect any neurologic, renal, circulatory, and cutaneous defects. All survivors should undergo an early neonatal brain scan and be enrolled for long-term neurodevelopmental follow-up.

Issues Applicable to Dichorionic and Monochorionic Twins

It seems justified to administer Rhesus prophylaxis when-ever a sIUFD is diagnosed in a Rhesus-negative woman. Maternal disseminated intravascular coagulation has been described in singletons after IUFD and retention of the fetus for more than 5 weeks. However, in twins its incidence with conservative management appears extremely low, and it can be treated with heparin when it does occur.[110,111] Vaginal delivery is not contraindicated after sIUFD, but labor may be obstructed, especially if the sIUFD occurs late and is presenting. A postmortem examination should be performed on the dead twin, and the placenta sent for histologic examination to confirm chorionicity.

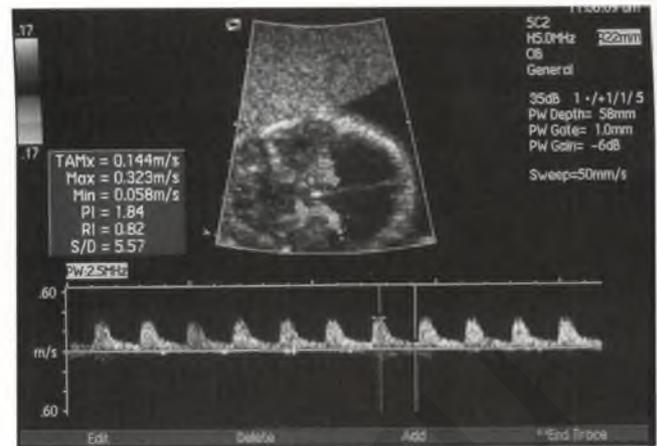
The family will require both psychological support and counseling prior to, during, and after delivery. The grief experienced after a sIUFD equals that for a singleton


FIGURE 24–15
Doppler examination of the middle cerebral artery of the surviving twin of a monochorionic pair at 20 weeks' gestation, within 4 days after sIUFD of the growth-retarded co-twin (see Color Plate 33).

loss, yet the parents rarely receive equal sympathy.[112] The death is also invisible for the parents and their immediate associates, which hampers the grieving process. Many parents worry the dead twin will have an adverse effect on the remaining fetus, and need reassurance that except for the possibility of an earlier delivery, no additional harm is expected. The delay between diagnosis and deliv-ery permits some grieving, but sorrow resurfaces at birth.[113] It is important not to ignore the deceased twin; the parents may wish to see it during ultrasound exami-nation and after birth. Demise after 12 to 15 weeks should end with an identifiable fetus at birth, though compressed and mummified, and parents should be pre-pared and told what to expect.[114]

TWIN REVERSED ARTERIAL PERFUSION

General

The twin reversed arterial perfusion (TRAP) sequence, also known as acardiac twinning, is an anomaly unique to monochorionic multiple pregnancies that affects approximately 1 of 35,000 pregnancies and 1% of monochorionic twins.[115] In TRAP, blood flows from an umbilical artery of the pump twin in a reverse direction into the umbilical artery of the perfused twin, via an arterioarterial anastomosis. The perfused (or acardiac) twin is a true parasite. Its blood is poorly oxygenated, and the hypoxemia contributes to variable degrees of deficient development of the head, heart, and upper limb structures. The lower half of the body is usually better developed, which may be explained by the mechanism of transfusion of the acardiac twin. Blood enters the acardiac twin via the umbilical artery, and flows through the common iliac artery and aorta. What little oxygen is present is extracted in the lower part of the body, allowing at least partial development of the lower limbs and abdomen. By the time the blood reaches the upper body, most of the oxygen will already have been extracted, leading to poor development of upper body structures[111] (Fig. 24–16).

Two criteria must be fulfilled for the development of a TRAP sequence. The first is an arterioarterial anastomosis and the second is discordant development[116] or IUFD[101] in one of monochorionic twins, allowing for the blood flow reversal. Not infrequently, chromosomal abnormalities are identified in the acardiac twin, while the pump twin has a normal karyotype.[117,118] Embryos/fetuses with chromosome abnormalities have a high rate of spontaneous IUFD, which in dichorionic twins would lead to a "vanishing" twin. However, in monochorionic twins, the "vanishing" can be prevented by the occurrence of persistent, yet reversed, flow to the chromosomally abnormal twin via the vascular anastomoses. Therefore, whenever sIUFD is suspected in monochorionic twins on a first-trimester scan, the differential diag-

FIGURE 24–16
Macroscopic image of an acardiac twin with absent head and partial development of lower limbs and abdomen. This acardiac mass weighed about 4 kg and was not diagnosed until the third trimester. The patient delivered at 37 weeks, and the pump twin survived (see Color Plate 34).

nosis or development of TRAP should be kept in mind and follow-up scans arranged.[93]

The diagnosis can be reliably made on ultrasound scan in the first trimester.[119] TRAP sequence is characterized by a grossly abnormal fetus that grows, may even show movements, but has no functional cardiac activity of its own. Rarely, a rudimentary heart may show pulsatility (Fig. 24–17). Marked hydrops and cystic hygroma are frequently present, especially toward the end of pregnancy. Doppler studies reveal pathognomonic features of reversed arterial perfusion through an arterioarterial anastomosis (Fig. 24–18). TRAP can easily be distinguished from sIUFD by the presence of fetal movements and the typical retrograde perfusion.

Fetal Risks

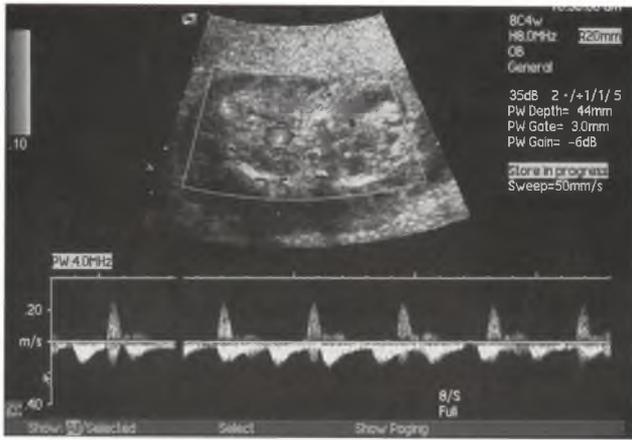
Risks for the pump twin include heart failure secondary to the strain of perfusing the acardiac twin and extreme premature birth associated with hydramnios.[117,120] The


FIGURE 24–17
Doppler examination demonstrating cardiac activity in the rudimentary heart (70 bpm) of the acardiac twin, with flow in the opposite direction in the aorta (140 bpm) (see Color Plate 35).

pump twin may be chronically hypoxemic if the deoxygenated blood from the acardiac returns by a vein to vein anastomosis.

The natural history of TRAP is poorly documented due to the rarity of the disorder. Reported perinatal mortality rates for the pump twin vary between 35% and 50%[117,120] of cases diagnosed at birth, whereas some series of antenatally diagnosed cases report better,[121] similar,[122,123] and worse [124] outcomes. One explanation for a better outcome in antenatally diagnosed cases may be spontaneous resolution of the TRAP sequence following complete cessation of flow to the acardiac twin[121,123,125] Conversely, outcome may also be worse due to spontaneous demise of the pump twin leading to an early second-trimester loss not otherwise identified as a TRAP [121]. Long-term outcome data are not available for pump twins, although it is reasonable to speculate the risk of long-term cardiac and neurodevelopmental sequelae is high[126,127] due to vascular imbalances in utero.

Prognostic prediction of outcome of antenatally diagnosed TRAP is challenging. An acardiac/pump weight ratio above 70% at birth was associated with increased rates of congestive heart failure, hydramnios, and prematurity, suggesting a relatively small acardiac mass is a good sign. Certainly, a larger acardiac mass will put a greater hemodynamic strain on the pump twin. However, antenatal weight estimation of the acardiac mass is hampered by the absence of normal biometric structures, and the errors are likely large. Others suggest a rapid increase in the acardiac mass is indicative of poor prognosis.[122] Doppler velocimetry is probably the best tool to predict outcome. Large differences in the umbilical artery Doppler values suggest relatively little flow to the acardiac twin, thereby predicting a more favorable outcome.[122–124,128] In contrast, small differences in the umbilical artery Doppler values would signify similar flows, the presence of large anastomoses placing a greater hemodynamic strain on the pump twin. Additional factors thought predictive of poor outcome are congestive heart failure with hydrops, hydramnios,[117] and certain morphologic characteristics of the acardiac twin such as the presence of a head and upper limbs.[120] It remains unknown to what degree these parameters apply in the early second trimester, and spontaneous resolution as well as sudden death of the pump twin remains largely unpredictable.

Management Options

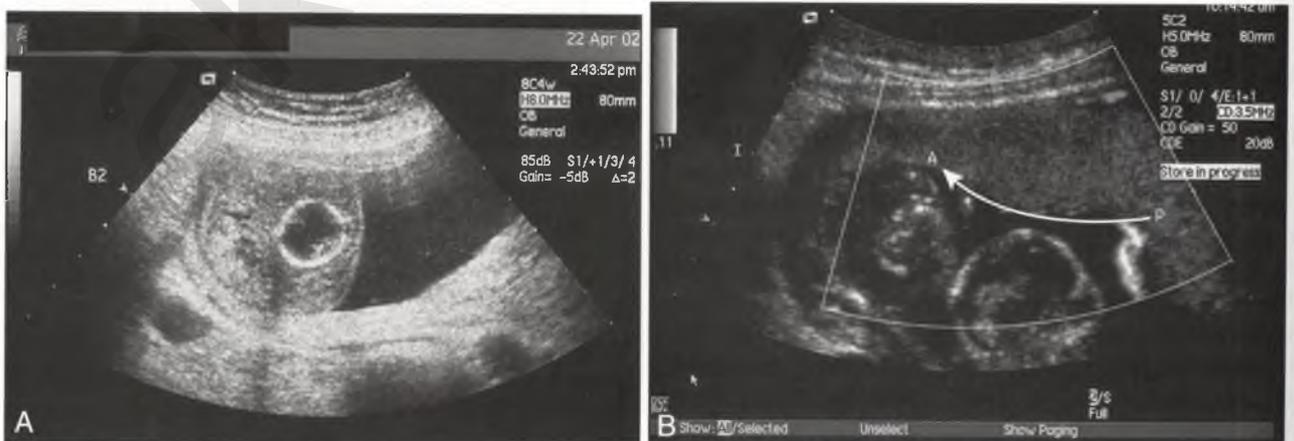
As the natural history of antenatally diagnosed TRAP has not been properly documented, its treatment is equally controversial and can be conservative, palliative, or invasive. Conservative management consists of close antenatal surveillance and timed delivery for signs of cardiac failure, whereas palliative treatment involves prolongation of pregnancy by serial amnioreduction and maternal administration of indomethacin for preterm labor and digoxin for cardiac failure. Reported perinatal mortality rates from conservative and palliative treatment vary widely between 10%[121] and 50%.[117] This range is not


FIGURE 24–18

surprising considering how poor the placental transport of digoxin is normally, much less when the fetus is hydropic. Also, little or no data are available on the long-term outcome of surviving pump twins, but as stated previously there is concern about long-term neurologic and cardiac sequelae.

Invasive treatment seeks to arrest the flow of blood to the acardiac twin. Several methods are proposed, ranging from hysterotomy and delivery of the acardiac twin[129] to embolization of the acardiac's circulation[130] to fetoscopic cord ligation[131] to ultrasound guided or fetoscopic coagulation of the umbilical cord[132,133] or intrafetal vessels.[134] Clearly, hysterotomy with selective delivery of the acardiac twin is unacceptable because of the high maternal morbidity risk. And embolization by the injection of thrombogenic substances into the acardiac twin's circulation (e.g., absolute alcohol, coils, and enbucrilate gel) is no longer advocated as a first-line treatment, as double IUFD is not uncommon owing to incomplete vascular occlusion or embolization of the product to pump twin.[135,136]

A number of minimally invasive techniques are now available to produce complete circulatory confinement of the acardiac twin. Fetoscopic cord ligation causes immediate and complete interruption of both arterial and venous flow, irrespective of umbilical cord size, but is cumbersome and has a high risk of PPROM. Although the published series are small, ultrasound or fetoscopic guided cord coagulation together with needle-based intrafetal coagulation appear to yield the most consistent results. The method of cord coagulation by laser is derived from that used for the coagulation of vascular anastomoses in TTTS.[133] It can be performed as early as 16 weeks using a double needle loaded with a 1.0-mm fetoscope and a 400-μm laser fiber (Fig. 24–19).[137] Fetoscopic laser coagulation is performed percutaneously under local or regional anesthesia using a single 1.3-mm

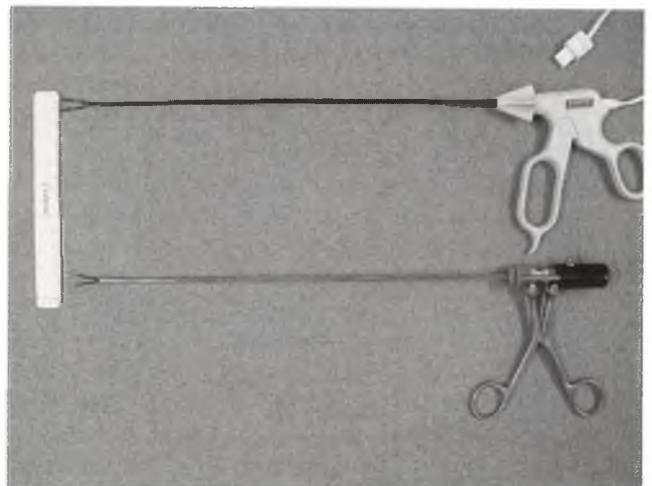
operating sheath or 10 Fr (3.3 mm) trocar, depending on the gestation. Fetoscopically guided laser offers good visual control of the coagulation site but may fail if the umbilical cord diameter is large or more rarely if the amniotic fluid is stained. In these instances, bipolar cord coagulation with purpose-designed 2.4- to 3-mm bipolar forceps under ultrasound guidance is a secondary technique (Fig. 24–20). Needle-based coagulation techniques using laser,[138] monopolar technique,[134] or radiofrequency[139] each involve the insertion of a 14- to 18-gauge needle into the fetal abdomen under ultrasound aiming for the intra-abdominal rather than umbilical vessels. This technique is attractive for its simplicity, the smaller membrane defect produced, and the seemingly lower risks of PPROM. However, it may fail at gestations above 21 weeks. The four reported successful cases of intrafetal coagulation with laser were before 19 weeks. And with monopolar and radiofrequency coagulation, three out of


FIGURE 24–20
A, Disposable 3-mm bipolar forceps (Everest Medical). *B*, Reusable 2.4-mm bipolar forceps (Karl Storz).

seven procedures reported between 22 and 24 weeks failed, whereas before 21 weeks all were successful. Currently, it is not possible to conclude what the best management is for TRAP. The outcome may be good without treatment if spontaneous arrest of flow occurs. Conversely, the pump twin may die unexpectedly or sustain sequelae from very preterm delivery, cardiac failure, and chronic hypoxia. At present, cases of TRAP are usually diagnosed early in the second trimester when it is impossible to predict outcome. Early intervention may preclude the difficulties achieving an arrest of flow in larger and often hydropic acardiac masses, and it seems preferable awaiting signs of decompensation. We believe it is justifiable to offer prophylactic, minimally invasive intervention if no spontaneous arrest of flow has occurred by 16 weeks, recognizing that the pump twin may survive without any intervention in at least half of cases. The choice of technique will reflect gestational age and the size of the acardiac twin. These procedures should be performed in specialized units by surgeons familiar with different techniques in order to tailor therapy to the needs of each individual case.

- hysterotomy and removal of acardiac twin (supplanted by above)	III	B	129
For invasive treatment before 21 weeks, intrafetal coagulation and cord coagulation (laser and bipolar) are effective methods to arrest flow	III	B	132,133,135
Beyond 21 weeks and in cases with hydropic cord, bipolar cord coagulation may be more effective	III	B	132
It is justifiable to offer invasive treatment if no spontaneous arrest has occurred by 16 weeks	–	GPP	–
Mode of delivery depends on factors such as presentation and fetal health	III	B	117

TWIN-TO-TWIN TRANSFUSION SYNDROME

General

Twin-to-twin transfusion syndrome (TTTS) is a complication unique to monochorionic multiple pregnancies. In most monochorionic twin gestations, interfetal transfusion across the anastomoses is a constant, but balanced, phenomenon. However, in 10% to 15% of monochorionic twins, a chronic imbalance in net flow develops, resulting in TTTS. Hypovolemia, oliguria, and oligohydramnios develop in the donor twin, producing the "stuck twin" phenomenon. Hypervolemia, polyuria, and hydramnios evolve in the recipient twin, who can develop circulatory overload and hydrops (Fig. 24–21). TTTS usually occurs between 15 and 26 weeks and is a sonographic diagnosis based on the following criteria: hydramnios in the sac of the recipient twin (defined as deepest vertical pocket of ≥ 8 cm prior to 20 weeks and ≥ 10 cm between 20 and 26 weeks) believed secondary to polyuria, combined with oligohydramnios in the donor's sac (deepest vertical pocket ≤ 2 cm) presumably secondary to oliguria. Quintero and associates suggested a staging system[140] based on the sonographic time sequence of cases with progressive deterioration. Stage I cases include those with hydramnios in the recipient sac but the bladder of the donor twin still visible. In stage II, the bladder

FIGURE 24-21
Ultrasound image of twin-to-twin transfusion syndrome. *A*, The donor is stuck to the uterine wall without bladder filling. *B*, There is hydramnios in the sac of the recipient, who has a distended bladder.

of the donor twin remains empty ("stuck twin"). Stage III is characterized by severely abnormal Doppler studies: absent or reversed end-diastolic flow in the umbilical artery of the donor fetus or abnormal venous Doppler pattern in the recipient, such as reverse flow in the ductus venosus or pulsatile umbilical venous flow. Fetal hydrops means stage IV and the end-stage V corresponds to fetal death of one or both twins. In medicine, the purpose of any classification system is to predict prognosis, to stratify therapy, and to predict the response to a given therapy. It is uncertain whether this staging does so. The onset of TTTS can be abrupt, and therefore, all monochorionic twins at our institution are scanned between 15 and 26 gestational weeks at 2-week intervals.

As already discussed, the differential diagnosis includes discordant growth, in which the growth-restricted twin may appear "stuck" due to oligohydramnios, but in which hydramnios is absent in the recipient twin. Likewise, the isolated presence of hydramnios in one sac with normal amniotic fluid in the other precludes the diagnosis of TTTS, and in that case other causes for hydramnios must be sought.

The pathophysiology of TTTS is most often explained on an angioarchitectural basis. Placental anastomoses can be arterioarterial (AA), arteriovenous (AV or VA), and venovenous (VV).[141] AA and VV anastomoses are typically superficial, bidirectional anastomoses on the surface of the chorionic plate, forming direct communications between the arteries and veins of the two fetal circulations. The direction of flow depends on the relative interfetal vascular pressure gradients. AV anastomoses are usually referred to as "deep" anastomoses. They occur at the capillary level deep within a shared cotyledon, receiving arterial supply from one twin and providing venous (well-oxygenated) drainage to the other twin. The supplying artery and draining vein of the AV anastomosis can be visualized on the placental surface as an unpaired artery and vein that pierce the chorionic plate at

close proximity of each other and supply the underlying, shared cotyledon (Fig. 24-22). The AV anastomoses allow flow in one direction only, and hence may create an imbalance in the interfetal transfusion, leading to TTTS, unless balanced by an oppositely directed transfusion through other superficial or deep anastomoses.

Both postnatal injection studies[10] and in vivo fetoscopic observations[142,143] indicate the presence of at least one unidirectional AV anastomosis as an anatomic prerequisite for the development of TTTS. Although a TTTS case was recently reported with only superficial anastomoses (one AA and one VV),[143] this seems the exception confirming the rule. The presence of bidirectional AA anastomoses is believed to protect against the development of TTTS because most non-TTTS monochorionic placentas have AA anastomoses (84%) in contrast to TTTS placentas (20%–30%).[10,143]

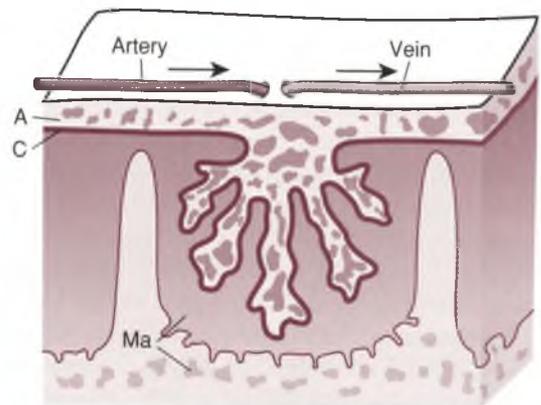
Although vascular anastomoses are an anatomic prerequisite for the development of TTTS, other pathophysiologic mechanisms are likely involved. Because


FIGURE 24-22

75% of sonographically defined TTTS have an intertwin hemoglobin difference less than 15%,[144] this syndrome cannot be explained by the simple transfer of blood from one twin to the other. Further, there is no increased erythropoietin production in the donor[145] and no evidence of iron depletion/overload in the donor/recipient.[146] It is suggested that discordant placental function may offset TTTS, as placental dysfunction is associated with an increased fetoplacental resistance, which may promote transfusion from the growth-restricted donor twin to the recipient twin. Reduced insulin growth factor II[147] and decreased leptin levels[148] in donors compared to recipients may indicate discordant placental development rather than transfusion as a cause of the growth restriction. Other hormonal changes occur in donors and recipients. Raised endothelin-1 levels were observed in recipients, potentially causing increased peripheral vasoconstriction and hypertension. Recipients have increased levels of atrial natriuretic peptide (ANP),[149] and those with severe cardiac dysfunction have higher levels of brain natriuretic peptide (BNP), suggestive of cardiac remodeling. Increased renin gene and protein expression are found in donor kidneys, but the expression is virtually absent in the recipient kidneys,[150,151] implicating a role of the renin-angiotensin system in TTTS. Thus, the pathophysiology of sonographically defined TTTS is most likely multifactorial with vascular anastomoses providing the anatomic basis, while hemodynamic and hormonal factors contribute in varying degrees to its clinical development.

Identification of monochorionic twin pregnancies at increased risk of TTTS would assist patient counseling and planning of follow-up. Further, early diagnosis and treatment of TTTS might improve outcome, although the extent to which earlier treatment will lead to a better outcome has yet to be determined. It has also been suggested undiagnosed TTTS may trigger cervical ripening, which may be an important prognostic factor for adverse outcome, increasing the risk of PPROM before or after therapy.[152]

An increased nuchal translucency (NT) (>95th percentile) in at least one fetus during the 11 to 14 weeks' examination occurs in 13% of monochorionic twins (37/287) and is a marker for chromosomal anomalies, cardiac defects, and a wide range of genetic syndromes. In monochorionic twins, an increased NT may reflect early cardiac dysfunction due to hypervolemic congestion in the recipient and thus herald the subsequent development of TTTS. Indeed, fetuses of monochorionic twin pregnancies with increased NT have a higher likelihood for the subsequent development of TTTS (likelihood ratio: 3:5; 95% CI 1.9–6.2).[153] However, the sensitivity of the NT measurement for TTTS is only 28% with a positive predictive value of 33%. Because 72% of TTTS cases had NT measurements in the normal range, it is not an ideal screening test. Furthermore, it may not be possible to predict TTTS as early as 12 weeks, as TTTS

may result from a random asymmetrical reduction in vascular anastomoses later in pregnancy.[154]

Folding of the intertwin membrane (Fig. 24–23) at 15 to 17 weeks may be a more promising sign for the prediction of TTTS. It is present in 32% of monochorionic twin pregnancies and believed to reflect oliguria and reduced amniotic fluid in the sac of the donor. It is associated with an increased likelihood for the development of TTTS (likelihood ratio: 4:2; 95% CI 3.0–6.0). Membrane folding is identified in 91% of TTTS cases with a positive predictive value of 43%.[153]

Another possible marker for the prediction of TTTS is the absence of AA anastomoses. These anastomoses can be detected by color flow mapping and pulsed Doppler[64] as early as 12 weeks, though the majority are detectable only after 18 weeks.[155] The difficulty with using the absence of AA anastomoses as a prognostic sign is that it is impossible in early pregnancy to ascertain whether they are truly absent or simply undetected. However, when an AA anastomosis is identified, only 15% of monochorionic twin pregnancies develop TTTS, compared to 61% when no AA anastomosis can be detected. Furthermore, the perinatal mortality rate is lower when AA anastomoses are present, whether or not TTTS develops.

Finally, a velamentous cord insertion increases the risk for TTTS and can be reliably detected by 18 weeks. Although this marker has not been evaluated antenatally, postnatal studies demonstrate that 60% of monochorionic twin gestations with a velamentous cord insertion develop TTTS, while 65% of those pregnancies that develop TTTS have a velamentous cord.[156]

Although none of the proposed markers are ideal for the prediction of TTTS, it is possible a combination of markers will improve risk stratification in the early second trimester. The performance of such a risk assessment system is currently being addressed by a prospective multicenter study funded by the European Commission (EuroTwin2Twin).[157]

Fetal Risks

Untreated, TTTS has been quoted to have a mortality rate of nearly 100%, although advances in neonatal care may have decreased that rate to 63%.[158] Spontaneous abortion and extreme preterm delivery are associated with hydramnios, and fetal death may result from cardiac failure in the recipient or poor perfusion in the donor. Substantial risks of cerebral and cardiac sequelae in survivors are due to the chronic hemodynamic imbalances. Both the donor and recipient are at risk of antenatally acquired cerebral white matter lesions with reported incidences of 35%[159] to 50%.[160] In donor twins, hypovolemia, hypotension, and anemia may induce cerebral hypoxia and brain damage, whereas in the recipient, hyperviscosity and cardiac failure may impair cerebral perfusion. Depending on the therapy used, the reported incidences of cerebral palsy and global developmental delay range from 4% to 26%.[108] The risks of neurologic damage are increased, especially after a sIUFD, presumably due to acute exsanguination of the survivor across the vascular anastomoses into the fetoplacental unit of the dead co-twin. Middle cerebral artery peak systolic velocity measurement seems a reliable noninvasive method to detect anemia after sIUFD in TTTS.[106] Though it is tempting to intervene based on this finding, it remains to be demonstrated whether a rescue transfusion decreases the risks of neurologic sequelae. Monochorionic twins with TTTS managed primarily by amniodrainage have a reported 7% prevalence of pulmonary valve stenosis in recipients.[161] Further, up to 48% of survivors have signs of transient oliguric renal failure affecting the donor as well as the recipient, although long-term renal impairment does not appear to be a problem.[162] More rarely, limb, gastrointestinal, and cerebral infarctions that preferentially affect the recipient are described, and may originate from hyperviscosity, hypoperfusion, or thromboembolic phenomena.[163]

Management Options

In view of the poor survival rates with conservative management, there is little disagreement that therapy should be offered. The four most commonly used therapies for midtrimester TTTS are amnioreduction, fetoscopic laser coagulation of the vascular anastomoses, septostomy, and selective feticide by cord occlusion.

Serial amnioreduction controls the amniotic fluid volume, is relatively simple, and is widely available. It may improve the fetal condition by reducing the amniotic fluid pressure and thus enhancing uteroplacental perfusion. Decompression also appears to prolong pregnancy.[164,165] However, amniodrainage does not address the vascular basis of TTTS, and in the event of a sIUFD, the surviving twin is at high risk for IUFD and neurologic damage. Amniodrainage techniques vary considerably in terms of the amount of fluid drained and whether the fluid is removed quickly or slowly. Denbow and associates advocate aggressive amniodrainage with the removal of 1 L for every 10 cm the amniotic fluid index (AFI) is raised, reducing the AFI to less than 25 cm.[166] An often-quoted fear of abruption following removal of such large volumes seems unfounded, because aggressive amniodrainage has a low complication rate (PPROM, abruption) (1.3%–3.8%).[167–169] Available data suggest that amnioreduction is effective only in mild cases of TTTS (stages I–II) and outright fails in a third. The overall perinatal survival rate in uncontrolled series with cases diagnosed prior to 26 weeks was 57%.[158] This rate was confirmed in a literature review compiled by Skupsi[170] (double survival, 50%; single survival rate 20%; total survival rate 61%). Further, amnioreduction is associated with a 16% to 26% risk of severe sequelae in survivors.[108,158]

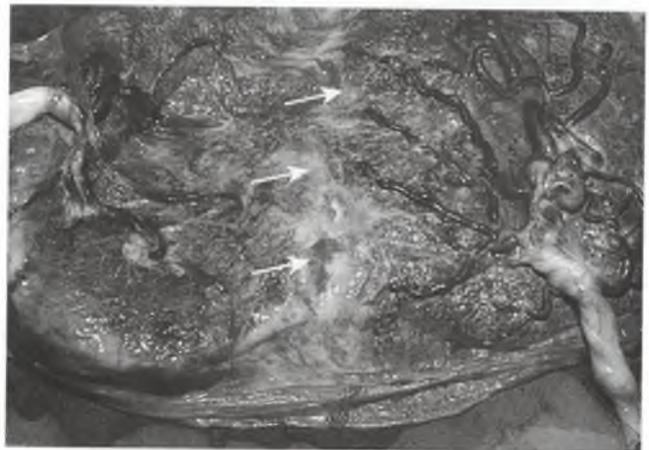
Whereas amniodrainage is a palliative and repetitive measure, fetoscopic laser coagulation of the vascular anastomoses seeks to address the underlying cause of the disease through a single intervention. Provided the vascular hypothesis is correct and that anastomosing vessels can be visualized during fetoscopy, their occlusion will result in the arrest of intertwin transfusion. Most fetoscopic laser centers concur that coagulation of nonanastomosing vessels should be avoided, as this increases the number of nonfunctional cotyledons and therefore the risk of IUFD. In most centers, the technique of coagulating all vessels crossing the intertwin septum is no longer practiced.[171] The vascular equator does usually not coincide with the membranous equator, and coagulation along the intertwin septum will lead to unnecessary placental loss. Nevertheless, most groups coagulate all anastomoses visualized (Fig. 24–24). A "hyperselective" approach, as discussed by Feldstein and associates,[172] coagulating only the causative AV anastomosis is interesting only from a theoretical point of view. It is


FIGURE 24–24

simply not possible to identify this anastomosis in the presence of others. Also, leaving certain anastomoses open puts the remaining fetuses at risk for hypovolemic events in case of sIUFD, and may lead even to a reversal of transfusion. However, in some monochorionic pregnancies with unequal placental territories or large shared part of the placenta, coagulation of all anastomoses may leave too little unshared placenta for one or both fetuses, leading to single or even double IUFD.

In Europe, Canada, and some sites in the United States, laser coagulation is performed percutaneously (Fig. 24–25) under local or locoregional anesthesia. A cannula or fetoscopic sheath is inserted into the hydramniotic sac, and the placenta is inspected. For coagulation, the laser tip is directed toward the target vessels at as close to a 90-degree angle as possible, and with a nontouch technique a 1-cm section of the selected vessel is photocoagulated (Fig. 24–26). At the conclusion, amniodrainage is performed until the amniotic fluid pockets on ultrasound are normal. With an anterior placenta, the amniotic sac as well as the vessels on the placenta may be more difficult to access. Some instruments have been purposely developed, but it is yet unclear whether they improve performance. So far, placental localization does not appear to influence outcome.[173]

PPROM remains the most important complication of invasive antenatal procedures: the incidence after fetoscopic laser coagulation is estimated around 10%.[174] In contrast to amniodrainage, when the death of one or both fetuses often occurs remotely from the procedure, most deaths with laser are diagnosed within 48 hours. However, the surviving twin appears far less likely to be anemic after laser[106] or to sustain neurologic sequelae[107] when compared with survivors of amniod-

rainage where the anastomoses remain patent.[108] Apart from IUFD, other fetal complications are uncommon but include congenital skin loss, gangrenous limb lesions, amniotic bands, microphthalmia, and intestinal atresia. These anomalies have each been described in TTTS not treated by laser[163,175–180] and are more likely related to the disease process than to the treatment. Maternal safety should remain a priority, and serious maternal complications should be registered carefully in a registry, such as the one set up by Eurofoetus.[181] Transient maternal Mirror or Ballantyne syndrome with pulmonary edema,

placental abruption, chorioamnionitis, and bleeding requiring transfusion are reported but none yet leading to maternal death. Hecher and associates demonstrated a learning curve, arguing against scattering the experience over too many centers.[182]

In uncontrolled series, the overall fetal survival rate has consistently been between 55% and 68%, with a risk for neurologic morbidity in survivors of 2% to 11% (Jan Nakyken, personal communication). The Eurofoetus research consortium was granted by the European Commission to conduct a randomized trial comparing serial amnioreduction versus laser coagulation followed by amnioreduction as a primary therapy (i.e., no treatment of any form prior to enrollment) for severe TTTS prior to 26 weeks. The primary outcome measure was survival of at least one twin at 6 months of age, and the secondary outcome measure was intact neurologic survival.[183] The findings are in press at the time this chapter was written. No staging system had been defined when the trial was initiated, but the vast majority of pregnancies would now be considered either Quintero stage II or III (Table 24–1). The technique of percutaneous laser coagulation was standardized with coagulation of all visibly communicating vessels between the two fetuses, as well as the ones from which it could not be excluded that they were anastomosing. Amniodrainage was performed through an 18-gauge needle or the fetoscopic cannula, until normalization of amniotic fluid levels as measured by ultrasound. Further therapy after the primary therapy was left to the physician's discretion.

There was no severe maternal morbidity (no woman required ICU admission or blood transfusion), although three placental abruptions occurred at the end of the amniodrainage (two in the drainage and one in the laser group); all required immediate delivery. There was no significant difference in the pregnancy loss rate before

24 weeks (17% versus 11%, $P = 0.37$). The median gestational age at delivery was significantly higher in the laser than in the amnioreduction group (33.3 versus 29.0 weeks' gestation; $P = 0.004$), with 53% and 78% delivering before 32 weeks. The interval between randomization and delivery was longer in the laser group ($P = 0.006$). Among liveborns, the birth weight was higher in the laser group (1757 g versus 1359 g; $P < 0.001$); differences between groups were significant for both recipients ($P = 0.02$) and donors ($P = 0.01$). Compared to the amnioreduction group, the laser group had a higher likelihood of survival of at least one twin to 6 months (76.4% versus 51.4%; $P = 0.002$). The number of stage I and IV cases was too low for an analysis of outcome by stage. However, stratified analysis by Quintero stage I and II or III and IV showed a significantly higher survival rate for stage I and II (73%) than for III and IV (55%), but laser-treated patients did better than amnioreduction-treated patients for all Quintero stages. Survival rates were similar for donors and recipients.

Overall, a higher percentage of infants were alive without major neurologic morbidity at 6 months of age or older in the laser group. Infants in the drainage group had a higher incidence of periventricular leukomalacia diagnosed in utero or during the first 6 months of life (laser 0.6% versus drainage 14%; $P = 0.02$), in particular the recipients. This led to spontaneous neonatal death in three cases and withdrawal of intensive care support during the first 6 months of life in another nine babies. There was a trend for lower rates of intraventricular hemorrhage (IVH) in the laser group, but this trend was significant only for recipients. Eight of 144 (6%) and 20 of 140 (14%) infants in the laser and in the amnioreduction groups respectively, had overt cystic periventricular leukomalacia. Other major neurologic morbidity was present in two (grade 3 IVH and blindness, respectively) and eight (1% and 6%) of the survivors in the laser and in the amnioreduction group, respectively. In conclusion, children were more likely to be alive and without clinical neurologic morbidity at 6 months when treated by laser (52%) than with amniodrainage (31%; $P=0.003$). This is the first randomized trial comparing these popular treatment modalities. Presently, the children are being followed until 2 years of age (EuroTwin2Twin study, also supported by the European Commission[157]), and these results are eagerly awaited. A recent long-term follow-up study of children surviving an uncontrolled series managed by laser (ages between 14 and 44 months) observed major neurologic problems in 11% of survivors.[184]

Intentional puncturing of the intertwin septum ("septostomy") with or without amnioreduction was suggested to be beneficial, but there is little evidence to support this technique, and the pathophysiologic rationale remains unclear. It definitely increases the amniotic fluid volume in the donor's sac but also creates an iatrogenic monoamniotic state with possibility of cord entanglement. A small retrospective study comparing amnioreduction to septostomy ($N = 14$) failed to identify any survival benefit with septostomy.[185]

TABLE 24-1

Randomized Controlled Trial of Fetoscopic Laser Surgery versus Serial Amniodrainage*

	LASER (N = 72)	AMNIOREDUCTION (N = 70)	P VALUE
Gestational age at randomization (weeks)	20.6 (±2.4)	20.9 (±2.5)	ns
Quintero stage at randomization

[§]Severe intraventricular hemorrhage was defined as ventricular bleeding with dilatation of the cerebral ventricles (grade III) or parenchymal hemorrhage (grade IV).
[¶]Cystic periventricular leukomalacia was defined as periventricular densities evolving into extensive cystic lesions (grade III) or extending into the deep white matter evolving into cystic lesions (grade IV).
**The median in the laser group is the median volume drained at the end of a single procedure.

Selective feticide was suggested in 1993 to try to salvage at least one twin in complicated cases of TTTS.[186] Selective feticide by bipolar cord occlusion has been suggested for the treatment of stages III and IV of TTTS.[187] This approach is certainly open for debate and may lead to some difficult decisions. It is not necessarily easy to determine which fetus will have the worst outcome, a major drawback because the maximum survival rate is 50%. Selective feticide should in our opinion be reserved for instances of discordant anomalies (such as hydrocephaly), when imminent death of one twin is anticipated, or in cases in which full visualization of the vascular equator is likely to be technically impossible.

SUMMARY OF MANAGEMENT OPTIONS

Twin-Twin Transfusion Syndrome (TTTS)

Management Options	Quality of Evidence	Strength of Recommendation	References
Serial amniodrainage does prolong pregnancy and improves fetal condition by reduced intrauterine pressure, although it does not protect the surviving twin in the event of sIUFD (single intrauterine fetal death) and is only effective in mild cases of TTTS.	IIb	B	106,164,168

SUMMARY OF MANAGEMENT OPTIONS

Twin-Twin Transfusion Syndrome (TTTS) *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Laser coagulation, as compared to amniodrainage, has been shown to have better survival rates and neurologic outcome, and is therefore considered to be the best first-line treatment for TTTS in centers experienced in this technique.	Ib	A	184
Septostomy does not seem to have a survival benefit as compared to amniodrainage.	IIb	B	186
Selective feticide by cord occlusion does arrest the transfusion process and is indicated for TTTS with associated discordant anomalies or in rare cases of imminent fetal death, or when laser coagulation with full inspection of the vascular equator is technically not feasible.	III	B	187

CONGENITAL ANOMALIES IN TWINS

Structural Anomalies

Structural anomalies are 1.2 to 2 times more common in twins than in singletons. Unfortunately, most studies do not subgroup incidence by either zygosity or placentation. Nevertheless, it seems that the rate per fetus in dizygotic twins is the same as in singletons, whereas the rate is two to three times higher in the monozygotic twins.[56] Abnormalities associated with twins are neural tube defects, brain defects, facial clefts, gastrointestinal defects, anterior abdominal wall defects, and cardiac defects.[188] Even in monozygotic twins, concordance (both fetuses similarly affected) for a structural anomaly is rare (<20%).[57] Also, discordance for genetic diseases is frequently reported in monozygotic twins and may reflect variations in gene expression secondary to postzygotic mutation, parental imprinting effects, asymmetrical chromosome X inactivation,[25] and differential DNA methylation.[189] The exact mechanism of the increased prevalence of structural anomalies in monozygotic twins remains largely unknown, although several mechanisms are proposed. It is possible the twinning process itself is teratogenic owing to an unequal distribution of the inner cell mass or to splitting after laterality gradients have already been determined, resulting in abnormalities such as midline defects.[25] Vascular events in early embryogenesis and later fetal life might account for part of the observed discordant brain and heart anomalies. The prevalence of cardiac anomalies in monochorionic twins is reported to be 2.3% in those without TTTS and 7% in those with TTTS, compared to 0.6% in the general population. Pulmonary valve stenosis in recipients accounts for all the additional congenital heart defects found in TTTS cases, suggesting a causative role of the hemodynamic imbalance. The global prevalence of congenital heart defects in monochorionic twins (3.9%) is

thus comparable to that in a family with a history of congenital heart disease (2.5%). Thus, detailed echocardiography is indicated both in second and third trimesters, because pulmonary artery stenosis is a dynamic process that may evolve until delivery.[161] Anomalies unique to monochorionic twins are the twin reversed arterial perfusion (TRAP) sequence and conjoined twinning as discussed earlier.

Chromosomal Anomalies

Risks of Chromosomal Abnormalities

In dizygotic twins, the age-related risk of Down syndrome for one twin is independent of the risk for the other and should be the same as in singletons. Therefore, the risk of at least one fetus having Down syndrome is double that in singletons. Whereas chorionicity can be accurately determined during the first trimester, there are no noninvasive means to establish zygosity antenatally. Nonetheless, dichorionic twins are dizygotic in about 90% of cases, and all dichorionic twins are for risk assessment considered to be dizygotic. In a dichorionic twin pregnancy, the age-related risk of at least one twin having Down syndrome can then be calculated by adding the age-related risks together (e.g. for a 40-year-old woman, $1/100 + 1/100 = 1/50$), whereas the risk of both fetuses being affected is obtained by multiplying the age-related risks ($1/100 \times 1/100 = 1/10,000$).

In a monochorionic (and by definition monozygotic) twin pregnancy, the age-related risk is the same for both twins and similar to that in singletons with usually both twins affected, although discordances in the phenotypic expression of the aneuploidy are frequently observed.[192,193] It is important to note that though rare, even monochorionic twins may be discordant for chromosomal anomalies and discordancy for nearly all common human aneuploidies (trisomy 13,[55] trisomy 21,[54] mono-

somy 45 X[54]) are reported. Most of these cases involve one twin with Turner syndrome and the other with either a female or male phenotype but usually a mosaic karyotype.[92] This rare phenomenon is called heterokaryotypic monozygotism and it reflects either a postzygotic mitotic event (nondisjunction or anaphase lag) or prezygotic meiotic errors. Several mechanisms may be involved. The zygote may initially have been karyotypically normal (46), but a trisomic (47) respectively monosomic cell line (45) develops because of a mitotic nondisjunction or anaphase lag. Conversely, the zygote may initially have been trisomic (47), but a diploid cell line (46) may be established as a result of a mitotic disjunction or anaphase lag, a phenomenon known as trisomic rescue. At the blastocyst stage, the embryo proper originates from only three to five progenitor cells and splitting at this stage will give rise to monochorionic twinning. If a mitotic error takes place in any of these cells, it may actually trigger the twinning process with the proliferative advantaged diploid cell line separating out the aneuploid progenitors (Fig. 24–27). If the aneuploidy is nonviable, then this aneuploid "twin" will vanish without leaving any detectable remnants.[194] However, if the aneuploidy is viable, then this may give rise to heterokaryotypic monochorionic twins.

Screening for Aneuploidies in Twins

Screening for aneuploidy is more complex in multiple pregnancies than in singletons, because although selective feticide is an option if only one fetus is affected, the procedures can cause the loss of the unaffected co-twin. It is therefore essential the parents be adequately counseled on the pros and cons of screening in multiple pregnancy. The screening tests should have good detection rates and an acceptably low false-positive rate, as invasive testing carries a higher risk and is technically more challenging in multiple pregnancy.

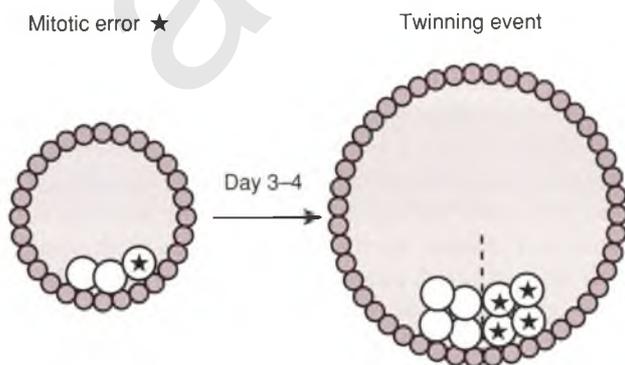
Second-trimester serum screening for aneuploidy has disappointingly low detection rates in twins (45% for a 5% screen positive rate),[191] presumably because the altered biochemical markers of the aneuploid fetoplacental unit are masked by the presence of an euploid co-twin.


FIGURE 24–27
Illustration of mitotic error in an initially euploid zygote leading to a twinning event. (Courtesy of T. Van den Bosch.)

Also, serum screening provides only the risk of at least one affected fetus (pregnancy-specific risk) and does not give a feature to identify the fetus at increased risk (fetus-specific risk). In contrast, first-trimester nuchal translucency (NT) measurement has better detection rates, identifies the fetus at increased risk, and allows a selective feticide in the first trimester. It is therefore the preferred screening method in twins. The combination of NT with first-trimester serum biochemistry further increases the detection rate. In a three-year review of combined NT and serum screening in the first trimester on 230 twin pregnancies, detection rate of Down syndrome was 75%, with 7% of fetuses and 9% of pregnancies (with at least one fetus) having a risk above 1/300.[195]

Although combined NT and biochemical screening allow a fetus-specific risk, it seems logical to quote only one risk for monochorionic fetuses (pregnancy-specific risk) because both will be affected or both will be unaffected in nearly all cases. Quoting the risk of the fetus with the largest NT may overestimate the true risk, especially because increased NT in a monochorionic twin pair may be an early sign of unbalanced intertwin transfusion.[153] Alternatively, one may quote the average of the two NT measurements. Unfortunately, there is little data at present to guide clinical practice. Nevertheless, it is proposed for combined NT and first-trimester biochemistry in monochorionic twins to use the average of the two NT measurements for a combined risk calculation. For dichorionic twins, it makes sense to quote the fetus-specific risk, although it is probably more relevant to the parents to hear what the risk is that at least one fetus will be affected (pregnancy-specific), which is obtained by adding the two fetus-specific risks. The risk that both are affected is extremely rare and is obtained by multiplying the two fetus-specific risks.

Invasive Antenatal Testing in Twins

Fetal karyotyping requires invasive testing by amniocentesis or chorionic villous sampling (CVS). Because these procedures are technically more demanding in multiple pregnancies, it is generally advocated they be performed in tertiary referral centers. The choice of invasive technique(s) will depend on the procedure related risk, on the accuracy of obtaining a result from both fetuses and on technical circumstances. Although genetic amniocentesis is a well-accepted procedure, it remains unclear whether the postprocedural loss is higher in twins compared to singletons and whether the risk increases with increasing number of fetuses. Historically, amniocentesis in twin pregnancies was considered to have higher procedure related loss rates (2.7%–8.1%).[196] However, this may be largely attributable to the higher background risk of fetal loss in twins (6%),[197] rather than to the invasive procedure. As such, Ghidini and associates found that amniocentesis in experienced hands did not increase loss rates significantly.[198] Conversely, Yukobowich and associates reported loss rates within 4 weeks after the procedure

that were five times higher in twins (2.6%) compared to singletons (0.6%) and unexposed twins (0.6%).[199]

Several techniques are used to ascertain that all fetuses are correctly sampled. No technique is shown to be superior, and the choice depends largely on operator preference. In any event, great care must be taken to note distinguishing features, such as gender, placental localization, umbilical cord insertion, and fetal positions. A diagram should be made to prevent the potentially disastrous consequence of incorrect sampling. Samples should also be meticulously labeled. Amniocentesis in twins can be done through a single or double uterine entry. With the double needling technique, each sac is sampled separately and consecutively. The injection of dyes after sampling of the first sac to ensure it is sampled only once is no longer recommended. Methylene blue is contraindicated because of well-documented fetal risks, such as intestinal atresia, hemolytic anemia, and fetal death.[200] Although no similar fetal risks are reported with indigo carmine, it has serotonergic properties[201] and may in theory lead to hypertension and bradycardia and is therefore best avoided. A less commonly used technique is the double needle simultaneous visualization technique.[202] An amniocentesis needle is advanced into the first cavity, while a second needle is introduced into the other amniotic cavity without altering the position of the transducer. This technique permits visualization of both needles simultaneously on either site of the septum but necessitates the presence of two operators. Finally, a single uterine entry technique is described[203] in which the needle is first advanced into the proximal sac and fluid aspirated. The stylet is replaced, and under direct visualization, the needle is advanced through the septum into the second sac. After discarding the first 1 mL of fluid to avoid contamination, a sample is aspirated from the second sac. This technique has the advantage of creating only one membrane defect, and to date, no cytogenetic errors have been reported, although there is the theoretic concern of contamination and the creation of an iatrogenic monoamniotic pregnancy.

CVS in multiple pregnancy can be performed using either the transabdominal approach, transcervical approach, or a combination of the two. In the hands of an experienced operator, the loss rate attributable to CVS in twins may be comparable to that after amniocentesis. However, cytogenetic results are incorrect in 1.5% to 2% of cases because of contamination of one sample with villi from the other, placental mosaicism, culture failure, or sampling the same fetus twice. As a result, the resampling rate approximates 2%. To reduce the rate of incorrect sampling, it is imperative placental sites are accurately mapped and the extreme ends of each placenta preferentially sampled. For example, in those cases with a lower and upper placenta, a combined technique with a transcervical approach for the lower placenta and transabdominal approach of the upper placenta may be used.

Which technique (amniocentesis or CVS) should be used in twins, and should both or rather one fetus be sampled? The answer largely depends on chorionicity and the risk of one or both being affected. For dichorionic twins, both CVS and amniocentesis are valuable options. As CVS can be performed in the first trimester, selective feticide can be done at an earlier stage in the event of discordant chromosomal anomaly with possibly lower risks for the healthy co-twin. On the other hand, because of the higher rates of contamination, it may be preferable to restrict CVS to fetuses at especially high risk (e.g., if the risk of first-trimester screening is greater than 1 in 50) and defer invasive testing to 15 weeks in lower risk cases for amniocentesis. It is generally recommended that both fetuses be sampled. Even though only one has an increased NT or anomaly, they can still be monozygotic. Amniocentesis is preferred to CVS in monochorionic twins, as rare heterokaryotypic monozygotic twins can only be diagnosed by sampling both sacs. Only if monochorionicity is accurately documented in the first trimester and none of the twins show any structural anomalies is it possibly justifiable to sample only one fetus (by CVS or amniocentesis). In heterokaryotypic monozygotic twins, CVS of the common placenta may show mosaicism, a normal or abnormal karyotype, depending on the type and timing of postzygotic event.[54] If trisomic rescue is the mechanism involved, then the diploid fetus will have a one in three risk of uniparental disomy (UPD) for the specific chromosomal pair that is trisomic in its co-twin. UPD, when both chromosomes in a pair are inherited from the same parent, will produce an abnormal phenotype if the involved chromosomal pair carries an imprinted region/gene or homozygous recessive mutation.[204] The presence of UPD should be excluded in heterokaryotic monozygotic twins. Counseling may be very difficult in hetorokaryotypic twins because it is not possible to exclude the presence of hidden, but phenotypically important, mosaicism in the twin with normal karyotype on amniotic fluid cells. Cordocentesis is of little help in monochorionic twins because blood chimerism is invariably present, making genotyping of lymphocytes unreliable.

Fetal Risks

In dichorionic twins, the presence of a discordant anomaly usually does not affect the well-being of the other twin unless associated with hydramnios (such as anencephaly, duodenal atresia) or spontaneous demise, which increases the risk of preterm delivery for the healthy co-twin. An ethical dilemma arises when elective preterm delivery for *ex utero* treatment or antenatal invasive procedures with risk of iatrogenic PPROM (such as shunt placement) to ameliorate the outcome for the affected twin places the normal co-twin at risk of iatrogenic prematurity. In contrast to dichorionic

twins, the spontaneous death of the anomalous twin may have disastrous consequences in a monochorionic twin pregnancy, because in addition to the consequences of severe preterm delivery it may lead to an acute exsanguination of the healthy co-twin with double fetal death in about 10% to 25% and cerebral damage in 25% to 45%.

Management Options

There are essentially three management options for discordant structural and chromosomal anomalies:

- Conservative management
- Selective feticide
- Termination of the whole pregnancy

Paramount to safe management is an accurate determination of chorionicity in the first trimester because the methods for selective feticide differ between mono- and dichorionic twins.

Management in Dichorionic Twins

If the abnormality is nonlethal but may well result in serious handicap, parents must decide whether the burden of a handicapped child is enough to risk the loss of the healthy twin from feticide-related complications. If the abnormality is lethal, it may be best to avoid such risk, and conservative management is preferable unless the condition threatens the well-being of the healthy twin. Such a dilemma is illustrated by dichorionic twins discordant for anencephaly, which is always lethal, but the associated hydramnios place the healthy co-twin at risk of severe preterm delivery. However, expectant management in such cases has been shown to have a favorable outcome for the unaffected fetus in dichorionic twins, with less than half developing hydramnios and none delivering before 29 weeks (mean, 36 weeks).[205] Selective feticide in the second trimester is associated with a higher gestational age at delivery but carries the risk of procedure-related fetal loss.[206]

Selective feticide in dichorionic twins is performed by intracardiac or intrafunicular injection of potassium chloride under continuous ultrasound guidance. It is of utmost importance to ascertain that the correct fetus is terminated by identification of gender differences, obvious structural anomalies, placental localizations, and cord insertions. The risks of selective termination are loss of the entire pregnancy and premature delivery. The overall loss rate reported by the international selective feticide registry of 402 multiple pregnancies, including some higher-order multiple pregnancies, is 7.5%. A breakdown by gestation (5.4% at 9–12 weeks; 8.7% at 13–18 weeks and 6.8% at 19–24 weeks) reveals a nonsignificant trend toward higher loss rates for procedures performed after 13 weeks. Preterm delivery before 33 weeks occurred in 22%, with 6% delivering between 25 and 28

weeks.[207] One center with 200 selective feticides reported an overall loss rate of only 4%, with significantly higher loss rates in triplets or higher-order multiplets (11%) compared to twins (2.4%), with only 16% of patients delivering before 32 weeks. This underlines the importance of referring to experienced centers. In order to reduce loss rates, it has been proposed to defer selective feticide to 28 to 32 weeks, which is only an option in countries where late termination is legal and may be emotionally more difficult to accept for both parents and doctors. In a series on 23 in dichorionic twins with nonlethal anomaly, there were no fetal losses, and all patients delivered beyond 35 weeks.[208]

Selective Feticide in Monochorionic Twins

For selective feticide in monochorionic twins, the conventional techniques of potassium chloride injection used in multichorionic pregnancies cannot be used because the potassium can reach the other fetus by the obligatory anastomoses.[209] In addition, patent intertwin vessels may lead to acute fetofetal hemorrhage into the terminated twin's fetoplacental unit, putting the surviving twin at risk for central nervous system damage or co-twin death.[62] Therefore, the appropriate techniques arrest and isolate the terminated twin's circulation completely and permanently,[210] although all have considerably higher risks for fetal loss and very early PPROM compared with systemic injection of potassium chloride. Further, although expectant management may be preferable in dichorionic twins for discordant anomalies with an expected spontaneous demise of the anomalous twin, monochorionic twins specifically warrant a preventive selective feticide. This is particularly relevant for discordant chromosomal anomalies as aneuploidy has a high spontaneous IUFD rate.[211,212]

As discussed in the management of TRAP, the preferred method for selective feticide is cord occlusion by either laser/bipolar coagulation or cord ligation. The initially reported method of umbilical cord embolization using a variety of agents, including absolute alcohol, coils, and enbucrilate gel, is no longer recommended because of failure rates greater than 60%.[136] Anecdotal successes are reported, but double IUFD is unfortunately common, probably due to incomplete vascular obliteration or migration of the sclerosants or thrombogenic products to the co-twin.

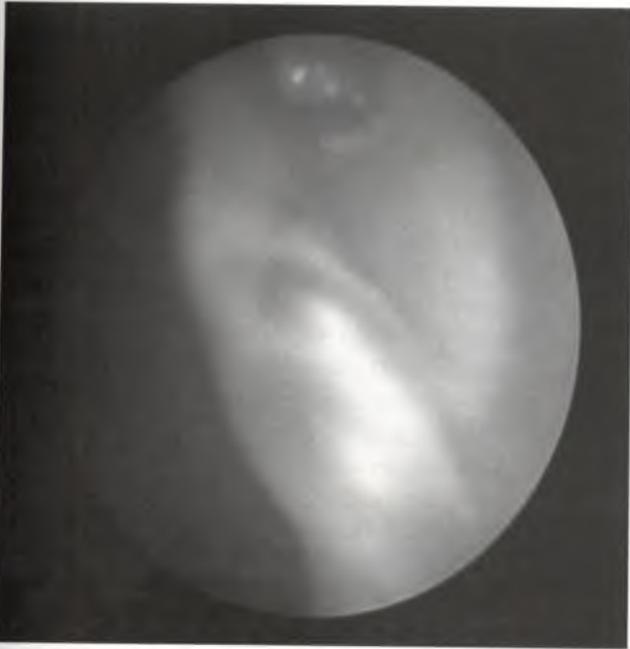
Fetoscopic cord ligation is already a historical technique, although it does cause immediate, complete, and permanent interruption of both arterial and venous flow in the umbilical cord. Though co-twin survival rates are over 70%,[213] these procedures are quite cumbersome with a high risk for PPROM. In comparison, laser cord coagulation (Fig. 24–28) is a relatively simple and straightforward procedure and uses similar instruments and set-up as for coagulation of the vascular anastomoses in TTTS. It is the preferred method, especially before 21


FIGURE 24–28
Fetoscopic image of laser cord coagulation (see Color Plate 40).

weeks. It can be performed as early as 16 weeks, using a double needle loaded with 1.0-mm fetoscope and a 400-μm laser fiber.[137] However, it may be difficult to coagulate the umbilical cord at later gestational ages. For this reason, bipolar energy was explored. Initially, a large-diameter forceps was used, but now purpose-designed devices of 3 mm or less are on the market as well as adapted cannulas and trocars. Most procedures can be done with a single port under ultrasound guidance (Fig. 24–29), but rarely an ancillary port is used for the fetoscope to identify the correct umbilical cord (e.g., monoamniotic twins). We always try to work within the sac of the target fetus and use amnioinfusion only where

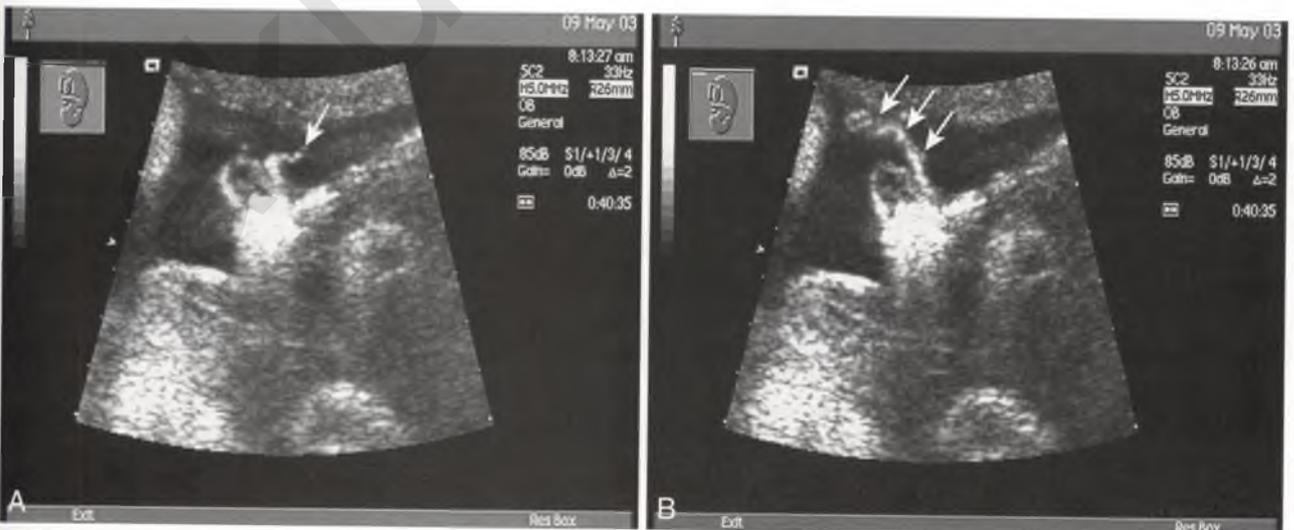
needed. In our initial series of 10 cases, two patients had PPROM and underwent a termination. The other eight patients delivered at a mean gestational age of 35 weeks (more than 15 weeks after the procedure).[63] Nicolini and associates reported their experience with 17 cases.[214] The survival rate was 81% (13 of 16 survivors; one patient had TOP because of an abnormality diagnosed later). There was one fetal hemorrhage caused by cord perforation, which is a complication of too much energy. We reported the outcome of 50 consecutive cord coagulations in complicated monochorionic twins by laser or bipolar coagulation performed between 16 and 28 weeks (mean 21 weeks).[215] Indications were TRAP (38%), discordant anomaly (38%), severe TTTS (20%), and selective IUGR (4%). In 75%, the laser was used as the primary technique; additional bipolar was necessary in about half of cases. Overall survival was 78% with normal outcome (range: 1–36 months, 100% follow-up), except for two children with mild developmental delay born after PPROM less than 28 weeks GA. Persistent PPROM before 30 weeks occurred in 21%, and if before 25 weeks, this was associated with a mortality rate of 80%. There were no serious maternal complications, except for one mild transient Mirror or Ballantyne syndrome. Four cases involved heterokaryotypic monochorionic twins (46,XY/47,XY,+21; 46,XX/47,XX,+13; 46,XY/45,X; 46,XX/45,X) and umbilical cord occlusion that resulted in a successful outcome in all four cases. All children were phenotypically normal at birth (range: 34–40 weeks GA) and are developing normally.[216] To avoid the risks of early PPROM for the healthy co-twin, it may be preferrable to defer selective feticide until after 26 weeks in highly selected cases of discordant anomaly when the risk of IUFD is small (such as in severe discordant CNS, genitourinary, skeletal anomaly). Bipolar coagulation can then be performed using the 3.0-mm forceps by over-


FIGURE 24–29
A, Ultrasound image of a bipolar cord coagulation in a monochorionic twin pregnancy. *B*, Ascending steam bubbles (*arrows*) confirm adequate coagulation impact.

stretching the blades whereupon the forceps opens more widely to accommodate for the larger cord diameter. We recently reported on a consecutive series of five cases in which selective feticide was performed between 26 and 30 weeks GA. All deliveries occurred beyond 31 weeks (range: 31–37 weeks). All infants survived, except for one unrelated neonatal death of a child born at 36 weeks due to a complication of failed therapy for pulmonary stenosis related to TTTS.[217] Needle-based intrafetal coagulation[218,219] does not appear to be an effective technique to achieve selective feticide in non-TRAP discordant monochorionic twins, and no successes have as yet been reported.

Currently, it is not possible to say what the single best method is for selective feticide in monochorionic pregnancies. The surgeon should be familiar with several techniques in order to tailor therapy to the individual requirements of each case. Generally, we recommend laser fetoscopic cord coagulation as a primary technique before 21 weeks, whereas beyond 21 weeks laser or bipolar coagulation can be used, depending on cord diameter.[220] Cord ligation should be available as backup if all other methods fail. These procedures should be performed in experienced tertiary referral centers to ensure a large enough caseload. Also, the surviving twin should be followed carefully throughout pregnancy and after birth with an early neonatal brain scan and developmental assessment at 1 year of age.

Issues Applicable to Monochorionic and Dichorionic Twins

As for singletons, Rhesus prophylaxis should be given in all instances of invasive prenatal procedures in Rhesus-negative women when the fetal genotype is unknown. As with sIUFD, the incidence of maternal disseminated intravascular coagulation appears to be rare after selective fetacide,[110,111] and routine checks of coagulation parameters may therefore be unnecessary. From 20 weeks onward, the use of fetal analgesia or anesthesia by administration of fentanyl or other opioid alternative should be considered prior to feticide to reduce fetal awareness and pain sensation.[221] To many people, any deliberate termination of a fetus is controversial, and the decision to proceed to selective feticide may be difficult. Therefore, psychological support and counseling for the family is strongly recommended before and after the selective feticide.

SUMMARY OF MANAGEMENT OPTIONS
Congenital Abnomalies in Twins

Management Options	Quality of Evidence	Strength of Recommendation	References
Issues Applicable to All Twins			
Options	–	GPP	–
Conservative management			
Selective feticide of the abnormal fetus			
Termination of the pregnancy			
Offer counseling and psychological support.	–	GPP	–
Accurate chorionicity determination is essential.	IIb	B	13,14
From 20 weeks onward, consider fetal analgesia or anesthesia.	III	B	222
Anti-D prophylaxis for procedures.	–	GPP	–
Serial surveillance of maternal coagulation status is often undertaken after feticide, but risks are low.	III	B	209
Dichorionic Twins			
Conservative management is usually preferred if the condition is lethal to avoid intervention loss rates (see below).	III	B	206
Selective feticide is performed by intracardiac or intrafunicular injection of KCl (potassium chloride).	III	B	208
Loss of the healthy fetus occurs in about 7.5% with delivery before 33 weeks in 22%.	III	B	207, 208

Careful follow-up of surviving normal twin.	–	GPP	–

CONCLUSIONS

- Multiplets have more problems during their *in utero* life than singletons.
- Management issues are complex, because more than one fetus has to be taken into account. This situation may pose some difficult dilemmas:
  - Should one save a distressed growth-retarded twin by conferring risks of iatrogenic prematurity to its nondistressed appropriately grown co-twin?
  - How does the burden of raising a multiplet with one handicapped child weigh against the risks of selective feticide for the nonaffected fetus?
- The shared circulation is responsible for the increased mortality rate in monochorionic multiplets and may lead to some unique complications.
- Chorionicity determination plays a key role in the management of multiple pregnancies and is accurately done in the first trimester. Correct determination of chorionicity is indispensable for the management of poor growth, intrauterine death of one twin, and discordant anomalies.
- Management issues are reasonably well-established for complicated dichorionic multiplets and recently also for TTTS. However, comparatively little is known about the natural history, best management, and long-term outcome of poor growth, sIUFD, TRAP, and monoamnionicity in monochorionic multiple pregnancies.
- Clearly, because of the rarity of these disorders, these questions can be addressed only by large multicenter prospective studies.

Fetal Hydrops

John Smoleniec

INTRODUCTION

Fetal hydrops is associated with high perinatal morbidity and mortality rates at all gestational ages (up to 100% in some series[1]). The reported incidence approximates 1:2500 to 1:3500 in neonates.[2] Traditionally, fetal hydrops was categorized into immune (IH) and nonimmune (NIH) disease. Although Rhesus (D) hemolytic disease was the most common cause of hydrops in the past (see Chapter 14), the widespread implementation of anti-D immunoglobulin prophylaxis and the improved antenatal management of at-risk fetuses has led to a remarkable decrease in its incidence and morbidity. At present, NIH is more prevalent than IH in most countries with adequate anti-D immunoglobulin prophylaxis supplies and fetomaternal expertise. A comparative incidence ratio of NIH to IH of 9:1 is reported.[3]

Advances in ultrasound make hydrops easy to diagnose. The pathogenesis of human fetal hydrops reflects the underlying etiology and as a result is often unclear. The "causes" or rather associations with NIH are many[4,5] (Table 25–1). Physiologic research using animal models[6–8] is providing some understanding of the complexity of fluid dynamics within the uterus (fetal, fetoplacental, fetoamniotic fluid, and between the uterine decidua and the placenta and membranes).

INCIDENCE

A prevalence of 1:1000[9] is reported, though the true incidence is regionally dependent. It is also subject to seasonal variation, for example, parvovirus B19 epidemics.[10,11] α-Thalassemia is the most common cause of fetal hydrops in Southeast Asia,[12] accounting for between 53% and 81% of cases.[13] Considering the population density in this region, it is probably the leading cause of NIH in the world. Population screening can reduce the incidence of thalassemia, as it has in Cyprus, providing the

resources are available. The uptake of first trimester nuchal translucency screening is likely to have an impact on the incidence of hydrops associated with aneuploidy, which is normally identified in the second and third trimesters. In those fetuses with an increased nuchal translucency but a normal karyotype, there is an increased risk of hydrops fetalis and cardiac anomalies.[14,15]

DIAGNOSIS

Hydrops is defined as the excessive extravascular accumulation of fluid in the interstitial compartment secondary to the disruption of the normal intravascular interstitial fluid homeostatic mechanisms. The excessive accumulation of interstitial fluid, particularly in serous cavities (peritoneal, pleural, pericardial), placenta, and amniotic fluid, facilitate the sonographic diagnosis of fetal hydrops (Figs. 25–1 and 25–2). Classically, the sonographic diagnosis of hydrops requires the presence of generalized edema plus the accumulation of fluid within two or more serous cavities, though clearly, many of the pathologies leading to such a diagnosis go through phases in which fluid is recognized sonographically only in one site.

PATHOPHYSIOLOGY

Hydrops occurs when the microvascular fluid exchange regulatory system is disturbed. Microvascular fluid exchange mechanisms in the human fetus are complex, gestationally dependent, and poorly understood. The number of fluid exchange pathways in the fetus is greater than in either the infant or adult. They include transplacental, transmembrane, and transcutaneous pathways. Transplacental fluid exchange has a large influence on blood volume, as the placental blood volume accounts for

†Tokieda et al.[84]

approximately 40% of the total fetal circulation.[16] Fetal development is associated with the changing influence of the different fluid exchange pathways and forces. These routes of fetal fluid exchange may be important compensatory mechanisms when fluid homeostasis is disturbed, as shown by the common clinical association of hydramnios and placental edema with fetal hydrops. The fetal extracellular fluid volume (ECF) exceeds the intracellular fluid volume (ICF), though the ECF:ICF ratio declines progressively with gestation, becoming less than 1 only in the newborn period.[17] The interstitial:plasma volume ratio is therefore greatest in the fetus and declines into adulthood. The control of this relatively large interstitial fluid compartment is fundamental to the understanding of fetal hydrops. Unfortunately interstitial fluid control mechanisms are poorly understood because of the

FIGURE 25-1
Skin edema and bilateral pleural effusions associated with a congenital heart defect.

difficulty of measuring plasma and interstitial volumes.[18] The many influences on fetal fluid homeostasis make it unlikely that there is a single or simple pathophysiologic explanation for all cases of fetal hydrops. The "Starling equation" does not provide pathophysiologic explanations in the fetus.[19] The fluid-dominated milieu of the fetus and the specific physiologic characteristics of the fetal heart and the lymphatic system make it particularly susceptible to hydrops. Animal research[6,7,20,21] coupled with clinical study[19,22,23] suggest that raised central venous pressure is a critical step in the pathophysiology of hydrops. The clinical use of umbilical venous pressure in the investigation and management of some cases of fetal hydrops is a vindication of the relatively recent physiologic research findings on the importance of the central venous pressure and the lymphatic system.[22,23] At the same time, some of the traditional pathophysiologic forces such as colloid oncotic pressure are being relegated to a lower tier of importance.

Ascites associated with a solid lung tumor.

MANAGEMENT OPTIONS

Once fetal hydrops is identified, the mother should be counseled regarding the following:

- Prognosis: namely, fetal risks in the short and long term, influenced by the diagnosis and may be unknown
- Diagnosis: based on maternal and fetal investigations (see Tables 25–2 and 25–3) and associated fetal risks from invasive procedures
- Treatment: if available and feasible in the circumstances

PROGNOSIS

Fetal Risks

The main fetal risks from hydrops are fetal death and infant morbidity:

- *Fetal death* may be the result of the underlying pathophysiology, invasive fetal investigations, or fetal treatment. The reported mortality rate ranges between 50% and 100%.[1] Complications of the various invasive diagnostic and therapeutic procedures include

abortion, preterm delivery, intrauterine fetal death, and fetal trauma (see Chapters 10 and 24).

- *Infant morbidity*: The short- and long-term prognosis depends on the underlying diagnosis and treatment, such as terminal cardiac failure and heart transplantation associated with parvovirus B19 infection,[24] cardiac anomaly needing surgical correction; chromosomal abnormality; or persistent generalized edema as a result of protein-losing enteropathy associated with congenital intestinal lymphatic hypoplasia.[25]

Maternal Risks

- *Prenatal* causes of hydrops include preterm rupture of membranes—risk of chorioamnionitis, preeclampsia ("mirror" syndrome),[26] anemia, hydramnios, maternal red blood cell alloimmunization, and placental abruption from invasive fetal procedures. In the event of fetal surgery,[27] the maternal risks include anesthetic risks, fluid overload and electrolyte imbalance, uterine hemorrhage (during entry for fetal shunting and intrauterine laser procedures),[28] psychological stress and associated mental illness, and even maternal death.[28]
- *During labor and delivery:* Hydrops may be associated with preterm labor and tocolysis side effects, dystocia (e.g., large tumors), cesarean delivery (e.g., associated with malpresentation, cord prolapse), abruption associated with membrane rupture in cases with hydramnios, postpartum hemorrhage (primary and secondary), and retained placenta.

DIAGNOSIS

Presentation

Fetal hydrops presents clinically in one of several ways (Table 25–4). The fetal sites of fluid collection and the amount of fluid (severity) may be helpful in the management of the hydrops once the cause is ascertained. In general, the absence of amniotic fluid is a poor prognostic sign.

Investigations

A comprehensive search in the mother and fetus for the "cause" usually involves antenatal invasive procedures (Tables 25–2 and 25–3). The severity, gestational age, ultrasound identified anomalies, and the parents' consent will influence the decision to perform these procedures. The ultrasound scan (see Figs. 25–1 and 25–2) may identify an associative cause in more than 50% of cases.[5] The diagnosis may not be possible in 10%[1] to 26%.[5] The most common invasive procedures are fetal blood sampling and amniocentesis. Fetal blood sampling is preferred (Table 25–5), but the associated mortality rates are likely to be higher than when the invasive procedures are performed for nonhydropic indications,[29,30] especially if the fetus is thrombocytopenic (e.g., parvovirus B19 infection) and when it is technically more difficult.

It is important to optimize the information available when planning intrauterine procedures (amniocentesis or fetal blood sample). For example, in the case of severe lung compression with heart axis deviation associated with large pleural effusions, a pleural tap may be combined with either procedure to determine the effect of decompression on the lungs and the restoration of the heart to its normal midline position. Pleural fluid can be used for investigations (karyotype, infection screen). Intrathoracic pressure and umbilical vein pressure measurements (if vein cordocentesis is performed) before and after the drainage may be used prognostically. The measurement of umbilical venous pressure

        chromosomes, and culture may take 2 weeks for a result)
    Infection screen
    Congenital erythropoietic porphyria (CEP)—amniotic fluid
        is dark brown which fluoresces red under Wood's light;
        increase in type 1 uro- and coproporphyrin isomers*
Fetal blood sampling
    Karyotyping (48–72 hours for a result in many centers)
    Hematologic causes (anaemia; hemoglobinopathies)
    Infection screen
    Umbilical vein pressure (UVP)

*Pannier et al.[2]

(UVP) is a surrogate for fetal central venous pressure (CVP). However, it requires an additional invasive procedure (amniocentesis and pleural aspiration) while measuring the UVP.

Amniotic fluid may be used to karyotype and to diagnose most infections associated with hydrops, such as parvovirus B19, cytomegalovirus (CMV), syphilis, toxoplasmosis, and herpes simplex virus (HSV) (see Chapters 30, 31 and 33). It has also recently been shown to be useful in the diagnosis of the rare condition of congenital erythropoietic porphyria.[2] The advantage fetal blood sampling has over amniocentesis is that more information can be obtained (anemia, Coombs' test, umbilical venous pressure) along with quicker karyotyping of all 23 pairs of chromosomes. Furthermore, treatment can be administered at the time of the procedure in cases of anemia.[31] It is important to screen for rare antibodies (Coombs' test), which can only be comprehensively done in regional blood transfusion laboratories, before making the diagnosis of NIH.[32]

Polymerase chain reaction investigation has revolutionized the diagnosis of fetal infection. A maternal infection screen should be performed before the fetal screen in order to optimize the use of the relatively small fetal sample. An extra 2-mL aliquot should be stored at −20°C in case the need for additional tests becomes apparent after the preliminary laboratory results have been completed.

The optimal time for prognostic counseling is after the results of the maternal and fetal investigations are available. After multidisciplinary counseling, the patient may elect to undergo a termination of pregnancy, if this is an option.

Postmortem Examination

When prenatal treatment has not been possible or successful, a postmortem examination of the fetus and placenta is to be encouraged.

TREATMENT

General

The proportion of cases amenable to prenatal treatment varies in each reported series, as they are generally small in number and reflect variation in the local referral practices. It is likely that no more than 20% to 30% of hydropic fetuses are potential therapeutic candidates.[33]

To date, fetal hydrops has proved amenable to fetal therapy only when associated with the following:

- Anemia
- Arrhythmia
- Hydrothoraces
- Twin-twin transfusion syndrome (TTTS)
- Tumors (few case reports)

Infection, arrhythmia, and twin-twin transfusion syndrome are conditions in which spontaneously reversible hydrops is clearly documented. The management of twin-twin transfusion syndrome is discussed in Chapter 24.

Anemia

Fetal blood transfusion is the only therapeutic option for the treatment of hydrops secondary to anemia (for details see Chapter 14). However, the prognosis may be worse than that for hemolytic disease secondary to red blood cell alloimmunization (e.g., with homozygous α-thalassemia, CMV infection, parvovirus B19 infection, trisomy 21, Gunther's disease).[2] It is important, therefore, to try to discern before intrauterine transfusion the cause of the anemia (α-thalassemia or fetomaternal hemorrhage) and whether it is secondary to another condition causing hydrops (e.g., trisomy 21 usually causes mild anemia unless the fetus is acidotic and terminal). This may mean not transfusing the fetus (with the patient's agreement) before all investigations (especially the parents for α-thalassemia trait) and fetal karyotype are available. This point should be discussed at the initial counseling session; otherwise, ill-advised intrauterine transfusions for the fetus with homozygous α-thalassemia may result in lifelong transfusions, iron chelation, and the associated morbidity.[34]

In Southeast Asia α-thalassemia is the main cause of fetal hydrops.[13] α-Thalassemia major (no functional α genes) is incompatible with life. Most fetuses develop hydrops (Fig. 25–3) and, if born alive, die within hours. This is in contrast with other common causes of fetal anemia for which the prognosis is generally good. Antenatal diagnosis is an option for those pregnancies at risk. Preconceptual education, screening, and counseling are to be encouraged (Chapter 39). The prognosis may change with advances in intrauterine therapy.[35]

In fetomaternal hemorrhage associated with hydrops, one should screen the patient and the fetus (using

FIGURE 25–3
Fetal hydrops (ascites) associated with α-thalassemia major.

ultrasound parameters) regularly for further episodes, as they may be fatal. Under these conditions, delivery may be considered once the pregnancy has reached an appropriate gestation.

There are no effective antenatal treatments for glucose 6-phosphate dehydrogenase (G6PD) deficiency and erythroleukemia. Gene therapy may prove possible in the future, and interdisciplinary counseling including pediatric colleagues and clinical geneticists is advisable.

Twin-Twin Transfusion Syndrome with Hydrops

The management of hydrops associated with TTTS has included intrauterine placental vessel (ideally selective) laser ablation, amniodrainage (poorer results compared with selective laser), umbilical cord occlusion (e.g., previable weight of donor with hydropic recipient), delivery, and termination. The reader is referred to Chapter 24 for a detailed discussion of TTTS. In some instances, intrauterine fetal transfusion was deemed necessary after selective laser therapy.[28]

Cardiovascular Defects

Cardiac anomalies are the most common anatomic anomaly associated with fetal hydrops.[5] In general, hydrops associated with a structurally abnormal heart

TABLE 25–6

Approximate Survival Rates for Major Treatable Causes of Fetal Hydrops

CAUSE	SURVIVAL RATES (%)
Anemia—parvovirus B19 infection	62.5[31] to 84%[74]
Cardiovascular—supraventricular tachyarrhythmia	60%[37] to 95%[38]
Pulmonary—primary hydrothorax	50%[51]

carries a poor prognosis, with a survival rate of 10% or less (Table 25–6).[36] Involvement of a pediatric cardiologist in the antenatal management (especially diagnosis and prognostic counseling) is advisable. The management options for these conditions are discussed in Chapters 16 and 17.

The majority of cases with a hydropic fetus associated with a tachyarrhythmia but a structurally normal heart respond to either transplacental (60%[37] to 95%[38] supraventricular tachycardia) or direct fetal therapy (see Chapter 16). Fetal tachycardia with hydrops associated with thyrotoxicosis in a patient with a history of Graves' disease can be treated with antithyroid medication in utero.[39] The prognosis is good in general with a survival rate of as high as 80%[37]; however, there may be neurologic morbidity associated with a long duration of hydrops.[40] Fetal myocarditis associated with congenital infection may unexpectedly have severe complications requiring perinatal heart transplantation.[24]

Pulmonary Defects

The prognosis for thoracic conditions associated with hydrops is generally poor and the number of successful therapeutic options limited. Diaphragmatic hernia is discussed in Chapter 20. The prognosis is better for drainage of fluid, cystic thoracic abnormalities (e.g., congenital cystic adenomatoid malformation [CCAM] type I; primary hydrothorax) as opposed to solid lesions (e.g., CCAM type III [Figs. 25–2 and 25–4] and some type II; pulmonary sequestration, see Chapter 23). The survival for solid CCAM masses ranges from as low as 0% with hydrops to 90% with no hydrops[41,42] and has led some to offer open fetal surgery to those with solid lesions and hydrops. It is associated with less than 50% survival and significant maternal and fetal morbidity.[43,44] There are case reports of other therapeutic options for solid lung lesions including percutaneous

FIGURE 25–4
Fetal hydrops associated with congenital cystic adenomatoid malformation (CCAM).

ultrasound guided injection of a vascular sclerosant (alcohol)[45] and laser vaporization.[46,47] There are also rare reports of spontaneous resolution of fetal hydrops[48,49] associated with regression of the lesion. In contrast, a number of hydropic cases with CCAM type I and II have been treated successfully using pleuroamniotic shunts providing they have a single large predominant cyst.[44,50]

Fetal hydrops associated with isolated primary or congenital hydrothorax has a much improved prognosis in contrast to the poor prognosis with solid thoracic lesions. The survival rate in hydrops and pleural effusions treated conservatively approximates 12%; however, the survival rate in cases treated with a pleuroamniotic shunt is around 50%.[51] The pathogenesis is unknown, but is often attributed to abnormalities of the lymphatic system of the lung and thoracic duct. The diagnosis of congenital hydrothorax is a diagnosis of exclusion—excess pleural fluid in the absence of another detectable cause. The hydrothorax typically presents after 24 weeks when human lung development has entered the canalicular phase. The lymphocyte content of the fluid is not relevant to either the prognosis or the diagnosis.[52] Although it was known since the early 1980s that placement of a thoracoamniotic shunt could reverse the hydrops,[53] the rate of reported success rates are quite variable.[51] This suggests more than one mechanism underlies the hydrops. The effectiveness of pleuroamniotic shunting is thought to be due to the relief of an obstructive cardiac return secondary to mediastinal deviation[54] resulting in low cardiac output (Fig. 25–5). It is further believed that relief of lung compression prevents pulmonary hypoplasia (assuming onset of the hydrothorax before 24 weeks) (Fig. 25–6). An initially elevated UVP associated with elevated intrathoracic pressure, both of which normalize after the effusion(s) have been drained, suggests that an elevated intrathoracic pressure is associated with the

FIGURE 25–6
Infant at birth immediately after removal of pleuroamniotic shunt (see pigtail drain on chest) with no need for respiratory support.

pathophysiology. If the effusion recurs, placement of a thoracoamniotic shunt should be curative. On the other hand, if the UVP is normal prior to decompression of the chest, or remains elevated after the chest has been drained and the heart has returned to its normal midline position, the placement of a thoracoamniotic shunt will not be beneficial.

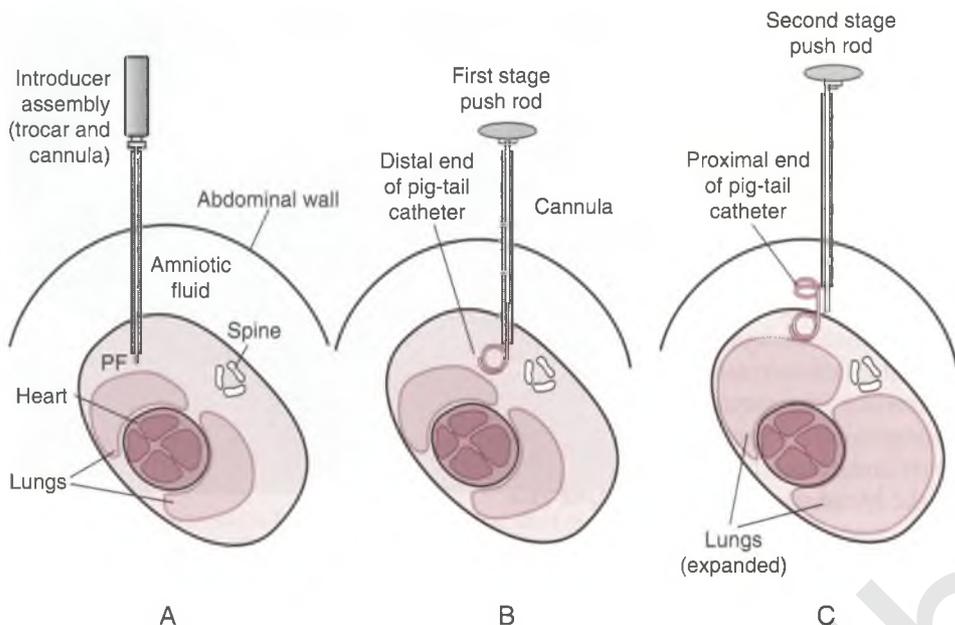
PROCEDURE: INSERTION OF FETAL THORACOAMNIOTIC SHUNT (FIG. 25–7)

METHOD

Hydramnios and iatrogenic oligohydramnios complicate the procedure. The usual preparations for a major invasive procedure (such as fetal blood transfusion) should be followed (see Chapter 14). The majority of procedures are performed under local anesthesia with the option of premedication. Maternal regional anesthesia[54] and rarely general anesthesia may be needed. The practice of using fetal paralysis varies. Fetal analgesia may also be used.[55]

In preparation for the procedure, the ultrasound transducer is positioned to give a transverse view of the fetal chest at the level of the maximal fluid collection. The optimal line of approach is chosen to avoid (if possible) the placenta and to avoid the broad ligament vessels (use color Doppler to identify) and to enter ideally the anterolateral aspect of the fetal chest. Once the line of approach is determined, the maternal abdomen is cleaned and draped and a local anesthetic instilled down to the uterine visceral peritoneum.

In order to overcome the problems with insertion of the pigtail catheter into the cannula, a guidewire and pusher are now available from the supplier. The double pigtailed catheter with its forming wire in place should be gently straightened. This can be done before inserting the introducer into the fetal chest to avoid delay. A stab incision (5 mm) is made with a blade into the abdominal wall to

FIGURE 25–5
Pleuroamniotic shunt in-situ showing lung expansion associated with drainage of the pleural effusion i.e. used to treat a fetus with primary hydrothorax.


Procedure for the insertion of a pleuroamniotic shunt. *A*, The introducer (trocar and cannula) are sited under ultrasound guidance in the left side of the fetal chest. *B*, The trocar has been removed, the pigtail catheter sited into the cannula, and the "first stage push rod" (shorter rod) used to push the distal end of the pigtail catheter in the fetal chest. *C*, The tip of the cannula is withdrawn from the chest into the amniotic space and the "second stage punch rod" (longer rod) is inserted into the cannula and displaces the proximal/maternal end of the pigtail out of the end of the cannula into the aminotic space, resulting in a pleuralamniotic pigtail shunt.

minimize the resistance of insertion. The introducer (trocar and cannula) is inserted along the optimal line of approach into the amniotic cavity, taking care to minimize amnion separation and to avoid contact with the fetus. The line of entry into the fetal chest is then reviewed and adjusted if necessary. Once this secondary adjustment is made, the introducer is inserted into the pleural cavity with a sharp, stabbing motion, taking care not to traumatize intrathoracic organs and vessels. The trocar is removed, and the elongated double pigtailed catheter with introducing guidewire carefully slid down into the cannula by an assistant, taking care not to remove the guidewire before the proximal end of the pigtail is sited within the shaft of the cannula using the guidewire pusher (to prevent jamming). Once the guidewire is removed, pleural fluid will escape through the cannula. After checking that the end of the cannula is still within the fetal chest, the shorter of the two push rods (i.e., the "first stage" pusher rod) is used to advance the distal part of the catheter (fetal component) into the fetal chest, where it should be seen to adopt its natural coiled shape. The introducing cannula is withdrawn from the fetal chest, into the amniotic cavity, taking care (using ultrasound) not to withdraw the cannula too far away from the fetal chest wall, otherwise one may pull the distant end of the catheter out of the chest. Ensure (by ultrasound) the end of the cannula is still within the amniotic cavity and not in the uterine wall. The maternal component of the double pigtailed catheter is now pushed out of the cannula into the amniotic cavity using the longer "second stage" push rod. The correct position of the pigtail catheter is confirmed ultrasonically. The cannula is now removed from the uterus and the wound sutured and dressed. If there are bilateral large effusions, a second shunt is required because decompressing only one side can actually worsen cardiac displacement.

A sonographic examination is performed 8 to 24 hours postoperatively to assess shunt function (Fig. 25–5). Resolution of the majority of the effusion is expected if the shunt is working well. The hydrops itself (and hydramnios if still present) may take an additional 10 to 14 days to resolve. The shunt will continue to function for a variable time interval. In a series of 28 cases the median interval was 12 weeks (range = 1–14) for the survivors, and 3 weeks (range = 1–11) for the perinatal losses (Nicolini, personal communication). If the pleural fluid reaccumulates, it is due to either blockage or displacement. At this juncture, the decision is made whether to replace the shunt or to deliver the fetus, depending mainly on the severity of any residual hydrops, the duration of the functional shunt, and the current gestational age.

At delivery the pigtail drain must be immediately occluded and then removed to prevent a pneumothorax (Fig. 25–6).

COMPLICATIONS

Insertion of a pleuroamniotic shunt is not without complications, which need to be included in the counseling of parents. Maternal complications of shunt placement include those associated with maternal analgesia, anesthesia (+/– epidural), hemorrhage, broad ligament hematoma, abortion, preterm rupture of membranes, preterm labor and delivery, maternal trauma, and red blood cell alloimmunization. The fetal complications include death, prematurity, fetal injury to thoracic organs and vessels, fetal severe hypoproteinemia,[56] shunt displacement into the fetal chest or blockage (12%),[51] and even limb entanglement with the development of circulatory compromise.[57]

Other Treatments

Serial intrapleural injections of OK-432 were used to treat a hydropic fetus, resulting in a liveborn infant with right renal dysfunction.[58] Termination of pregnancy is also an option if there is no improvement in the hydrops after treatment.

Tumors (See Chapter 23)

In selected cases with a poor prognosis, open fetal surgery[59] has been used for a small number (three) of surgically correctable conditions, in particular, solid pulmonary and sacrococcygeal tumors. Only a few centers in the world are willing to attempt such novel therapy. Other, less invasive (percutaneous) therapeutic options for the treatment of tumors have been tried to circumvent many of the problems of open fetal surgery with varying success. These include percutaneous alcohol,[60] radiofrequency ablation,[61] thermocoagulation,[62] and percutaneous ultrasound-guided injection of alcohol for the treatment of sacrococcygeal teratoma and placental chorioangioma.

Chromosomal Abnormalities

Chromosomal anomalies are found in about 13% of cases,[5] some of which will be associated with structural fetal anomalies. It is important to exclude aneuploidy before offering therapy, especially in fetuses with hydrothorax. Aneuploidy with hydrops has a dismal prognosis, and the option of pregnancy termination should be offered the parents (also see Chapter 2).

Infection

Fetal infection may be the etiology in 8% of fetuses with nonimmune hydrops.[63] The application of polymerase chain reaction technologies has revealed a number of previously unsuspected fetal infections. Viral hepatitis is the most common cause of noncardiac hydrops in some populations (see Table 25–1) (Weiner, personal communication). Hydrops of noncardiac origin does not generally progress, and preterm delivery is not usually required.

The common infectious causes of hydrops include parvovirus B19, cytomegalovirus (CMV), syphilis, and toxoplasmosis. Apart from parvovirus induced fetal anemia, very little can currently be done antenatally to treat these conditions once they produce hydrops.

Parvovirus B19 infection (see Chapter 30) is a recognized cause of human fetal hydrops.[64] Most common among school-age children, it is also known as "slapped cheek" syndrome, erythema infectiosum, fifth disease, or academy rash.[65] Twenty percent to 50% of pregnant women are susceptible to parvovirus infection.[66,67] It often occurs regionally in 3- to 5-year epidemic cycles,[68] at which time it may be the leading cause of hydrops

fetalis in the region.[10,11,69] The risk of fetal hydrops may be higher in mothers with asymptomatic infection.[10] Hydrops is mainly due to profound hypoplastic anemia, but can also be associated with myocarditis[24,69,70] and hepatitis.[31] The risk of fetal loss is greatest during the first half of pregnancy, with most reported cases of hydrops between 16 and 32 weeks.[71,72] However, the true incidence of first trimester losses due to parvovirus infection is unknown. The interval from maternal infection to fetal death is described between 1 and 16 weeks, with the majority occurring by 8 weeks.[72]

Management depends on the severity. Serial ultrasound examinations are used to assess severity.[73] Some suggest no fetal investigation is necessary with mild to moderate hydrops showing improvement on serial scans.[11,31] Of course, improvement can only be determined over time during which the fetus might also deteriorate. When longitudinal ultrasound studies are not possible, a fetal blood sample should be obtained. The finding of mild to moderate hydrops, coupled with the absence of severe thrombocytopenia, acidemia, and the presence of an increased reticulocyte count, suggests spontaneous recovery is under way. In severe cases without a reassuring hematologic or metabolic profile, intrauterine transfusion is indicated.[31,73] The risk of fetal blood sampling and therapy is increased because of the increased risk of associated thrombocytopenia. However, a successful outcome may be expected in the majority of cases (83.8%) (Table 25–6).[74] Myocarditis secondary to parvovirus is treated with fetal digitalization. Infant follow-up is mandatory in view of the risk of congenital red blood cell aplasia[75] and even the need for perinatal heart transplantation.[24]

Other Causes

Generalized lymphatic dysfunction (e.g., primary hydrothorax is believed to be a variant) can be associated with abnormal vascular development. The prognosis is guarded and may include significant infant morbidity.[25,76]

Recurrent idiopathic NIH is reported[33,77] and postulated to be related to a recessive gene. There are a few reports of familial hydrops consistent with autosomal recessive[78] and X-linked recessive[79] inheritance.

Fetal akinesia is another condition associated with fetal hydrops, with a large number of causes (cerebro-oculofacioskeletal, Pena-Shokeir, multiple pterygium, Neu-Laxova syndromes) that carry a poor prognosis. The risk of recurrence is generally low, but will be influenced by the cause if identified (e.g., Neu-Laxova syndrome has autosomal recessive inheritance[80]).

Renal associations with hydrops are discussed in detail in Chapter 19.

Few therapeutic options are available for antenatal treatment of other causes of fetal hydrops. Several case reports from Japan describe the localized injection of OK-432 into body cavities containing localized collections of

excessive extravascular fluid (e.g., cystic hygroma[81]; pleural effusion[58]) with poor results to date.[81,82]

Role of Uterine Venous Pressure in Treatment

The uterine venous pressure (UVP) measurement is helpful in the management of fetal hydrops. If it is raised and therapy reduces it, then the prognosis is good. Hydrops characterized by an elevated UVP not remedied by either surgical or medical therapy is usually progressive, and the fetus either dies in utero or requires preterm delivery for postnatal therapy.[23] However, not all disorders that increase the UVP are associated with hydrops, and cardiac dysfunction does not necessarily mean cardiac decompensation. And although there are many reports of hydrops not associated with an elevated UVP, there are no reports of reproducibly effective therapy.[19] Limited human study suggests a good correlation between the fetal UVP and central venous pressure, but this relationship was not true in the anemic fetal sheep.[8] It seems, therefore, that measurement of the fetal UVP should be viewed as a guide to therapy when fetal blood sampling is planned but is not, in and of itself, an indication for the sampling.

Fetal Albumin Therapy

Fetal hypoproteinemia or hypoalbuminemia from the pathophysiology appears to be a secondary effect.[8,19] It may occur in a third of nonimmune hydrops fetuses, but is distributed with equal frequency in groups with a high and low UVP (the exception being twin-twin transfusion syndrome, which is discussed in Chapter 24). Clearly, the practice of giving the fetus albumin[83] in the absence of knowing its cardiac status and its albumin level cannot be recommended, although some advocate its use.[81] A more productive approach is to try to discover other causes of fetal hydrops and to reduce this "idiopathic" group.

CONCLUSIONS

- Fetal hydrops is an uncommon but serious condition with a complex pathophysiology; it is associated with a wide range of etiologies and carries a poor prognosis overall.
- Comprehensive antenatal and postnatal investigations (e.g., postmortem) are necessary if the cause is to be identified, as the diagnosis may not be made in as many as a quarter of cases.
- Antenatal therapy should be directed at a specific pathologic condition, but is possible in less than a third of cases.
- Research into the pathophysiology is needed to improve our understanding of the fetal fluid-regulating mechanisms.
- In the short term, the largest impact on the incidence of NIH is made by implementing screening programs both preconceptually (e.g., populations at risk for α-thalassemia) and antenatally (e.g., nuchal translucency; monochorionicity and TTTS surveillance; anomaly scans, especially cardiac scans; being alert to outbreaks of parvovirus B19 infection in the local community).

SUMMARY OF MANAGEMENT OPTIONS
Fetal Hydrops (see also Chapter 14)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prevention			
Preconceptual and prenatal screening for:			
α-Thalassemia	III	B	13
Fetal aneuploidy	IIb	B	14,15
Fetal anomalies, especially severe cardiac disease	III	B	9
Monochorionicity screening for twin-twin transfusion syndrome	III	B	28
Diagnosis—Investigations			
Maternal (see Table 25–3)	III	B	3,4,5,9
Fetal (see Table 25–4)	III	B	3,4,5,9
Diagnosis will be made in 75–90% of cases.	III	B	3,4,5,9

SUMMARY OF MANAGEMENT OPTIONS

Fetal Hydrops (see also Chapter 14)

Management Options	Quality of Evidence	Strength of Recommendation	References
Diagnosis—Investigations—*Continued*			
Risks of fetal invasive procedures are increased in presence of hydrops.	III	B	29,30
Counseling and Prognosis			
Counseling is given before and after investigations.	–	GPP	–
Prognosis is determined by the underlying etiology.	III	B	3,4,5,9
The earlier it is detected, the worse the prognosis.	III	B	10,33
Earlier detection is more likely to be associated with chromosomal abnormality.	III	B	3,4,5,9
Presence of a congenital anomaly worsens the prognosis.	III	B	9
Bilateral pleural effusions are a poor prognostic sign.	III	B	14,15,17
Generally prognosis is good for psychomotor development in survivors.	III	B	17,18
Prevention of prematurity improves long-term outcome.	III	B	17
Management—Treatment			
In utero, therapy can be effective in selected cases (about one-third):			
Intrauterine transfusions for fetal anemia (hemolytic disease [see Chapter 14], fetal bleed, parvovirus)	III	B	33,83
Antiarrhythmic medication	III	B	33,38,83
Specific treatments for twin-twin transfusion syndrome (see Chapter 24)	III	B	52
Pleuroamniotic shunts for primary hydrothorax, cystic adenomatous malformation	III	B	28
Open surgery for chest lesions should be regarded as experimental.	III	B	59
Management—General			
Interdisciplinary approach is used for ongoing pregnancies.	–	GPP	–
Consider termination in those with severe hydrops at a pre-viable gestation with a condition for which there is no effective treatment.	–	GPP	–
Postnatal			
Perform postmortem examination in cases of fetal/neonatal death.	–	GPP	–
Pediatric follow-up and counseling are needed in survivors.	–	GPP	–

Fetal Death

Carl P. Weiner

INTRODUCTION

The death of a fetus is a tragic loss. The known threat of an embryonic loss has passed, and both patient and caregiver are optimistic about the future. Whether the death occurs in a singleton or multiple gestation, it triggers a change in management and the patient's psychosocial needs. It also spurs a search for an explanation. The results of this search may be crucial for the successful management of any subsequent pregnancy.

MANAGEMENT OPTIONS

Evaluation

The investigation of a fetal death involves both the fetus and mother. It is essential to determine the cause of death whenever possible. Only then can the likelihood of a recurrence and the possibility of prevention be ascertained. Further, knowledge of the actual cause of death aids the grieving process by eliminating the natural tendency for self-recrimination. A thorough maternal past and current medical history should again be obtained and the physical examination repeated in search of an unsuspected preexisting or acquired systemic illness. If the fetus is still in utero, a targeted ultrasound examination of the uterus and contents is performed in search of fetal or placental malformations and evidence of fetal growth restriction.

The more common, known causes of fetal death are listed in Table 26–1. Over the last 30 years the fetal death rate has declined, and the causes of fetal death have changed.[1] For example, fetal death due to intrapartum asphyxia and Rh disease has all but disappeared in some centers, and the death rate from unexplained growth restriction has also declined.[1] Unless the history and physical examination pinpoint the cause, a basic group of laboratory tests (Table 26–2) should be performed until a cause is found. An amniocentesis to both search for fetal infection (see Chapter 10) and obtain a karyotype is recommended. A chromosome abnormality is the explanation in 15% of second-trimester stillbirths. The karyotype should be documented in most fetuses, even in the apparent absence of extrinsic structural malformations, because the usual dysmorphic features of aneuploidy may be obscured by postmortem changes. In contrast to fetal fascia, muscle, or subcutaneous tissue, amniocytes can be cultured successfully weeks after the death has occurred. Placental tissue is also more likely to be a viable source for karyotyping.

After delivery, photographs of the child are made for both the medical record and the parents. If the parents decline the photographs, a common grief/fear response, the photographs should be stored with the medical record in case the parents subsequently change their minds. A fetogram is made (xerography is an excellent modality) and permission requested for an autopsy. The performance of an autopsy significantly increases the likelihood of discovering a presumed cause.[2] Ideally, an individual with both an interest and experience in perinatal pathology should perform the autopsy. The placenta is an important component of that examination. The fetal organ cavities are cultured for both bacteria and viruses even if an infection workup was initiated antenatally. A growing understanding in the role of viral infection in poor fetal outcome suggests that in some instances, the search for an infectious etiology be coupled with a molecular biologic search for the nuclear fingerprint of the infectious agent. Maternal serology is, in general, not useful.[2]

Many stillborn fetuses are small for gestational age. However, customized fetal growth charts may be needed to demonstrate this because the use of preterm neonatal birth weight charts, derived from preterm newborns who are commonly growth restricted, may obscure this.[3] In the absence of another explanation, growth restriction increases the likelihood that severe placental dysfunction of some etiology is the explanation.[3]

TABLE 26-1

Causes of Fetal Death

Maternal systemic illness:
  Diabetes mellitus
  Hypertension—includes prepregnancy and pregnancy-
    associated connective tissue disorders
  Any disorder causing septicemia with associated
    hypoperfusion—fetal malformations, structural and
    chromosomal
Fetal:
  Infection—bacterial, viral
  Fetal immune hemolytic disease
  Cord accident—includes prolapse, thrombosis, strangulation
  Bands or knots and torsion (likely to be greatly overdiagnosed)
  Metabolic disorders
  Placental dysfunction includes those associated with fetal
    growth restriction, postmaturity and abruption causing
    hypoxemia, placenta previa or infarction, twin-to-twin
    transfusion, fetal-to-maternal hemorrhage
  Inherited disorders: thombophilias

Pregnancy Management

The approach to the pregnancy after a fetal loss depends on whether it is a single or multiple gestation, the gestational age at death, and the parents wishes.

Singleton Gestation

Prior to 15 weeks' gestation, a dilation and evacuation can be performed. This remains an option until 24 weeks, although the risk of maternal hemorrhage may be increased after fetal death.[4] Caution is indicated. The second and more common alternative after 15 weeks' gestation is an induction of labor. This has the advantage of preserving the fetus intact for a postmortem examination.

Prior to the introduction of prostaglandin analogues for the induction of labor, women were observed until

TABLE 26-2

Routine Laboratory Evaluation and Follow-up of Fetal Death

Maternal (on detection)
  Fasting blood glucose
  Platelet count, fibrinogen
  Indirect Coombs' test
  Stain of a peripheral smear for fetal red blood cells
    (Kleihauer-Betke test)
  Anticardiolipins, antinuclear antibodies, lupus anticoagulant
  Fetal karyotype
  Thrombophilia workup
  Polymerase chain reaction studies of fetal products for
    evidence of viral infection
  Amniotic fluid culture for cytomegalovirus, anaerobic and
    aerobic bacteria
  Subsequent maternal weekly fibrinogen measurements and
    platelet counts if fetal death is of 4 weeks' duration or more
Fetal (at delivery)
  Repeat infection workup (see Chapter 27)
  Karyotype (if not done antenatally)
  Postmortem examination
  Fetogram (total body radiograph) if dysmorphic stigmata at
    postmortem examination

the onset of spontaneous labor after a late demise. First, 90% or more of women with an intrauterine demise spontaneously labor within 3 weeks of its detection.[5,6] Second, oxytocin is frequently ineffective because of the associated early gestation. Consequently, prolonged induction time was the rule. Though the instillation of intra-amniotic hypertonic saline or glucose was said to shorten the time interval, it was also associated with several maternal deaths. Thus, despite the considerable social pressure for delivery, observation was the best medical approach.

The disadvantage to observation is that about a quarter of women who retain their dead fetus for 4 or more weeks (i.e., after 20 weeks' gestation) develop a chronic, consumptive coagulopathy. This is a true disseminated intravascular coagulopathy (DIC) state characterized by degrees of decreased fibrinogen, plasminogen, antithrombin III, and platelets and increased fibrin degradation products.[7-10] The etiology of the coagulopathy has never been conclusively determined. Using sensitive coagulation tests, pathologic activation of the clotting cascade is demonstrable within 48 hours of the demise. The incidence of the coagulopathy increases with the duration of the delay, but less than 2% of these women experience a hemorrhagic complication. Fortunately, this chronic, low-grade intravascular coagulopathy can be reversed by the administration of low-dose heparin.[11-13] Traditionally, labor was induced after treatment of the coagulopathy even if the cervix was unfavorable. The coagulopathy resolves within 48 hours of delivery.

Fortunately, the development of the prostaglandin E and F analogues for the induction of labor eliminated the need to wait. The efficacy of these agents for the induction of labor exceeds 90% (reviewed in Kochenour[14]). Delivery shortly after detection of the demise has several advantages. First, it brings an end to an emotionally painful event and allows the psychological healing process to begin. Second, any postmortem examination is more likely to yield useful information if done before the development of severe autolysis.

The various prostaglandin preparations may be administered via oral, vaginal, intracervical, extraovular, or intramuscular routes, depending on regional availability. Misoprostol (either per vaginam or by mouth) has a favorable cost profile and is at least as effective as other forms of prostaglandin. When used specifically for pregnancy termination in the second trimester, misoprostol administered orally is less effective (i.e., more failures) than the vaginal route (relative risk [RR] 3.00, 95% confidence interval [CI] 1.44 to 6.24), and side effects may be more common.[15] A commonly used dose is 400 µg every 6 to 8 hours. A priming dose of 800 µg per vaginam is also recommended.[5] Neither misoprostol nor prostaglandin E_2 (PGE$_2$) vaginal suppositories are yet approved by the U.S. Food and Drug Administration (FDA) for the termination of pregnancy after an intrauterine demise of a fetus older than 28 weeks. However,

clinical experience supports both their reliability and safety.[14] Common complications include nausea and vomiting, fever, and tachycardia. Their prevalence is generally dependent on route of administration and dose and is greatly reduced by premedication.[17] Their use is further discussed in Chapter 68.

Multiple Gestation (See also Chapters 24 and 60)

The optimal management of the multiple gestation with a singleton demise is unclear. The incidence of this complication is low (<1% of all twin gestations), but the risk of prematurity, morbidity (especially neurologic), and neonatal death is high among antenatal survivors.[18,19] Several factors must be considered. First is the cause of death. Could the same stimulus, such as congenital infection or a maternal systemic illness, have caused a sublethal insult yielding a damaged survivor? If so, will continuation of the pregnancy worsen the outcome by prolonging the exposure? An informed decision requires knowledge of the cause and is a matter for individualization.

The second item to consider is whether the dead twin's continued presence poses a risk to the surviving twin. In monochorionic twin gestations, approximately half of the co-twins in an affected pregnancy will either die or experience serious morbidity[20] (see Chapter 24). Sequelae in survivors of monochorionic gestations with a single demise include bilateral renal cortical necrosis, multicystic encephalomalacia, gastrointestinal structural malformations, and even a disseminated intravascular coagulopathy.[21–26] It was previously suggested they result from the fetus-fetus transfer of necrotic, thromboplastic emboli through placental anastomoses. If this were true, delivery of the surviving twin as soon as possible would be prudent. However, there are no published reports of a fetal coagulopathy, and the evidence for necrotic emboli (as opposed to thrombotic phenomena) is weak. Further, the syndrome is also reported in monochorionic pregnancies uncomplicated by demise. Remembering that all monochorionic twins share placental vascular anastomoses, it seems more likely these sequelae share a vascular etiology. Most likely is an abrupt, hypotensive event either during the co-twin's death associated with extensive vascular anastomosis or after the death as the surviving twin acutely hemorrhages into the dead twin's placenta.[27] If this is, as it appears, the mechanism, preterm delivery may be too late to prevent the sequelae and may only add complications of prematurity. Thus, it seems prudent to observe the surviving co-twin very closely, if not continuously, for the first 7 days, should the gestation appear monochorionic. Survivors should be watched serially for evidence of multicystic encephalomalacia.

The course is clearer if the pregnancy is dizygotic because the risk of death to the surviving co-twin is less than 5%.[18] There is no reason for an iatrogenic delivery prior to 36 weeks solely for the indication of a dead co-twin.

The third and final concern after the death of a co-twin is the development of a maternal coagulopathy should the pregnancy continue. This is an uncommon but treatable event. Laboratory testing for hypofibrinogenemia and thrombocytopenia should be done biweekly after the first 4 weeks. Low-dose heparin, between 10,000 and 30,000 units given subcutaneously in divided doses, is usually adequate to reverse the hypofibrinogenemia.[28,29] There is no need to prolong the partial thromboplastin time. The amount of heparin necessary may seem quite high, reflecting the low antithrombin III concentration. Interestingly, the few reports suggest the need for heparin is temporary. It can usually be discontinued 6 to 8 weeks later without recurrence of the hypofibrinogenemia.[27–30]

Giving Bad News

Giving a patient bad news is one of the more difficult tasks most physicians face on a regular basis. Unfortunately, the act of teaching techniques for the breaking of bad news seem almost as awkward as the teaching of contraception must have been in the Victorian era. Yet, these techniques can be learned and applied in a busy clinical practice. The problem now is not whether it is necessary to tell the patient, but how to deliver it.

Why is it difficult to give bad news? There are a number of plausible explanations including the fear of causing pain, sympathetic pain, fear of being blamed for the poor outcome, fear of a therapeutic failure and all that it entails, fear of the medical-legal consequences, fear of eliciting a reaction, fear of saying "I don't know," and fear of expressing emotion.

Why are patients unhappy with the way they are given bad news? The most common complaints are that the physician is not listening, is using jargon, or is "talking down" to them. The process of informing a patient about bad news should follow the basic steps of the traditional medical interview: *prepare* for listening; *question*; *listen* actively; show verbally that you've *heard*; and *respond*. The necessary modifications and additions to the basic interview as they relate to fetal medicine include finding out how much the patient knows, how much misinformation must be corrected, and how much the patient wants to know before sharing the information in an unambiguous, plain-spoken fashion that minimizes the chance of denial; responding to the patient's feelings; and then presenting an appropriate action plan.

Perhaps the most difficult component of the interview arises when the patient starts reacting. It usually has begun by the time you enter the room. It is important to recall that people perceive bad news in a myriad of ways, some of which may not be clear to the health care provider. A mentally competent and informed patient has the right to accept or reject any treatment offered and to react to the news or express their feelings in any (legal) way they choose. Unexpected reactions often reflect a misunderstanding of the information presented. It is

important to reinforce those parts of what the patient has said that are correct and then continue from there. Avoid jargon, use diagrams and written messages, and then look for evidence of understanding. Listen for and try to address the patient's concerns; do not dismiss them as irrelevant. Common reactions run the gamut and include disbelief, anger, blame, shock, guilt, denial, hope, despair, depression, displacement, fear and anxiety, crying, bargaining, awkward questions, relief, threats, and humor. There is no question that giving parents bad news tests the entire range of one's professional skills and abilities. But if it is done poorly, the family will never forgive. And if the interview is done well, they will never forget.

Parental Psychosocial Care

Many hospitals have a counselor or psychologist on the perinatal team to facilitate the grieving process. Frequently, there are local support groups consisting of women who have experienced an intrauterine demise. It may be helpful if a representative of one of these groups meets with the patient shortly after the diagnosis is made. Where appropriate, pastoral care may also be helpful. The woman's partner is encouraged to remain and provide support during labor and after delivery when the couple should be encouraged to view and hold the newborn. Too often, patients incorrectly assume they have conceived a monstrosity. They should also be informed that any bruising and facial marks are normal. Neonatal footprints and handprints are made, and the parents encouraged to name the child. Photographs are taken, and if the patient does not want any of these remembrance items, they should be stored. Many women change their mind and later write to request them.

Upon discharge from the hospital, the patient is given an appointment to return after an interval, which should be individualized to her needs. The results of all studies performed are reviewed and the parents given an opportunity to voice any questions they may have about their care.

Evaluation Prior to Conceiving Again

If the cause of death was ascertained, its implications (if any) to subsequent pregnancies should be discussed at their initial postpartum meeting, and again prior to conception if desired. The actions needed should be cause-specific. For example, the discovery of a maternal thrombophilia or connective tissue disorder coupled with the history of a prior stillbirth might warrant prophylactic anticoagulation (see Chapter 42). The practice of ordering a barrage of antenatal surveillance tests when the cause of death was not hypoxemia due to placental dysfunction cannot be supported. When the cause of death has escaped detection, it is important to again reinforce to both parents that these events are not usually under their control and that they bear no guilt for its occurrence.

CONCLUSIONS

- Death of a fetus, whether anticipated or not, inevitable or not is a tragedy
- The first and ongoing priority in management is emotional and psychological support of the parents and family
- The second priority is to find an explanation
- The third priority is to implement an appropriate management strategy for future pregnancies

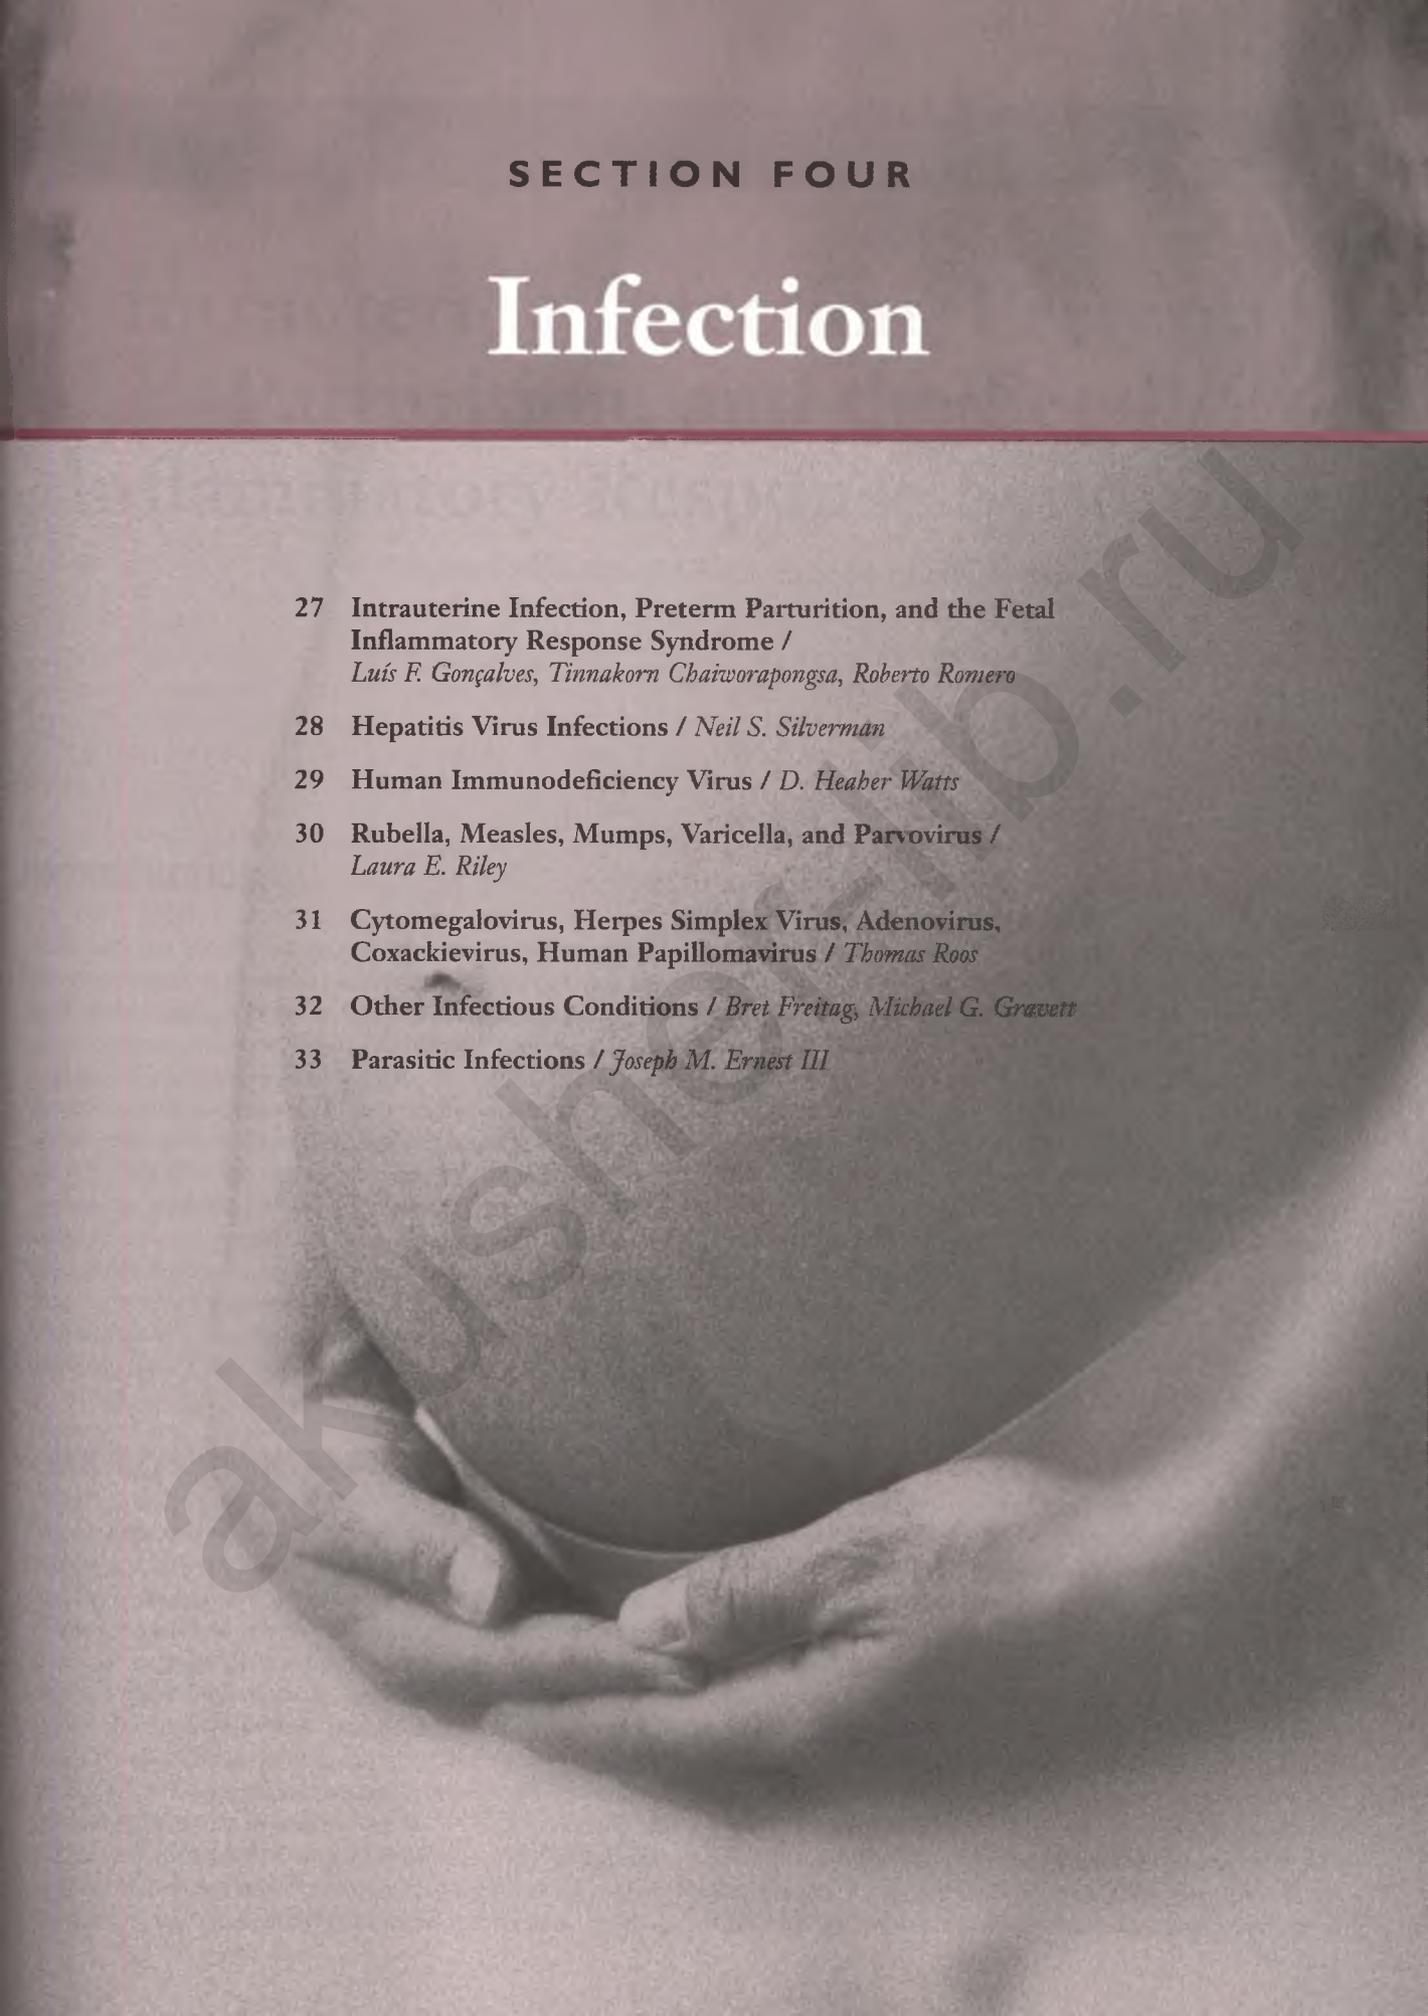
SECTION FOUR

Infection


Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

Luís F. Gonçalves / Tinnakorn Chaiworapongsa / Roberto Romero

INTRODUCTION

Infection has long been recognized as an important and frequent cause of preterm parturition.[1–8] Indeed, it is the only pathologic process for which both a firm causal link with prematurity has been established and a defined molecular pathophysiology is known.[9] Moreover, fetal infection/inflammation has been implicated in the genesis of fetal and neonatal injury[10,11] leading to cerebral palsy[12] and chronic lung disease.[13] In this chapter, we review the pathways of intrauterine infection, the microbiology and frequency of intra-amniotic infection, the fetal inflammatory response syndrome, and the contribution of fetal infection to short- and long-term neonatal morbidity. We conclude with the potential role of viral infection in adverse outcomes.

PATHWAYS OF INTRAUTERINE INFECTION

Microorganisms may gain access to the amniotic cavity and fetus using any of the following pathways: (1) ascending from the vagina and the cervix, (2) hematogenous dissemination through the placenta (transplacental infection), (3) retrograde seeding from the peritoneal cavity through the fallopian tubes, and (4) accidental introduction at the time of invasive procedures such as amniocentesis, cordocentesis, chorionic villus sampling, or shunting.[14–18] The most common pathway for intrauterine infection is the ascending route.[7,14,15,18] Evidence in support of this includes the following: (1) histologic chorioamnionitis is more common and severe at the site of membrane rupture than at other locations, such as the pla-

cental chorionic plate or umbilical cord[19]; (2) in virtually all cases of congenital pneumonia (stillbirths or neonatal), inflammation of the chorioamniotic membranes is present[14,16,18]; (3) bacteria identified in cases of congenital infections are similar to those found in the lower genital tract[15]; and (4) in twin gestations, histologic chorioamnionitis is more common in the firstborn twin and has not been demonstrated only in the second twin. This is taken as evidence favoring ascending infection, as the membranes of the first twin are generally opposed to the cervix.[15] This observation is consistent with those made during the course of microbiologic studies of the amniotic fluid in twin gestations. When infection is present, the presenting sac is always involved.[20]

STAGES OF ASCENDING INTRAUTERINE INFECTION

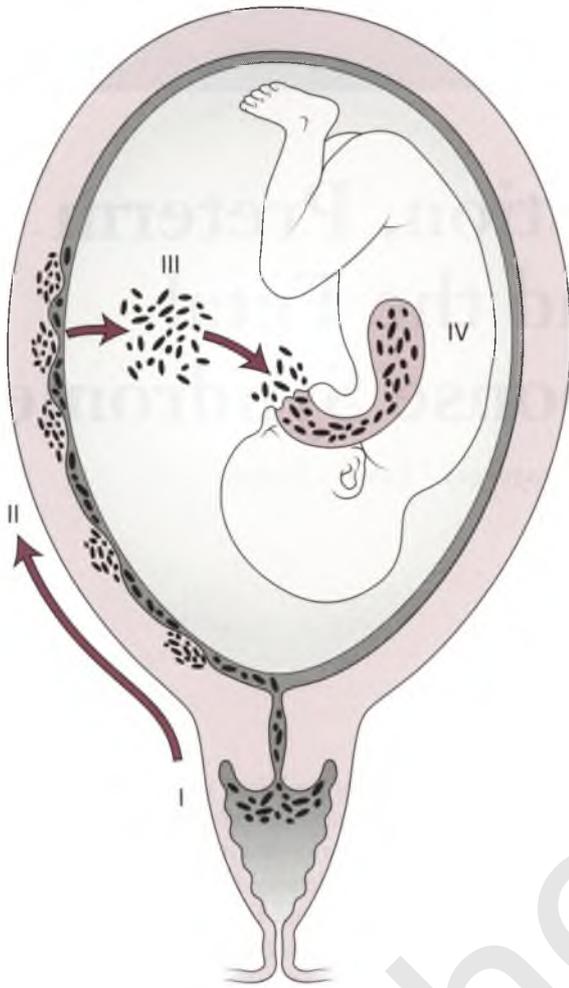
Ascending intrauterine infection has four stages (Fig. 27–1).[7] Stage I consists of a change in the vaginal/cervical microbial flora or the presence of pathologic organisms (i.e., *Neisseria gonorrhoeae*) in the cervix. Some forms of aerobic vaginitis[21] may be an early manifestation of this stage. Once microorganisms gain access to the intrauterine cavity, they reside in the decidua (stage II). A localized inflammatory reaction causes deciduitis initially and then chorionitis. Microorganisms may then reside in the chorion and amnion. The infection may invade the fetal vessels (choriovasculitis) or proceed through the amnion (amnionitis) into the amniotic cavity (stage III). Rupture of the membranes is not a prerequisite for intraamniotic infection, as microorganisms are capable of


FIGURE 27–1
The stages of ascending infection (From Romero R, Mazor M: Infection and preterm labor: Pathways for intrauterine infections. Clin Obstet Gynecol 1988;31:558).

crossing intact membranes.[22] Once in the amniotic cavity, the bacteria may gain access to the fetus by several ports of entry (stage IV). Aspiration of the infected fluid by the fetus may cause congenital pneumonia. Otitis, conjunctivitis, and omphalitis are localized infections that occur by direct seeding of the microorganisms from infected amniotic fluid. Seeding from any of these sites to the fetal circulation results in bacteremia and sepsis.

The last stage of ascending intrauterine infection is fetal microbial invasion. Clinical and experimental evidence is now available that suggests that the fetus is exposed to microorganisms and their products (i.e., bacterial endotoxin)[23,24] in the amniotic cavity and then responds by mounting both a cellular and humoral immunoresponse.[25,26]

MICROBIOLOGY OF INTRAUTERINE INFECTION

The most common microbial isolates from the amniotic cavity of women with preterm labor and intact mem-

branes are *Ureaplasma urealyticum, Fusobacterium* spp., and *Mycoplasma hominis*.[7,27–30] In patients with premature rupture of membranes (PROM), microbial invasion of the amniotic cavity by *U. urealyticum* is associated with a robust inflammatory response in the fetal, amniotic, and maternal compartments.[31] *U. urealyticum* is implicated in the genesis of clinical chorioamnionitis, puerperal endometritis, postoperative wound infections, neonatal sepsis, meningitis, and bronchopulmonary dysplasia.[31–33]

Other microorganisms found in the amniotic fluid include *Streptococcus agalactiae, Peptostreptococcus* spp., *Staphylococcus aureus, Gardnerella vaginalis, Streptococcus viridans,* and *Bacteroides* spp. Occasionally, *Lactobacillus* spp., *Escherichia coli, Enterococcus faecalis, N. gonorrhoeae,* and *Peptococcus* spp. are encountered. *Haemophilus influenzae, Capnocytophaga* spp., *Stomatococcus* spp., and *Clostridium* spp. are rarely identified.[34,35] In 50% of patients with microbial invasion, more than one microorganism is isolated from the amniotic cavity. The inoculum size varies considerably, and in 71% of the cases more than 10^5 colony-forming units per milliliter (cfu/mL) are found.[19]

FREQUENCY OF INTRA-AMNIOTIC INFECTION IN PRETERM GESTATION

Studies examining the clinical circumstances surrounding preterm delivery indicate that one third of all patients present with preterm labor and intact membranes and one third with preterm PROM. The remaining third are the result of delivery for maternal or fetal indications (e.g., preeclampsia, growth restriction).[36–39] We review the evidence supporting an association between intrauterine infection and spontaneous preterm labor (with or without intact membranes) to examine the relationship between microbial invasion of the amniotic cavity and preterm delivery.

Microbial Invasion of the Amniotic Cavity in Preterm Labor and Intact Membranes

The mean rate of positive amniotic fluid cultures for microorganisms in patients with preterm labor and intact membranes is approximately 12.8% (379/2963), based on a review of 33 studies.[30,40] Women with positive amniotic fluid cultures generally do not have clinical evidence of infection at presentation but are more likely to develop clinical chorioamnionitis (37.5% [60/160] vs. 9% [27/301]), be refractory to tocolysis (85.6% [101/118] vs. 16.3% [8/49]), and rupture their membranes spontaneously (40% [6/15] vs. 3.8% [2/52]) than women with negative amniotic fluid cultures. Several investigators have demonstrated higher rates of complications in neonates born to women with microbial invasion of the amniotic cavity than to those without infection.[28] Moreover, the earlier the gestational age at birth, the more likely microbial invasion of the amniotic cavity is present.[41]

Microbial Invasion of the Amniotic Cavity in Patients with Preterm PROM

The rate of positive amniotic fluid cultures for microorganisms is approximately 32.4% (47/142) in patients with preterm PROM.[30] Clinical chorioamnionitis is present in only 29.7% (49/165) of those with proven microbial invasion.[9,30] The rate of microbial invasion in preterm PROM is probably an underestimation of the true prevalence and reflects in part the sophisticated facilities required to make this determination. Further, available evidence indicates that women with PROM and a severely reduced volume of amniotic fluid have a higher incidence of intra-amniotic infection than those without oligohydramnios.[42,43] Since women with oligohydramnios are less likely to have an amniocentesis, there is an inherent bias to underestimate the prevalence of infection. Another bias stems from the fact that women with preterm PROM admitted in labor do not generally undergo amniocentesis. These patients have a higher rate of microbial invasion of the amniotic cavity than those admitted without labor (39% [24/61] vs. 25% [41/160], p <0.05). Finally, 75% of women who are not in labor on admission have a positive amniotic fluid culture at the time of the onset of labor.[44] Clearly, studies restricted to women not in labor provide a lower rate of microbial invasion of the amniotic cavity than those including patients in labor.

Microbial Invasion of the Amniotic Cavity in Patients Presenting with Acute Cervical Incompetence

Women presenting with a dilated cervix, intact membranes, and few, if any, contractions before the 24th week are considered to have clinical cervical incompetence. In one study, 51.1% of these patients had a positive amniotic fluid culture for microorganisms.[45] The outcome of patients with microbial invasion was uniformly poor because these individuals developed subsequent complications (rupture of membranes, clinical chorioamnionitis, or pregnancy loss). Therefore, infection is frequently associated with acute cervical incompetence.[46] Whether intra-amniotic inflammation is the cause or consequence of cervical dilation remains unknown. It is possible that clinically silent cervical dilation with protrusion of the membranes into the vagina leads to a secondary intrauterine infection.

Microbial invasion of the amniotic cavity occurs in 11.9% of twin gestations presenting with preterm labor and delivering a preterm neonate.[20] This finding is in contrast to the 21.6% culture positive rate in singleton gestations with preterm labor and delivery.[19] These data suggest that intra-amniotic infection is a possible cause of preterm labor and delivery in twin gestation, but does not support the hypothesis that intra-amniotic infection is responsible for a large part of the excessive rate of preterm delivery observed.

Chorioamniotic Infection, Histologic Chorioamnionitis, and Preterm Birth

Inflammation of the placenta and chorioamniotic membranes is a nonspecific host response to a variety of stimuli, including infection. Acute inflammation of the chorioamniotic membranes has traditionally been considered an indicator of amniotic fluid infection,[14–18,47–49] a view based on indirect evidence. In the context of preterm birth, this seems reasonable. Several studies demonstrate an association between acute inflammatory lesions of the placenta and the recovery of microorganisms from the subchorionic plate[50,51] and chorioamniotic space.[47] Bacteria were recovered from the subchorionic plate of 72% of placentas with histologic evidence of chorioamnionitis.[47,50,52] Furthermore, there is a strong correlation between positive amniotic fluid cultures for microorganisms and histologic chorioamnionitis.[48,49] Cassell and colleagues reported an association between positive microbial cultures obtained from the chorioamniotic interface and histologic chorioamnionitis.[32,53] The presence of inflammation in the umbilical cord (funisitis) represents evidence of a fetal inflammatory response.[54,55] In contrast, histologic chorioamnionitis reflects a maternal inflammatory response.

Several studies investigated the prevalence of inflammation in placentas from women delivering preterm infants. Collectively, the evidence indicates an association between preterm birth and the occurrence of acute chorioamnionitis; it also indicates that the lower the gestational age at birth, the higher the frequency of histologic chorioamnionitis and funisitis.[52]

Fetal Infection

The most advanced stage of ascending intrauterine infection is fetal infection (stage IV) (see Fig. 27–1). The overall mortality rate of neonates with congenital neonatal sepsis ranges from 25% to 90%.[56–63] The wide range may reflect the effect of gestational age on the likelihood of survival. In one study, which focused on infants born before 33 weeks' gestation, the mortality rate was 33% for infected and 17% for noninfected fetuses.[63] Carroll and coworkers reported fetal bacteremia in 33% of fetuses with positive amniotic fluid culture and in 4% of those with negative amniotic fluid culture.[64] Clearly, subclinical fetal infection is far more common than traditionally recognized.

INTRAUTERINE INFECTION/INFLAMMATION AS A CHRONIC PROCESS

Although intrauterine infection is traditionally considered an acute complication of pregnancy, accumulating evidence suggests that it may be a chronic condition. The evidence in support of this view is derived from studies of

the microbiologic state of the amniotic fluid, as well as the concentration of inflammatory mediators at the time of genetic amniocentesis.

Microbial Invasion of the Amniotic Cavity at the Time of Genetic Amniocentesis

Cassel and colleagues[32] recovered genital mycoplasmas from 6.6% (4/61) of amniotic fluid samples collected by amniocentesis between 16 and 21 weeks. Two cultures were positive for *M. hominis* and two for *U. urealyticum*. Patients contaminated with *M. hominis* delivered at 34 and 40 weeks without neonatal complications, whereas those with *U. urealyticum* had premature delivery, sepsis, and neonatal death at 24 and 29 weeks. Subsequently, Gray and colleagues[65] reported a 0.37% prevalence (9/2461) of positive cultures for *M. hominis* or *U. urealyticum* in amniotic fluid samples obtained at the time of second-trimester genetic amniocentesis. Except for one individual who had a therapeutic abortion, all patients (8/8) with a positive amniotic fluid culture had either a fetal loss within 4 weeks of the amniocentesis ($n = 6$) or preterm delivery ($n = 2$). Furthermore, all had histologic evidence of chorioamnionitis. These observations suggest that microbial invasion may be clinically silent in the midtrimester of pregnancy and that pregnancy loss/preterm delivery can take weeks to occur. Similar observations are reported by Horowitz and coworkers,[66] who detected *U. urealyticum* in 2.8% (6/214) of amniotic fluid samples obtained between 16 and 20 weeks' gestation. The rate of adverse pregnancy outcome (fetal loss, preterm delivery, and low birth weight) was significantly higher in patients with a positive amniotic fluid culture than in those with a negative culture (3/6 [50%] vs. 15/123 [12%], $p = 0.035$). Of note, women with a positive amniotic fluid culture were more likely to have an obstetric history that included >3 previous abortions than those with a negative culture (2/6 [33.3%] vs. 5/123 [4.0%]), $p = 0.034$).[66]

Chronic Intra-amniotic Inflammation/Infection and Preterm Birth

Amniotic fluid interleukin-6 (IL-6) concentration is a marker of intra-amniotic inflammation and is frequently associated with microbiologic infection in either the amniotic fluid or chorioamniotic space.[67–70] Romero and colleagues[71] conducted a case-control study in which IL-6 was measured in the stored amniotic fluid of women who had a pregnancy loss after a midtrimester amniocentesis and compared them to a control group who delivered at term. Patients who lost their pregnancies had a significantly higher median amniotic fluid IL-6 concentration than those with a normal outcome. Similar findings were reported by Wenstrom and colleagues.[72] In contrast, maternal plasma IL-6 concentration is not associated with adverse pregnancy outcome. Chaiworapongsa and colleagues[73] compared amniotic

fluid monocyte chemotactic protein-1 (MCP-1) concentration at the time of genetic amniocentesis in 10 patients who had a pregnancy loss after the procedure to a control group of 84 patients. MCP-1 concentrations were higher among those who had a spontaneous pregnancy loss after the procedure compared to those with a normal pregnancy outcome. An amniotic fluid MCP-1 concentration >765 pg/mL was strongly associated with pregnancy loss (odds ratio, 7.35; 95% confidence interval, 1.7–31.0).

An association can also be demonstrated between markers of inflammation in the midtrimester amniotic fluid of asymptomatic women and preterm delivery. The concentrations of matrix metalloproteinase (MMP-8),[74] IL-6,[75] tumor necrosis factor alpha (TNFα),[76] angiogenin,[77] and C-reactive protein[78] in amniotic fluid samples obtained at midtrimester amniocentesis were each elevated in patients who subsequently delivered preterm.

Collectively, the evidence suggests that a chronic intra-amniotic inflammatory process is associated with both spontaneous abortion and spontaneous preterm delivery. Whether intra-amniotic inflammation is detectable noninvasively remains to be determined. Goldenberg and colleagues[79] demonstrated that the maternal plasma concentration of granulocyte colony-stimulating factor (G-CSF) at 24 and 28 weeks' gestation was associated with early preterm birth. To the extent that G-CSF may reflect an inflammatory process, this finding suggests that a chronic inflammatory process identifiable in the maternal compartment is associated with early preterm birth.

Is the Relationship Between Intrauterine Infection and Spontaneous Premature Birth Causal?

An association does not mean infection *causes* preterm delivery. Indeed, it has been argued that microbial invasion of the amniotic cavity is merely a consequence of labor.[80–83] Determining whether or not this relationship is causal is critical because it has major clinical and therapeutic implications. The evidence supporting a causal role for infection in preterm parturition includes: (1) biologic plausibility, (2) temporal relationship, (3) consistency and strength of association, (4) dose-response gradient, (5) specificity, and (6) human experimentation.

Animal experimentation reveals that the administration of bacterial products or microorganisms to pregnant animals can lead to premature labor and delivery.[84–93] Three sets of observations suggest that infection precedes the spontaneous onset of preterm labor and delivery: (1) subclinical microbial invasion of the amniotic cavity or intrauterine inflammation in the midtrimester of pregnancy leads to either spontaneous abortion or premature delivery (see preceding section on intrauterine

inflammation/infection as a chronic process); (2) patients with preterm PROM who had a positive amniotic fluid culture for mycoplasmas (*U. urealyticum* or *M. hominis*, neither of which are visible on Gram stain) on admission have a significantly shorter amniocentesis-to-delivery interval than those with sterile amniotic fluid, suggesting that patients with preterm PROM and microbial invasion of the amniotic cavity are more likely to initiate preterm labor than those with a negative amniotic fluid culture[94]; and (3) abnormal colonization of the lower genitourinary tract with microorganisms is a risk factor for preterm delivery. These conditions include asymptomatic bacteriuria, bacterial vaginosis, and infection with *N. gonorrhoeae*.[95–106] The consistency and strength of association between infection and preterm delivery is demonstrated by the many studies in which amniotic fluid was cultured for microorganisms in women with preterm PROM and preterm labor with intact membranes. Moreover, the relative risk for preterm delivery in patients with preterm labor and intact membranes and microbial invasion of the amniotic cavity is high (>2) and the hazard ratio for the duration of pregnancy after preterm PROM is also high.

The likelihood of a causal relationship is increased if a dose-response gradient can be demonstrated. Is there a dose-response gradient between the severity of the infection and the likelihood of preterm delivery? Evidence supporting the existence of this gradient includes: (1) The median concentration of bacterial endotoxin is higher in patients in preterm labor than in patients not in labor.[107] (2) The microbial inoculum is significantly greater in patients with preterm PROM admitted with preterm labor than in those admitted with preterm PROM but not in labor.[44] Specifically, the proportion of patients with an inoculum <10^5 cfu/mL was 41.6% in patients with preterm labor and only 15% in patients not in labor ($p = 0.03$).[44] (3) Lastly, the rate of abortion/preterm delivery after the administration of *E. coli* bacterial endotoxin to pregnant mice exhibits a clear dose-response gradient.

One criterion for causality that is not met is specificity. Although intrauterine infection appears sufficient to induce preterm labor and delivery, it is not specific because many patients have a preterm delivery in the absence of evidence of intrauterine infection/inflammation. However, a high degree of specificity is rare in biologic systems. Although the causal relationship between smoking and lung cancer is widely accepted, it is also nonspecific. Lung cancer occurs in nonsmokers and, of course, smoking can cause diseases other than lung cancer, such as emphysema and chronic bronchitis. Second, the formulation of "the necessary and sufficient cause" can inappropriately restrict the conceptualization of cause. In the case of premature labor, microbiologic, cytologic, biochemical, immunologic, and pathologic data indicate that preterm labor is a syndrome and infection is but one of its causes.[9,108]

An important criterion for causation is whether eradication of the agent decreases the frequency of outcome or illness. Many trials of antimicrobial treatment for the prevention of preterm birth have been conducted. There is evidence that treatment of patients with asymptomatic bacteriuria will reduce the rate of prematurity/low birth weight[103] and that antibiotic treatment of patients with preterm PROM prolongs the latency period and reduces the rate of maternal and neonatal infection.[109] However, treatment of patients with preterm labor and intact membranes has not yielded positive results in most trials.[110–112] The reasons for this are complex and have been reviewed elsewhere but are probably related to the syndromic nature of preterm parturition, the chronic nature of the process, and the inclusion in the clinical trials of many patients who do not have intrauterine infection and thus cannot benefit from antimicrobial treatment. This applies to patients presenting with preterm labor as well as those with bacterial vaginosis.[113,114]

Detection of Microbial Footprints in the Amniotic Fluid with Sequence Based Techniques

Estimates of the frequency and type of microorganisms participating in intrauterine infections are based on standard microbiologic techniques (e.g., culture). These estimates are likely to change with the introduction of more sensitive methods for microbial recovery and identification. For example, surveys of terrestrial and aquatic ecosystems indicate that more than 99% of existing microorganisms may not be cultivated in the laboratory and that only molecular diagnosis can provide identification of these microorganisms.[115] In fact, the identification of the infectious agents for the following disorders became possible only recently with the aid of molecular diagnosis: hepatitis C virus for non-A, non-B hepatitis[116]; *Bartonella henselae* for bacillary angiomatosis[117]; *Tropheryma whippelii* for Whipple's disease[115,118]; and Sin Nombre virus for hantavirus pulmonary syndrome.[119]

Sequenced-based methodologies are likely to demonstrate how insensitive conventional microbiology methods are for the detection of already known and potentially "new" microorganisms in perinatal medicine. However, application of these techniques to clinical practice poses clinical, technologic, and conceptual questions and challenges. For example, when does the detection of microbial footprints in a biologic fluid by sequence-based methods represent true microbial invasion rather than contamination? What criteria should be used to determine causality between the presence of a microorganism and an infectious disease, as it is now possible to identify with sequence-based methods bacteria that cannot be cultured in diseased tissues and therefore, Koch's postulates cannot be met?[120]

These questions were explored in two studies[121,122] comparing the outcome of patients in preterm PROM or preterm labor with intact membranes who had cultures and polymerase chain reaction (PCR) performed for

U. urealyticum. Patients with microbial invasion of the amniotic cavity with *U. urealyticum*, as determined by sequence-based methods for microbial detection, had adverse outcomes with the same frequency as patients with positive amniotic fluid cultures.[121,122]

Two strategies have been used to detect microorganisms in the amniotic fluid with PCR. The first, also known as broad-range PCR, uses primer pairs designed to anneal with highly conserved DNA regions of all bacteria, such as the 16S ribosomal DNA. A positive result indicates the presence of bacteria, but identification of the specific organism requires subsequent sequencing of the PCR products. The second approach is to use specific primers for a particular microorganism. At the time of this writing, three studies used primers for the conserved sequence,[35,123,124] five used specific primers to recover bacterial DNA from amniotic fluid,[121,122,125–127] while one applied both approaches.[128]

Blanchard and colleagues[125] were the first to report the recovery of *U. urealyticum* from amniotic fluid samples using specific primers for the urease structural genes. They collected 293 amniotic fluid samples by amniocentesis at cesarean section. The samples were cultured for bacteria, mycoplasmas, and chlamydia and had PCR performed for *U. urealyticum*. Among the 10 PCR-positive amniotic fluid samples, only 4 were also culture-positive. Subsequently, Jalava and colleagues,[123] Hitti and colleagues,[35] and Markenson and colleagues[124] applied broad-spectrum bacterial 16S rDNA PCR for the detection of bacteria in the amniotic fluid. Jalava and coworkers[123] studied 20 amniotic fluid samples from patients with PROM and 16 control samples: PCR detected five microorganisms (*U. urealyticum* [n = 2], *H. influenzae* [n = 1], *Streptococcus oralis* [n = 1], and *Fusobacterium* spp. [n = 1]), but only two were positive in a routine bacterial culture. The two patients who developed infectious complications were correctly identified by PCR, and amniotic fluid glucose levels were lower in PCR-positive compared to PCR-negative patients. Hitti and coworkers[35] studied 69 women in preterm labor with intact membranes. PCR was positive in 94% of the culture-positive amniotic fluid samples (15/16) and in 36% of the patients with a negative culture. Five of the 14 women with an elevated IL-6 concentration had bacteria detected by PCR. In Markenson's study,[124] 55.5% of the amniotic fluid samples from 54 women in preterm labor but no clinical evidence of infection were PCR-positive, whereas only 9.2% of the cultures recovered a microorganism ($p < 0.05$). Two thirds (6/9) of the amniotic fluid samples with an elevated IL-6 were also PCR-positive.

Oyarzun and colleagues[126] described a PCR amplification technique aimed at detecting the 16 microorganisms most commonly cultured from the amniotic fluid of patients in preterm labor (*U. urealyticum*, *M. hominis*, *Gardnerella vaginalis*, *E. coli*, *Fusobacterium* spp., *Peptostreptococcus anaerobius*, *Bacteroides fragilis*, *Chlamydia trachomatis*, *H. influenzae*, *N. gonorrhoeae*, and *Streptococcus*

spp.). Amniotic fluid samples were examined with bacterial culture and PCR in 50 patients with preterm labor and intact membranes and 23 patients not in labor. All control samples were both culture- and PCR-negative. A higher proportion of samples were positive by PCR compared to culture (46% [23/50] vs. 12% [6/50], $p < 0.05$). The sensitivity of PCR for the prediction of preterm labor before 34 weeks was better than culture (64% [7/11] vs. 18% [2/11], $p < 0.05$). However, there were patients with positive PCR who delivered at term without maternal or neonatal complications.

The clinical implications of detecting *U. urealyticum* by PCR in patients with preterm PROM[121] or preterm labor and intact membranes[122] were evaluated by Yoon and colleagues. Patients with a positive PCR assay of amniotic fluid but a negative culture had a stronger amniotic fluid inflammatory reaction (higher amniotic fluid white blood cell count and IL-6), a shorter interval to delivery, as well as a higher rate of histologic chorioamnionitis, funisitis, and neonatal morbidity than those with a negative amniotic fluid culture and negative amniotic fluid PCR assay for *U. urealyticum*. These studies reveal that patients with preterm PROM or preterm labor with intact membranes and a positive PCR assay for *U. urealyticum* (but a negative culture) have worse pregnancy outcomes than those with a sterile amniotic fluid culture and negative PCR.

Gerber and coworkers[127] used PCR to detect *U. urealyticum* DNA in the amniotic fluid of 254 asymptomatic patients undergoing genetic amniocentesis. Test results were positive in 11.4% of the pregnancies (29/254) and, among these, 58.6% (17/29) delivered preterm. In contrast, only 4.4% (10/225) of the PCR-negative patients delivered prematurely ($p < 0.0001$). This study is consistent with the premise of chronic *U. urealyticum* infection since women with a positive *U. urealyticum* DNA in the amniotic fluid had a higher frequency of preterm births in previous pregnancies compared to women with PCR-negative amniotic fluid (20.7% [6/29] vs. 2.7% [6/225], $p = 0.0008$). In a smaller study of 78 patients undergoing genetic amniocentesis, bacterial 16S ribosomal DNA was detected in 18% (14/78) of the amniotic fluid samples.[128] In this study, no samples tested positive for *Mycoplasma* spp. DNA although it was specifically sought using a PCR/enzyme-linked immunosorbent assay. No association was found between the recovery of bacteria at the time of amniocentesis and either increased IL-6 concentration in the amniotic fluid or preterm delivery. Thus, further studies will be necessary to clarify this issue.

MOLECULAR MECHANISMS FOR PRETERM PARTURITION IN THE SETTING OF INTRAUTERINE INFECTION

A considerable body of evidence supports a role for inflammatory mediators in the mechanisms of preterm

parturition associated with infection. These factors may also play a part in spontaneous labor at term, although the evidence for this is less compelling. Much attention has been placed on proinflammatory cytokines such as IL-1β, tumor necrosis factor alpha (TNFα), and chemokines such as IL-8. However, other proinflammatory and anti-inflammatory cytokines may be relevant, including platelet activating factor, prostaglandins, and arachidonate lipoxygenase metabolites.[9] The current understanding of the pathophysiology of preterm parturition in the context of intrauterine infection is summarized here. The interested reader is referred to the references for a comprehensive discussion.[9]

Prostaglandins and Lipoxygenase Products

Intrauterine prostaglandins are considered by many to be the key mediators of the biochemical mechanisms regulating the onset of labor. They can induce myometrial contractility,[129–132] as well as changes in the extracellular matrix metabolism associated with cervical ripening,[133–137] and are thought to participate in decidual/fetal membrane activation.[9]

The evidence traditionally invoked in support of a role for prostaglandins in the initiation of human labor includes the following: (1) administration of prostaglandins induces early and late termination of pregnancy (abortion or labor)[138–146]; (2) treatment with indomethacin or aspirin delays the spontaneous onset of parturition in animals[147–149]; (3) concentrations of prostaglandins in plasma and amniotic fluid increase during labor[150–156]; and (4) intra-amniotic injection of arachidonic acid can induce abortion.[157] Infection can increase prostaglandin production by amnion, chorion, or decidua through the activity of bacterial products, proinflammatory cytokines, growth factors, and other inflammatory mediators. Indeed, amniotic fluid concentrations of the prostaglandins PGE_2 and $PGF_{2\alpha}$ and their stable metabolites, PGEM and PGFM, are significantly higher in women with preterm labor and microbial invasion of the amniotic fluid cavity than in women with preterm labor without infection. Similar observations have been made in patients with labor and high concentrations of proinflammatory mediators in the amniotic cavity (i.e., IL-1β, TNF, IL-6). Moreover, amnion obtained from women with histologic chorioamnionitis produces higher amounts of prostaglandins than amnion from patients without histologic chorioamnionitis.

Metabolites of arachidonic acid derived through the lipoxygenase pathway, including leukotrienes (LTs) and hydroxyeicosatetraenoic acids (HETEs), are also implicated in the mechanisms of spontaneous preterm and term parturition. Concentrations of 5-HETE, LTB_4, and 15-HETE are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic fluid cavity. Similarly, amnion from patients with histologic chorioamnionitis releases more LTB_4 in vitro

than amnion from women delivering preterm without inflammation. However, the precise role of arachidonate lipoxygenase metabolites in human parturition remains to be determined. 5-HETE and LTB_4 can stimulate uterine contractility, and LTB_4 is thought to play a role in the recruitment of neutrophils to the site of infection and regulation of specific arachidonic acid metabolites of the cyclooxygenase pathway. Additionally, LTB_4 can act as a calcium ionophore in human intrauterine tissues (i.e., it increases phospholipase activity and enhances the rate of prostaglandin biosynthesis).[158] Oxygen-derived free radicals are also proposed to have a role in the mechanism of preterm parturition.[159,160] Exposure of chorioamniotic membranes to superoxide anion in vitro results in increased activity of MMP-9, a matrix-degrading enzyme involved in the pathogenesis of PROM. Administration of the antioxidant N-acetylcysteine inhibits MMP-9 activity and the generation of superoxide within the membranes.[159]

Inflammatory Cytokines

Evidence for the participation of IL-1 and TNFα in preterm parturition includes the following: (1) IL-1β and TNFα stimulate prostaglandin production by amnion, decidua, and myometrium,[161–163] while prostaglandins are considered a central mediator for the onset of labor; (2) human decidua produces IL-1β and TNFα in response to bacterial products[161,164,165]; (3) amniotic fluid IL-1β and TNFα bioactivity and concentrations are elevated in women with preterm labor and intra-amniotic infection[166–169]; (4) in women with preterm PROM and intra-amniotic infection, IL-1β and TNFα concentrations are higher in the presence of labor[158,161–163]; (5) IL-1β and TNFα induce preterm parturition when administered systemically to pregnant animals[85,170]; (6) pretreatment with the natural IL-1 receptor antagonist prior to the administration of IL-1 to pregnant animals prevents preterm parturition[171]; (7) fetal plasma IL-1β is elevated in the context of preterm labor with intrauterine infection[172]; and (8) placental tissue obtained from patients with labor, particularly those with chorioamnionitis, produces larger amounts of IL-1β than that obtained from women not in labor.[173]

However, there is considerable redundancy in the cytokine network, and it remains unclear whether a particular cytokine signals the onset of labor. Experimental studies in which anti-TNF and the natural IL-1 receptor antagonist were administered to pregnant animals with intrauterine infection did not prevent preterm delivery.[174] The results of knockout animal experiments suggest that infection-induced preterm labor and delivery occurs in animals that lack a particular cytokine.[175]

The precise mechanisms by which IL-1 and TNF participate in the activation of the myometrium have been the subject of intensive research, and there is evidence that they involve the participation of cytosolic

phospholipase A_2 (PLA$_2$), cyclooxygenase-2,[176,177] MAP kinases,[178] and nuclear factor kappa B (NFκB). A role for thrombin (an enzyme with oxytocin-like properties generated during the course of inflammation) is also postulated to have a role.[179–183] A novel observation is that labor is associated with increased activity of NFκB, a transcription factor responsible for many of the actions of IL-1 and TNFα. NFκB may affect uterine function by generating a functional progesterone withdrawal.[184]

Matrix Degrading Enzymes

Preterm PROM accounts for 30% to 40% of all preterm deliveries. The mechanisms responsible for PROM are only partially understood. Since the tensile strength and elasticity of the chorioamniotic membranes are attributed to extracellular matrix proteins, matrix-degrading enzymes have been implicated in preterm PROM. There is now compelling evidence that preterm PROM is associated with increased availability of MMP-1,[185] MMP-8,[186–188] MMP-9,[189–191] and neutrophil elastase,[192] but not MMP-2,[193,194] MMP-3,[195] MMP-7,[196] and MMP-13.[197] Proposed mechanisms to regulate the expression and activity of matrix-degrading enzymes in fetal membranes include programmed cell death (apoptosis)[198] and increased availability of superoxide anions (redox state),[159] respectively.

Because intrauterine infection is present in 30% of patients with preterm PROM and proinflammatory cytokines can stimulate the production of MMP-1, MMP-9, and MMP-8, a genetic predisposition to overproduction of MMPs in response to microorganisms has been implicated in the genesis of PROM. Fetal carriage of two functional polymorphisms for MMP-1 and MMP-9 has been associated with preterm PROM.[199,200]

A polymorphism at nt-1607 in the MMP-1 promoter (an insertion of a guanine [G]) creates a core Ets binding site and increases promoter activity.[200] The 2G promoter has more than two-fold greater activity compared to the 1G allele in amnion mesenchymal cells and a cloned amnion cell line. Phorbol 12-myristate 13-acetate (PMA) increased mesenchymal cell nuclear protein binding, with greater affinity to the 2G allele. Induction of MMP-1 mRNA by PMA is significantly greater in cells with a 1G/2G or 2G/2G genotype than in cells homozygous for the 1G allele. After treatment with PMA, the 1G/2G and 2G/2G cells produce greater amounts of MMP-1 protein than 1G/1G cells. A significant association was found between the presence of a 2G allele in the fetus and preterm PROM. Thus, the 2G allele has stronger promoter activity in amnion cells, and confers increased responsiveness of amnion cells to stimuli that induce MMP-1. Carriage of this polymorphism augments the risk of preterm PROM.[200]

A second polymorphism implicated in preterm PROM is located within the MMP-9 gene.[199] Functional studies of the 14 CA-repeat allele indicate that the allele is a stronger promoter than the 20 CA-repeat allele in both amnion epithelial cells and WISH amnion-derived cells (yet the 14 and 20 CA-repeat alleles have similar activities in monocyte/macrophage cell lines). A case-control study concluded that the 14 CA-repeat allele was more common in newborns delivered to mothers who had preterm PROM than in those delivered at term. Thus, differences in MMP-9 promoter activity related to the CA-repeat number as well as fetal carriage of the 14 CA-repeat allele appear associated with preterm PROM.[199]

THE FETAL INFLAMMATORY RESPONSE SYNDROME

The term *fetal inflammatory response syndrome* (FIRS) was coined to define a subclinical condition originally described in fetuses of women presenting with preterm labor and intact membranes as well as those presenting with preterm PROM.[10,11] The operational definition was an elevation of fetal plasma IL-6 concentration above 11 pg/mL.[11] IL-6, a major mediator of the host response to infection and tissue damage, is capable of eliciting biochemical, physiologic, and immunologic changes in the host, including stimulation of the production of C-reactive protein by liver cells, the acute phase plasma protein response, and activation of T and natural killer cells. Fetuses with FIRS have a higher rate of neonatal complications[12,13] and are frequently born to mothers with subclinical microbial invasion of the amniotic cavity.[10]

Fetal microbial invasion or other insults result in a systemic fetal inflammatory response that can progress toward multiple organ dysfunction, septic shock, and perhaps death in the absence of timely delivery. Evidence of multisystem involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9,[201] an enzyme involved in the digestion of type IV collagen. In addition, these fetuses have neutrophilia, a higher number of circulatory nucleated red blood cells, and higher plasma concentrations of G-CSF than fetuses without inflammation.[202] FIRS is also associated with changes in markers of monocyte and neutrophil activation.[203] Fetuses with elevated concentrations of IL-6 in the umbilical cord blood have decreased amniotic fluid volume.[42] There is also evidence that FIRS is associated with cardiac dysfunction and neonatal hypotension.[204–206]

The original work describing FIRS was based on fetal blood samples obtained by cordocentesis.[10,11] Many of the findings have since been confirmed by studying umbilical cord blood at the time of birth, including the elevation of proinflammatory cytokines, and the relationship between these cytokines and the likelihood of clinical and suspected sepsis.[13]

Pathologic examination of the umbilical cord is an easy approach to determine whether fetal inflammation was present before birth. Funisitis and chorionic vasculitis are the histopathologic hallmark of FIRS.[55] Another approach is to measure C-reactive protein concentration

in umbilical cord blood, which was shown to be elevated in patients with amniotic fluid infection, funisitis, and congenital neonatal sepsis.[207] Neonates with funisitis are at increased risk for neonatal sepsis,[54] as well as long-term handicap such as bronchopulmonary dysplasia[13] and cerebral palsy.[12] Neutrophils in the amniotic fluid are predominantly of fetal origin.[208] Thus, the amniotic fluid white blood cell count is an indirect index of fetal inflammation.[208] Intra-amniotic inflammation is a risk factor for impending preterm delivery and adverse perinatal outcome in women with preterm PROM, even in the absence of documented intra-amniotic infection.[209]

Among women with preterm PROM, FIRS is associated with the impending onset of preterm labor, regardless of the inflammatory state of the amniotic fluid (Fig. 27–2).[10] This suggests that the human fetus plays a role in initiating the onset of labor. However, maternal cooperation must be present for parturition to occur. Fetal inflammation is linked to the onset of labor in association with ascending intrauterine infection. Systemic fetal inflammation may occur in the absence of labor when the inflammatory process does not involve the chorioamniotic membranes and decidua. Such instances occur in the context of hematogenous viral infections or other disease processes (i.e., alloimmunization).

Three approaches can be used to interrupt the course of FIRS: (1) delivery; (2) antimicrobial treatment of women in whom the FIRS is due to microbial invasion of susceptible bacteria; and (3) administration of agents that down-regulate the inflammatory response. Preterm delivery places the unborn child at risk for complications of prematurity. Therefore, the risks of prematurity and intrauterine infection must be balanced.

The administration of antimicrobial agents may eradicate microbial invasion of the amniotic cavity in cases of preterm PROM.[201,210] The results of the ORACLE I trial suggest that antibiotic administration may not only delay the onset of labor but also improve neonatal outcome.[109] These findings are supported by recent experimental evidence in pregnant rabbits inoculated with *E. coli*.[211] Antibiotic administration within 12 hours of microbial inoculation (but not after 18 hours) effectively prevented maternal fever, reduced the rate of preterm delivery, and improved neonatal survival. It is tempting to postulate that this was accomplished by improving or preventing a fetal inflammatory response.

Agents that down-regulate the inflammatory response, such as anti-inflammatory cytokines (i.e., IL-10),[212,213] antibody to macrophage migration inhibitory factor (MIF),[214,215] and antioxidants, may also play a role in preventing preterm delivery, neonatal injury, and long-term perinatal morbidity.[210,216,217] A combination of antibiotics and immunomodulators (dexamethasone and indomethacin) given to nonhuman pregnant primates was effective in eradicating infection, suppressing the inflammatory response, and prolonging gestation in experimental premature labor induced by intra-amniotic inoculation with group B streptococci.[218]

CONTRIBUTION OF FETAL INFECTION/INFLAMMATION TO LONG-TERM HANDICAP

Cerebral Palsy

Cerebral palsy (CP) is a symptom complex characterized by the aberrant control of movement or posture that appears in early life and can lead to costly lifelong disability.[219] The estimated annual prevalence of CP ranges from 1.5 to 2.5 per 1000 live births, depending on the cohort studied.[220,221]

Prematurity has a strong association with CP[222]; approximately one third of all neonates who later have signs of CP weigh less than 2500 g.[223] Newborns with birth weights <1500 g have a rate of CP 25 to 31 times higher than those with a normal birth weight. The most common form of CP affecting preterm babies is spastic diplegia.[223] In turn, preterm babies that subsequently develop spastic diplegia have a high rate of periventricular leukomalacia (PVL).[222,224–232]

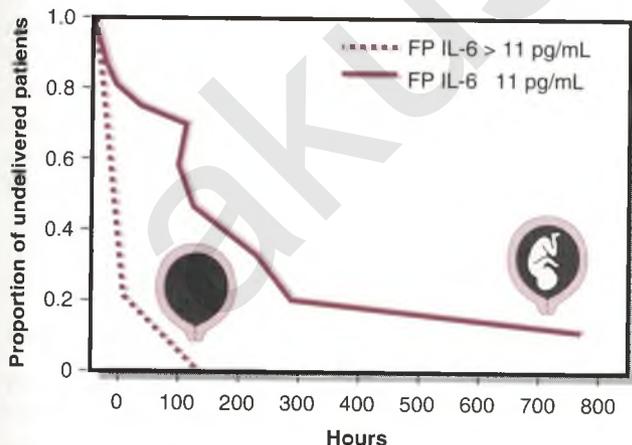
Strong evidence links brain injury and infant exposure to perinatal infection and inflammation.[219,233–236] In 1955, Eastman and DeLeon observed that intrapartum maternal fever was associated with a seven-fold increase in the risk of CP.[237] In 1978, Nelson and Ellenberg[238] showed, using data from the Collaborative Perinatal Project, that among low birth weight infants, chorioamnionitis increased the risk of CP from 12 per 1000 to 39 per 1000 live births. These observations were independently confirmed by several other studies.[225,233,239–241] The general view is that an initiator event (either prepregnancy infection or intrauterine infection) leads to


FIGURE 27–2
Fetuses with fetal plasma IL-6 levels >11 pg/mL have a shorter cordocentesis-to-delivery interval than those with plasma IL-6 concentrations ≤11 pg/mL (median, 0.8 days [range, 0.1 to 5 days] vs. median, 6 days [range, 0.2 to 33.6 days], respectively; $P < 0.05$) (From Romero R, Gomez R, Ghezzi F, et al: A fetal systemic inflammatory response is followed by the spontaneous onset of preterm parturition. Am J Obstet Gynecol 1998;179:186–193).

maternal and fetal inflammatory responses, which, in turn, contribute to adverse outcomes such as preterm delivery, intraventricular hemorrhage (IVH), white matter damage (WMD), and neurodevelopmental disability (mainly CP).[242] The following evidence supports this concept: (1) a fetal inflammatory response precedes spontaneous preterm delivery; (2) white matter lesions are associated with spontaneous preterm labor[222,240,243–246]; (3) chorioamnionitis is associated with an increased risk of CP[219,225,233,239–241,247,248]; (4) infection is causally linked to WMD[222,225,234,240]; (5) fetal cytokinemia is associated with IVH, WMD, and CP[235,242,249–255]; and (6) chorionic and umbilical cord vessel inflammation (fetal vasculitis) is associated with an increased risk for IVH, WMD, and cerebral palsy.[12,256–259]

Periventricular leukomalacia describes foci of coagulation necrosis of the white matter near the lateral ventricles. This condition is frequently associated with the subsequent development of CP,[260–262] is more common in infants born between 28 and 31 weeks, and 9 times more common among those with documented bacteremia.[222] Among preterm neonates, the frequency of IVH and PVL is significantly higher for those born after spontaneous preterm labor or PROM when compared to those infants delivered for fetal or maternal indications.[240,246]

Chorioamnionitis Is Associated with an Increased Risk of White Matter Damage and Cerebral Palsy

Maternal infection is also implicated as a significant risk factor for CP in term neonates. Grether and Nelson[219] investigated maternal infection during admission for delivery as a possible risk factor for CP in infants weighing 2500 g or more. In a cohort of 155,636 children in four Northern California counties, 46 children with disabling spastic CP who had no recognized prenatal brain lesions and survived to age 3 years were compared to 378 randomly selected controls. Maternal fever exceeding 38°C in labor or a clinical diagnosis of chorioamnionitis were strongly associated with subsequent development of CP (odds ratio, 9.3; 95% confidence interval, 2.7–31.0), as was histologic evidence of placental infection (odds ratio, 8.9; 95% confidence interval, 1.9–40.0). Twenty-two percent of children with CP had one or more indicators of maternal infection. Newborns exposed to maternal infection had signs attributed to birth asphyxia more often than those unexposed: 5-minute Apgar scores below 6, hypotension, need for intubation, neonatal seizures, and more clinical diagnoses of hypoxic-ischemic encephalopathy. A subsequent larger study by the same group confirmed that clinical chorioamnionitis is a significant independent risk factor for the development of CP in term or near-term infants.[263]

That the fetus is involved in clinical chorioamnionitis is strongly suggested by a study comparing plasma concentrations of IL-6 in umbilical venous blood obtained from pregnancies with (n = 26) and without (n = 111) clinical chorioamnionitis.[264] The median concentration of venous plasma IL-6 was higher in neonates born to mothers with clinical chorioamnionitis than in those born to women in the control group. Sixty-two percent (16/26) of the neonates born to women with clinical chorioamnionitis had elevated plasma concentrations of IL-6 >11 pg/mL in the umbilical vein. The observation that the concentration of IL-6 was higher in the blood from the umbilical artery than in the umbilical vein suggests a fetal origin of the excess plasma IL-6.

Experimental Evidence Linking Infection with White Matter Brain Damage

White matter damage is more common among children of pregnancies complicated by chorioamnionitis[240] and purulent amniotic fluid,[225] as well as among neonates with bacteremia.[222] Experimental evidence indicates that intrauterine infection results in WMD and neuronal lesions.[234,265–270] The reader is referred to the review by Hagberg and colleagues[269] for details. Yoon and coworkers[234] experimentally induced ascending intrauterine infection with E. coli in 31 pregnant rabbits; 14 controls were inoculated with sterile saline solution. Histologic evidence of WMD was identified in 12 fetuses born to 10 E. coli-inoculated rabbits compared to none in the control group (p < 0.05). All cases with WMD had evidence of intrauterine inflammation. Similar findings were reported by DeBillon et al.[266,267]

Fetal Cytokinemia Is Associated with Intraventricular Hemorrhage, White Matter Damage, and Long-Term Disability

Leviton[252] proposed that inflammatory cytokines (TNFα) released during the course of intrauterine infection could play a central role in the pathophysiology of brain WMD. TNF could participate in the pathogenesis of PVL by four different mechanisms: (1) induction of fetal hypotension and brain ischemia[253]; (2) stimulation of tissue factor production and release, which activates the hemostatic system and contributes to coagulation necrosis of white matter[271]; (3) induction of the release of platelet activating factor, which could act as a membrane detergent causing direct brain damage[254]; and (4) a direct cytotoxic effect of TNFα on oligodendrocytes and myelin.[250,251]

The hypothesis that fetal inflammation is linked to brain injury is supported by studies documenting higher concentrations of IL-6 in the umbilical cord plasma[246] and amniotic fluid[235] of fetuses who subsequently develop WMD. Moreover increased expression of TNFα and IL-6 is observed in hypertrophic astrocytes and microglia cells obtained from subjects with PVL.[249] Yoon and colleagues[235] advanced one mechanism to explain how inflammatory cytokines might lead to WMD and CP. According to their theory, microbial

invasion of the amniotic cavity (which occurs in approximately 25% of preterm births) results in congenital fetal infection/inflammation that stimulates fetal mononuclear cells to produce IL-1β and TNFα. These cytokines increase the permeability of the blood-brain barrier, facilitating the passage of microbial products and cytokines into the brain.[272] Microbial products then stimulate the human fetal microglia to produce IL-1 and TNFα, with subsequent activation of astrocyte proliferation and production of TNFα. TNFα damages the oligodendrocyte, which is the cell responsible for the deposition of myelin.

Fetal Vasculitis, Intraventricular Hemorrhage, White Matter Damage, and Cerebral Palsy

Yoon and colleagues[12] observed in a study of 123 preterm infants followed to age 3 years that the odds of developing CP were higher in the presence of funisitis (odds ratio, 5.5; 95% confidence interval, 1.2–24.5), increased amniotic fluid IL-6 concentrations (odds ratio, 6.4; 95% confidence interval, 1.3–33.0), and increased amniotic fluid IL-8 concentrations (odds ratio, 5.9; 95% confidence interval, 1.1–30.7). All 14 children who subsequently developed CP had evidence of WMD, and 11 had evidence of intrauterine inflammation. Fifty percent of the children (7/14) had positive amniotic fluid cultures. Although histologic chorioamnionitis was associated with subsequent development of CP, this association disappeared after adjusting for gestational age at birth. The findings of this study suggest that it is the fetal, rather than maternal, inflammatory response that predisposes to CP. Nonetheless, neither infection nor inflammation were considered sufficient causal factors for WMD or CP, as the latter did not develop in 82% (23/28) of fetuses with documented microbial invasion of the amniotic cavity and in 76% (34/45) of those with evidence of intrauterine inflammation. Factors implicated in the genesis of brain injury include: (1) gestational age; (2) virulence of the microorganisms; (3) fetal attack rate; (4) the nature of the fetal immunoresponse; and (5) vulnerability of the central nervous system. It is likely that genes coding for proinflammatory and anti-inflammatory cytokines as well as neurotrophic agents regulate the intensity of the inflammatory response and, therefore, the host response to infection and tissue injury.[256–259]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is one of the most frequent and clinically significant complications of prematurity; there is evidence of an association between fetal inflammatory responses and BPD.[13,273–275]

Watterberg and coworkers[274] studied the association between lung inflammation and chorioamnionitis in 53 low birth weight infants who required intubation. Lung inflammation was evaluated on days 1, 2, and 4 of intubation by measuring the concentration of IL-1β, throm-

boxane B_2, leukotriene B_4, and prostaglandin E_2 in tracheal lavage samples. Infants exposed to chorioamnionitis had a higher concentration of IL-1β in their tracheal fluid from day 1 of intubation forward and were more likely to develop BPD.

Antenatal exposure to proinflammatory cytokines is also a risk factor for the development of BPD.[273] Ghezzi and colleagues[273] measured IL-8 in the amniotic fluid of women with preterm labor with intact membranes or preterm PROM ($n = 47$) who delivered between 24 and 28 weeks of gestation. BPD was diagnosed in 23.4% (11/47). The prevalence of a positive amniotic fluid culture was 44.7% (21/47). IL-8 concentrations were higher in the amniotic fluid of neonates who subsequently developed BPD compared to those who did not. The majority of mothers whose fetuses developed BPD had an amniotic fluid IL-8 level greater than 11.5 ng/mL, and this relationship remained significant even after correction for the effect of gestational age and birth weight (odds ratio: 11.9; p <0.05). The relationship between amniotic fluid IL-6, TNFα, IL-1β, and IL-8 and the occurrence of BPD was further examined in a subsequent study[276] of 69 neonates delivered preterm (≤33 weeks) within 5 days of amniocentesis. BPD was diagnosed in 19% (13/69), and the median amniotic fluid concentrations of IL-6, IL-1β, and IL-8 were each significantly higher in the amniotic fluid of infants who developed BPD compared to those who did not.

Yoon and colleagues[13] studied the relationship between IL-6 concentration in umbilical cord plasma at birth and the occurrence of BPD in 203 preterm births (25 to 34 weeks' gestation). BPD was diagnosed in 17% (34/203). Neonates who developed BPD had a significantly higher median IL-6 concentration in umbilical cord plasma at birth than those in whom BPD did not develop (median 68.3 pg/mL [0.3–6150.0 pg/mL] vs. median 6.9 pg/mL [0–19, 230.0 pg/mL], p <0.001). This difference remained significant after adjustment for gestational age at birth (odds ratio, 4.2; 95% confidence interval, 1.6–11.2). This same group[275] has also observed an association between a fetal inflammatory response (defined as the presence of funisitis or umbilical cord plasma IL-6 concentration >17.5 pg/mL or amniotic fluid MMP-8 concentration >23 ng/mL) and the development of atypical chronic lung disease (defined as chronic lung disease in the absence of respiratory distress syndrome). Chronic lung disease was diagnosed in 70 newborns. A fetal inflammatory response was present in 76% (53/70) and was more common among those with atypical chronic lung disease (90% [27/30] vs. 65% [26/40]; p <0.05).

Perinatal Death

Infectious diseases, birth asphyxia, and prematurity are considered the major causes of neonatal death worldwide.[277] In one review of 27 hospital-based studies

evaluating the impact of infection as a cause of neonatal death, Stohl[277] observed that infection was associated with 7% to 54% of early neonatal deaths and 30% to 73% of late neonatal deaths. Even in the absence of a suggestive clinical history, infection and inflammation can still contribute significantly to perinatal mortality. In a study of 94 autopsies performed in fetuses and neonates, evidence of an infectious or inflammatory condition was present 48% (45/94) of the time.[278] In 58% (26/45) of cases, no previous signs or symptoms of infection/inflammation were present. The most common diagnosis was chorioamnionitis (79.1% [38/48]), followed by acute villitis (4.2% [2/48]), chronic villitis (4.2% [2/48]), disseminated cytomegalovirus infection (4.2% [2/48]), disseminated herpes simplex virus infection (2.1% [1/48]), pneumonia (4.2% [2/48]), and mixed placental infection (2.1% [1/48]). The reader is referred to a review by Goldenberg and Thompson[279] for a comprehensive summary.

Blackwell and colleagues[280] proposed that failure of the fetus to mount an inflammatory response sufficient to signal the onset of preterm labor might account for some cases of fetal death. Indeed, histologic chorioamnionitis (a maternal host response) is nine times more frequent than funisitis (20.9% [9/43] vs. 2.3% [1/43], $p = 0.008$) in cases of fetal death. Changes in the adaptive limb of the maternal immune response are also associated with unexplained fetal death. Evidence in support of this concept includes the finding that an increased proportion of "memory-like" T cells (CD45RO+ isoform) was observed in the maternal blood of pregnancies complicated by unexplained fetal death, suggesting that prior maternal exposure to microbial products (bacterial or viral) or other unidentified antigens occurred in these cases.[281]

THE ROLE OF VIRUSES IN FETAL INFECTION

Viral infections acquired during pregnancy are associated with a variety of severe but nonspecific outcomes, including spontaneous abortion, fetal growth disorders, microcephaly, hydrocephaly, congenital cataract, myocarditis, pericardial effusion, liver calcifications, ascites, and nonimmune hydrops. The consequences of fetal infection by rubella, cytomegalovirus (CMV), varicella zoster virus, parvovirus B19, herpes simplex virus (HSV), and lymphocytic choriomeningitis virus are detailed elsewhere (see Chapters 30 and 31). The detection of viral genome in the amniotic fluid, either in low risk pregnancies or pregnancies at risk for fetal infection, has expanded the list of potential fetal pathogens to include adenovirus, coxsackievirus, human papillomavirus, influenza, and respiratory syncytial virus (RSV). The list may grow with the application of novel diagnostic tools.[282] In addition to the well-known teratogenic effects, viral infection during pregnancy may also be implicated in the pathogenesis of

abnormal placentation[283–286] and in the etiology of neuropsychiatric disorders.[287–291]

Detection of Viral Genome in the Amniotic Fluid and Other Tissue Samples

Viral genome is detected in the amniotic fluid of up to 15% of asymptomatic low risk pregnancies[292–295] and 41% of pregnancies at risk for viral infection.[296–298] The most common viral DNA isolates, in both low and high risk pregnancies, are adenovirus, CMV, and enterovirus.[292,293,295–298]

Viral Genome in the Amniotic Fluid of Low Risk Pregnancies

Viral genomes have been detected in the amniotic fluid of asymptomatic low risk pregnancies at the time of midtrimester amniocentesis.[292,293,296] McLean and colleagues[294] were the first to report the detection of viral genome in the amniotic fluid of patients at low risk for viral infection at the time of genetic amniocentesis. Amniotic fluid samples were analyzed by polymerase chain reaction (PCR) for the presence of adenovirus, CMV, parvovirus, or HSV. Two hundred and forty-three samples had detectable DNA by β-globin chain amplification but none had detectable viral DNA. In three subsequent studies, however, the prevalence of viral genome in the amniotic fluid of asymptomatic low risk patients ranged from 2.6% to 15%.[292,293,295] The largest study conducted to date[292] reported a prevalence of viral genome in 6.4% (44/686) of amniotic fluid samples obtained at midtrimester amniocentesis. The most prevalent viral genome was adenovirus (37/44), followed by CMV (5/44), Epstein-Barr virus (EBV) (2/44), enterovirus (2/44), and RSV (1/44). Another finding of this study was a bimodal seasonal variation in prevalence of viral DNA in the amniotic fluid, with the highest detection rate observed during the summer and winter months.

Detection of Viral Genome in Biological Specimens of Pregnancies at Risk for Fetal Infection

Viral genome can be detected in the amniotic fluid of 12% to 41% of pregnancies at risk for fetal infection.[292,296] Van den Veyver and colleagues[296] analyzed amniotic fluid ($n = 233$) and other biologic samples (fetal blood at cordocentesis [$n = 42$], cord blood at the time of delivery [$n = 18$], ascitic fluid [$n = 8$], pleural fluid [$n = 10$], and other tissue samples [$n = 40$]) in 303 pregnancies at risk for viral infection. Risk factors included nonimmune fetal hydrops, pleural effusion, twin-to-twin transfusion syndrome, fetal ventriculomegaly, fetal intracranial calcification/microcephaly, fetal hepatic calcification or echogenic bowel, fetal myocarditis, maternal exposure to virus, polyhydramnios, oligohydramnios, intrauterine growth restriction, or a combination of these. Amniotic fluid from 154 controls was

obtained at the time of genetic amniocentesis. PCR was used to detect the presence of viral DNA or RNA (reverse transcriptase-PCR) for the following viruses: CMV, HSV, parvovirus B19, adenovirus, enterovirus, EBV, and RSV When all samples were considered in the analysis, viral genome was detected in 41% (124/303) of the cases. Among the high risk pregnancies, ascitic fluid was positive for one or more viral genomes in 50% (10/20), amniotic fluid in 41% (95/233), pleural fluid in 33% (6/18), and fetal blood in 22% (13/60). Fifty-five percent (50/91) of the fetuses with nonimmune hydrops had a viral infection. The most commonly recovered viral genome was adenovirus (24% [74/303]), which was also the most prevalent virus in cases of nonimmune fetal hydrops (60% of the positive samples [30/50]). CMV was present in 9.9% of the samples obtained from high risk pregnancies (30/303) and was frequently associated with the recovery of other viral genomes (such as adenovirus and enterovirus), as well as with the presence of several fetal abnormalities, including nonimmune hydrops, hepatic calcification, growth restriction, stuck twin syndrome, and fetal ascites. Enterovirus was present in 7.3% (22/303) of the cases and was associated with stuck twin syndrome, myocarditis, fetal ascites with pericardial effusion, hydramnios, and nonimmune hydrops. RSV and parvovirus were present in 3% (9/303) and 2.6% (8/303) of the high risk pregnancies, respectively, mainly those complicated by nonimmune hydrops (parvovirus and HSV) or stuck twin syndrome (HSV). Among low risk pregnancies, 2.6% (4/154) had positive viral genome in the amniotic fluid (adenovirus $n = 3$; CMV $n = 1$), and this finding was unassociated with fetal complications.

Baschat and coworkers[297] compared the prevalence of viral genome in amniotic fluid of normal pregnancies (genetic amniocentesis, $n = 240$) and amniotic fluid, fetal blood, or pleural fluid in pregnancies complicated by fetal anomalies, small-for-gestational age fetuses, or proven maternal infection ($n = 138$). The overall detection of viral genome was 12.4% (47/378). The most frequently isolated viral genome was adenovirus (10.3% [39/378], followed by enterovirus (1.3% [5/378]), CMV (0.8% [3/378]), RSV (0.3% [1/378]), EBV (0.3% [1/378]), and parvovirus B19 (0.3% [1/378]). The prevalence of viral genome was higher in pregnancies with an adverse outcome than in patients with a normal outcome (19.6% [27/138] vs. 8.3% [20/240], $p <0.005$).

Detection of Viral Genome in the Amniotic Fluid and Adverse Pregnancy Outcome

Reddy and coworkers[298] found an association between detection of a viral genome in the amniotic fluid and adverse pregnancy outcome. PCR was conducted for CMV, parvovirus B19, adenovirus, enterovirus, HSV, EBV, and RSV in 147 pregnancies. One hundred thirty-eight fetuses were chromosomally normal; among these, 25 (18%) had a positive amniotic fluid PCR. These fetuses were more likely to deliver prematurely, have preterm PROM, nonimmune hydrops, low birth weight, or an intrauterine fetal demise. When only structurally normal fetuses were analyzed, those with a positive amniotic fluid PCR for viral genome were more likely to die in utero and have both a lower gestational age and lower birth weight at delivery.

Detection of Viral Genome in the Amniotic Fluid and Pregnancy Loss

Wenstrom and colleagues[293] investigated the prevalence of viral DNA and measured IL-6 levels in the amniotic fluid of 62 patients who had a pregnancy loss within 30 days of genetic amniocentesis. Sixty control pregnancies delivering uneventfully at term were matched for the year that the amniocentesis was performed, indications for the procedure, gestational age, and maternal age. Amniotic fluid was studied by PCR for the presence of adenovirus, parvovirus, CMV, EPV, and HSV, and by reverse transcriptase PCR for enterovirus and influenza A. The prevalence of viral DNA was not significantly different between cases and controls (8% [5/62] vs. 15% [9/60], respectively; $p = 0.27$). Adenovirus was the most frequently recovered viral genome (64% [9/14]), followed by CMV (21% [3/14]), HSV (7% [1/14]), and parvovirus (7% [1/14]). Although IL-6 concentration was significantly higher in patients who lost their pregnancies within 30 days of genetic amniocentesis, no association between the detection of viral genome and the concentration of IL-6 in amniotic fluid was demonstrated. In summary, a developing body of work suggests that fetal viral infection can induce an inflammatory response. Most fetuses with evidence of viral infection do well. The response is likely altered by gestational age and genetic factors.

CONCLUSIONS

- Intrauterine infection/inflammation contributes significantly to pregnancy pathology:
  - Preterm labor/late miscarriage
  - Premature rupture of membranes
  - Chorioamnionitis
  - Neurodevelopmental disability after birth
  - Chronic lung disease
  - Perinatal death

- Molecular genetic techniques have allowed a greater understanding of the pathophysiologic processes.
- Although bacteria were thought to be the main trigger for intrauterine infection/inflammation, a role of viral infection is now emerging.
- Application of this knowledge has yet to change practice and improve outcome, though such mechanistic knowledge should ultimately do so.

SUMMARY OF MANAGEMENT OPTIONS

Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

Management Options	Quality of Evidence	Strength of Recommendation	References
Diagnosis of Intra-amniotic Infection/Inflammation			
Perform Amniocentesis to retrieve amniotic fluid	III	B	29
• **Rapid tests:** Gram stain, amniotic fluid wbc count, amniotic fluid glucose, and IL-6 concentration			
• **Culture:** Aerobic, anaerobic bacteria and genital mycoplasmas			
• **PCR** with specific primers for the detection of organisms in patients with intra-amniotic inflammation and negative culture			
Diagnosis of a Fetal Inflammatory Response Syndrome			
General			
• The diagnosis of fetal inflammatory response syndrome suggests antenatal exposure to an agent that promoted inflammation.	–	GPP	–
• It may have medicolegal value, as there is no current evidence that treatment can modify the natural history and the risk for adverse outcome (short- and long-term) conferred by fetal systemic inflammation.	–	GPP	–
Take levels from umbilical cord blood obtained at the time of delivery:	III	B	54, 55, 69, 207, 246, 299, 300–303, 308, 310
CBC and differential, platelet count			
C-reactive protein; elevated C-reactive protein is associated with:			
• Histologic chorioamnionitis			
• Funisitis			
• Neonatal sepsis			
IL-6 concentration; elevated IL-6 level associated with:			
• Positive amniotic fluid cultures (MIAC)			
• Histologic chorioamnionitis[55,300-302]			
• Funisitis			
• Neonatal sepsis			
• Congenital pneumonia			
• Necrotizing enterocolitis			
• Intracranial hemorrhage			

SUMMARY OF MANAGEMENT OPTIONS
Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
• Central nervous system white matter damage			
• Impaired neurologic outcome (lower Bayley psychomotor developmental index scores)			
Examine the placenta	III	B	51, 52, 54, 55
• Histologic chorioamnionitis is a maternal host response.			
• Funisitis is a marker of fetal inflammation.			
For Premature Neonates, After Birth			
Perform pathologic examination of the placenta	III	B	12, 225, 309, 311, 312
Specifically seek for evidence supporting the following diagnoses:			
Histologic chorioamnionitis associated with intracranial hemorrhage			
Funisitis associated with:			
• Neonatal sepsis			
• Intracranial hemorrhage			
• White matter damage			
• Cerebral palsy

Hepatitis Virus Infections

Neil S. Silverman

HEPATITIS A

General

Although person-to-person contact resulting in "infectious jaundice" was described in a review of hepatitis epidemics published by Blumer in 1923,[1] the hepatitis A virus was not identified until 1973, when Feinstone and colleagues, using immunofluorescent electron microscopy, described virus-like particles in filtered stool samples that stained positively when mixed with hepatitis A virus (HAV) convalescent serum.[2] These investigators also demonstrated a lack of cross-reactivity between HAV-specific antibodies and both hepatitis B virus and Norwalk particles, proving HAV to be a distinct infectious viral entity. Subsequent work by this group then demonstrated a temporal link between detectable shedding of the HAV antigen in feces and symptomatic illness in experimentally infected subjects.[3] HAV has subsequently been identified as a positive-strand RNA virus, with intact virions carrying the messenger RNA strand, and is classified in the family Picornaviridae. As a picornavirus, HAV is nonenveloped and is resistant to organic solvent dissolution owing to its lipid-poor coating.

HAV produces little to no typical cytopathic effect in cell culture and is difficult to propagate in tissue culture.[4] Compared to other picornaviruses such as poliovirus, HAV is relatively resistant to heat, surviving 60°C for 1 hour[5]; it is also resistant to inactivation by drying for up to 1 month.[6] Autoclaving, ultraviolet (UV) radiation, and heat extremes (>100°C), however, do prevent viral infectivity, as does chlorination.[7] This latter effect helps explain the ready propagation of HAV in areas of poor sanitation. All human HAV strains studied to date are extremely similar antigenically, if not identical.[8] Antigenic cross-reactivity has not been demonstrated between HAV and any other vectors producing viral hepatitis.

Because HAV produces a self-limited illness and does not result in a chronic carrier state, prevalence studies have been mostly limited to adult hospitalized populations. In these, HAV was responsible for approximately 20% of cases of acute hepatitis, with hepatitus B virus producing 50% and the remainder attributed to non-A, non-B hepatitis (now hepatitis C).[9]

The distribution of HAV is global, though outbreaks are typically seen in areas with crowded conditions or poor hygiene and sanitation. The virus can be isolated from the feces of all infected patients, which facilitates the fecal-oral route of transmission, not uncommonly via contamination of water or food. Parenteral transmission is rare, for the virus is present only transiently in serum.

Serologic evidence of past infection is nearly universal by age 10 in developing countries, whereas in industrialized countries, lower rates of infection in early life are seen.[10] Major risk factors for HAV infection in pregnant women in developed countries would include (1) travel to developing countries (especially Southeast Asia, Africa, central America, Mexico, and the Middle East), (2) household or sexual contact with infected individuals, and (3) contact with infected food or water. In the United States, sewage contamination of public and private water supplies (and the food products they supply) has been most frequently implicated in outbreaks of HAV.[11,12] Bivalve mollusks such as clams and oysters can act as reservoirs for HAV within contaminated waters; crustaceans such as shrimp do not seem to carry the same infectious risk. Infected food handlers have also been implicated in HAV outbreaks, especially when they are from global areas with endemic HAV infection rates.[13] In the United States, the incidence of hepatitis A in pregnancy is approximately 1 in 1000.

Although HAV infection tends to be clinically less severe than infection with other viral hepatitides, and serious complications are uncommon, distinction between infection with HAV and other viruses can only be made serologically. Conversely, not all HAV infections are symptomatic. Before immunoglobulin was available for preventive passive immunization, 80% to 95% of infected adults in HAV epidemics were symptomatic, two thirds of whom were icteric.[14] Severity of illness with HAV infection appears to be directly related to the patient's age (older patients are more severely ill), as well as to the size of the viral inoculum. Viral load also can accelerate the incubation period from infection to illness[15]; usually the mean incubation period is 28 to 30 days, with a range of 15 to 50 days.

Diagnosis

The initial clinical symptoms of acute HAV infection are nonspecific, consisting of fatigue, malaise, fever, nausea, and anorexia. Significant weight loss may be a presenting complaint in pregnant women. Arthralgias may be present, but frank arthritis or vasculitis is unusual.[16,17] The classic picture of icteric illness becomes apparent within 10 days of the generalized symptoms and is usually preceded by palpable hepatosplenomegaly. Liver function abnormalities, typically characterized by elevations in serum alanine aminotransferase (ALT) higher than aspartate aminotransferase (AST), peak prior to the appearance of jaundice. They may remain elevated for over a month in adults. Prolonged illness, with elevations in liver functions tests (LFTs) lasting over 12 months, has been reported in 8% to 10% of older patients, and jaundice and pruritus may persist despite an overall improving trend in symptoms and LFTs. Corticosteroids are usually not given to ameliorate symptoms because of the overall benign nature of HAV infection. Fulminant hepatitis, resulting in death, occurs in fewer than 1% of cases.[18]

HAV-specific immunoglobulin M (IgM) is the serologic marker for acute infection and can be reliably identified with an automated enzyme-linked immunosorbent assay (ELISA).[19] By the time a patient is symptomatic, she will almost uniformly be seropositive for IgM anti-HAV. IgM levels drop below the detectable range within 3 to 6 months in 85% to 90% of patients and parallel a concomitant normalization of LFTs in 80% to 85% of cases.[20] HAV-specific immunoglobulin G (IgG), however, will remain positive for years after acute infection.

Maternal and Fetal Risks

As an almost entirely self-limited illness, acute HAV infection does not confer an increased risk of adverse outcome to an infected pregnant woman. Supportive care for the patient is essential, and in areas where the virus may be endemic as the result of sanitation or housing issues, the availability of such care might not be assumed to exist. Poor maternal nutritional status has been linked to adverse pregnancy outcome in the context of viral hepatitis in general.[21] A chronic carrier state for HAV does not appear to exist. Perinatal transmission of the virus has failed to be identifiable in a number of published series,[22,23] and pregnant women with acute HAV infection should be reassured overall as to fetal risks and status. Administration of immunoglobulin is recommended for neonates born within 2 weeks of acute maternal illness with HAV; the globulin does not appear to be effective if given after 2 weeks after a known exposure.[23]

Management Options

No specific antiviral treatment of hepatitis A is currently available. However, both preventive vaccination and postexposure prophylaxis with immunoglobulin are available. The current HAV vaccine is available as either a single-agent vaccine (Havrix and Vaqta) or as one combined with hepatitis B virus vaccine (Twinrix). HAV vaccine is given as two doses, 6 to 12 months apart. As an inactivated-virus vaccine, there is no contraindication to the use of HAV vaccine during pregnancy. Women at risk for HAV infection, such as those traveling to endemic areas, should be vaccinated.[24]

Individuals who have close personal or sexual contact with an HAV-infected person should receive immunoglobulin if they have not been immunized, concomitant with also starting the HAV immunization series. Immunoglobulin is not contraindicated during pregnancy, and it should be administered, if indicated, to avoid potential illness in the woman. For postexposure prophylaxis, a single intramuscular dose of 1 mL should be given as soon as possible after contact with the infected individual, but not after 2 weeks. With the existence of a safe, effective HAV-specific vaccine, pre-exposure prophylaxis with immunoglobulin prior to travel is no longer a preferred option unless the time before travel (at least 2 weeks) does not permit initial protective impact of the vaccine. In such a case, both immunoglobulin and HAV vaccine should be administered.

HEPATITIS B

General

Infection with the hepatitis B virus (HBV) has been accepted as a health concern of worldwide importance because 5% to 10% of those infected become chronic HBV carriers,[25] and 25% to 30% of those carriers die as a result of long-term sequelae of HBV-related disease.[26] Workers in an endemic area in Asia (Taiwan) found more than 15% of subjects screened in a general program to be HBsAg (hepatitis B surface antigen) positive; deaths in 54% of the carriers were attributable to primary hepato-

cellular carcinoma (PHC) and cirrhosis compared with 1.5% of deaths among noncarriers.[27] Since that initial linkage, the virus has been shown to be the cause of approximately 80% of all cases of PHC globally.[28]

In areas endemic for HBV, up to 20% of the general population is chronically infected, with perinatal/neonatal and childhood infections existing as a primary route for perpetuating the reservoir of carriers. This finding is especially significant because the risk of chronic HBV infection for a child infected in the newborn period, in the absence of prophylactic therapy, is 70% to 90%.[29,30]

In areas of low endemicity for HBV carriage, however, such as the United States, screening programs for the general population have been targeted to decrease household, transfusion, sexual, and perinatal transmission risks among contacts of Hepatitis B surface antigen (HBsAg)-positive individuals. Population subsets have been identified that are at increased risk for HBV acquisition, and HBV vaccination is recommended for individuals within those groups who are serologically negative for HBsAg and Hepatitis B surface antibody (HBsAb). The efficacy of a serum-derived HBV vaccine was demonstrated initially on a large scale in a cohort of more than 1000 homosexual men in the United States; this trial showed an antibody (HBsAb) response in 96% of those vaccinated, with an overall protective efficacy of 88% against all HBsAg-positive events for vaccine compared with placebo.[31] More recently, a recombinant vaccine consisting of purified HBsAg particles derived from yeast cells was licensed in the United States,[32] eliminating even the theoretical (but never proved) risk of transmitting other viral agents with a serum-based vaccine. Controlled trials in homosexual men showed an equivalent prevalence of acquired immunodeficiency syndrome (AIDS) in groups receiving either placebo or the serum-derived HBV vaccine.[33]

Estimates in the United States tabulate approximately 200,000 new primary cases of HBV infection per year, only 25% of which are associated with acute symptomatic infection.[34] Interestingly, the dose of initial viral infection appears to correlate negatively with the risk of development of persistent disease. Survivors of fulminant hepatitis rarely have chronic infection, whereas experimental infections with low doses of virions result in longer incubation periods, milder clinical disease, and persistent antigenemia.[35]

Blood and blood products are the most thoroughly established sources of hepatitis B infection, although HBsAg has been demonstrated in a variety of body fluids. Of those, however, only serum, saliva, and semen have been associated consistently with transmission in experimental models.[36]

Percutaneous transfer of the virus is the most obvious route of transmission in the medical setting, either through blood products or needle-stick accidents. Contact of infectious material with broken skin or mucous membranes also can result in effective transmission. Recent surveys, however, show that up to 50% of health care workers at risk of contracting HBV have not been vaccinated against the virus.[37]

Compared with other transmissible viruses, such as the human immunodeficiency virus (HIV), HBV is a fairly stable virus and remains infectious on household surfaces that may then contact mucous membranes, such as toothbrushes, baby bottles, razors, and eating utensils.[38] Although transmission in households is more common through sexual contact than through fomite contact,[39] nonsexual household transmission has been established as a route for HBV infection.[40] In areas of the world with higher HBV carrier rates than the United States, nonparenteral transmission would be expected to constitute the major route of person-to-person HBV infection. Vertical transmission is a major source; investigators in Taiwan estimated that 40% to 50% of HBsAg carriers became infected in the perinatal period.[29,41]

Children born to carrier mothers who escape the neonatal period without evidence of infection are still at risk for childhood acquisition of HBV. One of the early vaccine trials conducted in Senegal showed that among children seronegative at the beginning of a randomized HBV vaccination trial, almost 10% acquired HBV infection in the absence of vaccination by the end of a 12-month follow-up period.[42]

Diagnosis

Hepatitis B is distinguished from the other viral hepatitides by its long incubation period (1–6 months), by the presence of extra hepatic symptoms in up to 20% of patients (arthralgia, rash, and myalgia thought to be a result of antigen-antibody complex deposition),[43] and, eventually, by the detection of HBV-specific serum markers.

The appearance of hepatitis B surface antigen (HbsAg) usually predates any clinical symptoms by 4 weeks on average and remains detectable for 1 to 6 weeks in most patients.[44] In the 90% to 95% of patients in whom chronic infection does not develop, HBsAg titers decrease as symptoms diminish. The appearance of hepatitis B surface antibody (HbsAb) defines the absence of the carrier state; titers increase slowly during the clinical recovery period and may continue to increase up to 10 to 12 months after HBsAg is no longer detectable. In most patients with self-limited, acute hepatitis B, HBsAb is detectable only after HBsAg titers in serum disappear.[45] A "window" of time has been described in which a patient still with clinical hepatitis is negative both for HBsAg and HBsAb. During this time, HBV infection still can be diagnosed by the detection of hepatitis B core antibody (HBcAb), which begins to appear 3 to 5 weeks after HBsAg does. HBcAb titers may drop off in the first 1 to 2 years after infection, although the antibody is still detectable years after acute disease in most patients.[45] The appearance of hepatitis Be antigen (HBeAg) parallels that of HBsAg; in self-limited infections, HBeAb is detectable shortly after the time that HBeAg disappears.

The chronic HBV carrier state usually can be predicted by HBsAg seropositivity for 20 weeks or longer. HBcAb is detectable in the serum of carriers at levels higher than those seen in either acute or recovering self-limited infections, and e-antigen markers are variable. HBeAb develops, with the disappearance of HBeAg, in one half to three quarters of carriers,[46] and its presence is inversely related to the relative infectivity index of a patient's serum.[47]

Maternal and Fetal Risks

Risks During Pregnancy

Acute HBV infection during pregnancy is treated mainly by supportive measures, as in the nonpregnant state. An increase in fulminance and mortality rates with acute HBV infection during pregnancy has been demonstrated in some HBV-endemic areas,[48] although other investigators in Western countries have suggested that these adverse outcomes were related more to health care conditions and maternal malnutrition.[49] No teratogenic association has been established for maternal HBV infections,[49,50] even though evidence of HBV infection at birth in children of HBV-carrier women has suggested the possibility of transplacental leakage of HBV-infected blood from mother to fetus in utero.[51,52] Encouragement is necessary to maintain adequate nutrition during the early symptomatic phase, and liver-metabolized drugs, if not avoidable, need to be monitored carefully through blood levels. Phenothiazines may be used, if needed, to control nausea and vomiting. In addition, household and sexual contacts of patients should be offered passive immunization with Hepatits B immunoglobulin (HBIG) after their HBsAg seronegativity is established.

Universal screening protocols for prenatal patients have been advocated by a number of groups. Routine screening with HBsAg testing detects both chronic carriers and asymptomatic, acutely infected patients. A positive HBsAg result in early pregnancy should be followed up by tests for liver function, as well as HBeAg and HBeAb; HBcAb is not helpful in distinguishing acute from chronic disease, and HBsAb rarely is present if HBsAg is still circulating. Repeating the tests for HBsAg and liver function later in pregnancy, however, does help to make the diagnosis and guide the need for perinatal prophylaxis of the neonate.

Hepatitis B Screening in Pregnancy

The unique opportunity to provide almost complete protection against perinatally acquired HBV infection makes antenatal identification of HBV carriers critical so that combined neonatal prophylaxis can be administered in a timely fashion. In nonendemic areas such as the United States, screening protocols were organized initially to test pregnant women who fell into HBV risk groups, as defined by the U.S. Public Health Service (Table 28–1).[53] Such recommendations, however, were not without

TABLE 28–1

Public Health Service Risk Groups for Prenatal Hepatitis B Virus (HBV) Screening Protocols (1984)

Asian, Pacfic-Island, or Alaskan Eskimo descent, whether immigrant or born in the United States
Born in Haiti or sub-Saharan Africa
History of acute or chronic liver disease
Rejection as a blood donor
Staff or patient in a hemodialysis unit
Staff or patient in an institution for the mentally retarded
Occupational exposure to blood in medical/dental settings
Repeated blood transfusions
Household contact with HBV carrier or hemodialysis patient
Multiple episodes of venereal disease
Percutaneous use of illicit drugs

From Centers for Disease Control and Prevention: Protection Against viral hepatitis: Recommendations of the Immunization Practices Advisory Committee. MMWR 1990;39 (RR-Z): 1–26.

problems. Reports from a number of groups working in geographically diverse areas around the country found that using risk groups alone for prenatal HBV screening would miss 40% to 60% of all HBsAg-positive parturients.[54–56] Overall, in these studies, the HBsAg-positive rate ranged from 0.3% to 1.5%. Even if risk factors were to be used to identify these women, however, evidence from one survey shows that only 60% of obstetricians could name more than two HBV risk groups, and less than 30% knew the recommended treatment for infants born to carrier mothers.[57]

Such findings led to recommendations by the Public Health Service[58] and, most recently, by the American College of Obstetricians and Gynecologists[59] that HBsAg screening be performed as part of routine prenatal testing in all pregnant women. An elegant cost-analysis study by Arevalo and Washington[60] shows that such a program, taking into account both acute and long-term costs of neonatally acquired HBV disease, is cost effective at a prenatal population prevalence for HBsAg of only 0.06%. In countries in which HBsAg carriage is endemic, funding for medical screening programs tends to be limited. In these settings, especially as the cost for HBV vaccine begins to decline, workers have advocated consideration of empiric vaccination for all newborns.[61]

However, protocols establishing prenatal HBsAg screening policies do not address the problematic issue of deliveries in inner-city populations among women with minimal to no prenatal care. Maternal HBsAg status, in the absence of prenatal testing, then can only be known in the 1 to 2 days after delivery, and the newborn may miss out on maximally effective HBV prophylaxis. Investigators have recognized this problem because most hospital laboratories perform HBsAg testing at best on a daily basis.[62] This fact is particularly important because evidence suggests that HBIG given as perinatal prophylaxis may have limited efficacy if it is not given as soon as

possible after birth.[63] A study from Philadelphia showed the rate of HBsAg carriage to be significantly higher among such unregistered women than in a comparison group enrolled in an inner-city clinic (7.8% vs. 0.8%), and that the increase was specifically related to substance abuse. Among unregistered women with positive urine drug screens, moreover, the HBsAg-positive rate was 15%, and a maternal urine drug screen was suggested as a rapid screening test to target neonates at highest risk for HBV infection for prophylaxis, before the 24 to 48 hours usually required to await maternal HBsAg status.[64]

Management Options

Prevention of HBV Infection

Immunoprophylaxis regimens to prevent HBV transmission in the perinatal period were a direct extension of the success of these therapies in high risk adult populations. Postexposure immunization was first demonstrated through the use of immunoglobulin preparations with high titers of HBsAb, when given within 4 hours of experimental infection with HBV.[65] Before the development of an effective HBV-specific vaccine, transient pre-exposure prophylaxis was demonstrated using hyperimmunoglobulin (HBIG),[66] although such use of HBIG is now of purely historical interest in terms of understanding the evolution of therapeutic standards. Currently, postexposure treatment consists of a single dose of HBIG administered as temporally as possible to the exposure. Immediate therapy is, of course, optimal for maximal protection, although 75% efficacy has been shown when HBIG is given within 7 days of exposure.[67] Although it does not increase the efficacy of HBIG therapy, a series of HBV vaccination also should be initiated if the exposure was within a setting of ongoing risk, such as a health care or institutional setting. This regimen consists of injections at 0, 1, and 6 months and results in high antibody titers in more than 90% of those younger than 60 years of age.[68] Administration of HBV vaccine simultaneously with HBIG does not diminish the immunologic response to the vaccine.[69] Still, the currently available HBV vaccine's efficacy is conferred by stimulating production of HBsAb by exposure to HBsAg; vaccine-related immunity can be distinguished from natural immunity in most cases by the absence of HBcAb in the serum of successfully vaccinated patients.

Preventing Perinatal HBV Transmission

Discussion of perinatal HBV infection focuses on the following three major areas:

- The transmissibility of the virus from mother to fetus
- The sequelae of neonatal infection
- The effectiveness of currently available modalities for prophylaxis

Finally, the extensive variance in prevalence rates worldwide requires that the feasibility of prenatal screening programs to identify carrier mothers be addressed.

The potential for vertical transmission of HBV at birth is significant. Most infants born to carrier mothers are HBsAg negative at birth but seroconvert in the first 3 months after delivery, suggesting acquisition of the virus at birth.[70] Mothers positive for both HBsAg and HBeAg are at highest risk for transmitting the virus; 85% to 100% of their offspring become infected, with 70% to 90% becoming chronic carriers. Mothers who are HBsAg positive but HBeAg negative, presumably indicating lower levels of replicating virus, do have a lower risk of transmitting the virus, but up to 35% of their children still will become carriers in the absence of neonatal therapy.[71,72] In addition to the long-term risks of HBV-related sequelae in chronic carriers, such as cirrhosis and hepatocellular carcinoma, fulminant fetal neonatal hepatitis[73] has been described in children born to HBsAg-positive mothers.

Early attempts at interrupting the perinatal transmission cycle employed HBIG alone, administered in the neonatal period. Globulin alone had a protective efficacy against the carrier state of 70% to 75%, although the protection was not permanent, and many children eventually became infected after the passively acquired antibody was cleared, undoubtedly through household contact.[74,75] With the advent of the hepatitis B vaccine, trials were established to test its efficacy when administered in the newborn period, both alone and in conjunction with HBIG. A combination of HBIG and vaccine in the newborn period conferred significantly greater protection against perinatally transmitted HBV than even the vaccine alone, increasing efficacy from a range of 75% to 85% up to 90% to 95%.[42,74-76] The small but identifiable percentage of babies who become infected, despite even combined HBV therapy at birth, is believed to represent in utero infection.[77,78] Still, combination HBV-specific immunotherapy provides the best opportunity to prevent the chronic carrier state in the offspring of HBsAg-positive mothers. In the United States alone, approximately 16,500 births occur to HBsAg-positive women each year, about 4300 of whom are also HBeAg positive.[58] Infants born to these women should receive HBIG (0.5 mL) intramuscularly (IM), ideally within 12 hours of birth. HBV vaccine should be administered concurrently at a different site (0.5 mL IM), or can be given up to 7 days after birth if it is not immediately available.[58] The timing of HBIG appears to be more critical than that of vaccine in achieving maximal effectiveness of passive–active therapy. Subsequent vaccination is performed, also 0.5 mL IM, at 1 month and 6 months of age. Follow-up for these infants is crucial, as one recent study confirms the concern that in the United States, groups at highest risk for HBV infection are also least likely to be compliant with follow-up care.[79]

The efficacy of perinatal HBV vaccination programs in preventing infection in children born to carrier mothers has led to the inclusion of the HBV vaccine series in the American Academy of Pediatrics' current recommendations for childhood vaccines for the general population.[80] Still, investigators have demonstrated that, even in high risk groups for perinatal HBV transmission, appropriate neonatal surveillance is critical. Among 426 children born to HBsAG-positive mothers in one longitudinal series, only 68% were completely vaccinated with the full three-dose sequence. Among the children followed, it was shown that the third vaccine dose was least likely to be received (64%). Serologic evaluation of the children in this well-conceived surveillance program showed 4% to have acquired chronic carrier status, with an additional 10% having evidence of resolved natural infection, as demonstrated by positive tests for anti-HBc. Not surprisingly, incompletely vaccinated children were more likely to be HBsAG positive than those completing the series (12% vs. 1%; relative risk 7.9 [confidence interval = 1.5–41.2]).[81] These findings underscore the need for reinforcement of complete vaccination for all children enrolled in the HBV vaccine series, particularly those born to carrier or other high risk mothers.

The beneficial impact of adequate childhood vaccination for HBV recently has been demonstrated dramatically in reports from Taiwan, where large-scale mass vaccination programs were begun in 1984. Researchers there have conclusively proved a link between HBV and hepatocellular carcinoma (HCC) by showing a significant decrease in the average annual incidence of childhood HCC since the institution of the program.[82,83] The decline in the rate of childhood HCC was also paralleled by a drop in the rate of HBsAg carriage among children born before the vaccination program was started, suggesting a herd immunity effect from the mass inoculation of children in the much more infectious younger birth cohorts, and resulting in a lower rate of horizontal HBV infection among the older unvaccinated children.[82] These researchers had demonstrated previously that 5 years into the institution of the vaccination program in Taipei, the HBsAg carrier rate in children younger than 5 years of age had decreased from 9.3% in 1984 to 2% in 1989.[84] These results even further bolster the need to identify HBsAg carrier mothers and provide timely and complete HBV vaccination to their children.

HEPATITIS C VIRUS

General

The term "non-A, non-B hepatitis" (NANBH) traditionally was used to describe the clinical picture of post-transfusion hepatitis in the absence of positive serologic markers for either hepatitis A or hepatitis B viral infec-

tions. Molecular investigation of the serum of such affected patients led to the reporting in 1989 of the identification of a novel viral agent, named hepatitis C (hepatitis C virus [HCV]), with a uniquely sequenced viral genome.[85]

Soon after HCV was identified, a number of studies employed screening with the first-generation assays for anti-HCV to describe seroprevalence rates for groups perceived to be both at high and low risks for HCV infection. Among presumably low risk volunteer blood donors in the general population, rates of 0.5% to 1.4% for anti-HCV seropositivity were described.[86] Higher risk groups, using HBV infection patterns as a model, were shown to have higher rates of HCV antibody positivity also. These high risk groups have included patients in sexually transmitted disease clinics (seroprevalence 1.5%–6.2%), prostitutes (2%–10%), hemophiliacs (64%–86%), and patients with drug abuse histories (56%–86%).[87–89]

Overall, the principal risk factors for HCV transmission are blood and blood products transfusion and use of intravenous drugs. At least 90% of reported cases of post-transfusion hepatitis can be traced to HCV, usually within 5 to 10 weeks of the transfusion.[90] Although mass screening of banked blood products for HCV antibodies has reduced the risk of transfusion-associated HCV substantially, up to 10% of donors later implicated in transfusion-related HCV may be seronegative carriers at the time of blood donation.[91,92] Current estimates place the risk of transfusion-associated HCV infection at approximately 1 in 100,000 per unit transfused (range 1 in 28,000 to 1 in 288,000).[92] This rate is significantly lower than was reported from the period before the use of HCV-specific assays for screening donated blood, when only surrogate markers of NANBH, such as elevated liver function tests, were employed. Still, it is higher than current estimates of transmission risks by transfusion for other viral vectors, specifically HIV (1 in 500,000 per transfused unit) and HTLV-1 (1 in 641,000 per unit).[92,93] In contrast, the risk of HBV transmission is approximately 1 in 63,000 per unit, so that HBV and HCV together account for 88% of the aggregate risk of transfusion-related infection of 1 in 34,000.[92] As the risk of HCV infection resulting from blood transfusions has diminished, a direct result of mass screening of blood products, the proportion of HCV infections attributable to drug use has markedly increased, from 20% to 60%.[94]

Sexual transmission of HCV has been variably implicated, though the overall rate of infection between HCV-discordant sexual partners appears to be relatively low, on the order of 0% to 4%.[95] In addition, an interaction increasing the risk of concomitant transmission of HCV and HIV has been described. With heterosexual sexual activity, men with evidence of infection with both HCV and HIV were five times more likely to transmit both viruses to a female partner than would have been expected by chance.[96] This potential interaction of HIV

and HCV to increase transmissibility of either or both agents also has become important in describing issues surrounding maternal-fetal HCV transmission.

Acute HCV infection occurs after an incubation period of 30 to 60 days. Asymptomatic infection occurs in 75% of patients; the remaining 25% of infected individuals present with the typical manifestations of other viral hepatitides. Fulminant hepatitis and hepatic failure attributable to HCV, as compared with that from other viral hepatitis agents, are uncommon.

Chronic liver disease occurs frequently after acute HCV infection; at least 50% of patients progress to chronicity, regardless of the mode of acquisition or severity of initial infection.[97] Chronic HCV infection has also been associated with an increased risk of developing both B-cell lymphomas and cryoglobulinemia.[98] HCV antibody has been detected in serum from patients with both cryptogenic cirrhosis and HCC, although a linkage between the latter and HCV is controversial and geographically may be quite variable.[99] Evidence also exists that coexisting HIV and HCV infections may accelerate progression of hepatic injury.[100]

Diagnosis

Although anti-HCV testing includes initial screening with an enzyme-linked immunoassay (ELISA), the false-positive rate of approximately 1%, especially for a low risk patient, raises the possibility of an improper diagnosis being given without appropriate confirmatory testing. In contrast to serologic diagnosis of hepatitis B infection, for which certified laboratories are required to perform supplemental confirmatory testing before issuing a positive HbsAg test result, no such automatic "reflex" testing has been mandated for HCV antibody screening. In a patient at high risk for HCV infection with a positive anti-HCV test result, the chance of a false-positive ELISA is exceedingly low. However, recognizing that the majority of laboratories report positive anti-HCV results using screening assays alone[101] despite previous recommendations,[94] the CDC expanded its HCV testing algorithm to include an option for supplemental testing based on "signal-to-cutoff (s/co)" ratios of positive assay results.[101] Because pregnant women do not constitute a high risk group requiring HCV screening by CDC guidelines unless other risk factors exist (Table 28–2), both the importance of understanding the limitations of even the most currently available screening assays and the ability to interpret test results for patients is critical for clinicians who might be ordering HCV screening tests.

Diagnosis of HCV infection also has been assisted by the use of the polymerase chain reaction (PCR) to amplify and detect extremely small amounts of HCV-RNA in serum, with both qualitative and quantitative tests currently available commercially.[102] PCR is still a technically demanding procedure, however, with a need to maintain stringent testing conditions to assure both accuracy and precision.

TABLE 28–2

Risk Factors Warranting Hepatitis C Screening: CDC Guidelines

Individuals who should be screened routinely

1. Persons who ever injected illegal drugs (even once)
2. Persons notified that they received blood/blood products from a donor who later tested positive for hepatitis C virus
3. Recipients of transfusions or organ transplants, particularly if received before July 1992
4. Persons ever on long-term hemodialysis
5. Persons with persistently elevated alanine aminotransferase (ALT) levels or other evidence of liver disease

Individuals for whom routine testing is of uncertain need

1. Recipients of tissue transplants (e.g., corneal, skin, sperm, ova)
2. Users of intranasal cocaine or other illegal noninjected drugs
3. Persons with a history of tattooing or body piercing
4. Persons with a history of sexually transmitted diseases or multiple sexual partners
5. Long-term steady sex partner of an HCV-infected individual

From CDC: Recommendations for prevention and control of hepatitis C virus (HCV) infection and HCV-related chronic disease. MMWR 1998; 47(RR-19):1-33.

Heparinized samples interfere with the polymerase in the assay, and sample storage techniques can have great impact on detectable viral particles. Prolonged sample storage at room temperature, for example, reduces PCR signal detection, as do repeated freeze-thaw cycles, even when the sample is otherwise stored appropriately at −70°C.

At least six distinct HCV genotypes have been identified with broad geographic variation,[103] and this mutability may limit the reproducibility of results from laboratory to laboratory, and from study to study, if primer standardization is not verified. Genotype prevalence of HCV infection varies widely by geographic location; variants of genotype 1 are the most prevalent types seen among infected individuals in the United States and Japan, for example.[104] This genotypic variability has been found to have a significant impact on disease progression and response to therapy for infected individuals, with genotype 1 associated with poorer outcomes and responses overall.[105] Despite this fact, HCV genotype has not been determined to be an independent risk factor for perinatal HCV transmission.[106]

Maternal and Fetal Effects

Seroprevalence data describing HCV antibody status among pregnant women or women of reproductive age emerged quickly as HCV testing became more readily available. In Taiwan, for example, where HBV infection is endemic, the prevalence of anti-HCV among a cohort of pregnant women was reported as 0.6%.[95]

A number of studies to date have looked specifically at HCV antibody seroprevalence in prenatal populations in the United States. One, designed as a vertical transmission study, reported a 4.5% positive rate in a county

hospital in New York; 74% reported a parenteral source of exposure, and 17% reported no risk factors. Of these, 17% (14 of 23) were also HIV positive.[107] Investigators in Dallas, Texas studied 1013 obstetric patients and found 2.3% to be positive for anti-HCV. Risk factors for infection were specifically studied, with history of intravenous drug use, prior sexually transmitted disease, substance-abusing partner, and more than three lifetime sexual partners being significantly associated with HCV antibody positivity.[108] A study from Philadelphia detected anti-HCV antibodies in 4.3% of pregnant women screened, which was significantly higher than infection rates for HIV (0.5%), HTLV-1 (0.8%), and HBV (0.8% HBsAg). The relative risk of other coexisting viral infections was significantly higher among anti-HCV positive women than for those who were antibody negative. Risk-factor–targeted screening would have failed to detect half the anti-HCV–positive women in the study.[109] A follow-up study from this group, using a larger cohort of more than 1400 women from a heterogenous socioeconomic sample, showed an HCV seropositive rate of 3.2%, with only 19% having HCV-RNA positive test results in newborn cord blood samples. Women who were antibody positive were also more likely to need to undergo cesarean section, suggesting an increased risk of other coexisting obstetric complications in that subpopulation.[110]

Information regarding the maternal-fetal transmission of HCV has continued to steadily accumulate. Although reported rates of transmission have been variable, overall it is encouraging that most series show the risk to be generally less than 5%. However, the definition of which mothers are most infectious dramatically alters the relative risks of vertical transmission. Surveillance of mothers and their newborns using HCV-specific antibodies in published reports has, on the whole, demonstrated low rates of transmission from anti-HCV–positive mothers to their offspring.[95] The designs of these earlier studies, however, were mostly retrospective, with limited neonatal follow-up. Subsequent work has used HCV-RNA as a marker of neonatal infection rather than antibody seropositivity only, with rates of newborn RNA retrieval averaging 5% to 10% when the mother is also HCV-RNA positive.[107,111,112]

More recent studies from Asia and Europe have established what appears to be a correlation between maternal viral titer of HCV near delivery and the risk of neonatal infection. These studies have used newer technologies to determine quantitative, rather than qualitative, PCR results. One team in Japan showed significantly higher (2 logs) HCV-RNA titers in transmitting mothers than in those whose infants remained uninfected.[113] Using similar techniques, another group in China drew similar conclusions, also demonstrating that perinatal transmission occurred only in those women whose serum was HCV-RNA positive.[114] A group from the United States, however, failed to establish a similar viral burden correlation in their series, suggesting a possible role for geographic variability in genotype and virulence in explaining the

variance in results.[112] More recent reports have continued to confirm clearly that maternal viremia (usually defined as HCV-RNA detected in maternal blood) is a key determinant for vertical HCV transmission, regardless of maternal HIV status. Still, the independent impact of quantitative maternal viremia ("viral load") on vertical transmission remains less uniformly established across the studies than the presence of viremia at all,[115–118] in direct contrast to previous experience with vertical HIV transmission.

Recent investigators also have confirmed earlier reports that women coinfected with HCV and HIV had significantly higher rates of perinatal infection than women infected with HCV alone. Earlier, smaller series suggested rates ranging from 15% to 87% in the face of maternal coinfection.[119,120] The more recent series have narrowed but not lowered the risk range to 23% to 44%.[112,115,121,122]

The interaction between maternal and fetal humoral and immunologic factors is thought to be a critical contributor to both the occurrence and persistence of perinatally acquired neonatal HCV infection. The fact that maternal or neonatal coinfection with HIV increases the risk of vertical HCV infection suggests that HIV-infected infants, who are known to have early deficits in cell-mediated and humoral immunity, may be less able to clear small amounts of perinatally presented HCV than HIV-uninfected infants.[121,122] Although no large-scale longitudinal follow-up studies exist into the natural history of perinatal HCV infection through childhood, at least one published case report has documented clearance of neonatally documented HCV-RNA by 24 months of age in a child born to an HIV-negative, HCV-RNA-positive mother.[123] Therefore, an intact neonatal immune system may allow for HCV clearance in early infancy, as can occur in HIV-uninfected adults.

The impact of maternal HCV infection on perinatal HCV transmission has been extensively studied, but the potential impact of pregnancy on maternal infection and HCV-related illness is less well documented. One large study of over 15,000 HCV-infected pregnant women in northern Italy, however, demonstrated a downward trend (almost 50% lower) in transaminase levels as pregnancy progressed, with no concomitant change in the proportion of women with documented viremia. The authors hypothesized that a favorable immunomediated positive effect of pregnancy on liver cell necrosis might be one explanation for these findings, though liver biopsy samples were not a routine prospective component of their study.[118]

Management Options

Optimal route of delivery, if, in fact, one exists, remains an area of controversy in the context of maternal HCV infection. This debate, to some degree, parallels the one that evolved regarding maternal HIV infection.

However, unlike with HCV infection, maternal HIV viral load was a clearly established independent predictor of vertical transmission[124] and had a direct bearing on the current guidelines regarding route of delivery and maternal HIV infection, specifically when maternal HIV viral load is durably suppressed to greater than 1000 RNA copies/mL.[125] Route of delivery appears to be much less clearly associated with an increased risk of HCV transmission, however.[115,117,118,121] Although the rate of cesarean section in HCV-infected mothers is higher than that for uninfected women, this increase is thought to be more related to the higher rates of obstetric complications and comorbidities in a subgroup of women whose primary risk factor for HCV infection is illicit drug use.[109,117,118] Current consensus opinions, therefore, recommend cesarean delivery in HCV-infected women only for usual obstetric indications.[126,127]

The experience with antiretroviral treatment in decreasing both maternal viral load and the risk of neonatal HIV infections[128] raises the question of potential comparable treatment options in the context of maternal HCV infection. Recent advances in combination therapy of HCV infection in nonpregnant adults have made sustained normalization of transaminase levels and clearance of HCV-RNA a reality, even in individuals with the less-favorable HCV genotype 1.[105] More recently, the modification of interferon alfa-2a via a branched-chain polyethylene glycol moiety has produced a compound, peginterferon alfa-2a, with prolonged absorption, slower clearance, and a longer half-life than standard interferon, with once-weekly dosing possible.[129] Randomized trials have shown peginterferon to be superior to standard interferon, either alone or combined with ribavirin, for the treatment of chronic hepatitis C infection in adults.[130] Even though the use of ribavirin is contraindicated during pregnancy,[131] interferon has been used safely for the treatment of T-cell leukemias during pregnancy,[132,133] and its potential role as an anti-HCV therapy for both maternal and fetal/neonatal benefits warrants further exploration.

Finally, questions surrounding the safety of breastfeeding frequently arise from HCV-infected women. Many of these women have other risk factors, such as ongoing substance addiction or coexisting HIV infection, which preclude breastfeeding in general and override concerns about transmission of HCV through breast milk. For those women who have no other obstetric or medical issues that prevent nursing, limited data have failed to demonstrate breast milk as an effective route for HCV transmission. Although most of these studies were not designed to specifically address this topic, the authors' evaluation of mother-infant pairs enrolled in some of the published vertical HCV transmission studies failed to document any neonatal HCV infection in breast-fed infants, even when the mother was HCV-RNA positive. One study from China that did look at breast milk specifically found a correlation between maternal HCV serum titer and detection of HCV by means of PCR in breast milk; however, no infants in this small series ($n = 15$) became infected with HCV.[134] More recent studies from Australia,[135] United Arab Emirates,[136] and Switzerland[137] have studied an additional 100 pregnancies in HCV-infected women who breast-fed (up to two thirds of whom were HCV-RNA-positive in sera), with no detectable impact of breastfeeding on the risk of neonatal infection. As a result of the currently available supporting data, consensus opinions do not view maternal HCV infection as a contraindication to breastfeeding except, perhaps, in cases in which a mother experiences cracked or bleeding nipples.[126,127] A recently published survey study, in fact, did demonstrate that that the majority of community-based obstetricians are questioning patients about issues that could relate to HCV infection risk. However, the authors showed that HCV screening practices and counseling provided were discrepant with CDC recommendations up to 53% of the time, particularly in the area of counseling against breastfeeding in the face of maternal HCV infection.[138]

CONCLUSIONS

- Viral hepatitis is one of the more serious infections that can occur during pregnancy, with risks for both the woman and her newborn.
- Hepatitis A tends to be self-limited and produces no chronic carrier state. Risks to the fetus and newborn are minimal.
- Hepatitis B can cause serious long-term sequelae in the woman, and carries significant (90%–95%) perinatal transmission risks for the newborn in the absence of appropriate, timely neonatal prophylaxis.
- Hepatitis C, while more difficult to acquire than hepatitis B, carries much higher long-term risks of chronic liver disease. Perinatal transmission rates of up to 10% have been reported in the absence of maternal HIV coinfection.

SUMMARY OF MANAGEMENT OPTIONS
Hepatitis Virus Infections

Management Options	Quality of Evidence	Strength of Recommendation	References
Hepatitis A			
Prenatal			
• Supportive care	–	–	–
Intrapartum/neonatal			
• Newborn Ig if acute maternal infection occurs proximate to delivery	IV	C	127
Prevention			
• Hepatitis A vaccine available; not contraindicated during pregnancy	IV	C	59
• Women traveling to endemic areas during pregnancy should be vaccinated	III	C	24
Hepatitis B			
Prenatal			
• Supportive care	–	–	–
• 20% rate of extrahepatic symptoms	–	–	–
Intrapartum/Neonatal			
• Newborns of chronic carrier mothers should all receive HBV immunoglobulin (HBIG) within 12 hours of birth and HBV vaccine within 72 hours of birth	Ib	A	75,76
Prevention			
• Universal screening of pregnant women (HbsAg), not risk-factor based	IIa	B	55,57,60
• No contraindications to HBV vaccine during pregnancy	IV	C	59
Hepatitis C			
Prenatal			
• Primary source currently illicit drug use	IIa	B	86,89
• Most cases asymptomatic; supportive care for clinical illness			
Intrapartum/Neonatal			
• No need to alter delivery route for maternal HCV infection	IV	C	126,127
• Risk of neonatal transmission up to 10%, only if mother is viremic	IIa	B	107,111,112
• No neonatal measures available to lower risk of transmission			
• Breastfeeding not contraindicated	IIa	B	134,136,137
Prevention			
• Screen pregnant women only if in high risk groups			
• No vaccine or passive (Ig) prevention available			
• Blood product screening has lowered risk of infection from that source	IIa	B	91,92

Human Immunodeficiency Virus*

D. Heather Watts

INTRODUCTION

The management of human immunodeficiency virus (HIV) infection continues to evolve rapidly. Amazing advances have been made in therapy of primary infection, prevention of opportunistic infections, and prevention of perinatal transmission since the first cases of acquired immunodeficiency syndrome (AIDS) were described in 1981. Perinatal transmission rates have decreased from 20% to 30% early in the epidemic to 1% to 2% in developed countries with the use of antiretroviral therapy and scheduled cesarean delivery. While reducing transmission, these interventions have increased the complexity of prenatal care for HIV-infected women. As standards of care evolve rapidly, providers are urged to access resources available on the Internet such as www.aidsinfo.nih.gov or www.WHO.int/hiv/topics/arv/ for the most recent update.

Women represent the fastest growing group of persons with new HIV infections. In the United States, over 100,000 women are estimated to be infected, and worldwide, the number is over 19 million.[1] Approximately 6000 HIV-infected women deliver annually in the United States, with approximately 280 to 370 infants acquiring HIV infection compared to 2 million deliveries to HIV-infected women worldwide resulting in over 600,000 HIV-infected infants.[1,2] Improvements in availability of prenatal care, HIV counseling and testing, antiretroviral therapy, and strategies to reduce HIV transmission through breastfeeding are vitally needed in areas of the world most affected by HIV to improve maternal health and survival and reduce perinatal transmission.[3] This chapter will focus on interventions currently available to maximize maternal health and minimize perinatal transmission in developing countries.

DIAGNOSIS

All pregnant women should be tested for HIV infection to allow optimal care for maternal health and preven-

tion of perinatal transmission. A policy of universal HIV testing, with patient notification and right of refusal, is recommended.[2] All pregnant women should be encouraged to be tested regardless of perceived risk factors or local seroprevalence, as many HIV-infected women were infected heterosexually and are unaware of their risk. If women decline testing, the reasons for declining should be explored and further education regarding the benefits and risks of testing provided. Federal policy recommends universal HIV testing along with other prenatal laboratory studies unless the woman refuses testing, and state laws may require detailed pretest counseling and written informed consent. Providers should be aware of their own local and state requirements while striving for universal testing for pregnant women.

The recommended algorithm for HIV testing consists of initial screening with an FDA-licensed enzyme immunoassay (EIA) followed by confirmatory testing with an FDA-licensed supplemental test, usually a Western blot (WB), if the EIA is repeatedly reactive.[2] If the EIA is repeatedly reactive and the WB is positive, HIV infection is confirmed, as false-positive WB results are rare.[4] However, given the implications of a positive HIV test result, repeat testing on a separate blood sample is recommended to rule out any possibility of mislabeling or other clerical error. A more common, though still infrequent, event is an indeterminate WB. Indeterminate WB results can be caused by incomplete antibody response to HIV seen with recent infection or late stage disease or by nonspecific reactions in uninfected persons, possibly related to recent immunizations or current or previous pregnancy. Although indeterminate results are more common among pregnant or parous women, they are estimated to occur during pregnancy at a rate of less than 1 per 4000 samples based on a study of over 1 million specimens.[5,6] Pregnant women with indeterminate WB results should be queried regarding recent exposures to HIV through occupational, sexual, or needle-sharing activity; have repeat testing to evaluate for evolving infection versus resolution of nonspecific reactivity; and consider testing of

---

*This chapter is in the public domain.

sexual partners to clarify risk. For women with repeatedly indeterminate testing, alternate testing for HIV itself using an approved HIV RNA test may be helpful, although these tests are not approved for diagnosis of HIV infection. If no recent high risk exposures are identified, women with repeatedly indeterminate WB results should be reassured that HIV infection is unlikely.

Women delivering with no prenatal care represent a group at high risk for perinatal HIV transmission. During the period 1993–1996, approximately 15% of HIV-infected pregnant women in the United States received no prenatal care, compared to 2% in the general population.[7] Thirty-five percent of HIV-infected pregnant women who used illicit drugs had no prenatal care compared to 6% of HIV-infected women who did not use drugs. Given the reduction in transmission achieved with several different intrapartum/neonatal prophylaxis regimens[8–11] and the increased risk of HIV infection among women presenting without prenatal care, rapid HIV testing should be offered to all pregnant women presenting in labor without prenatal care or documentation of previous testing during pregnancy.[2] Testing should be done only after pretest counseling, including discussion of the need for confirmatory testing if rapid assays are positive, and informed consent. Rapid testing may be done using the recently approved OraQuick Rapid HIV antibody test, other rapid tests as they become approved, the more complex Single Use Diagnostic System for HIV-1, or EIA testing.[12] The OraQuick test has been granted a Clinical Laboratory Improvement Amendments waiver, allowing its use as a point of care test.[13] Because of the relatively low prevalence of HIV even in this setting, the negative predictive value of a single negative rapid test is high, so no further testing is required to confirm a negative rapid test.[2,12] All positive rapid tests should be confirmed by supplemental testing with either a WB or immunofluorescence assay,[2] but decisions regarding use of antiretrovirals for prevention of perinatal transmission may need to be made pending confirmatory test results because initiation of therapy during labor or shortly after birth is required to reduce risk of transmission.[9] Use of a second, different screening test, such as EIA, can improve the positive predictive value of a single reactive rapid test. In studies done outside the United States, specific combinations of two or more rapid tests provided results as reliable as those from a combination of EIA and WB.[14] Thus, as more rapid tests are approved for use in the United States, combinations with enhanced specificity may become available, allowing more certain decision-making.

MATERNAL AND FETAL RISKS

Disease Progression

Studies in the United States and Europe have been consistent in not demonstrating an effect of pregnancy on HIV disease progression.[15–17] More recently, a report from the Women and Infants Transmission Study (WITS) did not show a difference in CD4+ lymphocyte count or HIV RNA trajectory or clinical AIDS rate between women with one or multiple pregnancies after HIV diagnosis.[18] Studies in developing countries suggest that pregnancy may enhance disease progression, but they included small numbers and may have had selection bias in HIV testing.[19,20]

Increased Toxicity of Antiretroviral Therapy

The hormonal effects of pregnancy may increase the risk of toxicity of antiretroviral therapy, especially the nucleoside reverse transcriptase inhibitors. Several cases of lactic acidosis and hepatic failure, some resulting in maternal deaths, have been reported among women on long-term nucleoside therapy during pregnancy, most frequently stavudine and didanosine in combination.[21,22] Clinical findings were similar to those seen in acute fatty liver of pregnancy, which occurs more frequently among women with heterozygous defects of mitochondrial fatty acid metabolism carrying fetuses homozygous for the defect.[23] Similar enhancement of mitochondrial toxicity due to reduced fatty acid oxidation has been shown in pregnant mice and in mice treated with high doses of estrogen and progesterone to simulate pregnancy.[24,25] The potential for lactic acidosis and hepatic failure is present with the use of any nucleoside agent, with the binding affinity for mitochondrial polymerase gamma, the key enzyme, highest for zalcitabine, then decreasing for didanosine, stavudine, lamivudine, zidovudine, and abacavir.[26] Thus, all pregnant women on nucleoside antiretroviral therapy should be educated regarding the signs and symptoms of lactic acidosis and hepatic dysfunction including nausea, vomiting, fatigue, tachycardia, dyspnea or hyperventilation, and abdominal pain, and clinicians should be vigilant for these signs and symptoms that may be difficult to distinguish from normal pregnancy symptoms.

Impact on Future Therapy

Another potential impact of pregnancy on HIV infection is the effect of short duration therapy during pregnancy for prevention of perinatal transmission on development of resistance and response to future therapy. Current indications for initiation of antiretroviral therapy in nonpregnant adults are an HIV RNA level above 55,000 copies/mL or a CD4+ lymphocyte count below 350 cells/μL.[27] Many women do not meet these criteria for therapy but will take antiretrovirals to reduce the risk of perinatal transmission and stop therapy after delivery. As will be discussed in more detail later, these women should receive highly active therapy with a combination of three or more drugs to minimize HIV RNA levels and risk of transmission.[28] Although aggressive combination

therapy with suppression of HIV RNA to undetectable levels during pregnancy should minimize the risk of resistance, the impact of short-term therapy on future response to therapy has not been well studied. In addition, the use of the two-dose nevirapine regimen (one dose intrapartum to the mother and one dose to the neonate) for women without prior antiretroviral therapy during pregnancy was associated with a 19% rate of nevirapine resistance at 6 weeks post partum, which did not persist at 1 year.[29] Nevirapine resistance was also observed among 14 (15%) of 95 women tested after exposure to the same regimen among women on established antiretroviral therapy at delivery in the Pediatric AIDS Clinical Trials Group (PACTG) 316 study.[30] The significance of these mutations for response to future therapy is unknown.

Pregnancy Complications

The effect of HIV infection and antiretroviral therapy on pregnancy outcome is another issue for consideration. The majority of , but not all, studies in developed countries done before the availability of antiretroviral therapy did not demonstrate an increased rate of adverse pregnancy outcomes among HIV-infected women compared to uninfected women with similar risk profiles.[31-33] Conversely, most studies in developing countries have suggested an increased risk of preterm birth, low birth weight, intrauterine growth restriction, stillbirth, and infant death among infants born to HIV-infected women, with increasing risk with more advanced HIV infection.[31,34] Factors associated with an increased risk of preterm birth and low birth weight among HIV-infected women included previous adverse pregnancy outcome, hypertension, multiple gestation, smoking, bleeding, alcohol use, low maternal weight, *Trichomonas vaginalis* infection, and other sexually transmitted infections, similar to risk factors in HIV-uninfected women.[33,36,37] Low CD4+ percentage was an additional risk factor for adverse outcome among women not receiving antiretroviral therapy,[36] but neither CD4+ lymphocyte count nor HIV RNA levels were associated with adverse outcomes among women receiving zidovudine therapy.[37]

Zidovudine monotherapy has not been associated with an increased risk of preterm birth or low birth weight in any study to date, but the potential impact of combination antiretroviral therapy on pregnancy outcome is unclear.[38,39] A small study from Europe and an analysis of the European Collaborative Study found an increased risk of preterm birth with increasing numbers of drugs, with the highest rate occurring among women receiving protease inhibitor therapy.[40,41] An analysis of several cohorts in the United States did not find an increased risk of preterm delivery among women on dual therapy or regimens including protease inhibitors, although there was a slight increase in risk of very low birth weight infants born to women receiving protease inhibitor therapy compared to those on no

therapy or zidovudine.[42] Clinicians should be aware of a possible increased risk of preterm birth with protease inhibitor use, but given the clear benefits for maternal health and reduction in perinatal transmission, these agents should not be withheld because of these concerns.

Perinatal Transmission

A major concern with HIV infection in pregnancy is the risk of perinatal transmission of HIV to the infant. Among untreated women who do not breastfeed, transmission will occur in 20% to 30%.[43] Estimates are that about two thirds of transmissions from untreated women occur at delivery and one third occur in utero, many late in pregnancy.[44] An additional transmission risk of 15% to 20% occurs during breastfeeding.[45] Maternal HIV RNA levels appear to be the factor most predictive of transmission.[46,47] Antiretroviral therapy during pregnancy and in the neonatal period is clearly beneficial by reducing the risk of perinatal transmission of HIV. The first study demonstrating this benefit was the PACTG 076 study with a transmission rate of 8.3% among those receiving oral antepartum, intravenous intrapartum, and oral neonatal zidovudine for 6 weeks compared to 25.5% among those receiving placebo.[38] The PACTG 185 trial found no benefit from addition of HIV immunoglobulin to the PACTG 076 regimen but demonstrated benefit of zidovudine among women with CD4+ lymphocyte counts under 500 cells/μL at enrollment, with a transmission rate of 4.6%.[48] Subsequent trials have demonstrated benefit from shorter courses of antepartum/intrapartum or antepartum/intrapartum/neonatal zidovudine or zidovudine/lamivudine compared to placebo, but no benefit was seen from intrapartum zidovudine/lamivudine alone.[10,49-54] In addition, the HIVNET 012 trial demonstrated the benefit of a two-dose nevirapine regimen (one dose intrapartum to the mother and one dose to the infant at 48 hours of age) compared to oral intrapartum and 1 week of neonatal zidovudine.[8] A subsequent trial demonstrated that intrapartum and 1 week of neonatal zidovudine/lamivudine therapy was similar in efficacy to the HIVNET 012 nevirapine regimen.[11] These trials provide data for implementation of shorter, less complex regimens for reduction of transmission of HIV in resource limited settings or for women diagnosed in the peripartum period as being HIV-infected.

A trial in the United States, Europe, and Latin America (PACTG 316) evaluating addition of the HIVNET 012 nevirapine regimen to established antiretroviral therapy demonstrated no benefit of adding nevirapine to ongoing therapy.[55] However, this trial provides the most current data regarding transmission of HIV with the use of combination antiretroviral therapy. The transmission rate overall was 1.5%, with rates of 2.1% for women on zidovudine alone, 1.1% with combination nucleoside therapy, and 1.6% with combination with protease inhibitor.[55] Similarly, an analysis from WITS, including

women enrolled from 1990 through 2000, observed transmission rates of 20.0% for women not receiving antiretroviral agents, 10.4% for women receiving zidovudine monotherapy (not necessarily the complete 076 regimen), 3.8% for those receiving dual nucleoside therapy, and 1.2% for those receiving highly active antiretroviral regimens.[43] These low rates of transmission with highly active regimens occurred despite potential confounding by indication in which women with the highest HIV RNA levels and lowest CD4+ lymphocyte counts were most likely to be treated with highly active regimens, especially early in the period of availability. Thus, current data demonstrate significant fetal benefit from combination antiretroviral regimens, which would require significant evidence of harm to negate.

Antiretroviral Therapy

Teratogenesis

Another concern with the use of antiretroviral drugs in pregnancy is the potential for birth defects, especially with first-trimester exposure. Limited data from animal studies are available for most of the drugs (Table 29–1). Of concern, birth defects, including anencephaly, microophthalmia, and cleft palate, were seen in 3 (20%) of 15 monkeys exposed to efavirenz in the first trimester.[28] One case of meningomyelocele has been reported in the literature after first-trimester efavirenz exposure.[56,57] Too few cases of first-trimester efavirenz exposure have been reported to the Antiretroviral Pregnancy Registry to assess risk thus far.[58] Other drugs with concerning animal data (see Table 29–1) include delavirdine and hydroxyurea, which are of limited utility for HIV therapy. No increase in birth defects was detected among infants born to women enrolled in the European Collaborative Study with first-trimester (compared to later or no) antiretroviral exposure.[59] No clear increase in birth defects associated with antiretroviral therapy has been noted among prospective cases reported to the Antiretroviral Pregnancy Registry, although adequate numbers to rule out a twofold or greater increased risk have been reported for only a limited number of drugs (zidovudine, lamivudine, stavudine, nelfinavir, nevirapine).[58] Providers caring for pregnant women receiving antiretroviral drugs are urged to report cases as early in pregnancy as possible to the Registry (1-800-258-4263 or http://www.apregistry.com) to allow better assessment of risks.

Mitochondrial Toxicity in Offspring

Another concern, potential mitochondrial toxicity in the children of women treated with antiretrovirals, has been suggested by French researchers. Eight children with clinical or laboratory abnormalities, including two who died, were reported from a cohort of 1754 HIV-uninfected children exposed to zidovudine or zidovudine/lamivudine during pregnancy and the neonatal period.[60,61] Subsequently, an increased risk of febrile seizures was reported among infants born to HIV-infected women with perinatal antiretroviral exposure (11/1000 by 18 months) compared to those without exposure (4.1/1000, P = 0.02) in the same cohort.[62] In a review of over 16,000 children born to HIV-infected women in several cohorts in the United States, no increase in death rate was found in children exposed to nucleoside reverse transcriptase inhibitors compared to those with no antiretroviral exposure.[63] No deaths definitely related to mitochondrial toxicity were noted. Monitoring for symptoms among living children is ongoing. In a follow-up of 395 children born to women randomized to zidovudine or placebo in Thailand, five children exposed to zidovudine experienced febrile seizures, compared to one in the placebo group. No other signs or symptoms of possible mitochondrial toxicity were noted in either group through 18 months of age.[64] No association was found between clinical findings suggestive of mitochondrial abnormalities and antiretroviral exposure among 2414 children followed in the European Collaborative Study, 1008 of whom had antiretroviral exposure.[65] Among infants enrolled in the PETRA study, which included three zidovudine/lamivudine arms with up to 5 weeks of treatment or placebo, the rate of symptoms potentially related to mitochondrial toxicity was low, 5 (0.28%) of 1798, and did not differ by treatment arm.[66] The French cases are concerning in light of recent studies demonstrating reduced levels of mitochondrial DNA among placentas and cord blood[67] and through 2 years of age[68] among infants exposed to nucleoside reverse transcriptase inhibitors during pregnancy and the neonatal period compared to infants born to HIV-negative or untreated women. Of note, infants born to HIV-infected women but not exposed to nucleosides had intermediate levels of mitochondrial DNA depletion.[68] Clinical correlation is lacking. The risk of clinically apparent mitochondrial toxicity related to antiretroviral therapy appears to be low and must be balanced against the known benefits in reduction of perinatal transmission. However, long-term follow-up of children exposed to antiretrovirals is required to assess for toxicity.

Transplacental Carcinogenesis

Another concern requiring long-term surveillance of children exposed to antiretrovirals is transplacental carcinogenesis. One study in rats treated with zidovudine in utero at about 30 times the human dose found an increase in liver, lung, and reproductive system tumors, yet a similar study using lower doses did not find an increased rate.[69,70] Among 727 children enrolled in the PACTG 076 study or WITS, no tumors occurred with over 1100 person-years of follow-up.[71] No tumors were identified among the 395 Thai infants followed for 18 months.[64] A recent study of HIV-infected children with

TABLE 29-1

Preclinical and Clinical Data Relevant to the use of Antiretroviral Drugs in Pregnancy[27,28]

DRUG	FDA PREGNANCY CATEGORY*	NEWBORN: MATERNAL DRUG RATIO	ANIMAL STUDIES	MAJOR TOXICITIES	HUMAN STUDIES; CONCERNS SPECIFIC TO PREGNANCY
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors				**Class Effect: Rare, but Potentially Fatal, Lactic Acidosis with Hepatic Steatosis**	
Zidovudine (Retrovir, AZT, ZDV)	C	~0.8 human	No effect on rodent fertility, but cytotoxic to mouse embryos. Positive teratogenicity in rodents only at near-lethal doses.	Bone marrow suppression, myopathy	ARV agent most used in pregnancy, safe in short term. See discussion of rodent tumors, mitochondrial toxicity in text.
Zalcitabine (HIVID, ddC)	C	0.3–0.5 rhesus monkey	No effect on rodent fertility, but cytotoxic to mouse embryos. Hydrocephalus in rats at 1000× human dose, skeletal defects and decreased weight at moderate doses.	Peripheral neuropathy, stomatitis	No studies.
Didanosine (Videx, ddI)	B	0.5 human	No effect on rodent fertility or mouse embryos. No teratogenicity in mice, rats, rabbits.	Pancreatitis, peripheral neuropathy, nausea, diarrhea	Pk study ($n = 14$) shows no need for dose modification, well tolerated.
Stavudine (Zerit, d4T)	C	0.76 rhesus monkey	No effect on rodent fertility, but cytotoxic to mouse embryos. No evidence of teratogenicity. Ossification delay at high doses in rats.	Peripheral neuropathy	Phase I/II study indicated no change in pk in pregnancy, well-tolerated.
Lamivudine (Epivir, 3TC)	C	~1.0 human	No effect on rodent fertility or mouse embryos. No teratogenicity.	Pancreatitis increased in children	Pk study ($n = 20$) shows no need for dose modification, well tolerated.
Abacavir (Ziagen, ABC)	C	Passage in rats	No effect on fertility in rodents. Anasarca, skeletal abnormalities at 35× human dose in rodents, not seen in rabbits.	Potentially fatal hypersensitivity reactions, symptoms: fever, rash, fatigue, nausea, vomiting, diarrhea, abdominal pain.	No studies.
Tenofovir (Viread)	B	0.17 monkeys	No effect on fertility. No birth defects, but growth restriction, reversible bone changes with chronic use in monkeys.	Asthenia, nausea, vomiting, diarrhea, headache, flatulence	No studies in human pregnancy thus far.
Non-Nucleoside Reverse Transcriptase Inhibitors				**Class Effects: Rash with Rare Cases of Stevens-Johnson Syndrome; Increased Transaminase Levels**	
Nevirapine (Viramune)	C	~0.9 human	Impaired fertility in female rats. Not teratogenic in rats, rabbits.	Rash, drug interactions, potential for fulminant hepatitis and hepatic failure	Increased risk of potentially fatal hepatotoxicity, in women starting therapy with CD4+ lymphocyte count >250 cells/μL. Single dose in labor and the neonate decreased transmission in otherwise untreated women. See text.
Delavirdine (Rescriptor)	C	Unknown	No effect on fertility in rodents. Embryotoxic in rabbits. VSD in rats, maternal toxicity, developmental delay, decreased pup survival.	Rash, drug interactions	No studies.
Efavirenz (Sustiva)	C	~1.0 cynomolgous monkey	Increased fetal resorptions in rats. Anencephaly, anophthalmia, or cleft palate in 3/20 monkeys treated with human doses.	Rash, drug interactions, CNS symptoms such as dizziness, insomnia, confusion	None planned. Use in pregnancy should be avoided because of primate teratogenicity.

	Category	Placental Passage	Animal Carcinogenicity/Teratogenicity Studies	Class Effects: Hyperglycemia, Possible Fat Redistribution and Lipid Abnormalities, Increased Bleeding Episodes in Hemophiliacs	Comments
Protease Inhibitors					
Indinavir (Crixivan)	C	Minimal	No effect on fertility in rodents. No teratogenicity in rats, rabbits, or dogs. Extra ribs in rats.	Kidney stones, hyperbilirubinemia, drug interactions, nausea	Phase I/II study in progress, suggests lower AUC in pregnancy. Theoretical concerns re: kidney stones, hyperbilirubinemia in neonate from maternal exposure.
Ritonavir (Norvir)	B	Minimal	No effect on fertility in rodents at half the human dose. Hepatotoxicity at higher doses. Developmental toxicity at toxic doses but no teratogenicity in rats, rabbits.	Nausea, vomiting, diarrhea; increased triglycerides, transaminases; drug interactions, paresthesias	Phase I/II study in progress.
Saquinavir (Fortovase)	B	Minimal	No effect on fertility in rodents. Negative teratogenicity.	Nausea, diarrhea, elevated transaminases	Insufficient levels in pregnancy with 1200 mg TID; adequate levels with SQV 800 mg/ritonavir 100 mg both BID.
Nelfinavir (Viracept)	B	Minimal	No effect on fertility in rodents. Studies negative in rats, rabbits.	Diarrhea, drug interactions	Phase I/II study showed low AUC with 750 TID, adequate levels with 1250 mg BID.
Amprenavir (Agenerase)	C	Unknown	No effect on fertility in rodents. Negative teratogenicity studies but deficient ossification and thymic elongation in rats, rabbits.	Nausea, vomiting, diarrhea, rash, oral paresthesias, increased liver function tests	No studies. Liquid formulation should not be used in pregnancy because of high propylene glycol content.
Lopinavir/ritonavir (Kaletra)	C	Minimal for ritonavir, unknown for lopinavir	No effects on fertility. No teratogenicity in rats, rabbits.	Nausea, vomiting, diarrhea, asthenia, elevated transaminase levels	Oral solution contains 42% alcohol so not recommended in pregnancy. Pk studies in pregnancy in progress.
Atazanavir (Reyataz)	B	Unknown	No effect on fertility. No teratogenicity in rats, rabbits.	Drug interactions, prolonged PR interval, hyperbilirubinemia, rash	No studies in human pregnancy. Theoretical concern of hyperbilirubinemia in neonate from maternal exposure.
Fusion Inhibitors					
Enfurvirtide (Fuzeon, T-20)	B	Unknown	No effect on fertility. No teratogenicity in rats, rabbits.	Injection site reactions, eosinophilia, rare systemic hypersensitivity	No studies in human pregnancy.
Other Agents					
Hydroxyurea	D	Crosses in animals	Testicular atrophy and decreased spermatogenesis in rats. Teratogenic with multiple defects seen in rats, rabbits, hamsters, cats, monkeys.	Bone marrow suppression, rash, fever, stomatitis, vomiting, diarrhea	Reported use in 16 women, 13 in first trimester. No anomalies seen. Because of unclear efficacy in HIV therapy and potential teratogenicity based on animal studies, use should be avoided during pregnancy.

*Food and Drug Administration pregnancy categories: A, adequate and well-controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester of pregnancy (and there is no evidence of risk during the later trimesters); B, animal reproduction studies fail to demonstrate a risk to the fetus and adequate and well-controlled studies of pregnant women have not been conducted; C, safety in human pregnancy has not been determined, animal studies are either positive for fetal risk or have not been conducted, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus; D, positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experiences, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks; X, studies in animals or reports of adverse reactions have indicated that the risk associated with the use of the drug for pregnant women clearly outweighs any possible benefit.

ARV, antiretroviral; AUC, area under the curve; BID, twice daily; CNS, central nervous system; Pk, pharmacokinetic; SQV, Saquinavir; TID, three times daily; VSD, ventricular septal defect.

malignancies did not identify zidovudine exposure, either in utero or after birth, as a risk factor for developing cancer.[72] Thus, human data thus far do not support zidovudine use as a risk factor for carcinogenesis, but long-term follow-up of exposed children is required.

MANAGEMENT OPTIONS

Prepregnancy

Ideally, all HIV-infected women would have a preconceptional visit to optimize their status before pregnancy.[28] Issues to be discussed include current maternal status and indications for antiretroviral therapy and opportunistic infection prophylaxis, choice of antiretroviral drugs to minimize risk of birth defects and toxicity, risk of perinatal transmission and strategies to reduce transmission, immunization status, optimal nutritional status and use of folate supplements, and assessment of other preconceptional issues such as family history pertinent to genetic screening, screening for other infectious diseases, and assessment for other medical or psychological conditions. The risk of perinatal transmission is most strongly related to HIV RNA levels, with the lowest transmission risk associated with undetectable HIV RNA.[46,47] For women currently on antiretroviral therapy or with indications for antiretrovirals based on current guidelines (HIV RNA level > 55,000 copies/mL or CD4+ lymphocyte count <350 cells/μL), a highly active regimen that does not include efavirenz should be used. Pregnancy should be delayed until HIV RNA levels are undetectable, if possible. For women not meeting criteria for therapy for their own health, initiation of therapy to prevent transmission after the first trimester should be discussed. Need for opportunistic infection prophylaxis should be assessed.[73] Ideally, if CD4+ lymphocyte counts are in the range where opportunistic infection prophylaxis is indicated, highly active antiretroviral therapy should be initiated to enhance immunity and obviate the need for prophylaxis during pregnancy. Pregnancy should be delayed until sustained CD4+ lymphocyte counts over 200 cells/μL are achieved to minimize the number of drugs needed during pregnancy. Any indicated immunizations should be provided before pregnancy to avoid the theoretical risk of increased transmission risk related to HIV RNA rebound after immunization. If the HIV-infected woman has not previously been tested for antibodies to *Toxoplasma gondii*, hepatitis C virus, or cytomegalovirus, antibody status should be documented at the preconceptional visit to establish risk for seroconversion or reactivation. Tuberculin skin testing should be done if not done within the past year. The range of transmission risks based on maternal HIV RNA levels and antiretroviral therapy should be discussed, and the woman must understand that although the risk is now low, there is no guarantee that transmission will not occur.

Prenatal

The same principles as outlined for preconceptional care should be followed for HIV-infected women presenting already pregnant. Women newly diagnosed with HIV infection during pregnancy should be assessed for any signs or symptoms suggestive of acute HIV infection or opportunistic infection and undergo laboratory testing (HIV RNA and CD4+ lymphocyte testing) to establish the stage of HIV infection. HIV infection should be confirmed by repeat testing if not previously done. In general, highly active combination antiretroviral therapy is indicated during pregnancy to prevent perinatal transmission and may also be indicated for maternal health.[28] A regimen recommended as first-line therapy for nonpregnant adults, generally including two nucleoside reverse transcriptase inhibitors with either one or more protease inhibitors or a non-nucleoside reverse transcriptase inhibitor, should be chosen.[27] However, nevirapine should not be initiated in women with CD4+ lymphocyte counts over 250 cells/μL as the risk of potentially fatal hepatotoxicity is greatly increased in this group compared to women with lower CD4+ lymphocyte counts.[28] Highly active antiretroviral therapy is indicated to lower HIV RNA levels to undetectable levels to minimize transmission risk and also minimize the risk of development of resistant virus. Extensive discussions with the woman should emphasize the importance of complete adherence to the regimen to prevent development of resistance. Unless contraindicated or not tolerated, the regimen should include zidovudine, which has the most data on efficacy in reducing transmission. Intravenous zidovudine should be given during labor, and the infant should receive zidovudine for 6 weeks after birth. For women with HIV RNA levels below 1,000 copies/mL who want to minimize their exposure to antiretrovirals, monotherapy with the PACTG 076 zidovudine regimen can be offered. In an analysis of data from several studies, transmission among women with HIV RNA levels below 1000 copies/mL during pregnancy was 9.8% among 368 untreated women and 1% among 834 women receiving zidovudine.[74] Zidovudine monotherapy during pregnancy was not associated with a difference in disease progression post partum among women in several studies.[75–77] The risk of developing resistance to zidovudine among women with HIV RNA below 1000 copies/mL is expected to be low given limited viral replication. The option of stopping therapy after delivery should be discussed with women who initiate therapy solely for prevention of perinatal transmission.

Indications for resistance testing during pregnancy should be the same as for nonpregnant adults.[28] Technical aspects of resistance testing and a more thorough discussion of the implications for pregnant women and their infants have been reviewed elsewhere.[44,78] The use of resistance testing to optimize therapy during pregnancy and to reduce the rate of perinatal transmission has

not been studied specifically. Resistance testing in adults has been most useful in the setting of a failing regimen to help guide the choice of the next regimen.[78] Because current resistance testing will detect resistant virus only if it constitutes at least 20% of the viral population, testing is unlikely to be useful in the therapy-naïve pregnant patient without acute infection, as wild-type virus will predominate in the absence of selective pressure from antiretroviral agents. For therapy-naïve women initiating therapy before the third trimester, a highly active regimen can be selected, and the response to therapy monitored with serial HIV RNA determinations.[28] If the expected response of at least a one log drop in HIV RNA in the first 8 weeks is not obtained, specimens for resistance testing should be obtained while the woman is on therapy before switching to an alternate regimen. For women initiating therapy late in pregnancy with high HIV RNA levels, consideration could be given to obtaining resistance testing either before starting or shortly after starting therapy to have results sooner to guide a switch in therapy if indicated.

The majority of studies evaluating the impact of resistance on risk of perinatal transmission have not found the presence of zidovudine, lamivudine, or nevirapine resistance to increase the risk of transmission.[78] One study, including women on zidovudine for their own health but not including intrapartum or neonatal zidovudine, found zidovudine resistance was not associated with an increased risk of transmission on univariate analysis but, after adjustment for total lymphocyte count and duration of membrane rupture, was a factor.[79] The women included in this study had low CD4+ lymphocyte counts and would now be recommended to receive highly active combination therapy during pregnancy. Given the currently observed rates of transmission of under 2% among women on highly active antiretroviral therapy during pregnancy, antiretroviral resistance does not appear to be a major issue in perinatal transmission. However, as the prevalence of resistant HIV increases among those with recent infection[80] and as women have repeat pregnancies, the chance of coexistent resistant HIV and pregnancy will increase and may become a larger problem. Resistance patterns among pregnant women and among infected infants must be monitored to allow adaptation of treatment guidelines.

For women presenting during pregnancy already taking antiretroviral therapy, management will depend on gestational age, regimen, HIV levels before starting therapy and time to response, and current symptoms such as nausea that may interfere with adherence during pregnancy. Women presenting after the first trimester should continue on their current regimen as long as HIV RNA levels are below the level of detection. Women presenting early in the first trimester should be counseled regarding the potential teratogenic risks of antiretroviral exposure in the first trimester versus the competing risk of rebound in HIV RNA levels if therapy is stopped, with

potential risk for perinatal transmission. Women on efavirenz-containing regimens should be switched to alternate regimens if they choose to continue therapy in the first trimester. Hydroxyurea should not be used during pregnancy. If a woman chooses to discontinue therapy during the first trimester, she should stop and restart all agents concurrently to minimize the risk of development of resistance.

If not previously documented, antibody status for *T. gondii*, hepatitis C, and cytomegalovirus should be obtained. Tuberculin skin testing should be performed if not done within the past year. Prophylaxis and treatment of opportunistic infection in pregnant women is generally the same as for nonpregnant women.[77] Ideally, use of highly active antiretroviral therapy should optimize the immune status so that prophylaxis is not indicated. For more detailed information regarding prophylaxis of opportunistic infections in pregnancy, providers should consult current guidelines at http://aidsinfo.nih.gov/guidelines.

HIV-infected pregnant women should receive counseling regarding issues of HIV and pregnancy and should be provided with psychosocial support during pregnancy and the postpartum period. Women can be reassured that pregnancy per se does not appear to have an impact on the progression of HIV infection. Women should be educated regarding signs and symptoms such as rash, nausea, vomiting, extreme fatigue, and muscle aches that may indicate toxicity related to antiretroviral drugs. The risks of perinatal transmission of HIV and the evaluation of the infant for infection should be discussed. The need for careful adherence to therapy to maximize response and minimize the development of resistance should be emphasized.

In addition to use of antiretroviral therapy to lower HIV RNA levels and reduce transmission, performance of cesarean delivery before the onset of labor and membrane rupture has been shown to reduce transmission among women on no antiretrovirals or on zidovudine.[81,82] In a meta-analysis of data from 15 cohorts, the adjusted odds ratio (AOR) for transmission was 0.43 (95% confidence interval [CI] 0.33–0.56) for those with cesarean delivery before labor or membrane rupture compared to those with other modes of delivery.[81] A similar benefit was seen among the subset receiving zidovudine. In a randomized trial of planned cesarean section compared to vaginal delivery, transmission occurred in 1.8% of infants assigned to planned cesarean group and 10.5% of 200 who delivered vaginally ($P < 0.001$).[82] A similar magnitude in reduction of transmission was seen among the subset receiving zidovudine, although small numbers did not reach statistical significance. Given transmission rates of under 2% among women receiving highly active antiretroviral therapy or with HIV RNA below 1000 copies/mL receiving zidovudine, it is difficult to assess for any additional benefit of planned cesarean delivery. Of note in the WITS analysis

was the suggestion of benefit in reduction of transmission from planned cesarean compared to vaginal delivery, even after adjustment for maternal HIV RNA level and level of antiretroviral therapy (AOR 0.27, 95% CI 0.06–1.12, $P = 0.07$).[43] Similarly in the European Collaborative Study, the AOR was 0.42 (95% CI 0.27–0.67) for transmission with elective cesarean compared to other modes of delivery, adjusting for maternal treatment group and CD4+ cell count.[59] Currently, cesarean delivery before labor or membrane rupture is recommended for women with HIV RNA levels above 1000 copies/mL in the third trimester.[83] Women with HIV RNA levels below 1000 copies/mL should have the option of planned cesarean delivery discussed with them, along with the lack of clear data regarding benefit in this setting. All HIV-infected pregnant women should be informed of the increased risks, primarily infectious, associated with cesarean compared to vaginal delivery. Despite early case-control studies suggesting increased rates of morbidity among HIV-infected compared to uninfected women undergoing cesarean delivery (reviewed by the CDC[28]), more recent cohort studies suggest that the increased risk is similar in magnitude to that observed in similar HIV-uninfected women.[84–87] Cesarean delivery may be scheduled at 38 weeks of gestation without amniocentesis, rather than the usually recommended 39 weeks, to minimize the risk of labor or membrane rupture, although this increases the risk of respiratory distress in the newborn.[88] To minimize risks of perioperative infection, genital infections such as bacterial vaginosis should be treated, and the use of antibiotic prophylaxis should be considered, although these interventions have not been specifically evaluated in HIV-infected women. Scheduled cesarean delivery also appears to confer a reduced risk of hepatitis C transmission to the infant among HIV-infected women with detectable hepatitis C viremia.[89]

HIV-infected women should undergo baseline testing of renal and hepatic function. The schedule of testing for drug toxicity will vary with drugs chosen. In general, visits for assessment for any new symptoms and laboratory testing should occur about every 2 to 4 weeks during the first 1 to 2 months of therapy. An optimal schedule of testing for early diagnosis of such complications as hepatic toxicity or lactic acidosis has not been established, but clinicians should consider evaluating hepatic function and electrolytes monthly in the third trimester and certainly in the presence of any new symptoms. Accurate blood lactate levels are difficult to obtain, and normal values in pregnancy have not been established. Routine testing of lactate levels is not recommended, but may be helpful during pregnancy if values are elevated above nonpregnant adult levels in the presence of suggestive symptoms. CD4+ lymphocyte counts should be done every 3 months during pregnancy. HIV RNA levels should be monitored as per guidelines in nonpregnant adults (i.e. every 4 weeks after initiating or changing therapy until undetectable, then every 3 months on stable therapy).[27] A drop of at least one log on HIV RNA levels should be seen after 4 to 8 weeks of therapy.

Protease inhibitor therapy has been associated with an increased risk of glucose intolerance and diabetes in non-pregnant adults.[90] Small studies in pregnancy have not shown an increased risk of gestational diabetes among pregnant women on protease inhibitors compared to those on no therapy or zidovudine monotherapy, but a review of women in the PACTG 316 study has suggested that long-term protease inhibitor use in pregnancy may increase the risk of gestational diabetes.[91] Clinicians may consider early 50g glucose load testing in pregnant women on protease inhibitor therapy with repeat testing at 24 to 28 weeks of gestation if earlier testing is normal.

Clinicians caring for HIV-infected pregnant women on methadone should be aware of potential drug interactions when initiating or changing therapy. Nevirapine, efavirenz, and protease inhibitors other than indinavir may decrease methadone levels and precipitate drug withdrawal so pregnant women should be monitored for symptoms in this setting.[27]

Counseling regarding options for prenatal diagnosis is complicated by HIV infection. Amniocentesis and other invasive procedures such as scalp electrode placement increased the risk of transmission by two- to fourfold in early studies among women not receiving antiretrovirals.[92,93] In more recent cohort studies among women receiving antiretroviral therapy, invasive testing has not been identified as a risk factor for transmission, but amniocentesis is uncommon and chorionic villus sampling rare among HIV-infected women. Thus, specific risk figures are not available to use in counseling. Further complicating the discussion is the recent suggestion that median serum human chorionic gonadotropin and α fetoprotein values may be higher among HIV-infected women and elevations may correlate with increasing disease severity, although confirmation is needed.[94] Women should be counseled regarding the unknown but potential risk of transmission of HIV infection with invasive testing that would be indicated in the event of an abnormal result on a screening serum marker or nuchal translucency test. If she would not undergo amniocentesis with an abnormal screening result, then such screening may be more anxiety-provoking than helpful. On the other hand, the woman must understand that only invasive testing can definitively rule out chromosomal abnormalities. If an invasive prenatal diagnostic procedure is planned for an HIV-infected woman, she should be on optimal antiretroviral therapy with an undetectable HIV RNA level beforehand to minimize the risk of transmission.

Labor and Delivery

Ideally, the decision regarding mode of delivery should be made after discussions throughout pregnancy, based on

HIV RNA results obtained at 34 to 36 weeks of gestation. If the decision is made to attempt vaginal delivery, zidovudine infusion at a dose of 2 mg/kg of body weight over 1 hour, followed by a continuous infusion of 1 mg/kg/hour should be given until delivery.[38] Other antiretroviral drugs should be continued as scheduled during labor, except stavudine, which may antagonize zidovudine and should be discontinued when zidovudine infusion is begun. If the woman is unable to tolerate zidovudine, then stavudine may be continued during labor. During labor, artificial rupture of membranes should be avoided if possible, and labor should be augmented as needed to minimize the duration of ruptured membranes. Fetal scalp electrodes, scalp blood sampling, and instrumented delivery should be avoided to limit fetal exposure to maternal blood. Infants should be washed before undergoing blood draws, injections, or other procedures.

If cesarean delivery is planned, it should be scheduled at or after 38 weeks of gestation.[83] Infusion of intravenous zidovudine as described earlier should be begun at least 3 hours before surgery and continued until cord clamping. Other medications should be continued as scheduled. For women who had planned on a scheduled cesarean delivery presenting with ruptured membranes, management must be individualized based on HIV RNA levels, time since rupture, stage of labor, and patient preference. The benefit of cesarean delivery shortly after rupture of membranes or onset of labor is unclear. Among women not receiving antiretrovirals or receiving zidovudine monotherapy, transmission rates increase with increasing duration of rupture before delivery.[95,96] However, in most studies, transmission rates were similar among women delivering vaginally and those delivering by cesarean after labor or rupture. Women with a short duration of ruptured membranes and an unripe cervix in whom a prolonged labor is anticipated may benefit from urgent cesarean delivery, and those progressing rapidly in labor may be less likely to benefit. In the setting of ruptured membranes without labor before 32 weeks of gestation, expectant management with continuing antiretroviral therapy, potentially including intravenous zidovudine, should be offered to attempt to prolong gestation and reduce complications of prematurity. HIV-infected women with preterm labor should be treated the same as HIV-negative women, with a decision regarding delivery mode based on obstetric considerations and recent HIV RNA levels once delivery is deemed to be inevitable.

For HIV-infected women presenting or diagnosed in labor or post partum without antiretroviral therapy during pregnancy, several options are available. Observational data from Wade and associates demonstrated transmission rates of 6.1% with zidovudine begun prenatally and continued intrapartum and to the neonate for 6 weeks, 10.0% given intrapartum and to the neonate for 6 weeks, 9.3% when started within 48 hours of birth and continued for 6 weeks, 18.4% when started after 48 hours, and 26.6% with no zidovudine for mother or infant.[9] Subsequent studies have demonstrated transmission rates at 14 to 16 weeks of 13.1% with the a single dose of 200 mg nevirapine to mother and 2 mg/kg to the infant compared to 25.1% with oral zidovudine during labor and for 1 week for the infant,[8] a rate at 6 weeks of 10.8% with oral zidovudine/lamivudine in labor and for 1 week in mother and infant compared to 17.2% for placebo,[10] and a rate at 8 weeks of 13.3% with the maternal/infant nevirapine regimen compared to 10.9% for zidovudine/lamivudine orally in labor and for 1 week in the infant.[11] The latter three trials were done in predominantly breastfeeding populations. Thus, any of these three regimens (intravenous zidovudine in labor and oral for the infant for 6 weeks; the maternal/infant nevirapine dosing; or oral zidovudine/lamivudine in labor and for 1 week in the infant) could be used for women presenting in labor without therapy during pregnancy. Some clinicians would choose to use a combination of zidovudine and nevirapine in this setting, although this regimen has not been studied specifically. No trials have been reported evaluating postpartum therapy alone for prevention of transmission, although by extrapolation, any of these regimens could be given. Some clinicians might choose to add additional drugs to these regimens to mimic postexposure prophylaxis recommendations, although formulations and dosing recommendations for neonates are limited.

Postnatal

The postpartum period is a very demanding period for all women, but HIV-infected women have the added stresses of administering medication to the infant and waiting to discern the infant's infection status. Additional psychosocial support is needed during this period. If she plans to continue antiretroviral therapy after delivery, measures to enhance adherence are indicated.[27] For women stopping antiretroviral therapy, all drugs should be stopped simultaneously to minimize the development of resistance. HIV-infected women should be counseled against breastfeeding as it increases the risk of transmission by 15% to 20%, based on studies of women not receiving antiretrovirals.[45]

Follow-up care for the woman, both reproductive and HIV-specific, and her infant should be assured before hospital discharge. During prenatal care, women should be counseled regarding contraceptive options. Condom use should be reinforced. Hormonal contraceptives may be used by HIV-infected women, although estradiol levels are reduced by nevirapine, ritonavir, nelfinavir, rifampin, rifabutin, and possibly amprenavir.[27] The impact on contraceptive efficacy of these interactions is unknown, although these changes may increase the risk of irregular bleeding. Possible pharmacokinetic interactions between depomedroxyprogesterone acetate and antiretrovirals are under study, although given the high

dose of progesterone used, contraceptive efficacy should be maintained. Studies in HIV-infected women suggest that intrauterine contraceptive devices may be used safely by HIV-infected women with a low risk of sexually transmitted infections without severe immune compromise.[97]

Infants born to HIV-infected women require HIV-specific as well as routine pediatric care. Infants should receive zidovudine syrup 2 mg/kg of body weight every 6 hours, or equivalent dosing schedule, for 6 weeks after birth.[28] A complete blood count should be obtained from the neonate before starting zidovudine as anemia is the primary side effect of the zidovudine. Use of additional antiretrovirals in the infant may be considered in some situations, such as for an infant born to women not receiving antiretrovirals during pregnancy.[28] Observational data suggest that transmission is reduced with 6 weeks of oral zidovudine in the infant if started within 24 hours of birth.[9] Infants should be started on prophylaxis for *Pneumocystis carinii* pneumonia at 4 to 6 weeks of age, with prophylaxis continued until the infant is confirmed to be HIV-uninfected.[98] Testing of the infant should be done within 48 hours of birth, at 2 weeks, 1 to 2 months, and 3 to 6 months of age or as soon as any positive result is obtained. HIV DNA PCR is the preferred method for infant diagnosis. Using this method, over 90% of infected children will be identified by 14 days of age.[99] HIV RNA PCR may also be useful for diagnosis in infants, but this methodology has not been studied as extensively. Infants with two positive HIV virologic tests on separate samples are considered to be HIV-infected. Infants with two or more negative virologic tests, with at least two different samples drawn at or after age 1 month and at least one sample at age 4 months or more can be considered to be HIV-uninfected if not exposed through ongoing breast-feeding. HIV-exposed children should be managed by or in consultation with a specialist in pediatric HIV infection.

Summarized here are recommendations for appropriate care for HIV-infected pregnant women to maximize maternal health and minimize the risk of perinatal transmission. Although huge advances have been made in management of HIV infection and prevention of transmission in developed countries, the greater challenge is to translate these interventions into practical and sustainable interventions throughout the world. Ultimately, the goal must be to prevent transmission of HIV to avoid the coexistence of HIV infection in pregnancy.

CONCLUSIONS

- A policy of universal HIV testing of pregnant women, with patient notification and right of refusal is recommended.
- All women presenting in labor without prenatal care or without documentation of HIV testing during pregnancy should be offered rapid HIV testing in the peripartum period.
- Pregnancy does not appear to enhance HIV disease progression among women in industrialized countries.
- Pregnancy may enhance the mitochondrial toxicity of nucleoside analogues, producing a syndrome similar to acute fatty liver of pregnancy.
- Use of combination antiretroviral therapy, especially regimens including protease inhibitors, has been associated with an increased risk of preterm birth in European but not U.S. studies.
- Rates of perinatal transmission of under 2% have been achieved with use of zidovudine and scheduled cesarean delivery or highly active antiretroviral therapy.
- Birth defects including anencephaly, microophthalmia, and cleft palate were seen in 3 (20%) of 15 monkeys after first-trimester exposure to efavirenz. Use of this drug in pregnancy should be avoided.
- In utero and neonatal exposure to nucleoside analogues may rarely cause mitochondrial toxicity in infants, but the risk is outweighed by the benefits in reduction of HIV transmission.
- Current guidelines for treatment of HIV infection during pregnancy, treatment of adults and children, and prevention of opportunistic infections can be found at *http://aidsinfo.nih.gov/guidelines*.
- Cesarean section done before labor and membrane rupture reduces the risk of perinatal HIV transmission among women not on antiretrovirals or on zidovudine. Scheduled cesarean delivery is recommended for women with HIV RNA levels over 1000 copies/mL late in pregnancy. The benefit for women with HIV RNA levels below 1000 copies/mL is unclear.
- Women should receive intravenous zidovudine in labor or before scheduled cesarean delivery.
- Regimens recommended for prophylaxis of transmission for women not treated with antiretrovirals during pregnancy include intravenous zidovudine in labor and oral zidovudine for the infant for 6 weeks; oral zidovudine/lamivudine in labor and for 1 week in the infant; single dose nevirapine in labor and to the infant at 48 hours of age; or a combination of the zidovudine and nevirapine regimens.
- HIV-infected women should not breastfeed if safe alternatives are available.
- Infants should be managed by or in consultation with an HIV expert, should receive zidovudine for 6 weeks, prophylaxis against *Pneumocystis carinii* pneumonia beginning at 4 to 6 weeks of age, and be tested for HIV using a DNA PCR assay.

SUMMARY OF MANAGEMENT OPTIONS
Human Immunodeficiency Virus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Careful counseling and offer of screening for at-risk women	–	GPP	–
Assess indications for antiretroviral therapy and opportunistic infection prophylaxis with HIV RNA, and CD4+ cell counts. Initiate highly active antiretroviral therapy if HIV RNA level >55,000 copies/mL or CD4+ cell count <350/μL. Avoid regimens containing efavirenz because of teratogenicity concerns.	Ia	A	27
Recommend against conception until HIV RNA level undetectable and no indication for opportunistic infection prophylaxis (CD4+ cell count above 200/mm³ for >6 months)	IIa	B	28
Complete other routine preconception assessments such as genetic screening, evaluation for other medical conditions.	IIa	B	28
Recommend folate supplementation.	Ia	A	28
Prenatal Screening Policy			
Screening practices vary—options:	–	GPP	–
Most centers offer screening to ALL women			
Counseling and offer of selective screening for at-risk women; most centers require informed consent before testing can occur			
All unscreened at-risk women should be managed as if they were HIV positive in terms of infection control measures with blood and other body products (preventative measures should be employed when handling blood from all women in pregnancy)	–	GPP	–
Prenatal—HIV Positive Patients			
Assess immunization status and update as needed for pneumococcus, influenza, hepatitis A and B, tetanus.	IIa	B	73
Assess antibody status to hepatitis C, *Toxoplasma gondii*, and CMV if not previously documented.	IIa	B	73
Perform tuberculin skin test if not done in past year.	IIa	B	73
Counsel regarding risk of transmission, methods to minimize risk (antiretroviral therapy with scheduled cesarean delivery if HIV RNA >1,000 copies/ml after 34 weeks), lack of impact of pregnancy on maternal disease progression, symptoms of drug toxicity, possible effects of therapy on infant, evaluation of infant after birth for HIV status.	Ia	A	28,31,100
Review antiretroviral therapy and opportunistic infection prophylaxis with HIV RNA level, CD4+ lymphocyte count. For women already on therapy, discuss risks/benefits of continuing or stopping. Modify regimen if first trimester and on efavirenz. If not on therapy, recommend highly active antiretroviral regimen including zidovudine for all women starting after first trimester, regardless of HIV RNA and CD4+ cell count, with option of zidovudine monotherapy discussed if HIV RNA level <1,000 copies/ml not on therapy. Provide opportunistic infection prophylaxis according to adult guidelines.	Ia	A	28,31,100
Monitor HIV RNA levels monthly after changing or initiating therapy. Level should drop by ≥1 log in first 4–8 weeks.	IIa	B	27
Monitor CD4+ lymphocyte counts each trimester.	IIa	B	28

Human Immunodeficiency Virus (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—HIV Positive Patients			
Perform complete blood count, liver enzymes, renal function frequently (every 2–4 weeks) on new regimen, monthly in third trimester.	III	B	28
Perform HIV resistance testing if not responding to regimen or confirmed rebound on previously suppressive regimen.	IIa	B	27
Perform ultrasound at 18–20 weeks of gestation to rule out anomalies and confirm dates.	–	GPP	–
Discuss risks versus benefits of scheduled cesarean delivery; advise cesarean section. Recommend for HIV RNA levels >1,000 copies/mL after 34 weeks. Schedule at or after 38 weeks of gestation if dating criteria adequate.	Ia	A	28,31,100
Routine prenatal care. If indicated, discuss unknown risk of transmission with amniocentesis or chorionic villus sampling. Perform only if on antiretroviral therapy with undetectable HIV RNA.	III	B	27, 28
Labor and Delivery			
Cesarean section reduces vertical transmission and should be advised	Ia	A	28,31,100
Start intravenous zidovudine infusion	Ia	A	28,31,38,100
a. For those choosing vaginal delivery 2 mg/kg over one hour followed by 1 mg/kg/hour until delivery with onset of labor			
b. Same regimen at least 3 hours before scheduled cesarean delivery.			
Continue other medications orally except stavudine, which may antagonize zidovudine.			
If vaginal delivery minimize duration of ruptured membranes as much as possible.	IIa	B	28,95,96
Avoid scalp electrodes, scalp sampling, instrumented delivery. Wash infant before blood draws, injections.	III	B	92,93
Postnatal			
Discuss option of stopping or continuing antiretroviral therapy if initiated solely for transmission prophylaxis. Reinforce adherence if continuing therapy.	IIa	B	28
Counsel against breastfeeding.	Ia	A	28
Provide contraception (condom preferred) and assure continued HIV and reproductive health care.	II	A	28
Provide psychosocial support as infant infection status assessed.	III	B	28
Assure routine and HIV specific care for infant including zidovudine 2 mg/kg every six hours or equivalent until six weeks of age, HIV DNA PCR testing, initiation of prophylaxis against *Pneumocystis carinii* pneumonia beginning at 4–6 weeks of age.	Ia	A	98

Rubella, Measles, Mumps, Varicella, and Parvovirus

Laura E. Riley

RUBELLA

Maternal and Fetal Risks

Rubella (German measles or third disease) is an exanthematous disease caused by a single-stranded RNA virus of the togavirus family.[1] Like rubeola, rubella is acquired via respiratory droplet exposure. After a 2- to 3-week incubation period, symptomatic patients develop a rash that spreads from the face to the trunk and extremities lasting about 3 days. Fever, arthralgias, and postauricular and suboccipital lymphadenopathy are characteristic. Severe complications such as encephalitis, bleeding diathesis, and arthritis are rare. Overt clinical symptoms occur in only 50% to 75% of rubella-infected patients, and thus, clinical history is not a useful marker of prior illness.[2]

Rubella infection is usually a mild illness in both adults and children. However, fetal infection may be devastating. Congenital rubella syndrome (CRS) may produce transient abnormalities, including purpura, splenomegaly, jaundice, meningoencephalitis, and thrombocytopenia or permanent anomalies such as cataracts, glaucoma, heart disease, deafness, microcephaly, and mental retardation. Long-term sequelae may include diabetes, thyroid abnormalities, precocious puberty, and progressive rubella panencephalitis.[2,3] Defects involving virtually every organ have been reported (Table 30–1).[4] A 50-year follow-up of 40 survivors of CRS born between 1939 and 1943 revealed that all had hearing impairment; 23 had eye defects related to the rubella.[5]

The results of one large survey of maternal rubella infection in pregnancy are summarized in Table 30–2.[6] The rate of fetal infection is highest at 11 weeks and greater than 36 weeks. However, the overall rate of congenital defects is greatest in the first trimester (90%) and declines steadily in the second and third trimesters.

Rubella vaccine became available in the United States in 1969. Vaccination given as a trivalent preparation of measles, mumps, and rubella (MMR) vaccine produces long-term immunity in 95% of vaccinees. The rates of rubella dropped precipitously after introduction of the vaccine. Ten years later, the annual incidence of rubella infections, including CRS, had decreased by 99.6%.[7] However, in the 1990s there were several outbreaks in groups of adults with unknown vaccination status living in close quarters.[8] The largest outbreak in the United States occurred in Nebraska in 1999 and involved 125 cases; 87% of these patients were born in Latin America.[9] In this outbreak, seven pregnant women were infected and one child was born with CRS. Almost half of these women had prior births in the United States and had missed prior vaccination opportunities.

Diagnosis

The clinical diagnosis of rubella infection is difficult. Most infections are subclinical, and the rash is nonspecific. Serologic testing is the primary mode of diagnosis using enzyme-linked immunoassay (ELISA). In a woman with exposure or suspected illness, seroconversion demonstrated by paired acute and convalescent specimens is indicative of acute infection. Acute infection may also be diagnosed by isolation of virus from the blood, nasopharynx, urine, or cerebrospinal fluid. Serologic testing for immunity is based on the assumption that rubella-specific antibodies of the IgG class are present for life after natural infection or vaccination.

Management Options

Prepregnancy

Vaccination of all children and susceptible adults will help prevent outbreaks of rubella. All children should

TABLE 30-1

Abnormalities in Congenital Rubella: Triad of Gregg

ABNORMALITY	DESCRIPTION
Eye	
Cataract	Usually bilateral and present at birth
Retinopathy	"Salt and pepper" appearance, may have a delayed onset, frequently bilateral, visual acuity is not affected
Microphthalmia	Often associated with cataract
Glaucoma	Is rare but leads to blindness if not recognized
Heart	
Patent ductus arteriosus	Common, often associated with persistence of the foramen ovale
Pulmonary valvular stenosis	Common, due to intimal proliferation and arterial elastic hypertrophy
Pulmonary artery stenosis	
Coarctation of the aorta	Infrequent
Ventricular septal defects	Rare
Atrial septal defects	Rare
Ear	
Commonly damaged	Injury of cells of the middle ear leading to sensorineural deafness may also have a central origin
Bilateral and progressive	May be present at birth or develop later in childhood. Severe enough for the child to need education at a special school; rare when maternal rubella occurs after the fourth month of pregnancy

Adapted from Freij BJ, South MA, Sever JL, et al: Maternal rubella and the congenital rubella syndrome. Clin Perinatol 1988;15:247–257.

receive a single dose of live, attenuated rubella vaccine at 12 to 15 months of age in a trivalent preparation of MMR strains. The second dose of MMR may be administered at least 1 month after the first dose but before 6 years of age. Susceptible young women should be vaccinated and refrain from pregnancy for 1 month following vaccination.[10] Evidence of immunity is required of health care workers and women of childbearing age.[11] According to ongoing studies, antibody to rubella virus should be detectable for up to 16 years after vaccination.[12] However, individuals with low levels of antibody after vaccination may be susceptible to viremia and clinical infection.[13] CRS after previous maternal rubella vaccination has been rarely reported.[14]

The rubella vaccine is a live virus preparation, which may cross the placenta; thus, it should not be administered to pregnant women. However, the Centers for Disease Control have monitored inadvertent rubella vaccination during pregnancy, collecting over 500 cases. No case of CRS due to vaccination was documented, although virus was isolated from the conceptus in several cases.[15] Thus, patients inadvertently vaccinated during pregnancy, or becoming pregnant shortly after vaccination, should be reassured and counseled that the risk of fetal infection is negligible.[16,17]

Prenatal

A pregnant woman infected with rubella is at little risk. However, depending on the gestational age at infection, the fetus may be at great risk for congenital anomalies. Methods for in utero diagnosis include fetal blood sampling measurement of rubella-specific IgM,[18] rubella-specific reverse transcription polymerase chain reaction (RT-PCR), and virus isolation from amniotic fluid or products of conception.[19,20] RT-PCR can detect the presence of viral RNA even when the fetal rubella virus-specific IgM obtained by fetal blood sampling is negative.[21] Although these tests may indicate fetal infection, the counseling is largely based on the gestational age related risk of congenital abnormalities due to CRS. No treatment other than pregnancy termination is available.

TABLE 30-2

Fetal Consequences of Symptomatic Maternal Rubella during Pregnancy

STAGE OF PREGNANCY (WEEKS)	INFECTION		DEFECTS		OVERALL RISK OF DEFECT (RATE OF INFECTION × RATE OF DEFECTS) (%)
	NO. TESTED	NO. POSITIVE	NO. FOLLOWED	RATE (%)	
<11	10	9 (90%)	9	100	90
11–12	6	4 (67%)	4	50	33
13–14	18	12 (67%)	12	17	11
15–16	36	17 (47%)	14	50	24
17–18	33	13 (39%)	10	0	0
19–22	59	20 (34%)			
23–26	32	8 (25%)			
27–30	31	11 (35%)			
31–36	25	15 (60%)	53	0	0
>36	8	8 (100%)			
Total	258	117 (45%)	102	20	9

From Miller E, Cradock-Watson JE, Pollock TM: Consequences of confirmed maternal rubella at successive stages of pregnancy. Lancet 1982;2:781–784.

Treatment for acute maternal rubella is generally symptomatic. Rarely, patients who develop thrombocytopenia or encephalitis may benefit from glucocorticoids or platelet transfusion. Immunoglobulin for pregnant women with acute infection is controversial. Furthermore, no data suggest that immunoglobulin will prevent fetal anomalies.

Labor, Delivery, and Postnatal

Acute infection during these time periods is unlikely. If suspected, appropriate infection control measures should be instituted. The neonate should be evaluated for infection following birth.

SUMMARY OF MANAGEMENT OPTIONS
Rubella

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Prevent by childhood vaccination.	III	B	24
Vaccination programs for girls in their early teens contribute to prevention.	III	B	11,24
Serologic evaluation and, if negative, vaccination of woman inquiring about status.	III	B	11,24
Prenatal			
Routine check of rubella immunity status at first visit for all women is standard practice in many centers.	III	B	17,24
Accidental vaccination in early pregnancy is not an indication for termination.	IIb	B	14–16
If suspected exposure in woman with immunity:	–	GPP	–
• Confirm presence of rubella-specific IgG (if immediately after exposure).			
• Confirm failure of appearance of IgM (acute phase) antibodies with two serum samples 2–3 weeks apart.			
• Reassure patient.			
If suspected exposure in susceptible woman:			
• Establish validity of diagnosis serologically in index case if possible.	III	B	11,24
• Check for appearance of IgM (acute phase) antibodies.	III	B	11,24
• If there is no serologic evidence of infection, reassure patient.	–	GPP	–
If maternal infection is confirmed serologically, options will depend on gestation at time of infection:			
• In early pregnancy, termination should be discussed; it may be performed immediately or only after confirmation by invasive procedure.	IIb	B	5,6
• In late pregnancy, confirmation of fetal infection by invasive procedure can be considered; fetal growth and health should be monitored if infection is suspected or confirmed.	–	GPP	–
Labor, Delivery, and Postnatal			
If fetal infection is suspected, cord blood should be sent for serologic confirmation.	III	C	24
If fetal infection is confirmed, careful pediatric assessment and follow-up are needed.	–	GPP	–

RUBEOLA

Maternal and Fetal Risks

Rubeola (red measles or first disease), caused by a paramyxovirus, is highly infectious, and commonly attacks children. The illness is spread by respiratory droplet and may include high fever, rash, cough and rhinorrhea, conjunctivitis, and the pathognomonic Koplik's spots on the oral buccal epithelium. The incubation period is generally 10 to 14 days. The infection is usually self-limited in children.[22] Rarely, the disease may be severe and may be complicated by bronchopneumonia, hepatitis, otitis media, diarrhea, or death.[23,24] Encephalitis occurs in 1 of every 1000 reported cases and may lead to permanent brain damage and mental retardation. Death, usually due to pneumonia or encephalitis, is reported to occur in 1 to 2 per 1000 cases in the United States. The fatality rate is greater in infants, young children, and adults. Additionally, subacute sclerosing panencephalitis, an extremely rare degenerative disease of the central nervous system, is caused by this virus presenting years after the initial measles infection.

The number of cases of measles in the United States and other industrialized countries has decreased markedly since the introduction of an effective vaccine in 1963.[24,25] Still, in 1990, there were 55,000 cases and 120 measles-related deaths. This resurgence was largely due to an increase in unvaccinated preschool children, particularly in urban areas.[25]

Some report that measles during pregnancy is not associated with increased maternal or fetal death rates.[26] Others find higher rates of measles-related hospitalization, pneumonia, and death for infected pregnant women.[27] Placental damage from the infection has been implicated in stillbirths.[28] Furthermore, measles infection of mothers in developing countries is associated with an increase in the perinatal mortality rate.[29] As with any febrile illness, measles infection may precipitate premature uterine activity and lead to premature delivery.[30]

No specific syndrome is attributed to intrauterine measles infection. However, the newborn delivered to a woman with active disease is at high risk for severe neonatal measles. Pneumonia is the primary cause of death and is more common in the premature newborn. Recent reports suggest an association between in utero measles infection and postnatal development of Crohn's disease.[31] This potential relationship has yet to be confirmed and does not warrant prenatal diagnosis in the fetus.

Diagnosis

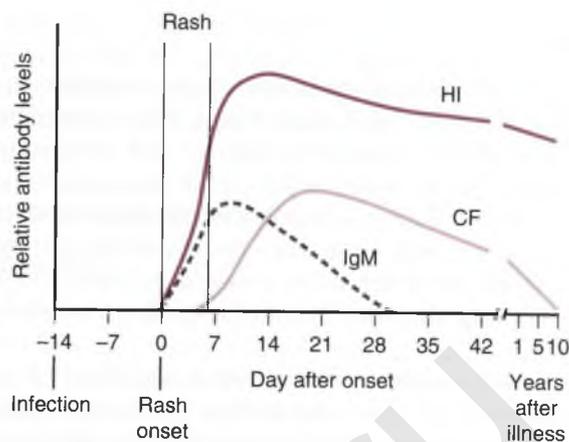
The clinical diagnosis of rubeola is based on the presence of a maculopapular rash occurring 1 to 2 days after a spe-


FIGURE 30–1
Immune response to an acute rubeola infection. HI, Hemagglutination inhibition antibody; CF, complement fixation antibody. (From Centers for Disease Control and Prevention: Update on adult immunization: Recommendations of the Immunization Practices Advisory Committee (ACIP). MMWR 1991;40(RR-12):1–52.)

cific exanthematous rash (Koplik's spots), photophobia, and upper respiratory symptoms. Serologic tests can provide a definitive diagnosis and include testing for hemagglutination inhibition antibody, which is present by the onset of the rash and remains positive for life, and a complement fixation antibody that rises slightly later but becomes undetectable after approximately a decade[32] (Fig. 30–1).

Management Options

Prepregnancy

Prevention is the best available mechanism to protect against measles. All children should receive one dose of the live measles virus vaccine as part of MMR between 12 and 15 months of age followed by a second dose at age 6. Vaccination results in long-lasting immunity in over 95% of recipients.

Likewise, immunity to natural infection is lifelong and the high infectivity of the virus during childhood leaves few susceptible adults. Women contemplating pregnancy with a negative or questionable history of measles illness or vaccination, or laboratory evidence of susceptibility, should receive the live, attenuated virus vaccine followed by a second dose not less than 1 month later. Women vaccinated before 1967 (and likely to have received a heat-killed viral vaccine), or who were vaccinated before 1 year of age, should also receive two doses of vaccine.[24] Pregnancy should be delayed 1 month after receiving MMR vaccine.

Prenatal

The upper respiratory symptoms of acute measles can be ameliorated with cough suppressants. Fever, especially if high, should be treated aggressively with antipyretics. Measles pneumonia may require respiratory support, and if superimposed bacterial pneumonia develops, antibiotic therapy is required. Even when there is no life-threatening disease, pregnant women should be closely monitored during the acute illness for evidence of uterine activity.

Although pregnant women are not candidates for vaccination with any live virus vaccine, accidental vaccination with rubeola vaccine is not a cause for alarm or an indication for pregnancy termination. Immune serum globulin (ISG) may be given to susceptible pregnant women exposed to rubeola in an attempt to prevent or modify the clinical expression of the disease.[33] The intramuscular preparation (0.25 mL/kg, maximum 15 mL) should be given within 6 days of exposure.[11]

Labor, Delivery, and Postnatal

There are no specific management recommendations for these intervals, because acute disease is unlikely. Clinicians, however, should be aware of appropriate isolation precautions instituted for rubeola in the hospital. Observation of the neonate for infection is mandatory.

SUMMARY OF MANAGEMENT OPTIONS
Measles (Rubeola)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Prevent by childhood vaccination.	III	B	24
Serologic evaluation and, if negative, vaccination of woman inquiring about status.	III	B	11, 24
Prenatal			
Treat acute infection symptomatically.	–	GPP	–
Antibiotics are given if secondary bacterial infection is suspected.	–	GPP	–
Observe and monitor for uterine activity for termination.	–	GPP	–
Immunoglobulin should be considered for the susceptible woman exposed to the infection.	III	B	24
Inadvertent vaccination is not an indication for termination.	III	B	24
Labor, Delivery, and Postnatal			
Appropriate isolation precautions must be taken when in hospital.	–	GPP	–

MUMPS

Maternal and Fetal Risks

Mumps is a contagious acute viral illness caused by a paramyxovirus, primarily infecting children and young adults. Human beings are the only recognized natural host for this pathogen. The classic presenting symptom for mumps is either unilateral or bilateral parotitis, which usually develops 14 to 18 days after exposure. Respiratory droplets typically transmit the virus. Prodromal symptoms include fever, chills, malaise, and myalgias. The disease can also remain asymptomatic in 20% of cases. Persons are considered infectious from 2 days before the onset of symptoms to approximately 9 days after the parotitis is noted.

Although generally a self-limited disease with symptoms resolving within 5 to 7 days, mumps can result in significant complications, particularly in the adult population. Orchitis occurs in up to 38% of cases in postpubertal males and may lead to infertility.[24] On the other hand, mastitis and oophoritis have been reported in women, but infertility is rare.[34] Other complications include aseptic meningitis, pancreatitis, and thyroiditis. Mumps meningoencephalitis can cause permanent sequelae such as sensorineural hearing loss, seizures, nerve palsies, and hydrocephalus.[24]

There are limited data on mumps in pregnancy. In a cohort study of measles, mumps, and rubella, Siegel reported an increased incidence of first-trimester pregnancy loss with acute mumps infection.[35] No data suggest mumps specifically increases the incidence of stillbirths or preterm deliveries. There were early studies that suggested an association between endocardial fibroelastosis and mumps virus antigen; however, a clear relationship of mumps to this or other congenital malformations has not been confirmed.[36]

The number of reported cases of mumps in the United States has decreased dramatically since the broad institution of effective vaccination. In 1968, over 180,000 cases of mumps were reported in the United States compared to 266 cases reported in 2001.[37] Most cases occurred in persons younger than 20 years of age. Although the presumption was that these outbreaks were due to failure to vaccinate, more recent surveillance data suggest that there may be a waning of vaccine-induced immunity over time, allowing for susceptibility to wild virus infection.[38] Current recommendations, which were enacted in 1989, include a second dose of MMR vaccine given at age 6 years. This practice has resulted in a further decline in mumps infection.[39] A remaining concern is that only 38% of countries worldwide use routine mumps vaccination. Therefore, the importation of mumps into previously protected communities has become increasingly recognized.

Diagnosis

The diagnosis of mumps is usually suspected based on presenting features of the disease in the appropriate clinical setting. Although the virus can be isolated in culture or by RT-PCR detection from a clinical specimen (saliva, CSF, urine, or other infected organ system), the diagnosis is more typically established by serologic techniques. Enzyme immunoassay is the most widely used methodology and is more sensitive than complement fixation or hemagglutination inhibition. Both IgM and IgG antibody testing is available. A positive mumps-specific IgM result from a reliable laboratory or a significant rise between acute and convalescent titers of IgG antibody helps establish the diagnosis of acute infection. After acute infection, it is presumed that one has lifelong immunity and persistent IgG titers.

Management Options

Prepregnancy

Two doses of mumps vaccine in combination with measles and rubella (MMR) are routinely recommended for children in the United States. Therefore, adequate protection against infection should be established prior to a woman reaching her reproductive years. There are no current routine recommendations to test for mumps immunity prior to conception. However, if there is reasonable concern that prior vaccination is not adequate, IgG testing can be obtained. If susceptible, a dose of MMR vaccine should be administered at least 1 month prior to attempting pregnancy.[40]

Prenatal

Because the mumps component in MMR is a live attenuated virus, the vaccine is contraindicated in pregnancy. Because there are no data indicating that mumps vaccination is associated with congenital malformations or other specific adverse outcomes, the inadvertent administration of the vaccine during pregnancy is not an indication for pregnancy termination.

During pregnancy, if exposure to an infected individual is reported, immediate testing for IgG antibody will in most cases confirm immunity and can be used to reassure the patient. In those individuals who lack proven immunity, postexposure immunoglobulin has not been shown to be beneficial as a prophylactic agent. Careful surveillance and symptomatic care should be instituted. Appropriate infection control procedures should be undertaken. These procedures can be rapidly procured from hospital infection-control authorities and via the Centers for Disease Control and Prevention (CDC) website.

Labor, Delivery, and Postpartum

There are no specific recommendations for these periods of time, because an acute outbreak is unlikely to occur. However, in suspected cases in the laboring gravida, the above-mentioned infection control measures should be started as the diagnostic workup is begun. The neonate should be carefully observed for early signs of infection manifested by parotitis or aseptic meningitis. Pediatric infectious disease consultation should be sought.

Observe neonate for parotitis or aseptic meningitis.	—	GPP	—

VARICELLA

Maternal and Fetal Risks

Varicella-zoster virus (VZV) is a member of the herpesvirus family and is the causative agent of varicella (chickenpox) and herpes zoster (shingles). Varicella is generally a mild, self-limited illness in healthy children. It is transmitted by infected secretions from the nasopharynx, by direct contact with vesicular fluids, or by airborne spread of the virus. This is followed by viral replication in regional lymph nodes and the tonsils. Viral replication continues for approximately 4 to 6 days. Primary viremia develops and virus spreads to internal organs. When the virus replicates again and is released into the bloodstream, it invades the skin, resulting in the classic viral exanthem by 14 days. Therefore, patients are infectious 1 to 2 days prior to developing this rash.

The incubation period of chickenpox is 10 to 12 days. Many patients have a prodrome of fever, malaise, or myalgia a few days prior to the rash, which is vesicular and erupts in crops over the trunk, face, oropharynx, and scalp. Several crops erupt every 2 to 3 days and last 6 to 10 days. Complications are rare but may include bacterial superinfection of vesicles, pneumonia, arthritis, glomerulonephritis, myocarditis, ocular disease, adrenal insufficiency, and central nervous system abnormalities.[41]

In the 1960s varicella pneumonia was reported in up to 50% of adult varicella cases.[42] Retrospective studies suggest that varicella pneumonia in pregnant women is more severe than in nonpregnant adults.[43] In a recent case-control study, smoking and the occurrence of 100 or more skin lesions were risk factors for developing pneumonia.[44] A pregnant woman with varicella and cough, dyspnea, fever, or tachypnea warrants immediate attention. Pneumonia generally develops within a week of the rash and may rapidly progress to hypoxia and respiratory fever. The mortality rate in untreated varicella pneumonia in pregnancy exceeds 40%.[45] If treated aggressively with intravenous acyclovir and supportive measures, reported mortality rates are less than 15%.[42]

Congenital varicella syndrome (CVS) is characterized by dermatomal scarring; ocular abnormalities such as cataracts, chorioretinitis, and microphthalmia; low birth weight; cortical atrophy; and mental retardation (Table 30–3). Most cases occur in infants whose mothers were infected between 8 and 20 weeks' gestation. However, the number of cases is low. Data compiled from multiple retrospective cohort studies have determined the rate of embryopathy is approximately 2%.[46–49] In fact, in a recent, prospective study of 347 varicella-infected mothers, the incidence of CVS was 3 per 231 births (1.3%, 95% CI 0.3 to 0.7) where followup was complete.[50]

Neonatal varicella generally occurs in neonates born to mothers who are infected with varicella within 2 weeks of delivery.[51] It is a serious illness characterized by fever and vesicular rash, which resolves, but in some cases disseminated disease or visceral involvement may ensue. In the latter, the mortality rate may be as high as 25%.

Herpes zoster or shingles, which arises from reactivated VZV, which had been dormant in the dorsal root ganglia, does not lead to congenital varicella syndrome.

TABLE 30–3

Fetal Abnormalities Associated with Congenital (Intrauterine) Varicella Infection

Cutaneous scarring
Limb hypoplasia
Missing/hypoplastic digits
Limb paralysis/muscle atrophy
Psychomotor retardation
Convulsions
Microcephaly
Cerebral cortical atrophy
Chorioretinitis
Cataracts
Chorioretinal scarring
Optic disk hypoplasia
Horner syndrome
Early childhood zoster

Diagnosis

Varicella is usually diagnosed clinically based on the characteristic exanthem. Culture of the vesicular fluid is a lengthy process. Serologic tests are useful to document immunity (when IgG is present) in a patient immediately following exposure. IgM antibody specific to VZV may be identified as soon as 3 days after the onset of symptoms in an acutely infected gravida. IgG seroconversion can be seen as of 7 days after VZV symptom onset. Paired sample analysis for IgG may be useful to establish the diagnosis of primary infection.

Prenatal diagnosis of varicella is possible. Ultrasonography may detect limb abnormalities, and fetal blood or amniotic fluid may be tested for VZV antibody or DNA.[52,53] However, despite detection of virus, the presence of embryopathy cannot be predicted.

Management Options

Prepregnancy

Varivax, a live attenuated varicella vaccine is recommended for susceptible children under age 13 and susceptible adults.[54] The vaccine is given in two doses 4 to 8 weeks apart, and approximately 82% of adults will seroconvert. Women should avoid pregnancy for at least 1 month after vaccination. Results from a voluntary registry of Varivax administered early pregnancy revealed no cases of CVS among 56 live births.[55] Thus, inadvertant Varivax exposure should not prompt medical recommendations for pregnancy termination.

Pregnancy

Varicella zoster immunoglobulin (VZIG) prepared from donors with high levels of VZV should be administered to pregnant women who are susceptible to VZV and are exposed to varicella or herpes zoster. VZIG should be administered with 48 hours of exposure but may be effective up to 96 hours. Although VZIG diminishes the severity of maternal disease, there is no evidence that VZIG prevents congenital varicella.

If a pregnant woman becomes infected with chickenpox, she may be offered oral acyclovir to decrease the number of febrile days and shorten the duration of active lesions.[56] As previously noted, parenteral antiviral therapy may be needed in cases of varicella complicated by pneumonia or central nervous system involvement.

Labor, Delivery, and Postnatal

There are no specific management recommendations for labor. Infected pregnant women should be placed in a negative pressure room for labor, delivery, and the postpartum period in accordance with infection control protocols. Neonates should be given VZIG after birth and monitored closely because the neonate at greatest risk for chickenpox is born within 4 days prior to or 2 days after maternal chickenpox.[57] A recent small study of 24 prenatally infected newborns suggests that VZIG in conjunction with intravenous acyclovir is a more effective prevention strategy than VZIG alone.[58]

SUMMARY OF MANAGEMENT OPTIONS
Varicella-Zoster (VZ) Infection

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Prevent by childhood vaccination.	III	B	11
Vaccinate susceptible adults.	IV	C	11
Prenatal			
If mother exposed to VZ virus, check immunity status.	–	GPP	–
If mother is IgG negative (susceptible), give VZIG within 96 hours of exposure.	IV	C	54,57
If mother develops chickenpox:			
• Counsel about minimal fetal risks.	IIa	B	46–51
• Offer acyclovir to decrease lesions.	IIa	B	56
• Monitor for dissemination to pneumonia or severe illness.	III	C	42–45
Labor, Delivery, and Postnatal			
Take appropriate infection control measures.	–	GPP	–
Evaluate newborn clinically and serologically.	–	GPP	–
Administer active or passive immunization to neonate if not infected.	IV	C	57, 58

PARVOVIRUS B19

Maternal and Fetal Risks

Human parvovirus B19 (erythema infectiosum, fifth disease) is an infectious exanthematous childhood illness transmitted by droplet. B19 viremia occurs 6 to 8 days after exposure and may persist for up to a week. An infected individual is contagious before the onset of symptoms, and the virus can be detected in the blood or secretions as early as 5 to 10 days after exposure. Parvovirus B19 infection is characterized by fever, rash, and arthropathy. The rash has a "slapped cheek" appearance on the face and a "lace-like" appearance on the trunk and extremities. The arthropathy may affect the joints of the hands, wrist, knees, and ankles. In addition, the virus may cause aplastic crisis in patients with sickle cell disease[59] and other hemolytic states,[60] chronic bone marrow failure in patients with immunodeficiency,[61] a chronic arthropathy,[62] and the childhood illness fifth disease (erythema infectiosum).[63]

Parvovirus B19 infection preferentially infects rapidly dividing cells and is cytotoxic for erythroid progenitor cells.[64,65] As a result, B19 virus also may stimulate a cellular process involving programmed cell death.[66] B19 infection during pregnancy may rarely be associated with fetal loss or hydrops fetalis. The risk of fetal loss appears highest in the first 20 weeks of pregnancy. In a prospective study of 186 pregnancies with confirmed parvovirus B19 infection, there were 27 first-trimester spontaneous abortions versus 7 abortions or fetal deaths in the second trimester and only one death in the third trimester.[67] There have been several additional series of parvovirus infection in pregnancy reported. When these series are summarized, the risk of fetal loss among pregnancies infected prior to 20 weeks' gestation is approximately 10%.[67–71] The risk of loss after 20 weeks' gestation is less than 1% and the risk of hydrops is 0.3%.[71] A prospective study of 618 exposed pregnancies showed no hydrops or fetal death attributable to B19 in 52 babies born to infected mothers.[72] The hydrops may develop rapidly within 7 to 14 days and can lead either to fetal death or can resolve spontaneously.[73,74]

Although B19 infection appears to be teratogenic in fetal animals (cerebellar hypoplasia and ataxia in cats and anencephaly, microcephaly, facial defects, and ectopic hearts in hamsters have been described), epidemiologic studies do not suggest that B19 infection is teratogenic in human fetuses.[75] Furthermore, long-term follow-up of offspring of women with B19 infections suggests the children are normal.[76,77]

Parvovirus B19 infection is distributed worldwide. Antibody to B19 virus occurs in 30% to 60% of adults.[78,79] Secondary attack rates for household contacts may be as high as 50% but as low as 20% to 30% for classroom contacts.[80] Serologic surveys of pregnant women revealed that 35% to 65% are B19 seropositive.[69,72] In one large study during an epidemic, the risk of seroconversion for pregnant women was highest in those with the greatest exposure to young children.[81]

Diagnosis

B19 virus is difficult to culture and clinical manifestations are often lacking. Serology is the easiest method to detect infection using either IgM antibody capture radioimmunoassay or enzyme-linked immunosorbent assay (ELISA). These tests will detect between 80% and 90% of B19 seropositive individuals.[82] IgM, indicating acute infection, can be detected approximately 10 days after exposure and can last for 3 months or longer.[83,84] IgG antibodies may be detected several days after IgM and can persist for years as markers of past infection. Polymerase chain reaction (PCR) to detect small amounts of B19 virus is useful to diagnose in utero infection from amniotic fluid.[85–87] Additional methods such as electron microscopy, detection of viral DNA, and hybridization assays for nucleic acids may be useful for pathologic specimens in the evaluation of stillbirths.

Management Options

Prepregnancy

Immunocompetent adults rarely need treatment; however, patients at risk for hemolysis may need multiple transfusions.

Prenatal

Pregnant women following exposure to B19 virus should have immediate serologic testing. Presence of IgG and absence of IgM suggests prior exposure to B19 virus and that the fetus is protected from infection. If the IgG is negative or positive and the IgM is positive, this finding is consistent with acute infection. Women should be counseled about the low risk of fetal loss in the first trimester and low risks of hydrops or stillbirth in the second and third trimesters. Prior to 20 weeks' gestation, no further action is required. However, after 20 weeks' gestation, periodic ultrasound examinations may be useful to identify hydrops. In addition, Doppler studies of the fetal middle cerebral artery peak velocity may yield an accurate reflection of fetal anemia.[88] In some reported cases hydrops did not appear until 8 weeks following maternal infection; hence the recommendation to continue monitoring for 8 to 12 weeks after infection.[89] If hydrops is noted, percutaneous umbilical blood sampling may be warranted to determine fetal hematocrit and provide transfusion.[90,91] Although some small series show improvement following transfusion, other reports note spontaneous resolution in the absence of intervention.[92,93]

The pregnant woman who is IgG negative and IgM negative is susceptible to infection. She should be counseled that repeat testing may be required if her serologic results were obtained within 2 weeks of her exposure. Preventive measures include minimizing contact with known parvovirus infection and good contact precautions. According to the CDC, there is no proven benefit to removing seronegative women from high risk employment for the duration of the pregnancy.

Labor, Delivery, and Postpartum

Onset of signs and symptoms suggesting acute infection during these time periods requires appropriate infection control measures. The neonate should be carefully observed for vertical transmission of the infection. Neonatal IgG levels immediately after birth reflect transplacentally passed maternal immunoglobulin.

SUMMARY OF MANAGEMENT OPTIONS
Parvovirus B19 Infection

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
If the diagnosis is confirmed before pregnancy, avoid contraception until clinical cure and antibody response.	–	GPP	–
Prenatal			
If mother is exposed to B19 parvovirus or symptoms are noted, check immunity status.	–	GPP	–
If mother is IgG negative/IgM negative (susceptible), repeat testing in 3–4 weeks.	–	GPP	–
If mother is IgG negative/IgM positive:			
• Counsel that risks are minimal.	IIb	B	67–72
• If greater than 20 weeks, screen with serial ultrasound for hydrops.	III	B	67–71
• If hydrops is detected, consider intrauterine fetal transfusion.	III	B	90, 91
Labor, Delivery, and Postnatal			
Take appropriate infection control measures.	–	GPP	–
Evaluate newborn clinically and serologically.	–	GPP	–

CONCLUSIONS

RUBELLA
- Outbreaks are sporadic but occur predominantly in unvaccinated individuals.
- Maternal infection is mild, but fetal malformations may be devastating, depending on the gestational age at infection.
- Inadvertent rubella vaccination does not lead to congenital rubella syndrome.

RUBEOLA (MEASLES)
- Severe disease caused by measles is rare.
- Measles during pregnancy may be associated with increased maternal or fetal morbidity.
- Prevention using MMR vaccine is the optimal mechanism to avoid infection.

MUMPS
- Mumps is generally a self-limited disease.
- Mumps infection during pregnancy is not associated with pregnancy complications or congenital malformations.

VARICELLA
- Varicella pneumonia is a rare but potentially serious disease in pregnant women.
- Congenital varicella syndrome occurs in less than 2% of pregnancies complicated by primary varicella before 20 weeks' gestation.
- Varicella immunoglobulin should be administered to susceptible pregnant women following exposure.

PARVOVIRUS B19
- Maternal infection is frequently asymptomatic.
- Following maternal infection before 20 weeks' gestation, the risk of fetal loss is approximately 10%.
- Fetal hydrops is rare but may be treated with in utero transfusions.

Cytomegalovirus, Herpes Simplex Virus, Adenovirus, Coxsackievirus, and Human Papillomavirus

Thomas Roos

INTRODUCTION

Viral infections can pose a serious threat to the fetus and the newborn. In the healthy adult, infections might be asymptomatic or cause only mild unspecific symptoms. Consequently, the virus may reside dormant for prolonged periods, and asymptomatic virus shedding may occur unnoticed. Virus can be transmitted by trivial interpersonal contacts such as occurs when handling a baby (cytomegalovirus, herpes simplex virus, adenovirus, coxsackievirus) or in a swimming pool (adenovirus). Sexual activities with multiple partners confer a high risk for infection with viruses associated with severe disease in the adult and in the infant. Pregnancy is associated with decreased maternal cell-mediated immunity to viral infections; thus, the pregnant woman and her fetus are theoretically at increased risk for serious illness. Depending on gestational age, transplacental viral infection may range from asymptomatic to severe, causing fetal or neonatal death, or long-term sequelae in the survivors. Intrauterine growth restriction (IUGR), nonimmune hydrops, isolated ascites, intracranial calcifications, microcephaly, and hydrocephaly are common ultrasound findings associated with in utero viral infection. The possible severe impact of viral infections and the lack of specific antiviral treatment options in the fetus and newborn available to date imply that prevention is the most important approach to disease containment. The development of antiviral drugs and vaccines in progress holds the promise of a reduced incidence of fetal viral infections and of their sequelae in the future.

CYTOMEGALOVIRUS

General

Cytomegalovirus (CMV), a DNA virus, is a member of the herpes family of viruses, which causes a number of infectious syndromes in humans. However, because CMV is highly efficient in remaining dormant or silent in the host, the most common manifestation of CMV infection in humans is the lack of demonstrable disease. Three disease states are particularly important: intrauterine and neonatal infection, heterophil-negative mononucleosis, and infection in the immunocompromised patient.

Diagnosis

Human CMV is readily grown in cell lines of human fibroblasts. In patients with symptoms suggestive of acute CMV infection, viral culture from urine, nasopharynx, or blood may document the presence of the organism. Direct immunofluorescence tests in combination with a limited culture can detect the virus more rapidly. More recently, nucleic acid amplification systems using polymerase chain reaction (PCR) techniques have been used to identify the virus in amniotic and other fluid samples.[1–3] High numbers of virus copies in the amniotic fluid can possibly signal a fetus at risk for severe CMV disease; however, this relationship needs further study. Tissue specimens (biopsy, necropsy) may also be evaluated for virus by immunofluorescence, in situ hybridization, or PCR techniques; these

specimens may also reveal the characteristic histologic changes associated with CMV infection.[4]

Because many previously infected patients excrete CMV intermittently throughout their lives depending on certain circumstances (e.g., pregnancy, AIDS), the presence of CMV in a specimen does not guarantee that the illness in question is caused by this particular virus. The physician must be extremely careful with the interpretation of these results.

Approximately 50% of reproductive age women have antibody to CMV. Thus, paired specimens are necessary, if seroconversion from negative to positive has not been documented. A significant rise in titer is usually consistent with a primary infection. Immunoglobulin M (IgM)-specific antibody is usually present 4 to 8 weeks after a primary infection but can increase periodically or persist at a low titer for years. IgM and less frequently IgA are of use in distinguishing transplacental transfer of maternal antibodies in the diagnosis of congenital infection.[5]

Serologic testing consists of the older complement fixation test or the more current indirect fluorescent antibody and anticomplement immunofluorescent tests. In a primary infection, these tests become positive sooner than the complement fixation test.[6] Enzyme immunoassay (EIA) methods also have been used to detect CMV-specific IgG, IgM, IgA, and IgE antibodies.[7] This is important because reactivation of latent CMV during pregnancy may not be accompanied by either an increase or reappearance of IgM antibodies (depending on the methodology used), which theoretically would help differentiate it from new infection.[8] Recently, more labor-intensive EIA assays have been used to detect low avidity IgG antibodies that are produced early in infection.[9–11] In a recent study, CMV immediate-early messenger RNA in maternal blood was detected only in cases of primary CMV infection and not in immune subjects; thus, EIA has been suggested to be helpful in differentiating primary from recurrent infection.[12]

Isolation of the virus or DNA from amniotic fluid and demonstration of viral DNA, immunologic response, or nonspecific markers in fetal blood collected by cordocentesis have all been used to supplement antenatal diagnosis.[13–16] A prospective evaluation of 1771 pregnant Belgian women by serial serology and culture of urine, saliva, and cervical secretions at each prenatal visit revealed a seronegative rate of 49%. Of this group, seroconversion occurred in 20 susceptible women (2.3%). Five of the seven who agreed to cordocentesis and amniocentesis had positive amniotic fluid cultures for CMV; three had a positive fetal IgM for CMV. The presence of CMV in fetal tissue was confirmed after termination, supporting the authors' contention that amniotic fluid culture is superior to fetal IgM in diagnosing fetal infection.[17] Others have reported either a lack of fetal CMV seropositivity for IgM in culture-positive fetuses or the failure of the fetus to sustain the IgM response. Thus, amniotic fluid culture or PCR analysis of amniotic fluid is superior to fetal CMV-specific IgM.[18,19] There have been a few reports of false-negative amniotic fluid cultures, as ascertained by neonatal shedding, but the relationship of these apparently negative results to the timing of infection and to long-term sequelae is unclear. Culture failure may be related to performance of amniocentesis too close to the time of initial maternal infection or too early in gestation; that is, before the fetal kidneys produce sufficient amounts of urine containing shedded virus.[20,21] The best results for detecting congenital CMV infection by testing amniotic fluid samples occur when amniocentesis is performed after 21 weeks' gestation and after an interval of at least 6 weeks from the first diagnosis of maternal infection.[22,23] Sensitivity to CMV can be enhanced using PCR or nested PCR assays.[9,24] Since all of these techniques can produce false-negative results, a negative diagnostic workup does not guarantee absence of infection.

Detection of specific IgM in the fetal blood has been found to be associated with severe CMV disease.[22] Some, but not all, infected fetuses have sonographic abnormalities (e.g., intracranial calcifications, growth restriction), anemia, thrombocytopenia, and elevated liver function test results.[13,25] The natural history of the disease was followed antenatally by serial ultrasound and cordocentesis in at least one reported case.[26] Hyperechoic bowel may precede development of ventriculomegaly, IUGR, non-immune hydrops, and fetal death in infected fetuses.[27] In a group of 50 pregnant women (51 fetuses) with primary CMV infection and confirmed in utero transmission, abnormal fetal ultrasound findings could be demonstrated in 22% (11 out of 51 fetuses). In the same study, however, 3 out of 16 newborns (19%) with normal ultrasound findings had neurologic abnormalities.[28] Thus, normal ultrasound findings in infected fetuses at 22 weeks' gestation can neither exclude an abnormal ultrasound later in pregnancy and the birth of a severely damaged child nor the birth of neonates afflicted by single manifestations at birth or later in life, of the kind not detectable by currently available ultrasonographic techniques.

Maternal and Fetal Risks

Approximately 10% of healthy adults infected with CMV for the first time may develop a syndrome of fever, atypical lymphocytosis, malaise, and mild lymphadenopathy, which generally follows a benign course. This illness is clinically indistinguishable from Epstein-Barr virus (EBV) mononucleosis, save that the heterophil-antibody test is negative in patients with CMV infection. Patients with CMV mononucleosis tend to be slightly older than patients with EBV infection. This syndrome is generally self-limiting, although the fever may last for over a month. Serious complications of the acute infection rarely occur, including interstitial pneumonitis, hepatitis, Guillain-Barré syndrome, meningoencephalitis, myocarditis, thrombocytopenia, and hemolytic anemia.[29] The virus may be excreted in tears, saliva, breast milk, cervical

secretions, and urine for weeks, months, or years after a primary infection. A latency period eventually occurs, but reinfection and reactivation are common.[30]

Cytomegalovirus infection in the immunosuppressed patient can be serious, depending on the type and degree of immunosuppression. Patients on immunosuppressive drugs because of organ transplantation or patients with AIDS most commonly exhibit the mononucleosis syndrome. The next most frequent manifestation is interstitial pneumonia, which may progress rapidly from asymptomatic to fatal disease (often in association with *Pneumocystis* infection in AIDS patients). A large percentage of persons suffering primary CMV infection exhibit hepatitis; severely immunosuppressed patients may develop clinical symptoms, including malaise, nausea, and vomiting. Gastrointestinal disease, including ulceration leading to hemorrhage and perforation, is another effect of CMV in the immunocompromised patient. The AIDS patient may suffer coexistent CMV infection with other infections such as cryptosporidiosis and *Mycobacterium avium-intracellulare*. In fact, endoscopic examination of the AIDS patient with colitis due to CMV may demonstrate lesions that resemble Kaposi's sarcoma. Finally, in the AIDS patient specifically, CMV infection of the eye may produce retinitis, typically noted in neonates with the disease, and miscellaneous effects on endocrine organs, including adrenals, pancreas, parathyroids, pituitary, and ovaries.[6]

Venereal spread of CMV is conceptually attributed to presence of virus in the semen and to cervical shedding. CMV has been isolated from semen of both homosexual and heterosexual men.[31] Heterosexual transmission has been demonstrated by outbreaks of CMV mononucleosis among populations of sexual partners.[32] Aside from the fact that differences in rates of cervical shedding are noted in different patient groups throughout the world, it is fairly clear that sexual activity, in particular higher numbers of sexual partners and earlier age at onset of sexual activity, is positively correlated with CMV isolation from the cervix.[33]

Whereas CMV is transmitted by such routes as transfused blood[34] and bone marrow,[35] a common route of acquisition is through perinatal transmission. The fetus may be infected either transplacentally or by exposure to the virus from the cervix and birth canal. The neonate may also be infected by virus excreted in breast milk.[36] Another source of childhood infection is exposure to other babies in nurseries and day-care centers,[37,38] since infected children tend to shed virus from the urine and respiratory tract for a prolonged time (unlike infected but otherwise healthy adults).

The rate of seropositivity varies by age and multiple demographic factors. The rate increases steadily after the first year or two of life. The prevalence is higher in underdeveloped countries[39] and in lower socioeconomic patient populations.[40] One study of over 21,000 women attending a prenatal clinic in London revealed marked variation by race (white, 46%; Asian, 88%; black, 77%), parity (increasing seropositivity with increasing parity),

and socioeconomic status.[41,42] Among most middle-income women in Alabama, 54% were seropositive, with whites having a lower rate than blacks.[40] The incidence of seroconversion in women of childbearing age approximates 2% in high socioeconomic groups and up to 6% in lower socioeconomic groups. The higher infection rate in young adults (hence mothers) does not necessarily lead to higher congenital infection rates.[43]

Primary infection occurs in 1% to 3% during pregnancy, with approximately 40% to 50% of women of childbearing age being serologically determined to be susceptible to such primary infection.[40,44] Serologic or culture evidence of in utero CMV infection is present in 0.2% to 2.2% of all liveborns. Thus, congenital CMV infection is a major health problem; CMV is still thought to be the most common congenital infection in the United States based on serologic study.[30,45,46]

Unlike other viral infections, CMV, on the basis of its latency and intermittent shedding from the female genital tract, may infect a fetus or neonate despite the presence of maternal antibody. Virus is shed from the cervix more readily as gestation progresses and occurs in approximately 0% to 2% of women in the first, 6% to 10% in the second, and 11% to 28% in the third trimester.[6] The infection rates at birth are higher in newborns whose mothers excrete virus. The most severe neonatal disease usually occurs in children born to women who experience primary infection during pregnancy. Vertical transmission of CMV occurs in 21% to 50% of fetuses following primary maternal infection.[22,23,47] A study of preconceptional and periconceptional primary CMV infection in 25 women identified a 9% risk for congenital fetal infection in the preconceptional group (1 out of 12 newborns) and a 31% risk in the periconceptional group (4 out of 13 newborns).[48]

Naturally acquired immunity results in a 69% reduction in the risk of congenital CMV infection in future pregnancies.[49] In addition, severe transplacental infection is not usually seen in children of women with preexisting antibody.[50]

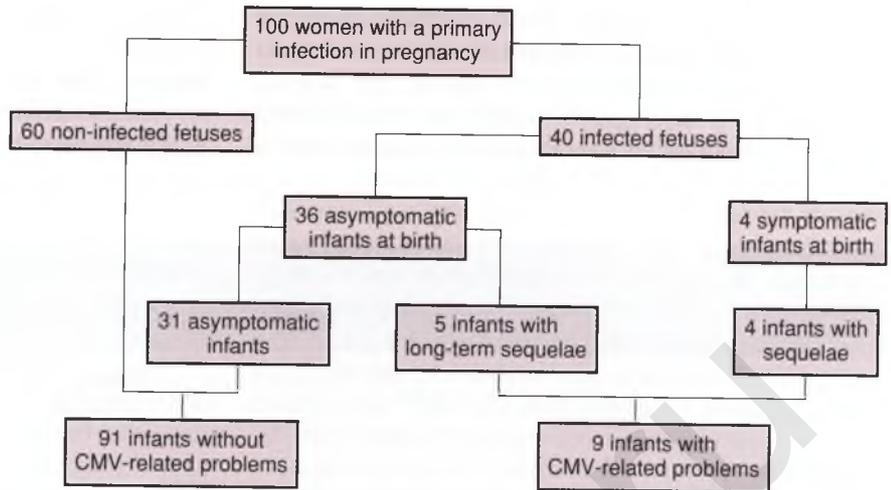
Cytomegalovirus is found in roughly 1% of all newborn infants. In the United States, this results in an estimated 33,000 infected newborns annually[29]; in the United Kingdom CMV causes much more neonatal disease than rubella.[45] Approximately 5% to 10% of infected newborns are clinically symptomatic at birth. This is one of the classic TORCH syndromes, consisting of hepatosplenomegaly, hyperbilirubinemia, petechiae, thrombocytopenia, intracranial calcifications, microcephaly, and often growth restriction. In primary infection, mortality may be as high as 20% to 30%, with 90% of survivors suffering late complications (Fig. 31–1) using "averaged" published data.[51] Of the asymptomatic infected neonates, 5% to 15% develop some abnormality attributable to CMV before their second birthday, primarily sensorineural hearing loss.[46,52] Vertical transmission may also occur in recurrent CMV infection[53]; however, the


FIGURE 31–1
Infant outcome following primary CMV maternal infection in pregnancy. (Adapted from Greenough A, Osborne J, Sutherland S [eds]: Congenital, Perinatal and Neonatal Infections. Edinburgh, Churchill Livingstone,1992, p 124.)

percentage of symptomatic children at birth or of those developing sequelae is much lower (Table 31–1).[54]

Cytomegalovirus is the most common cause of congenital sensorineural hearing loss, developing in 30% of neonates symptomatic at birth.[55] Hepatosplenomegaly is the most common clinical finding. Microcephaly, frequently associated with paraventricular cerebral calcifications, is also common.[56] Chorioretinitis, optic atrophy, mental and psychomotor delay, learning disabilities, and dental abnormalities are reported.

Management Options

Treatment of acute, symptomatic CMV infection in the immunocompetent normal individual is palliative. The vast majority of infections are asymptomatic; the remainder are mild. Currently, eradication of the virus is beyond the capacity of modern medicine. In the patient with compromised immunity, such as the transplant patient or the patient with AIDS, the antiviral drug ganciclovir provides temporary relief from such severe effects as retinitis.[6] To date, there is no accepted therapy for acute maternal or neonatal infection.[57]

There is progress in the development of a specific CMV vaccine,[58] although a number of real and theoretic obstacles remain.[59] Even though complete eradication of the virus may appear unlikely, antibody presence similar to that after primary human infection could reduce the rate of congenital fetal infection and its sequelae. Thus, an effective CMV vaccine will be a significant step forward. Passive immunization with specific anti-CMV immunoglobulins appears useful as prophylaxis only in cases of renal and marrow transplantation.[60] Thus, prevention of maternal infection is clearly the strategy to avert intrauterine infection. Three different areas offer potential to reduce the likelihood of maternal CMV infection in pregnancy: patient education, physician education, and vaccine development. CMV is typically spread by interpersonal contact with transmission of infected secretions from person to person, so, in particular, pregnant women working in high-risk situations (e.g., day-care centers) should be counseled to wash their hands carefully after changing diapers and after any contact with children's secretions (saliva, etc.).[57,61] Mouth-to-mouth kissing with children should be discouraged. Physicians need to be aware of the risk of transfusion-related CMV transmission.[62] Thus, when transfusing women of childbearing age who could potentially be or soon become pregnant, CMV-negative blood products should be used whenever possible. Any fetal transfusion in utero must use CMV-negative washed packed cells to avoid fetal CMV contamination. It is not appropriate, however, to screen all pregnant women either for anti-CMV IgG or viral excretion with the aim of isolating them for the duration of the pregnancy. The most reasonable course is to serologically screen all women in high risk areas (e.g., day-care workers) and recommend to susceptible individuals that they pay attention to hygiene measures. For prevention of CMV as well as other sexually transmitted diseases (STDs), all women with nonmonogamous relationships should be strongly encouraged to use condoms during sexual contact.[57]

TABLE 31–1

Sequelae in Children with Congenital Cytomegalovirus Infection According to Type of Maternal Infection

	PRIMARY	RECURRENT
Symptomatic disease at birth	24/132 (18%)	0/65 (0%)
Any sequelae	31/125 (25%)	5/64 (8%)
More than one sequela	7/125 (6%)	0/64 (0%)
Sensorineural hearing loss	18/120 (15%)	3/56 (5%)
Bilateral hearing loss	10/120 (8%)	0/56 (0%)
Microcephaly	6/125 (5%)	1/64 (2%)
Seizures	6/125 (5%)	0/64 (0%)
IQ <70	9/68 (13%)	0/32 (0%)
Death	3/125 (2%)	0/64 (0%)

From Fowler KB, Stagno S, Pass RF, et al.: The outcome of congenital cytomegalovirus infection in relation to maternal antibody status. N Engl J Med 1992;326:663–667.

No effective fetal therapy is yet available. Ganciclovir has been administered into the umbilical vein of a fetus at about 27 weeks. Dosage was 10 mg/day for 5 days, 15 mg/day for 3 days, and 20 mg/day for 4 days. Several episodes of bradycardia were noted after administration.

Although the viral load in amniotic fluid decreased dramatically over the time of treatment and liver function tests improved, a fetal demise was noted at 32 weeks.[63] Whether direct administration of antiviral agents to the fetus to treat CMV will be an acceptable treatment awaits more work.

SUMMARY OF MANAGEMENT OPTIONS
Cytomegalovirus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Advise women working in high risk environment (e.g., child care) about risks.	III	B	57, 61
Counsel pregnancy planning in women with history of proven CMV infection; establishing their "shedding status" may help.	–	GPP	–
Encourage use of condoms in nonmonogamous relationships.	IV	C	57
Use CMV-negative blood products in transfusions.	IV	C	62
Prenatal			
Advise women working in high risk environment (e.g., child care) about risks.	III	B	57, 61
Use CMV-negative blood products in transfusions.	IV	C	62
If patient is diagnosed to have CMV infection in pregnancy:	–	GPP	–
• offer careful counseling about fetal risks			
• consider invasive procedure to establish fetal risk			
• check fetal growth and health			
• consider pregnancy termination (if early gestational age)			
• no effective treatment, although acyclovir has been used in severe retinitis	IV	C	6
Labor, Delivery, and Postnatal			
If patient is diagnosed to have CMV infection in pregnancy:	–	GPP	–
• put infection control measures in place			
• conduct clinical and serologic evaluation of the newborn with pediatric follow-up if infection confirmed			

HERPES SIMPLEX VIRUS

General

The herpes simplex virus (HSV) is a DNA virus of the herpes family. HSV-1 has classically been considered the cause of orolabial herpes, referred to commonly as *fever blisters;* HSV-2 has been considered the cause of genital herpes infection, a well-known STD. Although these two types of HSV are generally thought to be segregated in this way, there is a great deal of overlap; that is, of HSV-2 causing oral disease and HSV-1 causing genital infection. In fact, up to a third of genital infections may be due to HSV-1. However, HSV-1 is somewhat less prone to produce recurrent infection than HSV-2. Generally, the two viruses may be considered identical in the clinical circumstance of a patient with characteristic ulcerative lesions.[64]

Diagnosis

Herpes simplex virus is relatively easy to culture; viral culture is the preferred test of genital HSV infection in patients who present with genital ulcers. The sensitivity of culture declines rapidly as lesions begin to heal, usually within a few days of onset. When more rapid diagnosis is desirable, fluorescent antibody (FA) staining performed

on short-incubation tissue culture slides allows identification within 48 hours, especially when the original specimen contains large numbers of virus. In high inocula situations, direct FA staining of the original specimen may give the diagnosis, though it is neither as sensitive nor as specific as tissue culture.[65,66] More recently, enzyme-linked immunosorbent assay (ELISA) tests directed toward virus antigens have been developed that provide rapid diagnosis of viral shedding, including asymptomatic shedding from the cervix, with reasonable sensitivity.[67,68] PCR assays for HSV DNA are highly sensitive and can be used to rapidly detect HSV DNA in pregnant women.[69]

Both type-specific and nonspecific antibodies to HSV develop during the first 6 to 8 weeks after infection and persist indefinitely. Antibodies can be detected using immunofluorescence, EIA, or immunoblot methods. Accurate type-specific assays must be based on the HSV-1 specific glycoprotein G1 for diagnosis of infection with HSV-1 and on the HSV-2 specific glycoprotein G2 for diagnosis of infection with HSV-2.[70] Sensitivity of serology tests vary between 80% and 90%, and false-negative results may occur, especially at early stages of infection. Specificity is >96%, and false-positive results can occur. Thus, repeat testing may be indicated in some settings. Type-specific serology in combination with HSV DNA testing by PCR might prove helpful in confirming a clinical diagnosis of genital herpes, especially in patients with healing sores or recurrent episodes of genital herpes when HSV culture provides false-negative results.[71] Clinical examination is likely to miss many cases of genital herpes,[72] and antepartum cultures may not accurately predict viral shedding at the time of delivery.[73] There are three stages of HSV infection based on clinical presentation and serology. Primary HSV infection is confirmed when no HSV-1 or HSV-2 IgG antibodies are present. In nonprimary first-episode disease, HSV-1 antibodies are present in the woman who has HSV-2 infection or HSV-2 antibodies are present in the woman who has HSV-1 infection. In recurrent infections, homologous antibodies are present.[74] Routine screening in the general population appears not to be cost-effective[75] and is not recommended.[70] However, identification of seronegative women provides the opportunity to properly address the risk of primary transmission during pregnancy and counsel serologically discordant couples, in particular.[76]

Maternal and Fetal Risks

Primary orolabial herpes is mainly a disease of childhood, children acquiring the infection from family members through close contact. Although 90% to 95% of primary oral infections are asymptomatic, a few may consist of a rather florid vesiculoulcerative outbreak in the oropharynx and lips about a week after exposure. Adenopathy and viremia, along with fever and malaise, may persist for a week or two, with viral shedding for up to 6 weeks. Thereafter, antibody production limits the virus such that it remains dormant, occasionally flaring up as localized blisters on the lips in times of stress, sunburn, or febrile systemic illness (hence the term *fever blisters*). During recurrent disease, viral shedding lasts up to a week.[77] HSV-1 infection is common in children, whereas HSV-2 is more common in sexually active adolescents and adults. Epidemiologic studies are hampered by the fact the two viruses cross-react in a number of serologic tests used. Confounding this technical difficulty is the latency of the virus. As a result, patients who have been infected and who may be infectious are for the most part asymptomatic. It should be noted that adults with recurrent oral herpes may transmit the illness through orogenital contact, causing infections typically thought to arise from sexual contact.

Genital herpes may occur after sexual contact, either genital-genital or orogenital, with an infected person. The incubation period is less than a week. Persons transmitting the virus may be asymptomatic themselves,[78] confusing identification of the origin of the infection. In one study, 10% of pregnant women were at risk of contracting primary HSV-2 infection from their HSV-2 seropositive husbands.[76] Subclinical cervical and vulvar shedding following a primary HSV infection occurs in 2.3% of women with HSV-2 infection and 0.65% with HSV-1 infection.[79] If the infected person possesses preexisting anti-HSV antibody, perhaps from HSV-1 infection acquired early in life, there are fewer constitutional symptoms, lesions, and complications, and the duration of the lesions and the time of viral shedding are reduced.[64] In the absence of circulating antibody, primary HSV genital infection can be severe, with symptoms of fever, malaise, myalgias, and aseptic meningitis. HSV encephalitis[80] and hepatitis[81] have proven fatal. Lower motor neuron and autonomic dysfunction may lead to bladder atony and urine retention. Extragenital lesions are present in a quarter of women with primary disease, possibly by autoinoculation rather than viremia. Increased viral shedding occurs for nearly 3 weeks in severe cases. Local disease may recur weeks or months later if the offending virus is HSV-2, in particular, which recurs much more frequently than does HSV-1, especially in the genital area.[82]

Genital herpes infection is common in the United States, with 45 million people ages 12 and older, or one out of five of the total adolescent and adult population, infected with HSV-2.[83] Since the late 1970s, the number of people in the United States with genital herpes infection has increased by 30%. HSV-2 infection is more common in women (approximately 1 out of 4) than in men (almost 1 out of 5), and more in blacks (45.9%) than in whites (17.6%). The largest increase is now occurring in young white teens. HSV-2 infection is now five times more common in 12- to 19-year-old whites, and it is twice as common in young adults ages 20 to 29 than it was 20 years ago.[83] Among sexual partners discordant for HSV infection, the annual risk of acquisition of genital HSV infection was 31.9% among women who were both HSV-1 and HSV-2 negative ver-

sus 9.1% among women who were HSV-1 positive.[84] Approximately 1.6 million new HSV-2 infections are acquired yearly, and approximately 2% of women seroconvert to HSV-2 during pregnancy.[85,86]

Herpes simplex virus infection during pregnancy has two important components: primary infection of the mother and transmission of infection (either primary or recurrent) to the fetus/neonate and subsequent disseminated infection. Because of the relative immunosuppression during pregnancy,[87] dissemination of HSV may lead to death from hepatitis, encephalitis, and general viral dissemination.[88] Primary infection early in pregnancy, perhaps due to a viral endometritis ascending from cervical infection, may end in spontaneous abortion. However, there are no consistent reports of a congenital syndrome due to intrauterine infection with HSV. The spectrum of fetal/neonatal infection includes abortion, prematurity, and intrapartum infection with resultant disseminated HSV infection.[89] Primary HSV infection in the second or third trimesters increases the risk for preterm delivery as well as the risk of virus transmission to the newborn.[90] The fetus acquiring HSV, especially if the mother suffers an acute, primary infection, may sustain severe neonatal morbidity, including chorioretinitis, meningitis, encephalitis, mental retardation, seizures, and death.[91]

Nonspecific tests for HSV (i.e., not differentiating between HSV-1 and HSV-2) demonstrate 90% seropositivity by the fourth decade of life.[92] Over the past decade or two, industrialized countries have reported a decrease in seropositivity rates of HSV-1, due perhaps to increasing sanitation measures, and increasing rates of HSV-2, due to increasingly permissive sexual behavior.[93] The rates of clinical genital HSV infection have risen dramatically since the 1960s in the United States,[94] United Kingdom, and other parts of Europe.[93]

The incidence of a positive culture in laboring women is 0.5% in the general population.[95] Rates of 0.96%[73] to 2.4%[96] have been reported in asymptomatic women with known histories of genital HSV infection. The rate of neonatal disease is in the range of 0.01% to 0.05%. The variability is due to differences in maternal antibody (and thus passively acquired fetal antibody) levels and the size of the viral inoculum (i.e., primary, severe infection versus mild, recurrent infection in the mother). The majority of infants developing neonatal HSV infection are born to mothers without symptoms or even a history of genital herpes infection and who test seronegative for specific HSV antibodies.[73,95,97] In Seattle, a prospective study was conducted in a cohort of 58,362 pregnant women, of whom 40,023 had genital HSV cultures at the time of labor and 31,663 had HSV specific serology; 202 women (0.5%) had a positive HSV culture, of whom 10 (5%) had neonates with HSV infection.[95] Women without a history of genital herpes were more likely to shed HSV subclinically than women with such a history. However, women with a history of genital herpes were more likely to have cesarean deliveries. The rate of vertical HSV transmission was 31.3% (5/16) in HSV-1 cul-

ture-positive mothers, and 2.7% (5/186) in HSV-2 positive mothers. Neonatal HSV infection rates per 100,000 live births were 54 among HSV-seronegative women, 26 among women who were HSV-1 seropositive only, and 22 among all HSV-2 seropositive women. Thus, the highest rate of neonatal HSV infection occurred in women who were seronegative and had no specific HSV antibodies. Heterologous antibody in this study did not seem to protect against transmission for primary versus nonprimary first-episode as, in contrast, did homologous antibody. The results emphasize the need for counseling seronegative women, in particular, to reduce the risk of neonatal HSV infection.

Most neonatal HSV infection is the consequence of delivery of a neonate through an infected birth canal. Most infants have localized skin, eye, and mouth disease, which usually is a mild illness. However, localized disease may progress to encephalitis or disseminated disease. Disseminated disease is associated with a 57% mortality rate, and CNS disease has 15% mortality; localized disease shows no mortality.[98] In a group of 202 women from whom HSV was isolated, HSV transmission occured in 9 out of 117 (7.7%) infants after vaginal delivery, and in 1 out of 85 (1.2%) newborns delivered by cesarean section.[95] Thus, cesarean section could reduce the rate of HSV transmission from mother to infant, but cannot completely prevent HSV infection in the newborn.

Management Options

Prepregnancy

The consistent, correct use of latex condoms can help protect against infection, particularly in women.[99] However, condoms do not provide complete protection because the condom may not cover the herpes sore(s) and viral shedding may nevertheless occur, which makes this STD difficult to prevent. In case of symptomatic genital herpes, it is best to abstain from sex and to use latex condoms between outbreaks. Pivotal efficacy trials of an experimental vaccine to prevent genital herpes indicated that the vaccine was effective in more than 70% of HSV-1 and HSV-2 seronegative women whose sexual partners were known to be infected.[100] However, for reasons not identified, it had no efficacy in men.

Prenatal

It is important that women avoid contracting herpes during pregnancy because a primary infection during pregnancy causes a greater risk of transmission to the newborn. All pregnant women should be asked whether they have a history of genital herpes. Women without known genital herpes should be counseled to avoid intercourse during the third trimester, in particular, with partners known or suspected of having genital herpes. In addition, women with no history of orolabial herpes should be advised to avoid cunnilingus during the third trimester with partners known or suspected to have oro-

labial herpes.[70] In case a women's sex partner has a history of HSV infection, serologic testing for HSV-1 and HSV-2 antibodies might prove to be helpful to identify and consequently counsel seronegative women at risk for primary HSV infection during pregnancy. Pregnant women with a significant primary HSV infection should be hospitalized and monitored closely for evidence of sequelae. Premature labor should be appropriately treated when necessary. Evidence of severe, disseminated disease such as hepatitis (elevated hepatic transaminase levels) and encephalitis (abnormal neurologic testing) should trigger the administration of intravenous acyclovir to prevent serious morbidity.[88] Treatment of primary genital herpes with oral acyclovir reduces viral shedding, reduces pain, and heals lesions faster.[101] Different studies have demonstrated that the use of acyclovir is safe during pregnancy and does not impose an increased risk to the developing fetus during the first trimester.[101,102] A first clinical episode of genital herpes may be effectively treated by oral acyclovir, 200 mg five times a day (or 400 mg three times a day) for 7 to 14 days, or until clinical resolution.[70,103] Recurrent HSV infection may be treated with the same dosage of oral acyclovir as in primary infection for 5 days.[103] Daily suppressive oral acyclovir (400 mg twice a day) has demonstrated significant reduction of symptomatic recurrences and subclinical virus shedding.[104,105] No induction of acyclovir-resistant HSV strains was noted in immunocompetent patients.[106] However, the extent to which suppressive therapy prevents HSV transmission to the infant is unknown.[70] In severe HSV disease, intravenous acyclovir is given at 5 to 10 mg/kg bodyweight every 8 hours for 2 to 7 days or until clinical improvement is observed. Oral acyclovir therapy should follow to complete at least 10 days total therapy.[70] Oral or intravenously administered acyclovir reaches therapeutic concentrations in the breast milk, the amniotic fluid, and the fetus.[107] Topical treatment with acyclovir offers minimal clinical benefit and is not recommended.[70] Newer antiherpetic drugs, valacyclovir and famciclovir, demonstrate increased bioavailability over acyclovir and thus require less frequent dosing. In the treatment of a first clinical episode of genital herpes valacyclovir is effective at 1000 mg orally twice a day for 7 to 14 days, and famciclovir at 250 mg three times a day for the same period.[103,108] Recurrent episodes of genital herpes may be treated orally with either valacyclovir (500 mg twice a day for 3–5 days) or famciclovir (125 mg twice a day for 5 days). Suppressive therapy requires oral valacyclovir at 500 mg once a day (9 or fewer recurrences per year) or 1000 mg once a day (>9 recurrences per year). Famciclovir is efficient in suppressive therapy at 250 mg twice a day. However, experience with prenatal exposure to valacyclovir and famciclovir is too limited to provide sufficient information on pregnancy outcome.

The management of pregnancy in the woman with active or historic herpes is aimed at preventing neonatal infection and subsequent dissemination. It was previously recommended that such women have weekly genital cultures for HSV in the latter weeks of pregnancy and be delivered abdominally if the most recent culture was positive.[109] However, it is now recognized that there is little correlation between prenatal HSV shedding and shedding at delivery,[73] and that most women whose infants develop HSV infection have no lesions or history.[73,97] Thus, weekly cultures are no longer recommended.[70]

Labor and Delivery

On admission to the delivery suite, all women should be questioned carefully about symptoms of genital herpes, and all women should be examined carefully for herpetic lesions.[70] In the absence of visible lesions in the genital area at the onset of labor vaginal delivery is permitted. If active genital lesions or prodromal symptoms of vulvar pain or burning (which may indicate an impending outbreak) are present, cesarean delivery is indicated. The incidence of infection in newborns whose mothers have recurrent infection is low, but cesarean delivery is warranted because of the serious nature of the disease.

The extent to which maternal antibodies will protect a neonate from an infection during a recurrence has not been determined with certainty. Cesarean delivery is not recommended in women with a history of HSV infection, but no active lesions, during labor.[70,103]

In women with premature rupture of membranes (PROM) near term and active HSV infection, cesarean delivery should be performed as soon as possible. It should not, however, be assumed the fetus is infected just because of prolonged rupture of membranes. Women with preterm PROM and active lesions are considered individually, taking into account gestational age and other relevant factors. Remote from term, expectant management and use of glucocorticoids is increasingly supported, and antiviral therapy is indicated because premature neonates are at greatest risk of infection.[103]

Lastly, fetal HSV infection has been attributed to the use of fetal scalp electrodes even in the absence of active lesions.[95,110] Thus, fetal scalp monitoring should be used cautiously even in women with a history of recurrent HSV and no active lesions. In case vesicular lesions develop at the site of the electrode, quick, accurate diagnosis should be followed immediately by the start of systemic antiviral therapy in the neonate.[103]

Postnatal

Postpartum, endometritis due to HSV infection has been reported,[111] and is responsive to acyclovir. Postnatally acquired HSV infections in the newborn can be severe, and mothers with skin or oropharyngeal lesions should use caution when handling their babies. HSV-1 is more likely to cause nosocomial infections in the infant than is HSV-2. Breast-feeding is unlikely to cause infection in the infant; only in the case of an obvious lesion on the breast is breast-feeding contraindicated.[103]

Herpes Simplex Virus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy and Prenatal			
Inform about nature of the disease and that sexual transmission can occur during asymptomatic periods; counsel about condom protection during asymptomatic intervals and sexual abstinence during active disease.	IV	C	70, 99
Perform HSV-type specific serology testing; allows more specific advice by identifying seronegative women at risk for HSV acquisition.	IV	C	70
• Advise HSV-2 negative women to abstain from intercourse during third trimester with men who have genital herpes.			
• Advise HSV-1 negative women to avoid intercourse with a partner who has genital HSV-1 infection; no cunnilingus with a partner who has orolabial herpes.			
Vaccine being developed; not available for clinical use.	Ib	A	100
Provide symptomatic treatment of infections (primary and recurrent); hospitalize for severe cases.	–	GPP	–
Give acyclovir for active disease:			
• Oral (7-14d) for primary local infection	Ib	A	101
• IV (for 2-7d then oral) for primary systemic disease	IV	C	88
• Oral (5d) for recurrent disease	III	B	103
Provide prophylactic acyclovir (400 mg bid) for last trimester in patients with previous HSV to reduce recurrence risk (no known effect on fetal/neonatal transmission).	Ib	A	104, 105
No information about newer anti-HSV drugs; not recommended for pregnancy.	–	GPP	–
Remain vigilant for dissemination.	–	GPP	–
Remain vigilant for preterm uterine activity.	–	GPP	–
Serial viral cultures are no longer recommended in the last trimester for patients who are asymptomatic; culture only to document a new case.	IV	C	70
Consider delivery with septicemic cases.	–	GPP	–
Labor and Delivery			
Enquire and inspect perineum, vagina, and cervix for HSV in all women at onset of labor (especially those with history of HSV).	IV	C	70
Allow vaginal delivery if no active lesions and no prodromal symptoms at time of labor.	–	GPP	–
Active lesions at time of labor is considered an indication for cesarean section by most obstetricians, though the risk of fetal infection is less with recurrent disease.	–	GPP	–
Counseling about the benefits of cesarean section in preventing fetal infection with membrane rupture is controversial, although most would still advise cesarean section. Expectant approach with suspected preterm labor and PROM is reasonable.	–	GPP	–
Avoid fetal electrodes and fetal scalp sampling.	Ib	A	95, 110
Postnatal			
Maintain infection control measures if mother has active lesions.	–	GPP	–
Treat maternal infection; reduces dissemination and morbidity.	III	B	103
Perform clinical, microbiologic, and serologic evaluation of the newborn if active maternal lesions are present.	–	GPP	–
Give IV acyclovir to HSV-infected newborns.	III	B	103

ADENOVIRUS

General

Adenoviruses are medium-sized (90 to 100 nm) double-stranded DNA viruses. There are 6 subgenera (A through F) with 49 immunologically distinct types that can cause infection in the human. Most commonly, in the healthy adult adenovirus infection causes gastrointestinal and respiratory tract illness with a wide range of symptoms.

In recent years, there has been considerable interest in developing adenoviruses as defective vectors to deliver and express foreign genes for therapeutic purposes.[112–114] Adenovirus is relatively easy to manipulate in vitro and the coupled genes are effectively expressed in large amounts. Direct administration of adenovirus gene vectors to the fetus can be achieved by fetoscopy or ultrasonographic guidance.[115,116] However, repeated prenatal exposure to an adenovirus vector was associated with pulmonary inflammation as reported in newborn sheep.[117] Alternatively, selective placental and maternal intravenous adenovirus vector application has demonstrated only low numbers of adenovirus replication in the fetus, thus reducing the risk of fetal exposure to the virus.[118] In addition, intraplacental adenovirus-mediated gene delivery showed only low numbers of virus in the mother, thus possibly providing a suitable strategy for basic studies of placental function or even a method of correcting placental dysfunctions in the future.

Diagnosis

Conventional virus culture, electronmicroscopy and serology tests,[119,120] and modern laboratory techniques such as antigen detection by immunofluorescence tests[121] and PCR assay[16] are all suitable means to identify adenovirus disease. Adenovirus typing requires the use of type-specific antisera in hemagglutination-inhibition and/or neutralization tests.[119,120] Adenovirus infection in tissues or cell smears can be identified using in situ hybridization technique.[122] The presence of adenovirus does not necessarily mean disease because viruses can be shed for a prolonged time. Adenovirus genome could be identified in amniotic fluid of 30 out of 91 (33%) fetuses with ultrasound evidence of nonimmune hydrops. However, concomitant infection with parvovirus, cytomegalovirus (CMV), enterovirus, HSV, and respiratory syncytial virus was found in the majority of cases by PCR technique.[16]

Maternal and Fetal Risks

In healthy adults, adenoviruses commonly cause respiratory illness with symptoms that range from the common cold to pneumonia, croup, and bronchitis. However, depending on the serotype or route of infection (inhala-

tion or ingestion), adenoviruses might cause febrile disease and keratoconjunctivitis, rash illness, gastroenteritis, or cystitis. Immunocompromised patients are susceptible to severe complications of adenovirus infections.

Transmission is by direct contact and the fecal-oral route. Adenoviruses are unusually stable in adverse conditions. Occasionally, waterborne transmission occurs, often centering around swimming pools and small lakes. Infection is usually acquired during childhood and at a higher incidence in late winter, spring, and early summer. Depending on the serotype, adenovirus infection can persist in either the tonsils, adenoids, or intestines of infected patients. Virus shedding can continue for years. Adenovirus types 40 and 41 are known to cause gastroenteritis, primarily in children. Inhalation of adenovirus type 7 is known to cause severe lower respiratory tract infection, and acute respiratory disease is most often associated with types 4 and 7.[119,120]

Adenovirus infection of the infant might occur transplacentally or at delivery via birth canal or contact with feces.

Amniotic fluid obtained from 303 pregnancies with abnormal ultrasound findings tested positive for adenovirus infection in 124 cases (41%).[16] PCR technique could demonstrate adenovirus to be the only viral genome present in the amniotic fluid of oligohydramnios in 18% (2/11; 2 additional patients positive for CMV), hydrothorax/pleural effusion in 22% (4/18; 2 additional patients positive for enterovirus and CMV), ventriculomegaly in 23% (6/26; 1 additional patient positive for CMV), microcephaly in 20% (1/5), and echogenic bowel in 5% (1/22; 5 additional patients positive for CMV and HSV). In the control group of 154 structurally normal fetuses, viral infection of the amniotic fluid was detected in 4 cases (3%), and adenovirus was the only microorganism in 2% (3/154; 1 additional patient positive for CMV). Intrauterine adenovirus infection might cause fetal myocarditis with tachyarrhythmia, dilated cardiac chambers, poor ventricular function, and subsequent hydrops fetalis.[123,124]

Severe neonatal adenovirus illness is rare, but is most often manifested as necrotizing pneumonitis.[121,122,125,126] Within 10 days of birth, infected infants demonstrate rapidly progressing pneumonia, thrombocytopenia, disseminated intravascular coagulopathy, hepatomegaly, and hepatitis. Respiratory failure might require extracorporeal membrane oxygenation in the newborn.[127] Case fatality might be as high as 84% and death often occurs around day 16.[125,128,129] Neonatal infection may also be seen in epidemic proportions in neonatal nurseries.[130] Severity of the disease in newborns seems to be less pronounced in the presence of maternal antibodies.

Management Options

Prepregnancy and Prenatal

To date, there is no specific therapy available for adenovirus infections in pregnancy or for the infected

newborn, although new antiviral drugs (cidofovir, ribavirin) show promising results in pediatric patients.[131,132] Thus, the best treatment of adenovirus infection is prevention. Women should be counseled on proper hygiene measures to avoid fecal-oral transmission. Also, inadequately chlorinated swimming pools should be avoided. Most infections are mild and require no therapy.

Severe adenovirus infection can be managed only by treatment of symptoms and complications. Fetal tachyarrythmia and associated fetal hydrops may be treated by maternal oral digoxin. Maternal therapy with oral digoxin at 0.5 mg loading, and 0.125 to 0.25 mg/day maintenance dose has shown to convert fetal tachyarrhythmia to normal sinus rhythm and to produce spon-

taneous resolution of hydrops. Transplacental transfer ratio of digoxin is at an estimated rate of 60% to 100%. Maternal digoxin levels or persistent fetal tachyarrhythmia might require adjustment of the daily administered digoxin dosage. Vaccines for adenovirus types 4 and 7 were developed for military use only. Risk to the general population is so low that vaccination is not a viable proposition.

Labor, Delivery, and Postnatal

Strict attention to good infection control practices is effective in stopping nosocomial outbreaks of adenovirus disease, such as epidemic keratoconjunctivitis.

Severe pneumonitis in the newborn might require extracorporeal oxygenation.	–	GPP	–

COXSACKIEVIRUS

General

Coxsackievirus is a single-strand RNA virus, a member of the picornaviridae, which includes human enteroviruses and rhinoviruses. The enterovirus serotypes are determined by type-specific antisera and are traditionally grouped into four classes: poliovirus, group A coxsackievirus, group B coxsackievirus, and echovirus. Newly discovered serotypes are assigned enteroviral numbers (e.g., hepatitis A virus: enterovirus 72).

In northern latitudes enterovirus infections are more firmly associated with a seasonal periodicity (pronounced

in summer and fall) than can be observed in more tropical climates. However, infections may occur at any time of the year. Group B coxsackievirus serotypes 2 to 5 are isolated more frequently, whereas other serotypes are rarely reported. Group A coxsackievirus infections have been identified less frequently, possibly due to poor growth in routine cell culture.

Enteroviruses are transmitted by direct contact with nose and throat discharge or feces of infected humans. Because many infections are clinically inapparent, spread of coxsackievirus infection may occur accidentally; the incubation period is 3 to 5 days (range, 2 to 15 days).[133]

In healthy, nonpregnant adults, enterovirus infections are either asymptomatic or cause simple febrile illness with

or without signs of upper respiratory tract infection or rash. However, some clinical syndromes are characteristically associated with enterovirus infection, including aseptic meningitis, pleurodynia, and the hand-foot-and-mouth disease. The rate of infection is higher in young children than among older children and adults.

Diagnosis

Coxsackievirus infection can be identified by virus culture from the oropharynx, stool, blood, urine, cerebrospinal fluid, and amniotic fluid. After virus isolation by culture, virus typing is performed by conventional neutralization tests. More rapid specific virus identification techniques using immunofluorescence assay (IFA) or ELISA have not proven to be useful because of the large number of different serotypes.[134] However, development of monoclonal group-specific antibodies that can be used for rapid identification of enterovirus groups by IFA and ELISA is in progress.[135–137] Modern laboratory methods provide accurate and fast diagnosis of coxsackievirus infection by PCR technique.[16,138] In addition, PCR seems to be more suitable for detection of Group A coxsackievirus that grows poorly in culture, which has led to a possible clinical underrecognition of this virus as a cause of disease.

Serology using hemagglutination-inhibition, complement fixation, and ELISA tests can readily identify IgG, IgM, IgA, and IgE classes of specific antibodies; however, the large number of different enterovirus type-specific antigens require the performance of large numbers of serologic tests. Recently, gene-sequencing technology has identified a common epitope in a number of enteroviruses, which might prove to be helpful for serology tests in the future.[137] When case serology is performed, paired specimens should be obtained to ensure proper diagnosis.

Tissue samples can be examined for specific enteroviral antigens by immunofluorescence or PCR technique.[139]

Maternal and Fetal Risks

The prevalence of enterovirus infection is inversely related to socioeconomic status and age, whereas individual factors, including age, sex, immune status, and pregnancy, are important determinants of the severity of infection.[140]

In pregnancy, most maternal coxsackievirus infections are either inapparent or cause only minimal symptoms similar to a viral upper respiratory tract infection or viral gastroenteritis[141]; however, hepatic failure has been reported.[142] The exact incidence of coxsackievirus infections in pregnancy is not known. There is no direct virologic evidence available that suggests that coxsackievirus infections in pregnancy may result in miscarriage.[134] However, an increased frequency of coxsackievirus IgM in women with spontaneous abortion has been

reported.[143] In a collaborative study serologic evidence of coxsackievirus B (types 1 to 6) infection during pregnancy was demonstrated in 9% of 198 women[144]; during peak enterovirus season a seroconversion rate of 25% was noted during the last 2 to 6 weeks of pregnancy among 55 women.[145] Most women were either asymptomatic or had only mild symptoms, and no newborn had signs of severe enterovirus infection. The incidence of neonatal coxsackievirus B infection, based on laboratory records, was estimated at a minimum of 50 per 100,000 liveborn children.[146] Thus, enterovirus infection during late pregnancy might be a rather common event; however, most infections did not produce a significant maternal or neonatal morbidity. Alternatively, in women delivering newborns with evidence of group B coxsackievirus infection, 59% to 65% had symptomatic illness during the perinatal period with febrile disease and upper respiratory symptoms, pleurodynia, myocarditis, and aseptic meningitis.[140,146]

In animal studies, pregnant mice experimentally infected with different strains of enterovirus have a shorter incubation period, develop higher titers in blood and various organs, and remain viremic longer. Susceptibility increases with advancing gestation and rapidly reverts to that of nonpregnant animals within days of delivery. In nonpregnant female mice, administration of corticosterone or estrogen reduced the resistance to encephalomyocarditis virus infection, but this resistance was not altered by exogenous progesterone. Group B coxsackievirus infection of the pregnant mouse may also result in infection of the fetus before delivery or in infection of the mouse intrapartum.[140]

In humans, in vitro experiments demonstrated that vertical infection from mother to fetus rarely happens through transplacental passage.[147] However, 22% to 25% of neonatal group B coxsackievirus infections have been attributed to antepartal transmission.[141,146] The mechanisms of intrauterine coxsackievirus infection are poorly understood. Evidence of congenital disease is inconsistently related to recovery of virus from the placenta and the respective fetus,[134,145,148] and it is assumed that besides hematogeneous transmission involving the placenta, a number of fetuses might be infected by ingesting coxsackievirus contained in the amniotic fluid.[149] Transplacental infection of the fetus occurs in the absence of maternal immunity and is unrelated to the clinical severity of the disease in the mother. Viral shedding from the cervix has been reported; however, ascending viral infection seems to be a rare event.[150] At the time of delivery infection of the infant might occur by cervical or fecal contamination. Fecal carriage rates of coxsackievirus was reported to range from 0% to more than 6% in different population groups.[134,145]

In a study of 630 infants with 778 anomalies of different organ systems, intrauterine infection with coxsackievirus B2 and B4 was associated with urogenital anomalies, and coxsackievirus B3 and B4 with cardiovas-

cular anomalies. The likelihood of congenital heart disease was increased by maternal infection with two or more coxsackievirus B serotypes rather than one. Also, first-trimester infection with coxsackievirus B4 occurred more frequently in mothers of infants with any anomaly than in the control group.[151] In 28 newborns with severe congenital defects of the central nervous system, neutralizing antibody to coxsackievirus B6 was demonstrated in 4 cases (14%); 2 had hydranencephaly, 1 had occipital meningocele, and 1 had aqueductal stenosis.[152] In a stillborn infant with calcific pancarditis and hydrops fetalis, coxsackievirus B3 antigen could be demonstrated.[148]

Newborns who acquire coxsackievirus infection in the immediate peripartum period are more likely to experience severe disease in the absence of protecting maternal antibodies. Neonatal infection might range from asymptomatic viral shedding to severe and rapidly fatal illness. Infection that occurs more than 5 days before delivery is likely to induce production of maternal IgG that can cross the placenta and protect the newborn from severe disease, but not necessarily from infection. In the newborn coxsackievirus infection may cause benign neonatal arrhythmias,[153] fever,[146] oral vesicular lesions,[154] vesiculopapular rash,[155] severe respiratory failure,[156] pneumonitis,[141] fatal pulmonary hemorrhage,[146,157] hepatitis, hepatomegaly, jaundice, bleeding diatheses, hepatic failure and necrosis,[134,146] aseptic meningitis,[146] meningoencephalitis, fatal encephalomyocarditis and encephalohepatomyocarditis,[141,158] acute aseptic and interstitial myocarditis,[159] and result in heart disease.[160] A study of 16 neonates with enterovirus hepatitis and coagulopathy demonstrated hemorrhagic complications in 10 out of 16 cases (63%); 5 infants had intracranial bleeding.[161] The overall fatality rate was 31% (5/16). In the group of 5 neonates with intracranial bleeding, 4 (80%) died. Overall, mortality rates are highest in children with myocarditis, encephalitis, or sepsis-like illness with liver involvement. In addition, prognosis seems to be related to the infecting viral strain. In general, infection with coxsackievirus B1 to B4 seems to carry the most ominous prognoses. Long-term sequelae are mostly reported with regard to heart and CNS-related impairment. Animal studies of coxsackievirus myocarditis demonstrated a T cell-mediated immunopathic process and a virus-induced autoimmunity. In a study of 7 newborn infants with neurodevelopmental delays, coxsackievirus was retrieved from the respective placenta in 6 of the 7 cases (86%).[156] A 28-year follow-up study of 145 patients, particularly those with coxsackievirus B5 CNS infection during childhood, demonstrated an increased risk for adult onset of schizophrenia or other psychoses.[162] In a group of 15 children who had meningoencephalitis due to coxsackievirus B5, 2 were reported to have developed spasticity, and their intelligence was low.[163] Epidemiologic and serologic studies suggest a role for intrauterine coxsackievirus infection for the onset of insulin-dependent diabetes mellitus in childhood (IDDM).[164–166] However,

conflicting serologic data exist that do not indicate an association of coxsackievirus infections during pregnancy with the development of islet autoantibodies; these results do not support a major role of fetal coxsackievirus infection in the development of IDDM.[167,168]

Infection with coxsackievirus A in neonates has been reported less frequently than with coxsackievirus B. Coxsackievirus A infection has been associated with small-for-gestational-age newborns,[141] sudden infant death,[169–171] anorexia, fever, bronchopneumonia, pericarditis and meningitis.[134]

A number of reports have confirmed that coxsackieviruses may be responsible for outbreaks of apparent infections with fatalities among neonates in obstetrical wards and maternity homes.[172–174] Most commonly, mild nonspecific febrile illness is observed in full-term infants. A careful history frequently reveals a trivial illness in a family member. Feeding difficulties are frequently observed, and short periods of vomiting and diarrhea may occur. The most consistent source of original nursery infection is coxsackievirus transmission from mother to her child, but introduction of the virus into the nursery by personnel also occurs. After infection of the pharynx and lower alimentary tract, minor viremia with spread to regional lymph nodes and secondary infection sites (CNS, heart, liver, pancreas, respiratory tract, skin) occurs on the third day. Major viremia ceases with the appearance of antibodies on day 7. Infection can continue in the lower intestinal tract for prolonged periods, and isolation measures are warranted.[134]

Management Options

Prenatal, Labor, and Delivery

Coxsackievirus infections during late pregnancy seem to be a common event, in particular during late summer and early autumn in temperate climates. Epidemics in the region may be signaled by the occurrence of aseptic meningitis, pleurodynia, or Bornholm disease (myalgia epidemica). Unseasonal respiratory tract infection or symptoms of fever, muscle pain, neck stiffness, skin rashes, and vesicular lesions (mouth, hand, foot) are suggestive of an enteroviral infection. Ultrasound examination in some cases may reveal an enlarged fetal heart with dilated chambers and unusually thick myocardium. Fetal arrythmias and congestive heart failure in combination with nonimmune hydrops may be treated by maternal digoxin (oral digoxin at 0.5 mg loading, and 0.125 to 0.25 mg/day maintenance dose). Conversion of fetal arrhythmia to normal sinus rhythm and, consequently, spontaneous resolution of hydrops may be observed. If a woman is suspected of having an acute coxsackievirus infection, she is a potential risk for transmitting coxsackievirus in the obstetrical wards. Isolation measures for delivery, newborn care, and postpartum care are warranted.[134] Coxsackievirus infection in the

adult usually takes a benign course. If delivery occurs within 4 days of maternal infection, the newborn is at risk for severe disease.

Postnatal

No specific therapy is available to treat coxsackievirus infection in the newborn. Commercially available immune serum globulin contains titers of antibodies to coxsackievirus; however, no beneficial clinical effect has been observed when administered to an infected infant.[175,176] However, viremia and viruria ceased earlier in treated infants than in the control group. Recent studies with new antiviral drugs (e.g., pleconaril) seem promising.[177]

In most cases, transmission of coxsackievirus occurs by direct contact from mother or staff members to the new-born or by mouth and gavage feeding. Coxsackievirus B and echoviruses have been recovered from specimens obtained from nurses and physicians caring for infected patients.[174] Rigorous attention to hygienic measures and handwashing after handling each baby are imperative to avoid the transmission of enteroviruses. Infected new-borns should be isolated, and closure on the neonatal unit to new admissions has been advocated.[134]

In sudden and virulent nursery outbreaks passive immunization by intramuscular or intravenous immunoglobulin can be useful in preventing disease.[175,178]

A vaccine to prevent coxsackievirus infection is not available. However, an experimental attenuated vaccine has been developed.[179] Because of the considerable morbidity and mortality associated with coxsackievirus B infection in neonates (and in older persons as well), these agents should be candidates for vaccine development.

SUMMARY OF MANAGEMENT OPTIONS
Coxsackievirus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal, Labor, and Delivery			
Suspect coxsackievirus infection if unseasonal respiratory tract infection and/or clinical signs of meningitis.	–	GPP	–
Treat infections symptomatically (hospitalize severe cases).	–	GPP	–
Evaluate hydropic fetuses for tachyarrhythmia, congestive heart failure; see Chapters 16, 17, and 25 for management options.	–	–	–
Deliver women suspected for acute coxsackievirus infection in an isolated unit.	IV	C	134
Postnatal			
Isolate women known to have coxsackievirus infection during postpartum care.	IV	C	134
Maintain strict attention to infection control measures.	IV	C	134
Provide clinical, microbiologic, and serologic evaluation of the newborn if acute maternal infection is present within the peripartum period.			
Isolate newborns of mothers suspected of having coxsackievirus infection.	IV	C	134
Consider passive immunization of newborns in case of sudden virulent coxsackievirus infection outbreak.	III	B	175, 178

HUMAN PAPILLOMAVIRUS

General

Human papillomavirus (HPV) is a double-stranded DNA virus that can persist as a latent provirus in epithelial cells after infection. Nucleotide sequencing of the DNA has identified more than 100 genotypes of HPV associated with epithelial neoplasias of the skin and mucosa. More than 30 different HPV types can infect the genital tract, and 8 HPV types are predominantly identified in the most common HPV-associated genital diseases.

HPV types 6 and 11 are detected in more than 90% of condylomata acuminata (genital warts), and also in laryn-

geal papillomatosis, and conjunctival, oral, and nasal warts. HPV types 16, 18, 31, 33, 51, and 54 have been designated high risk HPV types because they have been strongly associated with cervical intraepithelial neoplasia (CIN) and cervical cancer.[180] Genital warts are contagious and are spread during oral, genital, or anal sex. About two-thirds of people who have sex with a partner with genital warts will develop warts, usually within 3 months after contact.

Diagnosis

The diagnosis of condylomata acuminata can be made visually by the appearance of white or pink verrucous friable growths. However, most cases of HPV infection are subclinical. Cytologic evaluation of the Papanicolaou (Pap) smear may reveal evidence of infection in 10% to 30% of cases. If koilocytosis is noted on the Pap smear, liberal use of colposcopy is warranted, given the association of HPV infection and CIN. Colposcopy may identify up to 70% of infected cases. Directed biopsies can support diagnostic evaluation in certain cases (e.g., unresponsiveness to therapy, uncertain clinical diagnosis); however, it is not mandatory.[70] HPV isolation in culture is difficult to accomplish. Highly specific and sensitive DNA methods utilizing type-specific HPV gene probes can identify HPV infection in vaginal washings, Pap smears, and amniotic fluid. In situ hybridization technique is useful to demonstrate type-specific HPV infection in tissues and cervical cell scrapings. PCR methods can identify even the lowest levels of HPV infection in blood and other kinds of fluids or in tissue samples. The usefulness of DNA technology in the clinical diagnosis of genital warts is not supported by any data.[70] However, identification of high risk HPV types might prove helpful for follow-up strategies of women in whom cervical cytology has demonstrated atypical squamous cells of undetermined significance (ASCUS). Screening for subclinical HPV infection by DNA or RNA tests is not recommended.[70]

Maternal and Fetal Risks

Epidemiologic data suggest that HPV infection is the most prevalent STD. Although the occurence of grossly visible genital warts is infrequent, sensitive detection tests utilizing dot blot DNA analysis or PCR for detection of HPV DNA indicate that as many as 30% of sexually active adults in the United States may be infected,[181] with a similar rate seen in pregnancy.[182] The highest rates of genital HPV infection are detected in adults age 18 to 28. Major risk factors to acquiring genital HPV infection include multiple sex partners, younger age at first intercourse and first pregnancy, oral contraceptive use, pregnancy, and impairment of cell-mediated immunity.[181,183] Estimates indicate that approximately 1% of the sexually active population have clinically apparent genital warts.[181] Controversial data exist on a possible increase in the prevalence of HPV infections during pregnancy. An up to threefold increase in HPV DNA-positive women during the third trimester as compared to nonpregnant controls has been reported.[184,185] Possible underlying reasons to facilitate HPV infection during late pregnancy could involve hormonal changes inducing virus transcription and the transient immunosuppression experienced by pregnant women.

Genital HPV infections in pregnant women have long been suspected to cause genital warts or laryngeal papillomatosis in the respective infants.[186] Juvenile laryngeal papillomatosis represents the most common neoplasm of the larynx in infants and young children and usually occurs by age 5.[187] The symptoms range from hoarseness to complete upper airway obstruction. A history of genital warts can be obtained from over 50% of women whose infants subsequently develop laryngeal papillomatosis.[188] However, the absolute risk of laryngeal papillomatosis following exposure to maternal infection is extremely low. Conservative estimates suggest the risk of papillomatosis developing in an offspring of a mother with HPV genital infection is approximately 1 in 400.[187] Surgical excision is the mainstream therapy, and most afflicted patients experience spontaneous remission. However, some endure several hundred surgical procedures. Further development of new antiviral drugs (e.g., cidofovir) and preventive and therapeutic vaccines hold promise for eliminating the virus in cases of recurrent respiratory papillomatosis.[189,190] Genital warts in children show spontaneous resolution in up to 75% of cases. In a cohort of 41 children overall resolution of condylomata was noted in 31 infants (76%) with spontaneous resolution in 22 of 41 (54%); girls were affected three times more often than boys.[191]

Vertical transmission and persistence of high risk cancer-associated HPV in the infant is of great concern. Amniotic fluid samples of 37 women with cervical lesions tested positive for HPV in 24 cases (65%) using PCR technique.[192] HPV type 16 amniotic fluid infection was present in 54% (13/24), and HPV type 18 was detected in 21% (5/24). A correlation was noted between viral DNA amplification and grade of the cervical lesions. In a group of 11 women carrying HPV type 16, 7 infants out of 11 (64%) tested positive for HPV type 16.[193] Viruses were detected in buccal or genital swabs collected 24 hours after delivery, demonstrating infection rather than contamination. Persistence of HPV type 16 infection after a 6-month interval was noted in 83% of infants. In 270 healthy children between age 3 and 11, 131 (49%) buccal swabs tested positive for HPV type 16. Serologic study performed on 229 children demonstrated IgM seropositivity rates indicative of acute infection that peaked between age 2 and 5, and again between age

13 and 16.[193] Thus, given the lack of demonstrable disease in children, consequences of perinatal high risk HPV transmission need to be clarified in long-term studies to establish whether perinatal acquisition of high risk HPV types predisposes for an increased risk of cervical neoplasia later in life.

The frequency of perinatal HPV transmission is a controversial subject. Transmission rates may be as low as 5.3%, whereas other studies demonstrate vertical transmission in up to 73% of newborns.[193,194] Discrepancies in infection rates of the newborn may be due to different PCR techniques with up to a 100-fold difference in sensitivity, differences in study population (e.g., concomitant STDs), sampling technique (nasopharyngeal, buccal, genital), and timing (immediately after birth, contamination versus infection). HPV is thought to cause infection in the infant by direct contact during the passage through the birth canal. However, several studies have shown infants being infected with different strains of HPV despite being delivered by cesarean section.[195,196] In a study of 68 HPV-positive women, 35 delivered vaginally and 33 by cesarean section.[197] At 3 to 4 days of age buccal and genital swabs were collected. In the group of vaginally born infants 18 out of 35 (51%) had a positive HPV test, whereas in 9 out of 33 (27%) infants delivered by cesarean section HPV was detected. Although the study did show a lower incidence of HPV infection in infants delivered by cesarean section, the study also demonstrated that cesarean section did not consistently protect from vertical HPV transmission. In addition, the presence of HPV has been demonstrated in amniotic fluid, placenta, and cord blood; thus, the fetus is at risk for exposure to the virus prior to delivery.[192,196,198]

Management Options

Prepregnancy

Patients should be counseled on the nature of genital warts and advised on using protection (e.g., latex condoms) when having sex with an infected partner. Some genital warts may resolve spontaneously; however, treatment should be considered for expanding genital warts. Treatment for genital warts reduces but does not eradicate infectivity. In nonpregnant women, podophyllum resin 10% to 25% antimitotic solution, podofilox 0.5% solution, and 5-fluorouracil are commonly used for topical treatment; however, they should not be applied during pregnancy because of the potential for fetal toxicity. All treatments show a 10% to 40% probability of recurrence. Intralesional injections of different types of interferon have demonstrated comparable efficacy to other modalities for the treatment of genital warts; however, use of interferons has been frequently associated with systemic adverse effects. Interferons should not be used during pregnancy. Although some HPV types are associated with CIN and cervical cancer, HPV infection does not necessarily progress to cancer. It is important for women with a history of abnormal Pap smears to receive appropriate cytologic testing on a regular basis so that early treatment, if necessary, can be instituted.

Prenatal

There is no single definitive treatment for HPV infection in pregnancy. Treatment is dependent on the size, location, and number of identified lesions and entails the removal or ablation of all visible warts. Due to the subclinical and multifocal nature of HPV infection, recurrences are common. Certain treatment modalities that are effective in the nonpregnant patient are contraindicated during pregnancy.

In pregnant women topical application of 80% to 90% trichloroacetic acid (TCA) can be used for small lesions and is the least expensive treatment. TCA is not absorbed systemically and can be used in pregnancy. However, it has a cure rate of only 20% to 30% after a single application; therefore, weekly applications may be required until the lesions are resolved. TCA solutions have a low viscosity and can spread rapidly, thus, damaging adjacent tissues. If an excess amount is applied, the treated area should be powdered with talc, sodium bicarbonate, or liquid soap preparations to remove unreacted acid.[70] Cryotherapy with liquid nitrogen has also been successfully used in pregnancy and is a reasonable first-line treatment option. Cryotherapy is not recommended for use in the vagina because of the risk of vaginal perforation and fistula formation.[70] Surgical removal by tangential scissor excision, tangential shave excision, curettage, or electrosurgery has the advantage of eliminating warts at a single visit in most cases. Carbon dioxide laser vaporization has been used successfully in pregnancy, although recurrence rates of 10% to 14% have been reported. In particular, laser therapy is recommended for those patients with large or multiple lesions or with lesions refractory to TCA application or cryotherapy. Recurrences usually occur during the first 3 months after treatment, and a follow-up evaluation should be offered.

Imiquimod 5% cream, an immune-response modulator that induces host TH1 cytokines, including interferon-γ, has been demonstrated to be effective in eradicating genital warts when applied topically three times weekly in nonpregnant patients. Although not yet recommended in pregnancy, imiquimod may represent an effective alternative to other topical or destructive therapies during pregnancy. New antiviral drugs (e.g., cidofovir) have not been evaluated for safety and efficacy during pregnancy.[199]

Labor and Delivery

Elective debulking of genital warts should not be done at the time of delivery for two reasons: first, these lesions

may be very vascular and obstetric hemorrhage may ensue; second, most lesions regress to some extent after delivery.

Because of the lack of substantial evidence for the preventive value of cesarean delivery, cesarean section should not be performed solely to prevent transmission of HPV infection to the newborn.[70] However, cesarean section may be indicated in women with genital warts obstructing the pelvic outlet or when vaginal delivery would result in excessive bleeding.

SUMMARY OF MANAGEMENT OPTIONS
Human Papillomavirus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Identify and treat lesions:	–	GPP	–
• Topical therapy (podophyllum, podofilox, 5-fluorouracil)			
• Ablation (e.g., cryocautery)			
• Removal			
Counsel about risks (infectious condition) and use of condoms if partner infected.	IIa	B	201, 202
Advise that treatment does not eradicate infectivity.	–	GPP	–
Implications from cervical smear screening programs:	–	GPP	–
If Pap smear reports ASCUS but no other types of abnormalities:			
• Consider HPV testing			
If Pap smear reports ASCUS, and high risk HPV types are detected:			
• Perform colposcopy, consider biopsy			
• Perform pelvic exam, Pap smear on a regular basis			
Screening for subclinical HPV infection is not recommended.			
Prenatal			
Topical 80% TCA	III	B	203
Cryotherapy	IV	C	204
Electrodiathermy	IV	C	204
Laser vaporization (carbon dioxide)	III	B	203
Excision (tangential scissors, excision, curettage)	IV	C	204
Contraindicated preparations:			
• Podophyllum	IV	C	204
• Podofilox	–	GPP	–
• 5-fluorouracil	–	GPP	–
• Interferon	IV	C	205
Counsel about low newborn risk, and about nature of HPV infection in the infant.	–	GPP	–
Labor and Delivery			
Avoid treatment at delivery, especially debulking, because of risk of hemorrhage.	–	GPP	–
Cesarean section may be indicated in women with genital warts obstructing labor or vaginal delivery that would result in excessive bleeding; not recommended solely to prevent HPV transmission to the infant.	III	B	70
Postnatal			
Maintain vigilance for secondary infection, especially in episiotomy site.	–	GPP	–
Offer sitz baths.	–	GPP	–

Postnatal

Large lesions should be observed for secondary infection, if they involve an episiotomy site. Sitz baths may be particularly useful in comforting and cleansing the perineal area with multiple HPV lesions.

Currently, preventive and therapeutic vaccine development is in progress to possibly reduce HPV infection in the future.[200]

CONCLUSIONS

- Viral infections with cytomegalovirus, herpes simplex virus, adenovirus, coxsackievirus, and human papillomavirus pose a serious threat to the fetus and the newborn.
- Specific antiviral treatment options are scarce and cannot reduce the incidence of viral infection during pregnancy. Therefore, counseling patients and physicians about the infectious nature and on how to avoid viral transmission is the most viable and effective treatment modality to reduce congenital virus infections to date.
- Careful questioning and examination of pregnant women and subsequent use of specific diagnostic procedures are the most important methods to identify and counsel pregnant women at risk for viral infections.
- Perinatal and postpartum attention to infection control measures can greatly reduce the risk of severe neonatal infection.
- Progress in the development of new antiviral drugs for the treatment of the fetus and the newborn can possibly reduce the sequelae of congenital viral infection in the future.
- However, the development of vaccines and vaccination programs holds the most promising option to reduce congenital viral disease.

Other Infectious Conditions

Breton C. Freitag / Michael G. Gravett

INTRODUCTION

Infections are an important contributor to maternal and perinatal morbidity and mortality rates. Maternal immunosuppression that occurs during pregnancy, may alter the natural course of many infectious diseases. Higher attack rates are seen in pregnancy for a variety of bacterial and viral infections. Furthermore, many of these infections are associated with adverse outcomes of pregnancy, including preterm birth, low birth weight, and stillbirth. This chapter addresses a large group of infectious diseases not discussed in other chapters, including streptococcal infections, listeriosis, common sexually transmitted infections, and vaginitis.

GROUP A STREPTOCOCCUS

Group A streptococcus (*Streptococcus pyogenes*) has been associated with obstetric and neonatal infections since the 16th century. It is probable that group A streptococcus was responsible for much of puerperal sepsis, or "childbed fever," described by Semmelweis in 19th century Vienna.[1] However, with the advent of the antibiotic era, group A streptococcal (GAS) infections became increasingly infrequent until the 1980s, when GAS infections dramatically increased again for poorly understood reasons.[2] Group A streptococcus causes a broad spectrum of invasive and noninvasive diseases, including bacterial pharyngitis, impetigo, scarlet fever, necrotizing fasciitis, and the more recently recognized streptococcal toxic shock syndrome (STSS), as outlined in Table 32–1.[2,3]

Streptococcus pyogenes, the etiologic agent for GAS infections, was first described by Louis Pasteur in 1879. The *Streptococcus* genus is classified into groups, based upon polysaccharide capsular antigens and the cell wall M protein, as first described by Lancefield.[4] *Streptococcus pyogenes* is divided into serotypes according to the M protein, and to date more than 80 M protein serotypes have been identified. Different serotypes are associated with

different forms of infection, and M1 and M3 have been the most common serotypes identified in serious infection in recent years.[5]

M protein is also important as a virulence factor because of its antiphagocytic properties. Other significant virulence factors are the streptococcal pyrogenic exotoxins (SPE), which act as superantigens. Superantigens are able to bind to T-cell receptors and the class II major histocompatibilty complex (MHC) without first undergoing antigen processing and presentation. The cross-linking of a T-cell receptor with a class II MHC molecule by a superantigen stimulates the proliferation and activation of T cells and macrophages, causing them to release large amounts of cytokines, which can cause shock or inflammation and tissue damage.[2,6] A large number of SPE superantigens have been identified, but SPE A, SPE B, SPE C, SPE F, and streptococcal super-

TABLE 32–1

Classification of Group A Streptococcal Infections

1. Streptococcal toxic shock syndrome (streptococcal TSS)
2. Other invasive infections (isolation of *S. pyogenes* from a normally sterile site in patients not fulfilling criteria from streptococcal TSS)
   a. Bacteremia with no identifiable focus
   b. Focal infection with or without bacteremia (meningitis, pneumonia, peritonitis, puerperal sepsis, osteomyelitis, septic arthritis, necrotizing fasciitis, surgical wound infections, erysipelas, cellulitis)
3. Scarlet fever
4. Noninvasive infections (recovery of *S. pyogenes* from a nonsterile site)
   a. Mucous membranes (pharyngitis, tonsillitis, otitis media, sinusitis, vaginitis)
   b. Cutaneous (impetigo)
5. Nonsuppurative sequelae (specific clinical findings with evidence of a recent group A streptococcal infection)
   a. Acute rheumatic fever
   b. Acute glomerulonephritis

Adapted from The Working Group on Severe Streptococcal Infections: Defining the group A streptococcal toxic shock syndrome. JAMA 1993; 269:390.

antigen (SSA) are among the best characterized. By stimulating cytokine production these streptococcal exotoxins likely play an important role in the pathogenicity of invasive GAS infections by exacerbating the onset of clinical signs and symptoms of infection.

Maternal and Fetal Risks

Group A streptococcus may be recovered from skin or mucous membrane of asymptomatic colonized patients. GAS may gain entry to the body via the skin, mucosa, pharynx, and vagina and cause infections with both suppurative and nonsuppurative complications.[2,7] During pregnancy, the most notable GAS infections are bacteremia without a focus of infections and endometritis, but invasive infections including streptococcal toxic shock syndrome (STSS) and necrotizing fasciitis also occur (Table 32–2). The reasons for the increased susceptibility seen during the puerperium include the breach of integrity in the integumentary system associated with either vaginal delivery or cesarean section. Invasive infections are characterized by hypotension and shock, multiple organ failure, systemic toxicity, severe local pain, rapid necrosis of subcutaneous tissues and skin, renal dysfunction, and fever.[2,7] GAS invasive disease is characterized by a rapid, often fatal course and by difficulties in the early diagnosis, when intervention may be more successful.

Postpartum invasive group A streptococcal infection occurs in approximately 1 in 11,000 to 1 in 17,000 births, with an average of 220 cases occurring in the United States every year.[8,9] The rate of invasive GAS infection is 1.6- to 2.0-fold greater among black patients compared to white patients.[8] Maternal case fatality rate ranges from 3.5% to 30% in postpartum invasive GAS. Maternal GAS disease has also been associated with stillbirth.

Neonatal invasive GAS has also been reported and has a case fatality rate of up to 30%.[9–11] Although the neonate may be colonized following horizontal transmission within the nursery, vertical transmission from a colonized mother has been demonstrated.[10,12] Furthermore, 50% of neonatal cases of invasive GAS disease occur within the first week of life, suggesting that vertical transmission from a colonized parturient may be the most important route of infection. The most frequent manifestation of neonatal GAS disease is omphalitis, but cellulitis, meningitis, sepsis, and fasciitis also occur. Fortunately, neonatal GAS disease is rare, with an estimated incidence of 1 in 18,000 births.

Diagnosis

Group A streptococci can be readily recovered from most patients with evidence of GAS disease. Group A streptococci are catalase-negative gram-positive cocci that are beta-hemolytic on blood agar. The colonies may appear as highly mucoid to nonmucoid, and the organisms are usually 1 to 2 mm in diameter. Although cultures may be helpful in confirming the diagnosis of GAS disease, they are seldom available when considering the initial diagnosis. Group A streptococcal disease may progress rapidly, and therapy must be initiated before cultures are generally available.

Therefore, the diagnosis of GAS disease depends upon a high index of suspicion. Fever is the most common presenting sign, and 20% of patients have a flu-like syndrome with fever, chills, myalgia, nausea, vomiting, and diarrhea.[13] Confusion or altered mental status is present in over one half of patients. Renal dysfunction occurs in 80% of patients and may precede hypotension or shock. The presence of hemaglobinuria or an elevated serum creatinine are evidence of renal involvement. Hemoconcentration, as a result of a fluid shift to the extravascular compartment, and leukocytosis (often >20,000/mm³), with a predominance of immature neutrophils, are common. Respiratory failure and adult respiratory distress syndrome occur in approximately 50% of patients but usually develop after the onset of clinically recognized shock. Criteria for the diagnosis of STSS are outlined in Table 32–3.

Eighty percent of patients have evidence of soft tissue infection characterized by induration and erythema, which progress to necrotizing fasciitis in 70% of cases.[13] The hallmark of these soft tissue infections is the abrupt onset of severe pain, which usually precedes physical findings or is out of proportion to physical findings. Any patient suspected of having GAS-associated necrotizing fasciitis must have the diagnosis confirmed by immediate wound exploration and debridement. A purulent discharge is usually not present, and a limited wound inspection may fail to confirm the diagnosis. Upon opening the wound, a thin, watery, nonmalodorous discharge is frequently present. The diagnosis of necrotizing fasciitis can be easily confirmed by the bloodless blunt dissection of the superficial fascia and by pathologic frozen section.

TABLE 32–2

Diseases Seen among Patients with Postpartum Group A Streptococcus Infection

INFECTION	NUMBER (%) OF PATIENTS (N = 87)
Bacteremia without focus	40 (46%)
Endometritis	24 (28%)
Peritonitis	7 (8%)
Septic abortion	6 (7%)
Cellulitis	3 (3%)
Septic arthritis	3 (3%)
Necrotizing fasciitis	3 (3%)
Streptococcal toxic shock syndrome	3 (3%)
Chorioamnionitis	3 (3%)
Pneumonia	1 (1%)
Other	3 (3%)

TABLE 32–3

Diagnostic Criteria for Streptococcal Toxic Shock Syndrome

I. Isolation of *Steptococcus pyogenes*
   A. From a normally sterile site
   B. From a nonsterile site (throat, sputum, vagina, superficial skin lesion)
II. Clinical evidence of severity
   A. Hypotension (systolic blood pressure ≤90 mm Hg in adults or ≤*5th* percentile for age in children) and
   B. Two or more of the following:
      1. Renal impairment (serum creatinine ≥2.0 mg/dL or a twofold elevation over baseline level in patients with preexisting renal impairment)
      2. Coagulopathy (platelets ≤100 × 10⁶/L or disseminated intravascular coagulation)
      3. Liver involvement (AST, ALT, or total bilirubin ≥ two times upper limits of normal)
      4. Adult respiratory distress syndrome
      5. Generalized erythematous macular rash
      6. Soft tissue necrosis (necrotizing fasciitis, myositis, or gangrene)

Adapted from The Working Group on Severe Streptococcal Infections: Defining the group A streptococcal toxic shock syndrome. JAMA 1993;269:390.

In summary, the diagnosis of GAS disease should be considered in any patient with the sudden onset of hypotension and shock, or the abrupt onset of severe pain in a wound, or systemic signs and symptoms such as confusion, renal impairment, or respiratory distress in a patient with a wound or episiotomy infection. Aggressive intravenous fluid resuscitation, antibiotic therapy, and wound debridement are necessary in these patients.

Management Options

Prepregnancy

No current evidence suggests that the identification of GAS carriers prior to pregnancy is predictive of either subsequent pregnancy outcome or in reducing puerperal infectious morbidity. Therefore, prepregnancy screening is not recommended.

Prenatal

A high index of suspicion is necessary for the early diagnosis of GAS infection. Unfortunately, diagnosis may be difficult in the early stages of GAS infection, and delays in therapy may be associated with increased morbidity and mortality rates. Many patients die within 24 to 48 hours of infection.[13] In general, treatment must be directed at hemodynamic stabilization with intravenous fluids and vasopressors, antibiotic therapy, and in the case of soft tissue infections, surgical exploration and aggressive debridement of involved tissues. Massive amounts of intravenous crystalloids, in the range of 10 to 20 L/day, are often necessary to maintain blood pressure and tissue perfusion. Vasopressors such as dopamine are also fre-

quently required. In soft tissue GAS infections such as necrotizing fasciitis antibiotic therapy alone, without surgical debridement, usually results in maternal death. Intraoperative Gram stain and histologic frozen section may be necessary to fully delineate the extent of involved tissues. Hyperbaric oxygen therapy has no role in the treatment of necrotizing fasciitis but may be a useful adjunct in delineating necrotic tissue that must be surgically debrided.

Broad-spectrum parenteral antibiotics should be administered promptly. Penicillin G (200,000 to 400,000 U/kg/day) is the drug of choice for GAS invasive infections. However, studies in mice have demonstrated that even a short delay of 2 hours after initiation of infection dramatically reduces the efficacy of penicillin G.[14] Recent studies indicate that clindamycin may be more efficacious than penicillin when therapy is delayed. In an experimental model with mice, survival was 70% even when initiated 16 hours after GAS infection.[14] Several potential advantages to clindamycin therapy (900 mg intravenously every 8 hours) have recently been summarized.[7] First, in contrast to penicillins, clindamycin is not affected by bacterial inoculum size or rate of growth. Second, clindamycin suppresses the synthesis of bacterial toxins. Third, clindamycin facilitates phagocytosis of *S. pyogenes* by inhibition of M protein synthesis. Fourth, clindamycin has a longer postantibiotic effect than does penicillin. Last, clindamycin suppresses lipopolysaccharide-induced monocyte synthesis of tumor necrosis factor-alpha (TNF-α), a cytokine that contributes to hypotension and shock. However, a small proportion of GAS infections are resistant to clindamycin, and clindamycin should not be used alone until the organism is demonstrated to be susceptible by susceptibility testing. Therefore, initial therapy usually includes a combination of penicillin G and clindamycin.

Recent data also indicate that intravenous immunoglobulin (IVIG) (1–2 g/kg given once) may be a useful adjunct to antibiotic therapy in the treatment of GAS toxic shock syndrome. Commercial preparations of IVIG have been shown to contain neutralizing antibodies to several streptococcal virulence factors.[15] Recently, investigators reported a significant reduction in mortality rate among patients with GAS disease treated with IVIG when compared to a historical cohort.

Thus, the optimal treatment for invasive GAS disease includes a high index of suspicion, aggressive fluid resuscitation and hemodynamic support, surgical exploration and aggressive debridement, parenteral antibiotics including penicillin G and clindamycin, and possibly intravenous immunoglobulin.

Labor and Delivery

Group A streptococcus may be associated with intra-amniotic infection and with stillbirth. However, most patients with invasive GAS disease usually present in the postpartum period, frequently within the first 24 to 48

hours. Treatment should follow the general guidelines provided previously.

Postnatal

There are no current recommendations for screening for or treating asymptomatic parturients colonized with group A streptococcus. However, careful attention should be given to any parturient with the sudden onset of systemic signs such as hypotension or shock or to parturients with severe pain out of proportion of physical findings or rapidly progressive soft tissue infections, as noted earlier. Although these findings, which are consistent with necrotizing fasciitis, usually suggest a polymicrobial infection, group A streptococcus should be considered in the diagnosis, and broad-spectrum antibiotics including penicillin and clindamycin should be utilized in the initial management.

SUMMARY OF MANAGEMENT OPTIONS
Group A Streptococcal Infection

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
No benefit to screening and treatment.	–	GPP	–
Prenatal, Labor, and Delivery			
No benefit to screening and treatment.	–	GPP	–
May cause intra-amniotic infection.	–	GPP	–
Diagnosis requires a high index of suspicion:	III	B	13
Severe pain

GROUP B STREPTOCOCCUS

Group B streptococcus *(Streptococcus agalactiae)* has become recognized over the past 2 decades as one of the most important causes of neonatal infection and is currently considered one of the leading infectious causes of neonatal morbidity and death. Although early reports in the 1930s and 1940s linked group B streptococcus (GBS) with postpartum infections and neonatal meningitis, it was not until the early 1960s that the scope of perinatal and neonatal GBS infections became evident.[16] Initial case series reported case fatality rates as high as 50%. In the 1980s, trials of empiric intrapartum antibiotics to women at risk of transmitting infection to their newborns

demonstrated a protective benefit against neonatal infection in the first week of life (early-onset disease). In the 1990s, these efforts led to the implementation of guidelines for intrapartum antibiotic prophylaxis of at-risk mothers, endorsed and issued by the American College of Obstretricians and Gynecologists (ACOG),[17] the Centers for Disease Control (CDC),[18] and the American Academy of Pediatrics (AAP).[19] This practice has resulted in a significant reduction in early-onset disease, as well as a smaller impact on maternal morbidity. Based upon these results, in 2002 updated guidelines were issued by the CDC to recommend optimization of screening and treatment of pregnant women in an attempt to improve upon the success already demonstrated.[20]

Group B streptococci are one of many serologically distinct species within the genus *Streptococcus*. Streptococci are facultatively anaerobic gram-positive cocci, usually arranged in chains on Gram stain. The most important pathogenic streptococcal species for humans include group A (*Streptococcus pyogenes*), group B (*Streptococcus agalactiae*), group D (enterococci), *Streptococcus pneumoniae*, and *Streptococcus viridans*. Definitive identification is based on the presence of a polysaccharide group-specific antigen common to all group B streptococcal strains as determined by serologic testing. Group B streptococci can be further subdivided into eight distinct serotypes (Ia, Ib, Ia/c, II, III, IV, V, and VI) on the basis of distinctive type-specific polysaccharide antigens. About 99% of strains can be typed into one of these six antigen types. Group B streptococci can be recovered from the vagina or cervix in 10% to 30% of pregnant women at some point during gestation.[21] The colonization may be transient, chronic, or intermittent, and the rate of colonization does not vary with gestational age. There is evidence that the gastrointestinal tract is the major primary reservoir and that vaginal or cervical contamination and colonization occur from a gastrointestinal source. The frequency of GBS isolation increases as one proceeds from the cervix to the introitus, and GBS can be recovered twice as frequently from rectal cultures as from vaginal cultures. Group B streptococci can also be recovered from the urethra of 45% to 63% of the male consorts of female carriers, implying that sexual transmission may also occur.

Neonatal GBS colonization may occur either by vertical transmission from a colonized mother as the neonate passes through the birth canal or by horizontal transmission, including both nosocomial spread in the nursery from colonized nursery personnel or other colonized neonates and acquisition from community sources. Overall, 3% to 12% of all neonates are colonized with GBS in the first week of life. Forty percent to 70% of neonates born to colonized mothers become colonized, usually with the same serotype that is present in the mother. In contrast, only 1% to 12% of neonates born to noncolonized mothers will become culture positive. Several additional factors may modify or enhance the risk

of GBS vertical transmission. Higher neonatal transmission rates occur when women are persistently culture-positive carriers or when women are heavily colonized with GBS as demonstrated by semiquantitative vaginal cultures.[22] The site of maternal carriage is also important; vertical transmission is more likely to occur with cervical GBS carriage than with rectal carriage.

The most important determinant of susceptibility to invasive infection after colonization may be maternal antibodies directed against the capsular polysaccharide antigens of GBS. Immunity to GBS is mediated by antibody-dependent phagocytosis. Mothers of infants with type III GBS invasive disease have lower serum levels of type-specific antibodies than women giving birth to asymptomatically colonized infants. This antibody, which has some broad reactivity to all group B streptococcal types, is an IgG that readily crosses the placenta. When measured in mother-infant pairs, an excellent correlation exists between maternal and cord antibody levels. Baker and associates demonstrated that 73% of 45 GBS-colonized mothers with healthy neonates had high serum levels of type III antibody in contrast to only 19% of 32 GBS-colonized mothers whose neonates developed early-onset septicemia or meningitis ($P <0.001$).[23] Strain virulence is also an important determinant of disease. Although type III strains of GBS represent approximately one third of isolates from symptomatically colonized infants, they account for over 85% of the isolates from early-onset meningitis or late-onset disease. Overall, type III strains account for more than 60% of isolates from infants with all varieties of invasive GBS infections.

Maternal and Fetal Risks

Although most research has focused on GBS neonatal infection, GBS is also an important pathogen for maternal intrapartum, postpartum, and occasionally prenatal infections. Data from an earlier report suggest puerperal septicemia due to GBS occurs with an incidence of approximately 1 to 2 per 1000 deliveries and accounts for up to 15% of positive blood cultures from postpartum patients.[24] Postpartum endometritis is reported to be more frequently observed among GBS-colonized parturients than among noncolonized parturients. GBS is also associated with clinical intra-amniotic infection, and is a frequent isolate from amniotic fluid of patients with intra-amniotic infection. Finally, GBS has been isolated from the urine of pregnant women, with or without symptoms of urinary tract infection.

GBS has also been associated with premature rupture of the membranes and with preterm delivery prior to the 32nd gestational week in some, but not all, studies.[25] Previous studies have indicated that this association may be strongest for patients with GBS bacteriuria.[26] Thomsen and associates have demonstrated significant reductions in premature rupture of the membranes and

preterm labor among patients with asymptomatic GBS bacteriuria who were treated with penicillin.[27] However, antepartum antibiotic treatment to eradicate GBS from patients with asymptomatic vaginal colonization without bacteriuria has not been demonstrated to alter pregnancy outcome. Thus, a causal relationship between GBS colonization and prematurity still remains to be established.

In the past three decades, GBS has become a leading cause of septicemia and meningitis during the first 3 months of life in neonates. Early surveillance data in the 1990s suggested an incidence of 1.8 cases per 1000 live births. Two distinct clinical syndromes occur among neonates with GBS infections. These differ in the age at onset, pathogenesis, and outcome. The first clinical syndrome, early-onset infection, occurs within the first 7 days of life, and represent nearly three fourths of all cases in infants under 3 months age. The mean age at onset is 20 hours of life, and 72% will present within the first 24 hours of life.[28] A significant portion of these infections are apparent at birth or become symptomatic within the first 90 minutes of life, indicating that in utero GBS exposure and infection often occur. Early infection attack rates were estimated at 1.5 per 1000 for all live births prior to widespread use of intrapartum antibiotics. Among offspring of maternal GBS carriers, however, the attack rate is much higher, ranging from 10 to 60 per 1000.

Early neonatal infection is presumed to result from vertical transmission of GBS from a colonized mother. There is a direct relationship between neonatal attack rates and the size of the inoculum and number of colonized neonatal sites. In a recent epidemiologic review, early-onset infection presented as bacteremia (80%), pneumonia (7%), or meningitis (6%). Eighty-three percent of cases were in term infants (≤37 weeks' gestation). The overall case fatality rate was approximately 4% but was significantly higher in preterm infants, approaching 30% in infants of 33 weeks' gestation or less.[28]

The second type of disease (late-onset infection) occurs in infants after the first week of life until 3 months of age, with a typical range of 3 to 4 weeks. The overall attack rate is estimated to be 0.5 case per 1000 live births, and these cases represent 28% of infections in infants under 3 months of age.[28] In contrast to early-onset infection, nosocomial transmission may be as important as vertical transmission, although it is believed that some infants are colonized at birth, with subsequent development of invasive disease. The serotype distribution of strains recovered from late-onset infection does not reflect the serotypes present in the maternal genital tract; over 90% of late-onset infection is caused by type III GBS. Late-onset disease also presents most commonly as bacteremia (63%), but may appear as meningitis (24%, relative risk 4.3 versus early-onset disease, P <0.001) and may demonstrate other sites of infection, such as septic arthritis or osteomyelitis. The overall case fatality rate for late-onset disease is 2.8%.[28]

Approximately 50% of meningitis survivors will have neurologic sequelae, including cortical blindness, diabetes insipidus, deafness or other cranial nerve deficits, and spasticity.

Diagnosis

Group B streptococci can be easily grown on selective or nonselective media. Most group B streptococcal colonies appear on blood plates as small, 1 mm to 2 mm, gray-white colonies surrounded by a zone of beta-hemolysis, although 2% of strains are nonhemolytic. Preliminary identification and distinction of GBS from other streptococci is based on biochemical reactions including resistance to bacitracin, hydrolysis of sodium hippurate, and the production of a soluble hemolysin that acts synergistically with B-lysin of *Staphylococcus aureus* to produce hemolysis (CAMP test). Although GBS can be recovered after overnight growth on nonselective media, such as blood agar, the use of a selective broth medium such as Todd-Hewitt broth or Lim broth greatly enhances the isolation rate of GBS from any culture site.

A major limitation of cultures is the length of time necessary for growth and identification. A number of more rapid screening tests have been developed to directly detect GBS in either body fluids or in cervical-vaginal secretions. These culture-independent tests include Gram stain, latex particle agglutination (LPA), and enzyme immunoassay. A large number of studies have evaluated the ability of these indirect tests to rapidly detect GBS colonization of the maternal lower genital tract. Such identification is important to interrupt maternal-to-neonatal vertical transmission that leads to early-onset neonatal disease. However, subsequent studies have not confirmed initially encouraging results.[29,30] More recently, a study from Quebec reported a fluorogenic polymerase chain reaction (PCR) assay that demonstrated excellent sensitivity and specificity compared to traditional culture methods, but this assay awaits further testing to determine feasibility of widespread application.[31] In addition, only culture techniques currently allow for antibiotic sensitivity profiling of positive cultures, which is particularly important in cases of maternal penicillin hypersensitivity.

Management Options

Prepregnancy

No current evidence suggests that the identification of GBS carrier status prior to pregnancy is predictive of subsequent pregnancy outcome. Similarly, treatment of asymptomatic women found to be colonized with GBS prior to pregnancy does not impart any recognized benefit, with the possible exception of women with asymptomatic bacteruria.

Prenatal, Labor, and Delivery

Group B streptococcus rarely causes maternal symptoms in the prenatal period, but is an infrequent cause of urinary tract infection symptoms. However, GBS bacteriuria (whether symptomatic or not) provides a significant risk factor for neonatal disease, as previously mentioned. When detected, group B streptococcal bacteriuria should be treated according to current standard of care for urinary tract infections during pregnancy. Pregnant women with documented group B streptococcal bacteriuria at any time during their prenatal course will not require screening cultures to be performed and should receive intrapartum antibiotics, which will be discussed in further detail.

Although, in general, the attack rate for neonatal GBS infection is low, a variety of prevention strategies have been advocated because of the high mortality and morbidity rates seen in neonatal GBS disease. These strategies have involved chemoprophylaxis, aimed at eradicating the organism from the mother or the neonate, or immunoprophylaxis, aimed at inducing humoral immunity.

Antibiotic chemoprophylaxis has been advocated for the pregnant patient in either the antepartum or intrapartum period, or for the neonate in the immediate neonatal period. Attempts to eradicate GBS colonization with antepartum treatment have been unsuccessful, and early neonatal prophylaxis is also frequently unsuccessful because many neonates are already septic at birth as a result of in utero infection.[32] Initial chemoprophylactic prevention strategies released in the 1990s focused upon selective intrapartum treatment based upon either the presence of risk factors associated with neonatal infection, maternal genital tract colonization, or both.

Major risk factors for neonatal early-onset GBS disease include low birth weight (<2500 g), premature delivery (<37 weeks of gestation), prolonger duration of rupture of membranes (≥18 hours), and intrapartum fever (≥38.0°C). Boyer and associates have demonstrated that 74% of neonates with early-onset infection and 94%

of those infections with a fatal outcome occur among those neonates with one or more of these risk factors.[32] Additional risk factors include having previously had a neonate with invasive GBS disease and maternal GBS bacteriuria during the current pregnancy. A study in 1985 documented that the overall attack rate for early-onset neonatal GBS disease increased from the then observed 3.0 per 1000 births in the total population to 8.4 per 1000 births among those pregnancies in which risk factors were present.[33] The attack rate rose even more dramatically to 40.8 per 1000 births if risk factors were present and the mother was colonized with GBS.

Several studies utilizing the presence of risk factors, maternal colonization status, or both, as a determinant for prophylaxis have documented the efficacy of intrapartum chemoprophylaxis in reducing neonatal early-onset GBS disease.[34-40] A meta-analysis of these studies demonstrated a 30-fold reduction in early-onset disease with intrapartum chemoprophylaxis.[41] The two alternative approaches to intrapartum chemoprophylaxis were proposed in the United States by the CDC in 1996[18] and have been endorsed by both ACOG[17] and the AAP.[19] The first approach is based upon universal screening for maternal GBS colonization at 35 to 37 weeks of gestation. Intrapartum chemoprophylaxis is offered to all pregnant women identified as GBS carriers. In addition, intrapartum chemoprophylaxis is offered to women with a previous neonate with GBS infection, or GBS bacteriuria during the current pregnancy, or delivering prior to 37 weeks of gestation, regardless of maternal colonization status. Women with an unknown carrier status are offered prophylaxis in the event of an intrapartum fever of 38.0°C or higher, or rupture of membranes at 18 hours or before. It was estimated this screening-based approach would result in intrapartum chemoprophylaxis of 26.7% of all deliveries and prevent 86% of early-onset neonatal GBS disease (Table 32–4).[18]

An alternative prophylactic strategy, also initially endorsed by the CDC, is based upon offering intrapartum chemoprophylaxis only in the presence of risk

factors. In this risk-factor approach, prophylaxis would be offered only to those women with delivery prior to 37 weeks' gestation, rupture of membranes at or before 18 hours, an intrapartum fever at or above 38.0°C, a previously infected neonate, or with GBS bacteriuria in the current pregnancy. With this approach, 18.3% of pregnancies were estimated to merit chemoprophylaxis and 68.8% of early-onset neonatal disease would be potentially prevented.[18]

The impact of implementing these guidelines has been studied extensively in the period following their initial recommendation. In the surveillance areas studied, the incidence of early-onset disease declined from 1.7 per 1000 in 1993 to 0.6 per 1000 in 1998, a 65% reduction, with the steepest decline occurring in 1996 following the initial release of consensus guidelines from the CDC. Schrag and associates recently published the first comprehensive study directly comparing the two management strategies, and found that the screening-based approach was greater than 50% more effective in preventing perinatal GBS disease.[42] This result was felt to stem from two main factors. First, the screening-based approach identified mothers who were GBS positive but did not exhibit risk factors during pregnancy or labor, a group representing 18% of all parturients during the study period. Second, women identified as being GBS positive were more likely to receive intrapartum antibiotics than women who qualified on the basis of risk factors (89% versus 61%, P <0.001), indicating improved compliance

with the guidelines utilizing the screening-based approach. In this study, similar numbers of patients (24%) in each group received intrapartum prophylaxis, negating previous concerns that the screening-based approach would result in a significant increase in the use of antibiotics and potential contribution to antibiotic resistance. Also, other studies have suggested that the increased cost of performing routine cultures on all eligible pregnant women would be offset by the impact of disease prevention.[20] This idea led to the release of new guidelines by the CDC in 2002, recommending a universal screening-based approach (Fig. 32–1). In addition, a new algorithm is provided for the management of women with preterm delivery, summarized in Figure 32–2.

Intravenous penicillin G (5 million units IV initially, then 2.5 million units every 4 hours until delivery) is preferred for intrapartum chemoprophylaxis. Ampicillin (2 g IV initial dose, then 1 g every 4 hours until delivery) is an acceptable alternative, but penicillin G is preferable because its narrower spectrum of activity may be less likely to select for antibiotic-resistant microorganisms. Previous debate had centered on the minimum duration of therapy for effective prophylaxis, in terms of length of therapy versus number of doses of antibiotics administered prior to delivery. Recent evidence has confirmed that an initial dose of antibiotics at least 4 hours prior to delivery is as effective as two or more doses of antibiotics in preventing GBS transmission[43] and early-onset disease,[44] and this emphasis is maintained in the current guidelines.

Vaginal and rectal GBS screening cultures at 35–37 weeks' gestation for ALL pregnant women (unless patient had GBS bacteriuria during pregnancy or a previous infant with invasive GBS disease)

Intrapartum prophylaxis indicated
- Previous infant with invasive GBS disease
- GBS bacteriuria current pregnancy
- Positive GBS screening culture during current pregnancy (unless a planned cesarean delivery, in the absence of labor or amniotic membrane rupture, is performed)
- Unknown GBS status (culture not done, incomplete or results unknown) and any of the following:
  ➤ Delivery at ≤37 weeks' gestation
  ➤ Amniotic membrane rupture ≥18 hours
  ➤ Intrapartum temperature ≥100.4° F (≥38.0° C)

Intrapartum prophylaxis not indicated
- Previous pregnancy with a positive GBS screening culture (unless a culture was also positive during the current pregnancy)
- Planned cesarean delivery performed in the absence of labor or membrane rupture (regardless of maternal GBS culture status)
- Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors

FIGURE 32–1

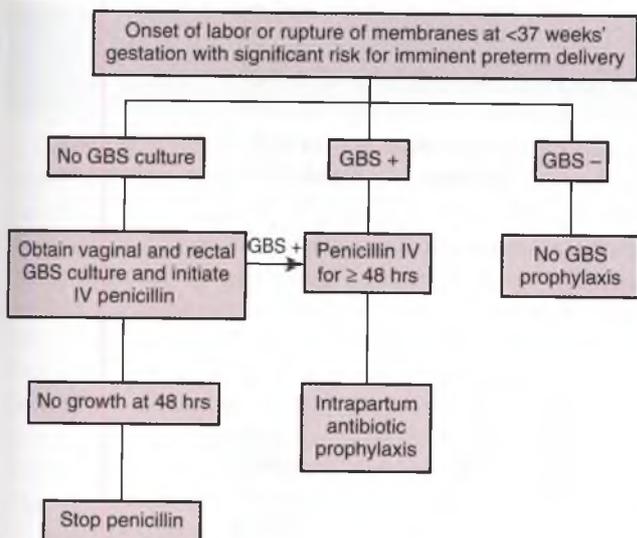
Indications for intrapartum antibiotic prophylaxis to prevent prenatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks' gestation from all pregnant women. (From CDC: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. MMWR 2002;51(RR-11):1–18.)


FIGURE 32–2

Sample algorithm for GBS prophylaxis for women with threatened preterm delivery. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate. (From CDC: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. MMWR 2002;51(RR-11):1–18.)

If pencillin resistance is documented but the risk of anaphylaxis is judged to be low, cefazolin (2 g IV initial dose, then 1 g every 8 hours) may be used. Clindamycin (900 mg IV every 8 hours) or erythromycin (500 mg IV every 6 hours) may be used in the severely penicillin-allergic patient. However, increasing resistance in GBS to both of the agents has led to the recommendation of routine susceptibility testing of positive cultures if penicillin allergy is suspected or documented. In cases of resistant organisms (or unknown susceptibility) and high risk for anaphylaxis to penicillins and cephalosporins, vancomycin (1 g every 12 hours) is the preferred treatment. This underscores the need to accurately determine true beta-lactam allergy as well as risk for anaphylaxis.

An alternative approach to intrapartum chemoprophylaxis is to immunize pregnant women. As noted previously, women delivering neonates with invasive early-onset disease usually have very low (less than 2 μg/mL) serum concentrations of type III GBS antibody.[23] Recent preliminary trials have been conducted among nonpregnant adults utilizing monovalent protein-conjugate vaccines containing capsular polysaccharide antigens against serotypes Ia and Ib,[45] type II,[46] and type III.[47] Further work is needed in this area prior to the implementation of a vaccination strategy toward women of childbearing age and pregnant women.

Postnatal

In the asymptomatic parturient receiving intrapartum chemoprophylaxis, there is no need to continue antibiotics following delivery. Conversely, in the symptomatic patient with intra-amniotic infection, therapy should be continued as described previously. Because GBS may also be associated with postpartum endometritis, known carriers should be observed closely for this and treated accordingly. Of note, Schrag and associates reported a modest but significant reduction in invasive GBS disease, including postpartum endometritis, among pregnant women following implementation of the original guidelines for intrapartum prophylaxis, from 0.29 cases per 1000 live births in 1993, to 0.23 per 1000 in 1998 ($P < 0.03$).[42] It should be recognized that postpartum endometritis is frequently a polymicrobial infection and broad-spectrum antibiotics should be utilized, even among those patients known to be colonized with GBS.

SUMMARY OF MANAGEMENT OPTIONS
Group B Streptococcal Infection

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Treatment of GBS carrier before pregnancy has no benefit.	–	GPP	–
Immunization strategies currently are being evaluated.	–	GPP	–
Prenatal, Labor, and Delivery			
Treat symptomatic bacteriuria during prenatal period.	–	GPP	–
Recommended universal screening–based approach:	III	B	18,42
Perform rectal and vaginal cultures on all pregnant women at 35–37 weeks' gestation. (Exception: women with documented GBS bacteriuria during current pregnancy or history of previous GBS-infected infant warrant intrapartum prophylaxis and do not require screening.)

SUMMARY OF MANAGEMENT OPTIONS
Group B Streptococcal Infection *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal and Delivery			
Intrapartum antibiotic prophylaxis (IAP) is recommended for all women with positive culture unless delivery by cesarean section prior to rupture of membranes and onset of labor.			
If culture status is unknown at time of delivery, administer IAP for gestation <37 weeks, rupture of membranes = 18 hours, or intrapartum temperature = 38.0°C.			
Suggested management of threatened preterm delivery:	III	B	18
No culture done: obtain cultures and initiate IAP for 48 hours until results obtained or delivery occurs.			
Culture positive prior to or during labor: IAP for 48 hours or until delivery occurs.			
Culture negative prior to labor (or after 48 hours): no IAP (or stop IAP).			
Recommended prophylaxis regimens:	Ia	A	41,43,44
Penicillin G 5 million U IV followed by 2.5 mU IV every 4 hours until delivery (ampicillin 2 g IV initially followed by 1 g IV every 4 hours until delivery is acceptable but less preferred due to broader spectrum activity).			
For penicillin allergic (low anaphylaxis risk), cefazolin 2 g IV initial dose followed by 1 g IV every 8 hours until delivery.			
For penicillin allergic (high anaphylaxis risk, documented susceptibility of GBS), clindamycin 900 mg IV every 8 hours, or erythromycin 500 mg IV every 6 hours.			
For penicillin allergic (high anaphylaxis risk and resistance to clindamycin and erythromycin or susceptibility unknown), vancomycin 1 g IV every 12 hours.			
Immunization strategies currently are being evaluated.	–	GPP	–
Postnatal			
Antibiotic prophylaxis need not be continued after delivery.	–	GPP	–
Diagnosis of postpartum endometritis in a GBS-positive woman should be treated with broad-spectrum antibiotics.	–	GPP	–

LISTERIOSIS

Listeriosis is a relatively uncommon infection, caused by the organism *Listeria monocytogenes*, an aerobic and facultatively anaerobic, non-spore-forming, motile, grampositive bacillus. However, the infection shows a predilection for populations with relative immunosuppression, including infants, the elderly, and the pregnant woman, with the latter group demonstrating an incidence of 12 per 100,000 (compared to 0.7 per 100,00 in the general population, a 17-fold increase).[48] Most cases of human listeriosis during pregnancy are sporadic with occasional epidemic common-source outbreaks, mostly attributed to contaminated food substances, particularly soft cheeses, other milk products, or processed meats.

Maternal and Fetal Risks

Listeria exhibits an unusual life cycle, demonstrating obligate intracellular replication and spread, without significant exposure to the extracellular environment and its defense mechanisms. Thus, cell-mediated immunity is

the primary host defense, and this may explain the unique susceptibility of humans to this infection during periods of relative suppression of cell-mediated immunity, including pregnancy.[49]

Listeria infection is well established as a cause of pregnancy loss in domestic and wild animals. Subsequently, it has been implicated as a possible cause for recurrent spontaneous abortion in pregnant women. An Israeli study reported a significantly increased rate of multiple positive cervical cultures for *Listeria* in women with a history of recurrent losses, compared to a control group without such history.[50] However, subsequent studies failed to replicate this association, and at this time the association is controversial.[51–53] Multiple gestation pregnancies may also be at increased risk for listeriosis, as reported by Mascola and associates.[54]

Pregnant women with listeriosis most commonly suffer from a flu-like illness, with fever, general malaise, and other nonspecific symptoms. Rarely it may cause meningoencephalitis or sepsis-like manifestations. In one large series, 65% of patients had fever (defined usually as temperature at or above 38.2°C), 32% a "flu-like" illness, 21.5% abdominal or back pain, and less commonly headache, myalgia, or sore throat.[55] The average duration of symptoms prior to diagnosis was 6.6 days. Of note, 29% of patients were asymptomatic.

The primary mode of transmission to the fetus or newborn has not been proved, but is suspected to occur via either ascending infection through the vaginal canal, or transplacentally secondary to maternal bacteremia.[48] Neonatal listeriosis may present as respiratory distress, fever, neurologic symptoms, or skin rash, or it may be asymptomatic. Rarely, the infant may present with granulomatosis infantisepticum, which classically exhibits disseminated granulomatous reaction in the lung, skin, liver, and other locations. Similar to group B streptococcal infection in the neonate, there is a bimodal distribution of disease. Early-onset infection (usually defined as less than 5 days of life) is more commonly associated with maternal illness and produces a sepsis-like illness, with onset of disease exhibited within hours of birth. Late-onset disease presents more commonly as meningitis, is less commonly associated with maternal symptoms or positive *Listeria* cultures, and may be associated with nosocomial or environmental acquisition.[56]

Outcomes of pregnancies complicated by listeriosis vary. In the study by Mylonakis amd associates, 1 in 5 pregnancies resulted in spontaneous abortion or stillbirth.[55] In the remainder, 68.3% of the infants demonstrated infection with a positive culture from one or more sites. Of these infants for which follow-up was available, 62.8% recovered completely, 24.5% died, and 12.7% recovered with neurologic sequelae or other long-term complications. The worst prognosis occurred in patients with meningeal involvement. Similar data were reported

in a British review of 248 perinatal cases of listeriosis from 1967 to 1985 in which 19% of cases in which the outcome was known resulted in abortion or stillbirth.[56] Of the remaining infants in which gestational age was known, 58% were delivered prematurely (defined as <38 weeks). The overall neonatal mortality rate in known outcome cases was 35%.

Diagnosis

Listeria grows well on most routine media, although the use of selective media may be required when cultures are obtained from sites of heavy bacterial colonization such as vagina or rectum. Owing to morphologic similarity, it may be confused with nonpathogenic diphtheroids. However, the organism produces a characteristic tumbling motion when viewed on wet preparation, allowing it to be distinguished. Of the four serotypes, subtypes 1/2a, 1/2b, and 4b are responsible for the vast majority of infections, and serotype analysis may be useful in epidemic settings.[48]

The diagnosis depends upon clinical suspicion and isolation of the organism from a culture of appropriate source. In the large series mentioned previously, *Listeria* was most commonly isolated from cultures of the blood (43%), cervix/vagina (34%), and placenta (12%). It may also be cultured from amniotic fluid obtained by amniocentesis performed for suspected intra-amniotic infection. Staining of amniotic fluid by meconium, especially in the preterm infant, may increase clinical suspicion for listeriosis, as this was observed in 12 of 23 infants in a reported series from Australian authors.[57]

Management Options

Prepregnancy

Treatment of listeriosis in the nonpregnant woman is identical to that of other adult patients and dependent on the site of the infection (i.e., bacteremia versus meningitis or other location). As mentioned, the possibility of *Listeria* colonization or carriage as a risk factor for subsequent pregnancy loss has been previously evaluated with inconclusive results. Thus, the role of *Listeria* as a cause of poor obstetric outcome in asymptomatic patients is questionable, and routine screening is not recommended at this time.[48]

Prenatal, Labor, and Delivery

Prevention of maternal listeriosis has been targeted as a primary objective following epidemiologic data confirming the role of contaminated food products as a major source for listeriosis, both in epidemic and sporadic cases. A large outbreak occurred in 1985 in the Los Angeles area, in which 65.5% of all cases were pregnant women or their offspring.[58] A surveillance project followed,

TABLE 32–5

Dietary Recommendations for Pregnant Women

Do not eat hot dogs, luncheon meats, or deli meats **unless they are reheated** until steaming hot.

Do not eat soft cheeses such as feta, brie, camembert, blue-veined cheeses, and Mexican-style cheeses such as "queso blanco fresco." Hard cheeses, semisoft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese can be safely consumed.

Do not eat refrigerated pâté or meat spreads. Canned or shelf-stable pâté and meat spreads can be eaten.

Do not eat refrigerated smoked seafood **unless** it is an ingredient in a **cooked** dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel, which are most often labeled as "nova-style," "lox," "kippered," "smoked," or "jerky." This fish is found in the refrigerated section or sold at deli counters of grocery stores and delicatessens. Canned fish such as salmon and tuna or shelf-stable smoked seafood may be safely eaten.

Do not drink raw (unpasteurized) milk **or eat** foods that contain unpasteurized milk.

beginning in 1986, coordinated between the Food and Drug Administration (FDA) and CDC over multiple diverse demographic areas throughout the United States. This effort led to identification of many at-risk food sources and implementation of more stringent regulations for these food groups over the next several years.[59] In 1992, multiple agencies including the CDC, FDA, and FSIS (Food Safety and Inspection Service) issued dietary recommendations for persons at increased risk, including pregnant women. Results of this project resulted in a decrease of perinatal listeriosis in the surveillance areas from 17.4 per 100,000 (1989) to 8.6 per 100,000 (1993, $P <0.003$).[59] A list of at-risk food substances has been summarized in a handout for pregnant women on the FSIS website and may be viewed in Table 32–5.[60]

For women with suspected or confirmed listeriosis during pregnancy, intravenous antibiotics are indicated. Multiple cases have been reported of successful antepartum treatment of listeriosis with normal neonatal outcome, including cases diagnosed in the first and second trimesters.[60-62] First-line therapy consists of ampicillin 2g given every 6 hours for 10 to 14 days. The addition of gentamicin for synergistic activity has been recommended in some cases but lacks adequate study to determine a conclusive advantage. Because of its bactericidal activity and excellent intracellular concentration, trimethoprim/sulfamethoxazole (20 mg/kg/day TMP component IV divided into four daily doses) is the recommended second-line therapeutic agent in cases of penicillin-allergic patients.[49] However, because of fetal effects, its utility must be evaluated in each case individually, weighing the potential risks and benefits. This underscores the necessity of accurately determining true penicillin-allergy status and consideration of desensitization therapy. Other second-line considerations include erythromycin, vancomycin, or the carbapenems, but experience is limited. Cephalosporins are not effective against *Listeria*.

Postnatal

For mothers with proven listeriosis, antibiotic therapy should be continued for a total of 10 to 14 days for bacteremia or superficial infections, or 14 to 21 days for meningitis. Care of the neonate should involve obtaining blood and CSF cultures to assess potential infection, and empiric treatment with ampicillin and gentamicin pending culture results. Antibiotic therapy is recommended for a minimum of 14 days in cases of bacteremia or pneumonia, and 21 days in cases involving the CNS.

Evaluate neonate with blood and CSF cultures.	–	GPP	–

SEXUALLY TRANSMITTED DISEASES

Gonorrhea

Gonorrhea is a common sexually transmitted disease caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus. The prevalence of gonococcal infection in pregnancy varies, depending upon the population studied, from 0.5% to 7.4% in the United States.[63,64] Risk factors for gonococcal infection include multiple sexual partners, young age, nonwhite race, low socioeconomic status, and being unmarried.

Maternal and Fetal Risks

The most prevalent type of gonococcal infection in pregnancy is asymptomatic infection of the cervix. *N. gonorrhoeae* may also cause acute cervicitis, proctitis, pharyngitis, and disseminated systemic infection. The rate of pharyngeal gonococcal infection increases during pregnancy, possibly as a result of altered sexual practices.[65] Disseminated gonococcal infection (DGI) also occurs more frequently in pregnant than nonpregnant women.[66] DGI is characterized by a bacteremic phase associated with malaise, fever, and a pustular hemorrhagic rash, a secondary septic arthritis stage usually with asymmetrical involvement of the knees, wrists, or ankles. Acute salpingitis secondary to gonococcal infection may rarely occur during the first trimester but is rare after the 12th week of gestation because obliteration of the endometrial cavity by the pregnancy prevents ascending infection. In pregnancy, gonococcal cervicitis has been associated with premature rupture of the membranes, premature delivery, chorioamnionitis, and both postabortion and postpartum endometritis.[67,68] In addition, gonococcal ophthalmia neonatorum may develop in up to 40% of newborns exposed to maternal infection and who did not receive ocular prophylaxis.

Diagnosis

It is estimated that up to 80% of women with gonococcal infection of the cervix are asymptomatic; for this reason, prevention of sequelae of gonorrhea depends upon prenatal screening to detect infected parturients. Diagnosis depends upon the demonstration of gram-negative intracellular diplococci within leukocytes of a smear obtained from an exudate, if present, or upon culture. Cultures should be inoculated immediately after collection onto a selective medium such as Thayer-Martin. Culture-independent identification of *N. gonorrhoeae* by immunoassay or DNA detection assays, are also available and have been demonstrated to be highly specific and sensitive for the detection of gonococcal infections.

Management Options

PREPREGNANCY

Guidelines are similar for most STDs with regard to the identification and treatment of these diseases prior to pregnancy. Test of cure cultures should be done, as well as partner notification and treatment.

PRENATAL

Uncomplicated gonorrhea in pregnancy should be treated with cefixime 400 mg orally in a single dose, ceftriaxone 125 mg intramuscularly in single dose, or spectinomycin, 2 g intramuscularly in a single dose (Table 32–6). Because concurrent cervical infection with *Chlamydia trachomatis* occurs frequently,[69] azithromycin 1 g orally in a single dose or erythromycin base 500 mg orally four times daily for 7 days should also be administered, unless specific testing for *C. trachomatis* has been done. For disseminated gonococcal infection, hospitalization and parenteral therapy are recommended for initial therapy. Recommended regimens include ceftriaxone 1 g intramuscularly or intravenously once daily, ceftizoxime 1 g intravenously every 8

TABLE 32–6

Treatment of Uncomplicated Gonococcal or Chlamydial Infections in Pregnancy

Gonococcal infection
  Recommended:
    Cefixime 400 mg orally in a single dose, or
    Ceftriazone 125 mg IM in a single dose
  Alternative:
    Spectinomycin 2 g IM
    Aqueous procaine penicillin G, 4.8 million units IM or
    Amoxicillin 3 g orally, both with probenecid 1 g orally*
    All regimens followed by erythromycin 1 g orally in a
    single dose or base 500 mg orally four times daily for
    7 days, or amoxicillin 500 mg orally three times daily for
    7 days

Chlamydial infections
  Recommended:
    Azithromycin 1 g orally in a single dose, or
    Erythromycin base 500 mg orally four times daily for
    7 days
  Alternative:
    Erythromycin base 250 mg orally four times daily for
    14 days
    Amoxicillin 500 mg orally three times daily for 7 days
    Clindamycin 450 mg orally four times daily for 7 days

*Recommended only if infection source known not to have penicillin-resistant gonorrhea.

hours, or cefotaxime 1 g intravenously every 8 hours. Parenteral therapy should be continued until 24 to 48 hours after symptoms resolve and then converted to oral therapy for a total of 1 week of antibiotics. In areas where penicillin-resistant strains are uncommon, parenteral ampicillin, 1 g intravenously every 6 hours, may be used. Identification, screening, and treatment of sexual contacts of patients with gonococcal infection is recommended.

Tetracyclines and the quinoline antibiotics are also highly effective in gonococcal infections but are contraindicated in pregnancy because of potential adverse fetal effects.

LABOR AND DELIVERY

Rapid diagnostic screening tools such as Gram stain, immune-based assays, and DNA detection assays are available. These tests can be useful in evaluating the intrapartum patient at risk for infection. Intrapartum treatment of the mother may reduce the neonate's risk for infection, although specific treatment and ocular prophylaxis of the infant after delivery is usually done.

POSTNATAL

Treatment guidelines for the postpartum patient are similar to those outlined previously. However, doxycyline or the quinolone antibiotics may be used in nonlactating women.

Chlamydia Trachomatis

Chlamydia trachomatis is the cause of one of the most prevalent sexually transmitted bacterial infections in the world and is the most prevalent sexually transmitted bac-

terial organism in the United States.[70] Chlamydiae are obligate intracellular organisms. *Chlamydia trachomatis* may be differentiated into 15 serotypes. Serotypes A, B, and C cause endemic trachoma, a chronic ocular infection considered to be the leading cause of blindness in the world. Serotypes L1, L2, and L3 cause lymphogranuloma venereum, discussed later in this chapter. Serotypes D through K cause genital and ocular infections, discussed in this section. The prevalence of genital infection in pregnant women in the United States has been reported as between 2% and 37%, with an average estimate of 5% to 7%.[71-73] Risk factors for cervical infection include young age, single marital status, multiple sexual partners, and previous history of sexually transmitted disease.[70]

Maternal and Fetal Risks

The majority of infected patients have asymptomatic cervical infection. In the nonpregnant female, chlamydial infections may cause mucopurulent cervicitis, endometritis, acute salpingitis, infertility and ectopic pregnancy, and acute urethral syndrome. The role of maternal chlamydial infection in pregnancy is more controversial. Several studies have found an association between maternal cervical infection and preterm delivery, premature rupture of the membranes, low birth weight, perinatal death, and late-onset postpartum endometritis.[74-77] Two prospective studies have found that only those women with recently acquired infection, as detected by the presence of IgM serum antibody to *C. trachomatis*, are at increased risk for premature rupture of membranes, preterm delivery, and low birth weight.[73,78] Treatment and eradication of maternal cervical chlamydial infection reduce the risk of premature rupture of the membranes and premature delivery.[79-81] Thus, the available data suggest an association between maternal chlamydial infection and adverse pregnancy outcome and that screening and treatment in pregnancy is warranted.

Maternal chlamydial infection also poses significant risk to the neonate. Approximately 50% to 60% of the neonates delivered vaginally to a women with chlamydial cervicitis will be colonized with *C. trachomatis*.[72] The most common manifestations of neonatal infection are inclusion conjunctivitis and pneumonia. Eighteen percent to 50% of exposed infants develop conjunctivitis within the first 2 weeks of life, and 11% to 18% will develop pneumonia in the first 4 months of life.

Diagnosis

The diagnosis of chlamydial infections is based upon isolation of the organism, or culture-independent detection by immunoassay, DNA detection by PCR and serologic testing. Because chlamydiae are obligatory intracellular bacteria, isolation by culture requires inoculation onto a susceptible tissue culture cell line. Cell

cultures are both labor intensive and expensive and are not readily available to most clinicians. Antigen detection kits are widely available to detect chlamydia and represent a less costly alternative to culture. More recently, detection of *C. trachomatis* DNA from the genital tract, or from urine, by PCR or LCR has been demonstrated to be greater than 90% sensitive and specific for the detection of *C. trachomatis* and has largely replaced cultures and antigen detection assays. A serum microimmunofluorescent antibody test is also available to detect recent or past infection but is more useful as a research tool than for the clinical diagnosis of chlamydial infection.

Management Options

PREPREGNANCY

Chlamydia trachomatis is susceptible to a wide range of antibiotics including azithromycin, erythromycin, doxycycline, tetracycline, and ofloxacin. For the nonpregnant patient azithromycin 1 g orally in a single dose, erythromycin base 500 mg orally four times daily for 7 days, doxycycline 100 mg orally two times a day, or tetracycline 500 mg orally four times a day for 7 days is recommended. Ofloxacin, a quinoline antibiotic, given as 300 mg orally twice a day, is also highly effective in the nonpregnant patient.

PRENATAL

In pregnancy, azithromycin 1 g orally in a single dose, erythromycin base 500 mg orally four times a day for 7 days, or erythromycin ethylsuccinate 800 mg orally four times a day for 7 days is recommended (see Table 32–6). If gastrointestinal intolerance occurs, these doses may be reduced in half, and therapy extended to 14 days. Erythromycin estolate should probably not be used because it may be associated with hepatotoxicity when given during pregnancy. Because erythromycin therapy is frequently associated with gastrointestinal intolerance in pregnancy, alternative regimens have been proposed. Therapy with either amoxicillin, 500 mg orally three times a day for 7 days, or clindamycin, 450 mg orally four times a day for 14 days, results in cure rates (98% and 93%, respectively) comparable to cure rates with erythromycin base therapy, and are better tolerated by the patient.[82,83] Sexual contacts should be examined and treated.

LABOR AND DELIVERY

See the section on gonorrhea.

POSTNATAL

The incidence of neonatal inclusion conjunctivitis can be reduced by ocular prophylaxis at birth with 0.5% erythromycin ocular ointment or 1% tetracycline ointment, but not as well by 1% silver nitrate drops. Conjunctivitis that does occur, or pneumonia, should be treated with oral erythromycin for 2 weeks.

Genital Mycoplasmas

Maternal and Fetal Risks

Mycoplasmas are a ubiquitous group of microorganisms that inhabit the mucosa of the genital and respiratory tracts. They differ from bacteria in that they lack a cell wall, but they are susceptible to antibiotics that inhibit protein synthesis. The two most common genital mycoplasmas are *Mycoplasma hominis* and *Ureaplasma urealyticum*. The prevalence of these two microorganisms in the lower genital tract in sexually active women has been reported as 40% to 95% for *U. urealyticum* and 15% to 70% for *M. hominis*. Their high prevalence rates among otherwise healthy women make it difficult to determine their role in adverse pregnancy outcomes. In general, *M. hominis* has been associated in some, but not all, studies with septic abortion, postpartum endometritis, and postpartum fever.[78,84,85] *Ureaplasma urealyticum* has been associated with histologic chorioamnionitis, low birth weight, and perinatal death.[86-89]

Serologic evidence of infection with *M. hominis* has been found in 50% of febrile abortions versus 17% of afebrile abortions.[84] In a recent study of early postpartum endometritis among women, genital mycoplasmas, including *M. hominis*, accounted for 30% of the total endometrial isolates and 19% of the total blood isolates, but were usually recovered in association with other pathogenic bacteria, suggesting a mixed infection.[85] *M. hominis* has also been isolated from amniotic fluid of patients with amniotic fluid infection, but almost always in association with other bacteria, again implying a mixed infection.[24] Significantly, infected patients from whom *M. hominis* is recovered almost always respond to therapy with beta-lactam antibiotics, which have no activity against genital mycoplasmas.

A number of studies have found an association between *U. urealyticum* and chorioamnionitis[87,88] and with perinatal death.[88,90] In one study, *U. urealyticum* was isolated as the sole isolate from fetal lungs in 24 (8%) of 290 perinatal deaths.[90] Twenty-two of these deaths occurred in utero and all but one were associated with pneumonia and chorioamnionitis, implying an ascending intrauterine infection. Some studies have also found decreased birth weight among offspring of women colonized with *U. urealyticum*,[86] but this association has not been confirmed by others.[78] Intervention treatment trials have also been inconclusive. McCormack and associates demonstrated an increase in birth weight among the offspring of women colonized with *U. urealyticum* treated with erythromycin in the third trimester when compared to colonized women treated with placebo.[91] Because the presence of potential genital pathogens was not ascertained, their potentially confounding influence upon birth weight cannot be excluded. In contrast, Eschenbach and associates found no beneficial effect of erythromycin taken for up to 14 weeks by a large cohort of women colonized for *U. ureaplasma* upon birth weight,

gestational age at delivery, frequency of premature rupture of membranes, or in neonatal outcome.[92] In this study, women also colonized with either *Chlamydia trachomatis* or group B streptococci were excluded from analysis, eliminating any potential confounding bias from coinfection.

Management Options

Taken collectively, the data linking either *M. hominis* or *U. urealyticum* to adverse pregnancy outcome are inconclusive. At present, antenatal vaginal cultures for either of these mycoplasmas cannot be recommended. Current evidence does not support the treatment of colonized patients for the prevention of adverse pregnancy outcomes. If treatment is deemed necessary, tetracycline is effective against both *M. hominis* and *U. urealyticum* but should not be used in pregnancy. *Ureaplasma urealyticum* is also sensitive to erythromycin but is resistant to clindamycin; *M hominis* is resistant to erythromycin but sensitive to clindamycin. Because the mycoplasmas lack a cell wall, they are resistant to beta-lactam antibiotics.

Chancroid

Maternal and Fetal Risks

Chancroid is an acute ulcerative disease, usually of the genitals, caused by infection with *Haemophilus ducreyi*, a facultative gram-negative bacillus. Although rare in North America and Europe, it remains an important public health concern in developing countries. Chancroid is spread only through sexual contact and is much more prevalent in men than women. The incubation period after transmission is usually between 4 and 7 days. A chancre then develops at the site of entry, beginning as a small papule that, over the course of 1 to 2 days, becomes eroded and ulcerated. Although the ulcer is usually quite painful in men, it is frequently not painful in women. In women, the majority of ulcers are on the fourchette, vestibule, or labia minora. The classic ulcer of chancroid is shallow with an irregular border surrounded by erythema. The base of the ulcer is frequently covered with a necrotic exudate. Painful inguinal adenopathy develops in about 50% of cases and may lead to suppuration and spontaneous rupture if untreated. These buboes appear 7 to 10 days after the initial ulcer and are unilateral in two thirds of cases. *Haemophilus ducreyi* has not been shown to cause systemic infection or spread to distant sites and poses no special risk to pregnancy.

Management Options

The diagnosis of chancroid is based upon clinical characteristics and Gram stain and culture of the ulcer or aspirated bubo. The Gram stain may reveal gram-negative rods that form chains but has a sensitivity of only 50%.[93] Cultures should be taken from the base of the ulcer and

placed on selective media. Cultures are both sensitive and specific in the diagnosis of *H. ducreyi* infection, but may not be readily available. An enzyme-linked immunosorbent assay has been developed that is both sensitive and specific and may represent a good alternative when culture is not available.

H. ducreyi is susceptible to a variety of antibiotics, although resistance to sulfonamides and tetracycline has emerged which precludes their use. Quinolones, which are very active against *H. ducreyi*, are contraindicated during pregnancy. Current recommended regimens which may be given in pregnancy include (1) azithromycin 1 g orally in a single dose; (2) erythromycin base 500 mg four times daily for 7 days; (3) ceftriaxone 250 mg intramuscularly as a single dose; and (4) trimethoprim/sulfamethoxazole 160/800 mg orally two times daily for 7 days. Azithromycin and ceftriaxone offer the advantage of single-dose therapy. Although evidence of fetal toxicity is lacking, trimethoprim/sulfamethoxazole is generally not recommended for use in pregnancy if other alternatives are available because it is a folic acid antagonist. Treatment of sexual partners is recommended.

Lymphogranuloma Venereum

Maternal and Fetal Risks

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by *Chlamydia trachomatis* serotypes L1, L2, and L3. It is characterized by inguinal lymphangitis, anogenital lesions, and fibrosis with gross distortion of the perineal tissues. Although LGV occurs sporadically in North America, Europe, and Australia, it is endemic in Africa, India, Southeast Asia, and parts of South America.[94] LGV is predominantly a disease of lymphatic tissue characterized by thrombolymphangitis and spread of the inflammatory process into the adjacent tissues. Three stages of infection are recognized: primary, secondary, and tertiary. The primary lesion is characterized by a small shallow genital ulcer that appears at the site of infection after an incubation period of 3 to 12 days and heals rapidly and is associated with few symptoms. The secondary stage occurs 10 to 30 days later and is characterized by inguinal lymphadenitis, buboes, inflammatory mats of contiguous lymph nodes, and loculated abscesses. The tertiary stage is characterized by a chronic inflammatory response with progressive tissue destruction, ulceration, fistula formation, and lymphatic obstruction. Antibiotic treatment during the secondary stage will prevent these tertiary complications.

The course of the disease is not dramatically altered by pregnancy, and transmission to the fetus does not occur. However, infection may be acquired during birth and passage through the infected birth canal.

Management Options

The diagnosis of LGV is based upon clinical appearance, serologic test, and recovery of *C. trachomatis* from

infected tissue or its identification by the direct immunofluorescent antibody test. The Frei intradermal antigen test, formerly used in the diagnosis of LGV, has now largely been replaced by the complement fixation test for *Chlamydia* group antibodies. This test is very sensitive and titers greater than 1:64 are diagnostic of infection.

A variety of antibiotics have been used to treat LGV. Nonpregnant patients and sexual partners of pregnant patients should be treated with tetracycline (500 mg orally four times a day) or doxycycline (100 mg orally two times a day) for 21 days. An alternative regimen that may be used in pregnancy is erythromycin base 500 mg orally four times a day for 21 days. Late sequelae such as fistulas or strictures may require subsequent surgical repair.

Granuloma Inguinale (Donovanosis)

Maternal and Fetal Risks

Granuloma inguinale (GI) is a rare, chronic genital infection characterized by granulomatous ulcers. It is common in tropical climates and developing countries, but extremely rare in temperate climates.[95] Granule inguinale is caused by infection with Calymmatobacterium granulomatis, a facultative, gram-negative bacillus. Although most infections probably result from sexual transmission, autoinoculation and nonsexual transmission also occur. The infection is only mildly contagious, and repeated close physical contact is necessary for transmission.[96] Following infection, the incubation period varies from 8 to 80 days. The disease begins as a subcutaneous nodule that erodes through the skin and slowly enlarges to form an exuberant, granulomatous heaped ulcer, which is usually painless.

Redundant, beefy-red granulation tissue may be present, giving an exophytic appearance to the lesion. In the female, these lesions are most commonly on the labia.

Pregnancy may accelerate the growth of these lesions. The effects of GI upon the fetus are not completely understood, but perinatal transmission at the time of birth through an infected birth canal has been reported.[97]

Management Options

The diagnosis of GI is based upon the clinical appearance of the disease. The diagnosis is readily confirmed by examination of a smear of a crushed tissue preparation of the lesion. The smear is stained with Wright or Giemsa stain and examined for Donovan bodies. Donovan bodies are the darkly stained organisms within cytoplasmic inclusions contained in infected mononuclear cells. Their presence is diagnostic for GI. Neither cultures nor serologic tests are available.

The treatment of GI for nonpregnant patients is tetracycline 500 mg orally four times a day for a minimum of 3 weeks. Chloramphenicol and gentamicin have been used successfully for resistant cases. In pregnancy, erythromycin base (500 mg orally four times a day) for at least 3 weeks or trimethoprim-sulfamethoxazole (two tablets orally twice a day) are effective. Azithromycin (1 g orally per week for at least 3 weeks) may also be effective. The addition of a parenteral aminoglycoside should be considered if improvement is not evident within the first few days of therapy. Treatment should continue for a minimum of 3 weeks and until lesions are completely healed to prevent recurrence. Treatment of asymptomatic sexual partners is generally not recommended.

VAGINITIS

Vaginal discharge is one of the most common complaints of pregnant patients. The discharge may be the result of normal physiologic adaptations of pregnancy or may result from infectious vaginitis, with possible increased risk for pregnancy complications. The vagina has both a nutrient-rich biochemical mileau and a complex microbial flora. A normal vaginal discharge consists of water (primarily as a serum transudate), desquamated epithelial cells, microorganisms, electrolytes, and organic compounds including organic acids, fatty acids, proteins, and carbohydrates (primarily glycogen).[98] Normal vaginal fluid contains two to nine species of facultative and anaerobic bacteria in concentrations of 10^9 colony-forming units/mL.[99] Normally, facultative lactobacillus species account for the majority of the total organisms present. These microorganisms utilize the available glycogen, producing lactic acid, which serves to acidify the vaginal pH to less than 4.5, inhibiting the growth of non-acid-tolerant potentially pathogenic microorganisms. They also produce hydrogen peroxide, a potent antimicrobial toxin to other microorganisms including *Candida albicans*, *Gardnerella vaginalis*, and anaerobic bacteria.[99,100] When this complex relationship is changed, potentially pathogenic microorganisms indigenous to the vagina such as *C. albicans* or *G. vaginalis* and the anaerobes, may proliferate and cause vaginal discharge. Alternatively, sexually transmitted exogenous microorganisms, such as *Trichomonas vagi-*

nalis, may disrupt the normal vaginal ecosystem and lead to vaginitis.

Pregnancy may also lead to physiologic changes of the lower genital tract, which may predispose to vaginitis. During pregnancy, the vaginal walls become engorged with blood, leading to increased transudation, and the glycogen content of the vagina increases.[99] Elevated levels of progesterone seen during pregnancy enhance the adherence of *C. albicans* to vaginal epithelial cells. Finally, cell-mediated immunity is impaired during pregnancy, predisposing to candidal infections.

The three most commonly occurring causes of infectious vaginitis in pregnancy are bacterial vaginosis, candidiasis, and trichomoniasis. Although frequently asymptomatic, these infections have been implicated in a variety of adverse pregnancy outcomes. Bacterial vaginosis has been associated with premature rupture of the membranes, preterm labor and delivery, amniotic fluid infection, chorioamnionitis, and postpartum endometritis.[75,85,89,101,102] *Trichomonas vaginalis* has been associated with premature rupture of the membranes and a reduction in gestational age at delivery,[71,103] and *Candida albicans* has been associated with intraamniotic infection.[102]

The diagnosis of vaginitis is based in large part upon the appearance of the discharge and microscopic examination of the discharge. However, microscopic examination is somewhat insensitive and accurately identifies only 60% to 70% of women with symptomatic infection. Cultures for *Candida* species and *T. vaginalis* are both highly sensitive and specific but are not widely available, and vaginal cultures for anaerobes or *G. vaginalis* are not useful in the identification of bacterial vaginosis. Other adjunctive diagnostic tests, as described later, are therefore frequently utilized in confirming the diagnosis of vaginitis.

Bacterial Vaginosis

Maternal and Fetal Risks

Bacterial vaginosis is the most common vaginal infection of sexually active women. Bacterial vaginosis occurs in approximately 20% of pregnant women.[75,101,102] In contrast to other vaginal infections, bacterial vaginosis cannot be attributed to a single pathogenic microorganism. Rather, the symptoms associated with bacterial vaginosis result from an increase in the prevalence and concentration of certain facultative and anaerobic bacteria normally found as part of the vaginal microflora. Specifically, there is an increased prevalence of *Gardnerella vaginalis*, selected anaerobes (*Bacteroides*, *Peptostreptococcus*, and *Mobiluncus*), and *Mycoplasma hominis*, and a decreased prevalence of hydrogen peroxidase–producing *Lactobacillus*.[100,104] Additionally, there is a 100-fold increase in the intravaginal concentration of *G. vaginalis* and a 1000-fold increase in the concentration of the

Hillier, 1995[108]	1.4	1.1–1.8

anaerobes.[104] Thus, the diagnosis of bacterial vaginosis does not depend upon the recovery or identification of any single microorganism from the vagina, but rather requires the recognition of the altered vaginal microbial milieu. An association between bacterial vaginosis and adverse pregnancy outcome has been reported in several studies. Bacterial vaginosis has been associated with preterm labor or delivery, amniotic fluid infection, chorioamnionitis, and postpartum endometritis. This association is based upon the following:

- Case-control and cohort studies demonstrating an approximate twofold increase in preterm labor or delivery among women with bacterial vaginosis (Table 32–7)
- The recovery of bacterial vaginosis–associated microorganisms from the amniotic fluid of 30% of women with intact fetal membranes in preterm labor and subclinical amniotic fluid infection (see Martius and Eschenbach[101] for a review)
- The frequent recovery of bacterial vaginosis–associated microorganisms from amniotic fluid of women with overt clinical amniotic fluid infection[105] or from the chorioamnion of women with histologic chorioamnionitis or preterm delivery[89]
- The recovery of *Gardnerella vaginalis* or anaerobes associated with bacterial vaginosis from the endometrium in over 60% of women with early postpartum endometritis[106]

Little is known about the mechanisms by which bacterial vaginosis may cause prematurity. The increased intravaginal concentrations of bacteria may simply overwhelm the local host defenses, allowing for ascending infection. Alternatively, these bacteria could also produce protease or phospholipases, which weaken the membranes or stimulate prostaglandin production.[107] Although the magnitude of the increased risk for prematurity noted in

these studies is modest (approximately a twofold increased risk compared to patients without bacterial vaginosis), the total impact upon prematurity may be much greater given the high prevalence of 20% for bacterial vaginosis in pregnancy. It has been estimated that as many as 6% of preterm deliveries of infants with low birth weight may be attributable to bacterial vaginosis.[108]

Thus, bacterial vaginosis represents an important, and potentially preventable cause of prematurity. Two recent studies have demonstrated significant reductions of 40% to 50% in preterm deliveries among pregnant women with bacterial vaginosis, who were otherwise identified as at high risk for preterm delivery, treated with metronidazole.[109,110]

However, routine prenatal screening for bacterial vaginosis and treatment of asymptomatic cases among low risk obstetric populations has not been well studied and cannot yet be recommended until adequate randomized prospective treatment trials have been performed to ascertain whether treatment reduces the risk of an adverse outcome of pregnancy.

Diagnosis

The most common symptom among women with vaginosis is thin, watery nonpruritic discharge with a fishy odor. However, one half of women with bacterial vaginosis are asymptomatic.

Criteria for the clinical diagnosis of bacterial vaginosis are well established.[106] These criteria include (1) the presence of a thin, homogeneous discharge, which adheres to the vaginal walls; (2) a vaginal pH above 4.5; (3) the release of a fishy odor upon alkalinization with 10% potassium hydroxide; and (4) clue cells on a saline wet mount. The diagnosis of bacterial vaginosis requires the presence of three of these four criteria. The diagnosis of bacterial vaginosis can also be made by direct Gram stain of the vaginal discharge. The Gram stain is both highly sensitive (97%) and specific (79%) when compared to the clinical diagnosis and offers the advantages of being easily performed, readily available, and inexpensive with high interobserver reproducibility.[106]

Management Options

The treatment of choice for symptomatic bacterial vaginosis is metronidazole given orally in a dose of 250 mg three times daily for 7 days, or 375 mg or 500 mg twice daily for 7 days. This results in cure rates of 90%. A single 2-g oral dose of metronidazole is also effective. Oral clindamycin, 300 mg twice a day for 7 days, may be used an an alternative. In pregnancy, it is usually recommended that treatment with these systemic regimens be deferred until the beginning of the second trimester, when fetal organogenesis is complete. There has been some concern about the use of nitroimidazoles in pregnancy. Nitroimidazoles cross the placenta and are mutogenic in bacteria and carcinogenic in some animals. However,

human studies have not revealed any increase in the expected frequency of congenital anomalies among the offspring of mothers treated with metronidazole during the pregnancy.[111] Further, long-term surveillance studies of women treated for trichomoniasis have not found any increase in the occurrence of cancer attributable to metronidazole.[112] Although evidence of fetal or maternal harm is lacking, the nitromidazoles should probably be avoided during the first trimester. Cure rates utilizing topical therapy with metronidazole vaginal gel 0.75%, given intravaginally once daily for 5 days, or clindamycin cream 2.0%, given intravaginally once daily for 7 days, are comparable to systemic therapy and may safely be utilized at any gestational age. However, topical therapy may not be adequate to reduce the risk of preterm delivery. Further studies are necessary to address this important consideration. Treatment with other antimicrobial agents, including sulfa cream, amoxicillin or ampicillin, and erythromycin has resulted in disappointing cure rates of 14% to 56% and cannot be recommended.

Candida Vaginitis

Maternal and Fetal Risks

Candida vaginitis may be caused by many species of *Candida*, but the predominant species is *Candida albicans*, which is responsible for 80% to 90% of infections. The remainder are caused by *Candida (Torulopsis) glabrata* and other *Candida* species. These organisms are saprophytic fungi, which may be recovered from the vagina in 25% to 40% of asymptomatic women. *Candida* also accounts for approximately 25% of all symptomatic vaginitis among nonpregnant patients and up to 45% of vaginitis in pregnancy. In pregnancy, alterations in the vaginal microflora, glycogen availability, and a depression in maternal cellular immunity may all contribute to increase the risk of *Candida* overgrowth leading to vaginitis. Although infrequent, *C. albicans* has been reported as a cause of amniotic fluid infection.[102]

Diagnosis

Women with vaginal candidiasis experience vulvar and vaginal pruritus, external dysuria, and a nonmalodorous flocculent discharge. Examination usually reveals an erythematous vulvar rash and a characteristic white "cottage cheese" discharge that adheres to the vaginal walls. The vaginal pH is usually lower than 4.5 and no odor is present. Microscopic examination of material suspended in 10% potassium hydroxide reveals typical mycelial forms and pseudohyphae in 80% of patients with symptomatic infection. Because *Candida* species may exist in the vaginal flow in low concentrations among normal asymptomatic patients, cultures are usually not indicated. Cultures should be limited to women in whom candidiasis is suspected but cannot be confirmed by microscopic examination.

Management Options

Treatment by local application of antifungals results in relief of symptoms and eradication of the yeasts in 70% to 90% of patients. The mainstay of treatment has been with imidazoles. These broad-spectrum antifungals include miconazole, clotrimazole, teraconazole, and butaconazole. These agents inhibit fungal ergosterol synthesis, resulting in disruption of the cell membrane. They may be given as a one-time intravaginal suppository or as either 3-day or 7-day courses of intravaginal suppositories or creams given once daily at bedtime. In recognition of the immunosuppression of pregnancy, most clinicians prefer a 7-day course of either suppositions or cream. These imidazoles are not absorbed systemically and are safe to use in pregnancy. Boric acid powder, in 600-mg capsules, placed intravaginally daily for 14 days is also 90% effective in eradicating symptomatic vaginal candidiasis and has the advantage of being very inexpensive.[113] Although borate is poorly absorbed systemically in nonpregnant women, its absorption during pregnancy is uncertain. Thus, boric acid should probably not be used during pregnancy if alternative therapies with topical imidazoles are available. Two other antifungal agents that are systemically absorbed after oral or intravenous administration are ketoconazole, an imidazole, and fluconazole, a triazole. These both have superb activity against *Candida* species and are useful in the treatment of systemic fungal infections or chronic, recurrent vaginal candidiasis in nonpregnant women.

Trichomoniasis

Maternal and Fetal Risks

Trichomoniasis is caused by *Trichomonas vaginalis*, a sexually transmitted anaerobic protozoa. *T. vaginalis* may be recovered from 40% of women screened in sexually transmitted disease clinics, and from the prostatic fluid of 70% of the male contacts of the women with symptomatic trichomoniasis.[114,115] The prevalence of trichomoniasis in pregnancy ranges from 6% to 22%. Risk factors associated with *T. vaginalis* colonization include black race, cigarette smoking, greater number of sexual partners, and a history of gonorrhea.[116] It is estimated that approximately 50% of women harboring *T. vaginalis* are asymptomatic.[114]

In addition to vaginitis, *T. vaginalis* may also cause other infections of the lower genitourinary tract including bartholinitis, urethritis, periurethral gland infection, and cystitis. Although risk of infection to the neonate is low (less than 1%), vaginitis and cystitis may occur as manifestations of neonatal disease. *T. vaginalis* has also been rarely suspected as a cause of neonatal pneumonitis. Although the relationship between vaginal trichomoniasis and adverse pregnancy outcome has not been well studied, two prospective studies have found a decrease in mean gestational age at delivery and an increase in premature rupture of membranes among women infected with *T. vaginalis*.[71,103] Further studies are necessary to confirm these relationships.

Diagnosis

Women with trichomoniasis characteristically complain of a profuse and sometimes frothy malodorous, pruritic vaginal discharge. Dysuria and lower abdominal tenderness may also be present. On examination, a gray or yellow-green purulent discharge is frequently present. The pH of the discharge is usually higher than 4.5 and may have an amine odor after addition of 10% potassium hydroxide. Small submucosal punctate hemorrhages of the cervix, the so-called "strawberry cervix" are present inconsistently. Microscopically, motile trichomonads may easily be identified on a saline wet mount by their characteristic pear shape, flagella, and rapid, jerking motility. Polymorphonuclear leukocytes are also present on saline wet mount microscopy and may be so abundant that they obscure the trichomonads. The sensitivity of the saline wet mount, when compared to culture, is 60%, but its specificity is near 100%.[117] *Trichomonas* cultures are easily performed utilizing Diamond's medium and are highly sensitive (92%–95%) and specific. However, cultures have limited practicality in the clinical setting because 3 to 7 days are needed for growth before the diagnosis can be confirmed. Trichomonads can also be seen on a Papanicolaou smear with a similar sensitivity to the wet mount, but with a higher rate of false positive results. Other sensitive and specific rapidly performed diagnostic tests have recently been developed, including direct immunofluorescence assay, enzyme-linked immunoassay, and latex particle agglutination. These are not, however, in widespread use currently. All women with trichomoniasis, whether symptomatic or not, should have a culture taken for *Neisseria gonorrhoeae* because of the frequency of coinfection.

Management Options

Because *T. vaginalis* resides not only in the vagina but also in the urethra and bladder, systemic therapy is necessary for treatment. The only effective therapy for trichomoniasis are the nitroimidazole antibiotics, including metronidazole, ornidazole, and tinidazole. Standard treatment with metronidazole consists of either 250 mg orally three times daily for 7 days, 375 mg or 500 mg orally twice daily for 7 days, or alternatively, a single 2-g oral dose. These regimens result in a 90% cure rate and the choice of regimen depends upon the physician and patient. With tinidazole, a single 1.5-g oral dose is usually adequate to eradicate *T. vaginalis*. Patients should be advised not to drink ethanol for 24 hours after the last dose because of a disulfiram-like effect of the medication. Simultaneous treatment of the male consort is required to prevent recurrent trichomoniasis in the female.

The treatment for patients who do not respond to the initial therapy is controversial. Metronidazole-tolerant and metronidazole-resistant strains of *T. vaginalis* do occur, but infrequently. Low to moderate levels of resistance (metronidazole-tolerant strains) occur in 1 of every 200 to 400 cases of trichomoniasis and highly metronidazole-resistant strains occur in 1 in every 2000 to 3000 cases.[117] Most cases associated with strains that have low to moderate resistance can be cured by oral administration of 2 to 2.5 g metronidazole per day, in divided doses, for 7 days. Most cases caused by highly resistant strains can be cured by increasing the dose of metronidazole to 3 g daily, orally, in divided doses, for 14 days. Alternatively, cures have been reported with the use of intravenous metronidazole, 2 g given every 6 to 8 hours for 3 days.[118] Metronidazole-associated neurotoxicity may occur with longer courses of therapy.

Although cross-resistance to other nitroimidazoles among metronidazole-resistance strains occurs, it is usually incomplete. Sixty-five percent to 70% of metronidazole highly resistant strains are susceptible to tinidazole. For those cases, treatment with oral tinidazole, 2 g daily for 7 to 14 days, has been highly effective in eradicating *T. vaginalis*.[117]

There has been concern regarding the use of nitroimidazoles in pregnancy, as noted previously. Although evidence of fetal or maternal harm is lacking,[119] systemic nitroimidazoles should probably be avoided during the first trimester. As an alternative treatment in the first trimester, treatment with intravaginal 100-mg clotrimazole suppositories (a chemically related nonabsorbed imidazole antifungal) daily for 14 days provides symptomatic relief in approximately 50% of patients with trichomoniasis.[120,121]

Ideally, treatment should be given prior to pregnancy, because treatment during pregnancy has not been demonstrated to reduce the occurrence of adverse pregnancy outcomes[108] and has been associated with an increased risk of spontaneous preterm birth in recent studies.[109,120,122]

SUMMARY OF MANAGEMENT OPTIONS
Bacterial Vaginosis, Candidiasis, Trichomonas

Management Options	Quality of Evidence	Strength of Recommendation	References

Trichomonas			
Prepregnancy, Prenatal, and Postnatal			
Treat patient and partner systemically with a nitroimidazole antibiotic (metronidazole, ornidazole, tinidazole).	IV	C	117,118

CONCLUSIONS

- GAS infection can result in a potentially fatal infection in the mother requiring intensive therapy in the form of parenteral broad-spectrum antibiotics, inotropic support, immunoglobulin, and possible surgical debridement; the fetus is at risk of preterm delivery, chorioamnionitis, and stillbirth.
- GBS is largely asymptomatic in the mother but can produce a profound neonatal illness with a high mortality rate; routine screening at 35 to 37 weeks to identify GBS carriers and subsequent use of peripartum antibiotics will reduce this risk significantly.
- Listeriosis is a rare infection with an increased risk of miscarriage or fetal death; preventive measures should be directed at food handling.
- Sexually transmitted diseases are mainly a risk to the mother and are amenable to antibiotic therapy.
- Bacterial vaginosis is important because of its association with preterm labor and delivery; effective treatment can reduce this risk.
- *Candida* and *Trichomonas* infections produce troublesome symptoms for the mother, but they are very responsive to treatment.

Parasitic Infections

J. M. Ernest

INTRODUCTION

In the developing world, pregnant women frequently experience a cycle of undernutrition and parasitic infections, resulting in adverse pregnancy outcomes, including abortion, malformation, and neonatal death. Although malnutrition in general and parasitic infections specifically are less common in developed countries, no society is immune from their potential effects during pregnancy. Five parasitic infections that have major health, financial, or combined consequences worldwide are Lyme disease, malaria, tuberculosis, syphilis, and toxoplasmosis.

LYME DISEASE

General

In the early 1970s, a mysterious clustering of juvenile rheumatoid arthritis-like cases occurring in children in and around Lyme, Connecticut, was subsequently recognized as a distinct disease and named Lyme disease. Further investigation revealed that tiny deer ticks infected with a spirochetal bacteria later named *Borrelia burgdorferi* were responsible for the outbreak.[1] Subsequent research has discovered additional vectors, three distinct stages of the disease, and multiple therapy options.

Ticks, obligate blood-sucking members of the order *Acarina* and class *Arachnida*, are the most common agents of vector-borne diseases in the United States.[2] Black-legged ticks *(Ixodes scapularis)* are responsible for transmitting *B. burgdorferi* to humans in the northeastern and north central United States; on the Pacific Coast, the bacteria are transmitted to humans by the western black-legged tick *(Ixodes pacificus)*. The life cycle of ticks is 2 years and includes egg, larva, nymph, and adult. *I. scapularis* nymphs appear to be the most important vector

for transmission of *B. burgdorferi*. Ixodes ticks are much smaller than common dog and cattle ticks and usually feed and mate on deer during the adult part of their life cycle. The larvae (or seed ticks) are six-legged, whereas adult and nymphs are eight-legged. In their larval and nymphal stages, these ticks are no bigger than a pinhead. According to laboratory studies, a minimum of 36 to 48 hours of attachment of the tick is required for transmission,[3] presumably because of the time required for the bacteria to travel from the midgut of the tick to its salivary glands.

In the United States, Lyme disease is mostly localized to states in the northeastern, mid-Atlantic, and upper north central regions and to several counties in northwestern California, although it has been reported in 49 of the 50 states. In 2000, 17,730 cases of Lyme disease were reported to the Centers for Disease Control and Prevention (CDC), making it the most common vector-borne illness in the United States.[4] Ninety-two percent of these were from the states of Connecticut, Rhode Island, New York, Pennsylvania, Delaware, New Jersey, Maryland, Massachusetts, and Wisconsin. Most cases occur in the United States between May and August, corresponding with increased outdoor human activity and nymphal activity.

Diagnosis

Clinically, Lyme disease has three stages:

- early-localized
- early-disseminated
- late-stage disease.

Only the early-localized stage contains a hallmark unique to Lyme disease—the erythema migrans rash—which is present in 60% to 80% of patients at the site of the bite.[5] Adding to this difficulty in diagnosis is the frequent absence of notable tick bite in many individuals who subsequently have symptoms of Lyme disease.

Although the gold standard for diagnosis of an infectious disease is isolation of the causative organism, this confirmation is often difficult in Lyme disease and the reliability of other methods currently available is questionable.[6] The diagnosis of Lyme disease is therefore based on the history of a tick bite in an endemic area and on characteristic clinical findings. Serology using enzyme-linked immunosorbent assay (ELISA) is the most common laboratory test to screen for antibodies to *B. burgdorferi*, but the test is not standardized and results may vary between laboratories, with false-negatives and false-positives commonly seen.[7] If obtained, a positive or equivocal ELISA should be followed by an immunoblot on the same specimen to detect IgM and IgG antibodies. If positive, the diagnosis is confirmed.[6] In patients with only cutaneous disease, laboratory testing is neither necessary nor recommended; in suspected cases of extracutaneous Lyme diseases, laboratory studies are essential.

Diagnosis of Early-Localized Disease

The hallmark of Lyme disease—the erythema migrans rash—typically occurs within 1 week of infection, but can develop as late as 16 weeks after the tick bite. The rash develops centrifugally as an erythematous, annular, round to oval, well-demarcated plaque and can reach a diameter of more than 30 centimeters. Occasionally, the lesion might be hemorrhagic or nonmigratory. The rash may be accompanied by constitutional symptoms such as myalgia, arthralgia, low-grade fever, and regional lymphadenopathy. Untreated, the lesions usually resolve within 3 to 4 weeks. Within days to a few weeks after the infection, hematogenous and lymphatic dissemination of the organism to distant sites occurs, leading to the early-disseminated stage.

Diagnosis of Early-Disseminated Disease

The most characteristic manifestations of this stage occur in the skin, musculoskeletal system, and neurologic system.[8] Skin manifestations during this stage include the development of other annular plaques resembling erythema migrans, found in up to half of patients. About 6 months after infection, approximately 60% of patients develop musculoskeletal symptoms, including arthralgias and myalgias early in the process, and asymmetrical, oligoarticular arthritis primarily of the large joints (especially the knee) later in the disease. The most common neurologic feature is cranial neuropathy, including unilateral or bilateral facial paralysis. Cardiac involvement, a less common component of this stage, may include atrioventricular block (in up to 8% of patients), left ventricular dysfunction, pericarditis, or fatal pancarditis.[9]

Diagnosis of Late-Stage Disease

Manifestations of late-stage disease can occur months to years after the initial infection and most commonly involve the skin, musculoskeletal system, and neurologic system. Localized scleroderma-like lesions may involve the skin, and approximately 10% of patients in the United States with untreated disease will develop chronic Lyme arthritis, an asymmetrical oligoarticular or monoarticular arthritis. Permanent joint disease is unusual. The central and peripheral nervous system can be affected, most commonly with intermittent distal paresthesias or radicular pain.[7]

Maternal and Fetal Risks

Although transplacental transmission of *B. burgdorferi* has been reported, it seems to be infrequent.[10,11] In a report by Markowitz and colleagues, in which 19 cases of Lyme disease were collected retrospectively, 5 had adverse outcomes, including syndactyly, cortical blindness, intrauterine fetal death, prematurity, and rash. Neither trimester of acquisition nor therapy administered seemed to be associated with the outcome.[12] Weber and Pfister collected 58 cases from Slovenia, including 13 in the first trimester, 27 in the second trimester, and 18 in the third trimester, and concluded that the outcomes of one missed abortion and five preterm infants revealed no causal connection between the organism and adverse fetal effects.[13] Likewise, Williams and Strobino divided a group of 463 infants after birth into those serologically positive and negative to *B. burgdorferi* and found no difference in the incidence of malformations based on the infant's serology or geographic location.[14] Therefore, recommendations for therapy during pregnancy are similar to those of nonpregnant individuals, with the exception of avoidance of tetracyclines and doxycycline in pregnancy.

Management Options

Prepregnancy and Prenatal

With the exception of the avoidance of tetracyclines during pregnancy, management options are similar before and during pregnancy. Four clinical situations can occur during which the practitioner may need to consider Lyme disease and the need for therapy:

- tick bites without signs of infection
- early-localized
- early-disseminated
- late-stage disease.

TICK BITES WITHOUT SIGNS OF INFECTION

Although some practitioners routinely treat patients who have been bitten by *I. scapularis*, a meta-analysis pooling over 600 patients estimated that if amoxicillin rather than doxycycline were used, 8 cases of drug-associated rash (including 1 severe life-threatening reaction) would occur for every 10 cases of early Lyme disease that were prevented. The authors concluded that routine prophylaxis is

not indicated in this situation.[15] Due to the current limitations of the techniques, routine serologic tests after a tick bite are also not recommended. Persons who remove attached ticks should be monitored closely for signs and symptoms of tick-borne diseases for up to 30 days and should be especially observant for the occurrence of a skin lesion at the site of the tick bite (which may suggest Lyme disease) or a temperature >38°C (which may suggest other tick-related illnesses). Persons who develop a skin lesion or other illness within 1 month after removing an attached tick should promptly seek medical attention.

EARLY-LOCALIZED STAGE

Identification of the bulls-eye rash of erythema migrans should prompt early oral treatment for nonpregnant adults with doxycycline 100 mg PO twice a day for 10 to 21 days. Pregnant women should be given amoxicillin 500 mg PO three times a day for 21 days. If allergic to penicillin, cefuroxime axetil 500 mg PO twice a day for 21 days or erythromycin 250 to 500 mg PO four times a day for 21 days may be substituted.[16] More than 90% of infected individuals respond to antibiotic therapy; when prompt and complete response is not seen the practitioner should consider a later or underdiagnosed stage of disease (such as unsuspected neurologic disease) or co-infection with other tick-borne infections, such as ehrlichiosis or babesiosis.

A Jarisch-Herxheimer–type reaction may occur in the first 24 hours of treatment, consisting of fever, chills, myalgia, headache, tachycardia, increased respiratory rate, and mild leukocytosis.[17] Defervescence usually takes place within 12 to 24 hours, and the patient can be managed by bed rest and appropriate antipyretics.

EARLY-DISSEMINATED AND LATE-STAGE DISEASE

In the absence of neurologic involvement or third-degree atrioventricular heart block, oral doxycycline or amoxicillin are recommended for early disseminated disease. Cefuroxime axetil is an acceptable alternative when the patient is unable to take either doxycycline or amoxicillin. Parenteral antibiotics such as ceftriaxone 2 grams IV daily for 14 to 28 days may be used for acute neurologic disease and third-degree atrioventricular heart block.

Labor and Delivery

No specific recommendations apply to the intrapartum period.

Postnatal

Women who develop Lyme disease during pregnancy should be monitored for up to 1 year for symptoms that may represent late-stage disease. These include localized scleroderma-like lesions of the skin, chronic Lyme arthritis involving single large joints such as the knee, and intermittent distal paresthesias or radicular pain.

SUMMARY OF MANAGEMENT OPTIONS
Lyme Disease

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy and Prenatal			
Avoid tick-infested areas when possible and carefully remove all ticks as soon as recognized.	IV	C	16
Observe skin after tick bites for up to 30 days for signs of infection.	IIb	B	16
Prophylactic antibiotics are usually not warranted in absence of infection.	Ib	A	15
Doxycycline 100 mg po bid for 10 to 21 days for nonpregnant or amoxicillin 500 mg po tid for 21 days for pregnant adults are comparable therapies for early-stage disease.	Ib	A	13,16
Intravenous therapy should be considered for late-stage disease.	III	B	13,16
Postnatal			
Observe the patient for up to 12 months for signs of chronic Lyme disease.	IV	C	13,16

TUBERCULOSIS

General

Tuberculosis (TB) is a disease with enormous worldwide implications; the World Health Organization (WHO) estimates that approximately one third (1.9 billion people) of the world's population is infected with *Mycobacterium tuberculosis*. The disease is thought to cause at least 3 million deaths each year, and the annual number of new cases is now nearly 8 million.[18-20]

Tuberculosis may be caused by any one of three mycobacterial pathogens: *M. tuberculosis* (the most common), *Mycobacterium bovis*, and *Mycobacterium africanum*. *Mycobacterium microti*, also a tubercle bacilli, does not cause disease in humans.

Tuberculosis is spread from person to person through the air by droplet nuclei, particles 1 to 5 μm in diameter that contain *M. tuberculosis* complex.[21] Droplet nuclei are produced when persons with pulmonary or laryngeal TB cough, sneeze, speak, or sing. Droplet nuclei, containing two to three *M. tuberculosis* organisms, are so small that air currents normally present in any indoor space can keep them airborne for long periods of time.[22] These particles are small enough to reach the alveoli within the lungs, where the organisms replicate.[23] Organisms deposited on intact mucosa or skin do not invade tissue. After inhalation, the droplet nuclei are carried down the bronchial tree, where the tubercle bacilli are ingested by alveolar macrophages. The organisms can multiply there, growing for 2 to 12 weeks until a critical number of 10^3 to 10^4 is reached, which is sufficient to elicit a cellular immune response that can be detected by a reaction to the tuberculin skin test (TST).[24]

Before the infected individual develops cellular immunity, tubercle bacilli spread via the lymphatics to the hilar lymph nodes and through the bloodstream to more distant sites. After cellular immunity develops, granulomas are formed that limit multiplication and further spread.

Diagnosis

In non-HIV-infected patients, the majority of reported TB cases are limited to the lungs. Advanced infection with HIV, however, results in extrapulmonary involvement over 60% of the time.[25]

Systemic effects of tuberculosis include fever (present in up to 80% of patients),[26] weight loss, increases in peripheral leukocyte count and anemia (present in approximately 10% of patients),[27] and hyponatremia, occurring in as many as 11% of patients.[28]

Cough is the most common symptom of pulmonary tuberculosis, beginning as nonproductive but subsequently becoming sputum-producing. Hemoptysis is uncommon early in the disease process. Physical findings in pulmonary TB are generally unhelpful, although the chest film almost always reveals abnormalities, generally seen as a middle or lower lung zone infiltrate, often associated with ipsilateral hilar adenopathy when the disease is primary and is occurring as a result of a recent infection. TB that develops as a result of endogenous reactivation of latent infection usually causes abnormalities in the upper lobes of one or both lungs and may also involve cavitation.[29]

Pending confirmatory cultures, which may take several weeks, pulmonary TB can be diagnosed with sputum samples that show the presence of acid-fast bacilli (AFB), identified in 50% to 80% of patients with pulmonary TB.[29] A series of at least three single specimens should be collected on different days. Specimens should be transported to the laboratory and processed as soon as possible. If delay is inevitable, the specimen should be refrigerated until prompt delivery can be assured. No fixative or preservative agents should be used. Direct amplification tests using gene probes or PCR testing and high-performance liquid chromatography may also be useful in some circumstances in evaluating the patient. Regardless of the method used to diagnosis TB, cultures of the organism are essential for confirmation and to allow for drug susceptibility testing, a critical component of TB infection management.

Extrapulmonary tuberculosis can present as a disseminated form or in the lymph nodes, pleural cavity, genitourinary system, skeleton, CNS, abdomen, or pericardium. The ease and accuracy of diagnosis of extrapulmonary TB depend on the system involved.

In addition to symptomatic tuberculosis, patients who may have asymptomatic latent infection require careful consideration and thoughtful diagnosis as well. Current recommendations discourage screening of low risk populations because of false-positive results and subsequent inappropriate and potentially hazardous drug administration.

When screening for latent infection is considered, the preferred skin test for *M. tuberculosis* is the intradermal, or Mantoux, method. It is administered by injecting 0.1 mL of 5 tuberculin units (TU) PPD (purified protein derivative) intradermally into the dorsal or volar surface of the forearm. Tests should be read 48 to 72 hours after test administration, and the transverse diameter of induration (not inflammation) should be recorded in millimeters. Multiple puncture tests (Tine and Heaf) and PPD strengths of 1 TU and 250 TU are not sufficiently accurate and should not be used.

Three cutoff levels have been recommended for defining a positive tuberculin reaction: ≥5mm, ≥10mm, and ≥15mm of induration, depending on the risk group in which the patient resides. For persons who are at highest risk for developing TB disease if they become infected with *M. tuberculosis*, a cutoff level of ≥5mm is recommended. This group contains immunosuppressed patient and those with recent close contact with a patient with infectious TB. A reaction of ≥10mm of induration should be considered positive for those persons with an increased probability of recent infection or with other

clinical conditions that increase the risk of TB, such as recent immigrants from endemic areas, IV drug users, or those with normal or mildly impaired immunity including groups with poor access to health care. This level is reasonable for pregnant patients. A reaction of ≥15mm of induration should be used for groups at low risk for latent infection, should that group be tested.[30] In most individuals, PPD skin test sensitivity persists throughout life. Over time, however, the size of the skin test may diminish or disappear. If a PPD test is administered in this situation, the initial test result may be small or nonidentifiable. However, there may be accentuation of response on repeated testing. This is called the *booster effect* and does not represent a skin test conversion. This two-step method is commonly used in healthcare workers who undergo repeated tests and involves an initial test that, if negative, is followed in 1 to 3 weeks by a second and similar TB skin test, administered at a different site. The second test should be considered the "correct" one and the results from its induration measurement used. Because of the small amount of antigen administered, repeated skin testing with tuberculin will not induce a positive skin test reaction in individuals who have no cellular immunity to the antigens in PPD.[31]

Previous immunization with bacillus Calmetté-Guerin (BCG) has been shown to protect against disseminated TB and meningitis in children, but has not been conclusively demonstrated to have protective effects against pulmonary disease in children or adults.[32] Millions of people around the world have been vaccinated with this attenuated strain of *M. bovis*, which frequently causes a false-positive Mantoux skin test. However, to avoid undertreatment of those truly infected, it is considered prudent by many experts to consider induration of more than 5 mm as indicating infection with *M. tuberculosis*, even with a history of BCG immunization.

Maternal and Fetal Risks

Tuberculosis during pregnancy appears to progress in a similar fashion as in the nonpregnant individual. There appears to be no risk to the fetus with maternal exposure or positive skin testing in the absence of active pulmonary or extrapulmonary disease, although the tubercle bacillus has been reported to cross the placenta and granulomas rarely are found in the placenta.[33–35] Because of these reassuring findings, risks to mother are similar to those of the nonpregnant individual, and both mother and fetus share potential medication side effect risks.

Management Options

Prepregnancy and Prenatal

The main points about prepregnancy and prenatal care in patients with TB are the following:

- Pregnancy does not affect the course of tuberculosis.[30,34]
- Tuberculosis is unlikely to have fetal effects, and maternal effects of latent disease are primarily related to side effects of medications.[34]
- Latent disease should be treated with isoniazid and pyridoxine during pregnancy or immediately postpartum.[30,34]
- Active disease should be treated aggressively during pregnancy, with a combination of isoniazid, rifampin, and ethambutol.[34]
- Streptomycin should be avoided during pregnancy.[34]

Labor and Delivery

Factors that should be considered when managing an intrapartum patient with TB include the following:

- Masks worn by persons exposed to an infectious source are less effective than are masks worn by patients, because most airborne droplet nuclei are much smaller than their parent droplets.
- Droplet nuclei do not settle but remain suspended in the air for long periods of time.[22]
- Within 2 days of therapy that includes isoniazid, there is a 2 log/mL reduction of colony counts in sputum, with an additional 1 log/mL reduction within the next 12 days.[36]

Asymptomatic patients under appropriate medical therapy do not pose a risk to healthcare providers. However, patients with untreated or undiagnosed disease may pose a serious threat to the healthcare team. In labor and delivery, any coughing patient who comes in contact with the healthcare team should immediately be provided a surgical mask, tissues, and a container to collect tissues. Patients with any of the following symptoms should be evaluated for the presence of TB: persistent cough for 3 weeks or more, bloody sputum, night sweats, weight loss, or fever. If any of these are noted, a chest x-ray should be obtained and sputum sent for AFB. If active TB is suspected, use of an isolation room with airborne transmission precautions should be implemented until further workup is complete. Healthcare workers should wear respirators capable of filtering particles to 1 μm in diameter with facial leak of 10% or less. Healthcare workers exposed to patients with active disease should have a PPD administered immediately and again in 12 weeks. Nursery personnel should be alerted when a newborn has an actively infected mother.

Postpartum

Patients with recent skin test conversion who have not been treated during pregnancy should be considered for therapy in the postpartum period. Although antituberculous drugs can be measured in breast milk, breastfeeding is safe during therapy for TB.

MALARIA

General

Malaria is produced by intraerythrocytic parasites of the genus *Plasmodium* that are transmitted by the bite of the infective female anopheline mosquito. One billion people worldwide are estimated to carry parasites at any one time,[37] and estimates for annual malaria mortality range from 0.5 to 3.0 million people.[38] Its name is derived from the belief of the ancient Romans that *mal-aria* was due to the bad air of the marshes surrounding Rome.

Four plasmodia produce malaria in humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. Most deaths are the result of *P. falciparum* and occur in children under age 5 years, although pregnant women are also at increased risk for severe disease. Early treatment usually results in cure without recurrence, although *P. ovale* and *P. vivax* may remain dormant and recur months or years after the initial infection. Once infected, partial immunity may develop.

Human infection begins when sporozoites in the salivary gland of the female *Anopheles* mosquito are inoculated into the human host as the insect feeds. These parasites infect human hepatocytes within 30 minutes of entering the human body.[39] In the hepatocyte, each sporozoite divides and differentiates to form up to 30,000 merozoites, which rupture the hepatocyte and enter the bloodstream to infect erythrocytes.[40] Sporozoites of *P. vivax* and *P. ovale* may also form hypnozoites, dormant forms that remain in hepatocytes and may lead to recurrent infection months or years later. Merozoites actively enter the host erythrocytes, where they differentiate into ring-shaped trophozoites. These trophozoites develop into a schizont, which fills with merozoites, subsequently rupturing the erythrocyte and infecting other red blood cells (RBCs). Periodically, merozoites differentiate into male or female gametocytes, sexual forms that are ingested by *Anopheles* mosquitoes feeding on the infected human host. In the mosquito midgut, gametocytes merge to form a diploid zygote that differentiates into a motile ookinete that enters the gut wall to form an oocyst.

Sporozoites released from the oocyst migrate to the salivary glands of the mosquito to repeat the cycle.[39]

Rupture of erythrocytes by proliferating merozoites occurs with a periodicity related to the species of plasmodia. This cycle repeats every 72 hours for *P. malariae* (*quartan malaria*) and every 48 hours for other malaria species (*tertian malaria*). Fever greater than 40°C is lethal to schizonts; consequently, the life cycle tends to be synchronized over the course of the infection, leading to periodic fever spikes rather than continuous fever.[41] Anemia develops in the infected human as a result of erythrocyte rupture by merozoite proliferation and by sequestration of normal uninfected RBCs by an engorged liver and spleen. Iron stores are depleted as hemoglobin from lysed RBCs is lost in urine.

Renal failure can result from a number of causes, including the rigidity of RBCs filled with merozoites that fail to pass through venules and capillaries, leading to microvascular sludging and ischemia in the kidneys. Cerebral malaria (the most common cause of death in this disease) occurs only with *P. falciparum* infection, as clumps of erythrocytes occlude the cerebral microvasculature, causing diffuse cerebral ischemia.

Acutely ill patients with malaria typically have either *P. falciparum* or *P. vivax* infections.[41] Partial resistance to malaria occurs in the presence of sickle cell trait (due to decreased intra-erythrocytic ATPase activity, which decreases surplus energy available to support parasite proliferation[39]) and in the absence of the Duffy antigen (due to the propensity of merozoites of *P. vivax* to invade erythrocytes by binding to that antigen).

Diagnosis

Fevers, chills, and headaches are the hallmark of malarial infection. The chills can last for periods of 1 to 2 hours. Concomitant with lysis of RBCs, the febrile stage is characterized by rigors, flushing, headache, and muscle aches with temperatures of 39° to 42°C. This stage can last for up to 6 hours, followed by profuse sweating and, as these symptoms disappear, excessive fatigue. Although most cases of malaria are classified as mild or uncomplicated, as the degree of parasitemia in patients with *P. falciparum* rises above 2%, the risk of severe malaria grows. Severe malaria is characterized by renal failure (sometimes accompanied by gross hemoglobinuria from lysed RBCs, termed *black-water fever*), noncardiogenic pulmonary edema, severe anemia, jaundice, seizures, parasitemia of greater than 5%, coma, circulatory collapse, or hypoglycemia, in the presence of either recent exposure to malaria or *P. falciparum* on smear.[42]

For the past 100 years, confirmation of the diagnosis of malaria has been made with the demonstration of intraerythrocytic parasites by Giemsa-stained thick and thin smears of fresh fingerprick blood. All four *Plasmodium* species may be identified in this fashion. Although the thin smear is easier to read, the thick smear is 10 to 40 times

more sensitive and can detect as few as 50 parasites/μL.[43] Detectable parasitemia may lag behind aches, fevers, and chills by 2 days. If malaria is suspected, thick and thin smears should be done every 8 to 12 hours on at least three occasions, the collection of which should not be tied to fever spikes. Persistently negative smears after this time period argue against the presence of malaria.[41]

Several alternative laboratory methods have been developed, including the quantitative buffy-coat centrifugal hematology system, immunofluorescence, ELISA tests for the detection of the *P. falciparum* antigen, and the polymerase chain reaction (PCR) technique. Because of cost and complexity, none of these tests are used routinely.[44] Rapid blood tests using a dipstick or test strip with monoclonal antibodies directed against the target parasite antigen histidine-rich protein 2 (Pf HRP2) or parasite-specific lactate dehydrogenase (pLDH) are currently commercially available. Limitations in these methods include persistent Pf HRP2 antigenemia despite microscopic and clinical cure and positivity of pLDH only when viable parasites are present.[41]

Maternal and Fetal Risks

Pregnant women have an increased risk of malarial infection compared to their nonpregnant adult counterparts,[45] the difference being most marked during the first pregnancy. In one study in Malawi, the incidence of parasitemia in primigravidas was 66%, falling to 29% in second and 20.9% in subsequent pregnancies.[46] This increased susceptibility may be due to a number of reasons. Pregnant women seem to be more attractive to the female *Anopheles* mosquito than nonpregnant women and incur a significantly greater number of bites.[47] Sequestration of *P. falciparum* in the placenta may be another; in one case in which a woman's peripheral blood parasitemia was 3% at presentation (and presumably less after treatment), her placenta at delivery showed a local parasitemia of 70%.[48]

Although the major adverse effect of malaria in pregnancy on the mother is anemia, the risk of developing severe and complicated malaria is three times higher in pregnancy[49] and that of developing hypoglycemia is seven times more likely.[50] Both *P. falciparum* and *P. vivax* have been associated with an increased incidence of low birth weight.[51] Studies have demonstrated an increased incidence of intrauterine growth restriction when parasitemia is found during the antenatal period and an increased incidence of premature birth when cord blood parasitemia (probably reflecting recent active infection) is seen.[52,53]

Management Options

Prepregnancy

Malaria chemoprophylaxis and therapy before pregnancy is similar to that administered to other adults, and can be

reviewed at www.cdc.gov. Management principles are similar to those discussed in the following sections, with the exception that additional drugs are available to the nonpregnant adult that are not appropriate for the pregnant woman.

Prenatal

Management of the pregnant patient involves two components: prevention of infection and treatment of disease. To prevent serious infection in pregnancy, pregnant women should be advised to avoid travel into areas where there is chloroquine-resistant *P. falciparum* malaria. However, when travel is unavoidable into these regions, use of pyrethroid-containing flying-insect spray in living and sleeping areas during evening and nighttime hours is advisable. Bednets, especially those sprayed with the insecticide permethrin, are effective in limiting mosquito bites, and use of the insecticide DEET is a safe and effective means to minimize bites during pregnancy as well.[55] Recommended chemoprophylaxis in areas *without* chloroquine-resistant *P. falciparum* is chloroquine phosphate (Aralen) 500 mg/week (300 mg chloroquine base) once weekly beginning 2 weeks before travel and during exposure and for 4 weeks after leaving the endemic area. Recommended chemoprophylaxis in areas *with* chloroquine-resistant *P. falciparum* is mefloquine (Lariam) 250 mg/week following the same schedule as chloroquine. It is critical that the patient continue the medication for 4 weeks after leaving the endemic area because infection is not prevented by the chemoprophylaxis, since sporozoites released into the bloodstream by the biting mosquito still reach the liver even in the presence of these medications. As the developing merozoites are released into the bloodstream, the infection succumbs to the drugs at this point.[55]

Before treating a pregnant patient with malaria, one should consider the place where the infection occurred, the trimester of pregnancy, and whether the clinical and parasitologic situation is severe. Consideration of the place where the infection occurred allows the clinician to use drugs that should meet with the least chance of resistance in the parasite. Consideration of the trimester of pregnancy allows the clinician to use drugs with the least chance of fetal toxicity, and consideration of the clinical and parasitologic situation allows the clinician to determine the aggressiveness and length of therapy. The drug or drugs chosen should be effective in the reduction of the asexual forms in the blood and in the placenta in order to prevent or reduce the severe clinical forms. Although the latest recommendations regarding specific treatment from certain regions may be obtained from the CDC, we review concepts of malaria therapy and drugs useful in the pregnant patient.

CHLOROQUINE

Although in many areas of the world, 80% or more of *P. falciparum* infections exhibit a high degree of chloro-

quine resistance,[56] chloroquine is still considered one of the safest antimalarials. It is not considered to be a cause of spontaneous abortion or teratogenesis when used for chemoprophylaxis or in recommended dosages for treatment,[57] but when given in large doses, has been reported to cause alterations of the eighth cranial nerve and retinal pigmentation in the fetus.[58]

QUININE AND QUINIDINE

Quinine and quinidine remain effective therapies for malaria, and a quinine-tetracycline combination cures nearly 100% of *P. falciparum* infections no matter in which region of the world the disease is contracted.[41] Unfortunately, although quinine may be used during pregnancy, tetracyclines should be avoided because of adverse fetal effects. Quinine may cause cinchonism (headache, tinnitus, nausea, vision disturbances) and, if glucose-6-phosphate dehydrogenase deficiency is present, hemolysis. Quinidine may be used intravenously with caution, because of its cardiosuppressant effects and its tendency to cause severe hypotension when administered rapidly. It can also cause hypoglycemia in the pregnant patient because of its tendency to stimulate the beta cells to produce insulin.[42]

Quinine has been shown to be safe in therapeutic doses in the first trimester of pregnancy.[59]

ANTIFOLATE DRUGS

The drug combinations sulfadoxine/pyrimethamine and sulfamethoxazole/trimethoprim work synergistically on two enzymes of the *Plasmodium* organism: dihydropteroate synthase and dihydrofolate reductase. Pyrimethamine has produced a teratogenic effect in laboratory test animals (which can be avoided by the administration of folinic acid), and sulfa administration to the mother near delivery has a theoretical risk to the fetus of kernicterus. Because of these concerns, these combinations should be limited to second or early third trimesters.

MEFLOQUINE

Mefloquine is critical for chemoprophylaxis or therapy in areas of chloroquine-resistant *P. falciparum*. Studies have not shown significant adverse effects on mother or fetus when mefloquine is administered in the second or third trimester of pregnancy. Observations made on a group of 1133 women who used mefloquine before conceiving or during pregnancy failed to show any toxic or teratogenic effects on the embryo.[60] Side effects in general may include the induction of neuropsychiatric alterations including anxiety, affective disorders, hallucinations, psychosis, and convulsions.[61]

CLINDAMYCIN

Clindamycin is useful in the treatment of resistant *P. falciparum* and is an alternative to tetracycline or doxycycline, because it does not produce important adverse effects in the pregnant patient or fetus. Clindamycin in

combination with quinine has been used for over 20 years in Brazil and has been found to be an effective therapy for multiresistant strains of malaria, with no observed significant side effects in mother or fetus.[45]

ARTEMISININS

These antimalarials, isolated by Chinese scientists from *Artemisia annua*, currently are the fastest acting of all antimalarial drugs and have not shown significant toxicity.[62]

Resistance is rare, and while experimental studies with laboratory animals showed that doses above 10 mg/kg weight cause fetal resorption,[63] preclinical studies did not show any mutative or teratogenic effects.[64] Therefore, use should be limited to the second or third trimesters of pregnancy.

Labor and Delivery

No specific recommendations are needed for labor and/or delivery in these patients.

Postpartum

Breastfeeding patients should use the same chemoprophylaxis schedule and medication regimen for therapy as the pregnant patient.

Malaria Vaccines

Due to the various life cycles of the protozoan and other features of the infection, development of a malaria vaccine remains elusive.[65]

SUMMARY OF MANAGEMENT OPTIONS
Malaria

Management Options	Quality of Evidence	Strength of Recommendation	References

Continued

SYPHILIS

General

Syphilis is a complex systemic illness caused by the spirochete *Treponema pallidum*. Debate about the origin of syphilis has continued for nearly 500 years, with sixteenth century Europeans blaming each other, referring to it variously as the Venetian, Naples, or French disease. Recent evaluations of several hundred skeletons from archaeological sites in the United States and Ecuador ranging in age from 400 to 6000 years favor a New World origin.[66] Syphilis currently is a worldwide malady that can lead to serious maternal and fetal complications. The nickname "lues" came from the Latin *lues venereum*, which means "disease," "sickness," or "pestilence" and originally was loosely applied to any venereal disease. It became a synonym for syphilis at the beginning of the 20th century.

Despite continued declines among African Americans and women of all races, overall rates of primary and secondary syphilis have recently increased for the first time in more than a decade. Primary and secondary syphilis in the United States rose by 2% between 2000 and 2001 (from 5979 cases in 2000 to 6103 cases in 2001). The overall syphilis rate in the United States increased from 2.1 per 100,000 people to 2.2 per 100,000 people, the first such increase since 1990.[67]

The causal agent of syphilis is *T. pallidum* spp. *pallidum*, which belongs to the family Spirochaetaceae. Other members of the genus *Treponema* that can infect humans are *Treponema pallidum* spp. *pertenue* (yaws), *Treponema carateum* (pinta), and *Treponema pallidum* spp. *endemicum* (bejel, nonvenereal, or endemic syphilis). A number of nonpathogenic treponemes have also been isolated from humans, particularly from the oral cavity. Other pathogenic organisms of the family Spirochaetaceae belong to the genera *Borrelia* and *Leptospira*.[68]

Syphilis can be acquired by sexual contact, by the fetus during pregnancy or birth, by kissing or other close contact with an active lesion, by transfusion of fresh human blood (banked less than 24 to 48 hours), or by accidental direct inoculation. The overwhelming majority of cases of syphilis are transmitted by sexual intercourse, but for all practical purposes a patient cannot spread syphilis by sexual contact 4 years or more after acquiring the disease.[68] Clinically, syphilis can be divided into five stages: incubating, primary, secondary, latent, and late syphilis. Diagnosis, therapy, and risk to the fetus vary with the stage of the disease.

Within hours or days after *T. pallidum* penetrates the intact mucous membrane or gains access through abraded skin, it enters the lymphatics or bloodstream and disseminates through the body. Virtually any organ, including the CNS, may be invaded. The minimum dose for human infection is not known, but in rabbits, an inoculum containing as few as four spirochetes can establish an infection. The incubation period is directly related to the size of the inoculum.[69] The median incubation period is 21 days, but can range from 3 to 90 days. During this stage, a spirochetemia develops that sets the stage for subsequent multiple organ invasion. The first symptomatology to develop occurs in the primary stage, which can last for 4 to 6 weeks (range, 2 to 8 weeks), and which usually includes development of the chancre. This painless ulcer (which may be slightly tender to the touch) occurs at the site of inoculation. A small inoculum produces only a papular lesion; a larger inoculum produces the ulcerative chancre. Persons with a history of previous syphilitic infection fail to develop any lesion or develop only a small, darkfield-negative papule.[69] Multiple chancres may occur.[70] Chancres heal spontaneously in 3 to 6 weeks (range, 1 to 12 weeks), leaving no trace or a thin atrophic scar. The manifestations of secondary syphilis often develop while the chancre is still present,[71] especially in HIV-infected patients.

The secondary or disseminated stage becomes evident 2 to 12 weeks (mean, 6 weeks) after contact. The generalized nature of this stage becomes evident as parenchy-

mal, constitutional, and mucocutaneous manifestations may develop. The greatest number of treponemes is present in the body during this stage, and the classic and most commonly recognized lesions involve the skin. Macular, maculopapular, papular, or pustular lesions, and combinations and variations thereof, all may occur.[71] Vesicular lesions are notably absent. In warm, moist intertriginous areas, the papules enlarge, coalesce, and erode to produce painless, broad, moist, gray-white to erythematous, highly infectious plaques called *condylomata lata*. Constitutional symptomatology is also frequently present during the secondary stage and may include low-grade fever, malaise, pharyngitis, laryngitis, anorexia, weight loss, arthralgias, and generalized painless lymphadenopathy. The CNS may be involved in up to 40% of patients—headache and meningismus are common. The differential diagnosis of secondary syphilis is extensive—hence the name "The Great Imitator."

Latent syphilis is by definition that stage of the disease during which a specific treponemal antibody test is present but during which there are no clinical manifestations of syphilis. It does not imply a lack of progression of disease. Early latent syphilis distinguishes the first year of that period, and late latent syphilis begins after 1 year. Only during the first 4 years of latent syphilis may a relapse occur; thus, the patient must continue to be considered infectious during those 4 years. After 4 years of late latent syphilis, the patient develops host resistance to reinfection and to infectious relapse. However, a pregnant woman with late latent syphilis can transmit the infection vertically to her fetus.

Late or tertiary syphilis is a slowly progressive, inflammatory disease that may affect any organ system and is usually subdivided into neurosyphilis, cardiovascular syphilis, and gummatous syphilis.

Diagnosis

Unlike many nonpathogenic treponemas, the virulent treponemes, including *T. pallidum*, cannot be cultivated in vitro.

Direct Examination for Spirochetes

In primary, secondary, and early congenital syphilis, the darkfield examination (a wet-preparation method for direct visualization of living *T. pallidum* spirochetes) or immunofluorescence staining of mucocutaneous lesions are the quickest and most direct laboratory methods of establishing the diagnosis.[72] Examination of a serous transudate from moist lesions such as a primary chancre or condyloma latum is productive because these lesions contain the largest number of treponemes. *T. pallidum* may be demonstrated from dry skin lesions or from lymph nodes by saline aspiration, if the saline is free of bactericidal additives. Specimens from mouth lesions are not accurate because *T. pallidum* cannot be distinguished from nonpathogenic treponemes with certainty.

Serologic Tests

Two different types of antibodies are measured in the evaluation of syphilis: the *nonspecific* nontreponemal reaginic antibody and the *specific* antitreponemal antibody.

Syphilis reaginic antibodies are immunoglobulin G (IgG) and IgM directed against a lipoidal antigen resulting from the interaction of host tissues with *T. pallidum* or from the organism itself. The earliest antigens used to measure reaginic antibody were phospholipid extracts made from beef livers and subsequently from beef hearts (hence the name *cardiolipin*). The standard nontreponemal test is the VDRL (Venereal Disease Research Laboratories) slide test, although most laboratories have adopted a modification for routine screening called the rapid plasma reagin (RPR) test or other similar method. The quantitative RPR test should become nonreactive 1 year after successful therapy in primary syphilis and 2 years after successful therapy in secondary syphilis.[73] A patient with late syphilis should have a negative response after 5 years.[74] However, the longer the disease has been present before treatment, the longer the VDRL takes to become nonreactive. In many cases after the secondary stage, it will never become nonreactive, even with adequate treatment (this is called *Wasserman fastness*). A prozone phenomenon occurs in about 2% of infected patients, especially in secondary syphilis and pregnancy, and appropriate dilutions should be performed whenever the index of suspicion is high.[75]

The principal specific antitreponemal antibody tests done today are the fluorescent treponemal antibody absorption test (FTA-abs), the *T. pallidum* particle agglutination (TPPA) test, *T. pallidum* hemagglutination assay (TPHA), and the microhemagglutination assay—*T. pallidum* (MHA-TP) test. The FTA-abs is a standard indirect immunofluorescent antibody test that uses *T. pallidum* harvested from rabbit testes as the antigen. Because of the difficulty with standardization between labs and with quantifying results and the meticulousness with which the test must be performed, the TPHA, which uses a sorbent for increased specificity, or the MHA-TP, an adaptation of the TPHA, are commonly used today. Once positive, the patient usually remains positive for life, although patients treated early may revert to a nonreactive state in up to 10% of cases.[68] Acute or transient false-positive nontreponemal reaginic test reactions may occur whenever there is a strong immunologic stimulus, such as with an acute bacterial or viral infection, vaccination, or early HIV infection. Positive reactions that last for months may occur with parenteral drug abuse, in those with autoimmune or connective tissue diseases, and in patients in hypergammaglobulinemic states. Syphilis may be excluded if a biologic false-positive (BFP) test is suspected by obtaining a negative specific treponemal antibody test, such as the FTP-abs or MHA-TP. Other spirochetal illnesses, such as relapsing fever (*Borrelia* spp.), yaws, pinta, leptospirosis, or rat-bite fever (*Spirillum minus*) may also

yield a positive nontreponemal test. Infection with *Borrelia burgdorferi* (Lyme disease) results in a positive FTA-abs test but does not cause a positive nontreponemal reaginic reaction with either the VDRL or RPR.

Because of expense and ease of performance, screening large numbers of patients such as in pregnancy is usually done with reaginic antibody tests (RPR, VDRL), and confirmation is done with the specific treponemal tests (FTA-abs or MHA-TP).

Ultrasound

The prenatal diagnostic test with the greatest potential for identifying the severely infected fetus is ultrasound. Ultrasound findings suggestive of in utero infection include placentomegaly, intrauterine growth restriction, microcephaly, hepatosplenomegaly, anemia, and hydrops.

Maternal and Fetal Risks

Maternal risks of syphilis acquired during pregnancy are similar to those for acquisition in the nonpregnant state. However, because up to 75% of infants born to mothers with active syphilitic infections will become infected in utero,[76] it is critical to identify infections as early in pregnancy as possible to reduce this risk. Although vertical transmission can occur during any stage of infection in the untreated or inadequately treated gravida, infection of the fetus before 16 weeks' gestation is rare; therefore, early abortion is unlikely to be the result of syphilis. Treatment of the mother during that period usually ensures that the fetus will not be infected. Later in pregnancy, depending on the severity of the maternal infection, abortion, stillbirth, neonatal death, neonatal disease, or latent infection may be seen.[72] Recent evidence indicates that these manifestations appear to be caused largely by dysfunction of the maternal-fetal endocrine axis, resulting in decreased levels of dehydroepiandrosterone produced by the fetal adrenal glands.[77] Neonatal manifestations of congenital syphilis include rhinitis (snuffles), which may be followed by a diffuse maculopapular, desquamative rash with extensive sloughing of the epithelium, particularly on the palms, on the soles, and around the mouth and anus. Hepatic involvement with associated splenomegaly, anemia, thrombocytopenia, and jaundice are also common findings. Neonatal death is usually caused by liver failure, severe pneumonia, or pulmonary hemorrhage. Renal involvement and a generalized osteochondritis and perichondritis may be seen as well.

Management Options

Prepregnancy

Although the efficacy of penicillin in the treatment of syphilis is well established, there remains uncertainty regarding optimal dose and duration of therapy, especially during pregnancy.[78] Therefore, treatment regimens must be viewed with this in mind and with the understanding that treatment failures do occur and must be recognized and re-treated. From work with experimental infections, it is known that penicillin concentrations as low as 0.018 µg/mL sustained for 7 days in the nonpregnant adult results in almost 100% treponemicidal activity.[79] It has also been recognized that *T. pallidum* has been isolated from the cerebrospinal fluid (CSF) of patients with only a chancre.[80] Therefore, to adequately treat this infection that may affect the CNS, one must treat the parasite in the CSF. However, despite the fact that benzathine penicillin does not reliably achieve treponemicidal levels in the CSF[81] and that re-treatment may be required in as many as 1 in 33 cases,[82] clinical experience continues to suggest that benzathine penicillin remains a mainstay of therapy. When an early diagnosis is made, fewer treponemes exist and the likelihood of a complete cure is greatly enhanced. Because of the high risk of infection, treatment should be given to anyone exposed to infectious syphilis within the preceding 3 months. Serologic studies must be done to establish the diagnosis and monitor success of therapy.

Prenatal

Pregnant patients should receive penicillin in the same dosage schedules as nonpregnant adults for comparable stages of the disease. When a well-documented penicillin allergy exists, desensitization (which can be accomplished in as few as 3 to 4 hours) is recommended.[83,84]

For primary and secondary syphilis and for early latent syphilis, administer benzathine penicillin G 2.4 million units IM once. For late latent syphilis or for latent syphilis of unknown duration, administer benzathine penicillin G 7.2 million units total, as three doses of 2.4 million units IM each at 1-week intervals. Regimens for syphilis in pregnancy that do not include penicillin have not been documented to be adequate therapy to prevent congenital syphilis. Pregnant patients with concomitant HIV infections should be considered for treatment as if they have neurosyphilis, regardless of their clinical findings.[85]

All women should be screened serologically for syphilis at the first prenatal visit. In populations in which prenatal care is not optimal, RPR test screening and treatment (if the RPR test is reactive) should be performed at the time a pregnancy is confirmed. For communities and populations in which the prevalence of syphilis is high or for patients at high risk, serologic testing in addition to routine early screening should be performed twice during the third trimester: at 28 weeks' gestation and at delivery.

The fetus with hepatomegaly or ascites is more likely to fail prenatal therapy and may benefit from a more extended course than usual and more intense monitoring throughout the remainder of the pregnancy.[86]

The Jarisch-Herxheimer reaction is a systemic reaction that occurs 1 to 2 hours after the initial treatment of syphilis with effective antibiotics. It consists of the abrupt onset of fever, chills, myalgia, headache, tachycardia, hyperventilation, vasodilation with flushing, and mild hypotension. Additional findings at or beyond 24 weeks' gestation include uterine contractions (42%) and recurrent variable fetal heart rate decelerations (38%).[87] It lasts for 12 to 24 hours and may be treated in pregnancy with antipyretics or prednisone, although no studies have documented a clearly effective prophylaxis.

Labor and Delivery

In the United States some states mandate screening for syphilis at delivery for all women. Any woman who delivers a stillborn infant after 20 weeks' gestation should be tested for syphilis.

Postpartum

No infant should leave the hospital if maternal serologic status has not been determined at least once during pregnancy and preferably again at delivery. All patients with early or congenital syphilis should have repeat quantitative nontreponemal tests at 3, 6, and 12 months. All patients with secondary syphilis or syphilis of more than 1 year's duration should also have a nontreponemal serologic test 24 months after treatment. Many experts recommend examination of the CSF for those patients treated with benzathine penicillin because of its poor ability to penetrate the CSF. Re-treatment should be considered whenever clinical signs and symptoms of syphilis persist or recur, whenever there is a sustained level or an increase in the titer on the nontreponemal test, or whenever a positive RPR reaction persists beyond 12 months in primary syphilis, 24 months in secondary or latent syphilis, or 5 years in late syphilis.[68]

SUMMARY OF MANAGEMENT OPTIONS
Syphilis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Identify and treat with penicillin (provided not allergic) before pregnancy.	IV	C	78
Initiate contact tracing and treatment.	–	GPP	–
Confirm response with serial serology.	–	GPP	–
Prenatal			
Provide routine serologic screening in early pregnancy.	IV	C	78
Treat with penicillin (provided not allergic) all with T. palladum–positive lesions (rare).	IV	C	78
Probably safer to treat all women with positive serology with penicillin (provided not allergic) even if history suggests they have been treated in the past; treatment before 16 weeks will usually prevent congenital syphilis.	IV	C	78
If significant penicillin allergy is determined, the pregnant patient should be desensitized, because only penicillin will adequately treat the fetus.	III	B	83, 84
Initiate contact tracing and treatment.	–	GPP	–
Confirm response with serial serology.	IV	C	78
Labor and Delivery			
Some states in the U.S. require testing of all women at delivery.	–	GPP	–
Evaluate all cases of stillbirth >20 weeks for the presence of syphilis.	IV	C	68
Inform pediatricians.	IV	C	86
Postnatal			
Alert pediatricians to the presence of syphilis during pregnancy so that they can properly evaluate the neonate for early (snuffles, rash, hepatosplenomegaly, jaundice) and late (deafness, hydrocephalus, optic nerve atrophy, mental retardation) manifestations of congenital syphilis.	IV	C	86
Follow-up tests should occur up to 2 years after treatment, with concomitant fall in titers during that period.	III	B	68, 76

TOXOPLASMOSIS

General

Toxoplasmosis is caused by the obligate intracellular parasite *Toxoplasma gondii*. Its name is derived from "toxon" (Greek for *arc*, the shape of the parasite during its acute infectious phase in humans) and "gundi" (the North African rodent from which the parasite was originally identified). Infections in immunocompetent individuals are frequently subclinical and innocuous unless the individual is pregnant, during which time vertical transmission can occur and lead to significant disease and possibly death in the fetus or neonate. The organism has three distinct forms: the tachyzoite, or arc form, found in the parasitemic or acute phase of infection; the tissue cyst, found in the quiescent or latent phase in many organs of humans and animals; and the oocyst, which originates only in the digestive tract of members of the family *Felidae* (including domestic and feral cats).

Toxoplasmosis can be transmitted to humans by three principal routes. It is estimated that approximately 50% of the toxoplasmosis cases in the United States are caused by eating inadequately cooked meat[88] (especially pork, mutton, and wild game meat) containing the tissue cyst form of the organism.[89] A second means of acquiring toxoplasmosis is by inadvertently ingesting the oocysts that cats have passed in their feces, either from a cat litter box, from infected soil where a cat has defecated, or from unwashed fruits or vegetables that have contacted infected soil. Under favorable conditions (i.e., in warm, moist soil), oocysts can remain infectious for approximately 1 year. A third means of transmission is transplacentally, when a primary infection occurs during pregnancy. Other than vertical transmission and the rare incidence of blood or organ donation between individuals, it is not possible to acquire toxoplasmosis from either a neonate or another adult. In adults, the incubation period ranges from 10 to 23 days from ingestion of undercooked meat, and from 5 to 20 days from ingestion of oocysts from cat feces.[90]

Since the 1960s, rates of infection with *Toxoplasma* in the United States appear to have declined from 14% (in a study of U.S. military recruits at that time) to a seroprevalence of 9.6% in a second study of recruits in 1989.[91,92] In the Third National Health and Nutrition Examination Survey (NHANES III) conducted in the United States from 1988 to 1994, 17,658 individuals were tested for *Toxoplasma*-specific IgG antibodies; 23% were found to be positive. Of 5988 women of childbearing age (12 to 49 years) in that series, 14% were seropositive.[93]

Determining the number of cases of congenital toxoplasmosis is more difficult than estimating seroprevalence, although prospective studies in the United States from the 1970s[94,95] and from the period 1986 to 1992[96] indicate an infection rate of between 1 in 10,000 to 10 in 10,000 live births. With an estimated 4 million births annually in the United States, 400 to 4000 neonates yearly will be born with congenital toxoplasmosis.

Although some studies identify cleaning the cat litter box[97] or owning a cat[98] as risk factors, the presence of a cat has not been a consistent risk factor for *T. gondii* infection. Owning a cat was not shown to be a risk factor for *T. gondii* infection in two studies of pregnant women[99,100] and in a study of HIV-infected persons.[101] Cats generally only shed oocysts for several weeks during their lives if they become infected with *T. gondii*. Cats kept indoors that do not hunt prey or are not fed raw meat are not likely to acquire *T. gondii* infection and therefore pose little risk. Because of their grooming habits, fecal matter has not been found on the fur of clinically normal cats, and adult cats are not diarrheal during the period in which they are shedding oocysts.[88] Therefore, the possibility of transmission to human beings via touching cats is minimal to nonexistent.[88] Because cats may not develop antibodies to *T. gondii* during the oocyst-shedding period, serologic examination of cats does not provide useful information regarding the ability of a particular cat to transmit the infection.[88]

Outbreaks of toxoplasmosis in humans have been attributed to ingestion of raw or undercooked ground beef, lamb, pork, venison,[102–107] unpasteurized goat's milk,[108] contaminated unfiltered drinking water,[109–110] soil exposure,[111] and aerosolized soil exposure.[112]

Diagnosis

Because most acute *Toxoplasma* infections are relatively asymptomatic, a universal challenge for obstetricians is how to identify acute infections during pregnancy. In France and Austria, where the incidence of toxoplasmosis is much higher than in the United States, universal screening is mandatory.[113] In the United States, although universal screening has frequently been discussed, it is not generally practiced. A recent article using decision analysis estimated that universal screening with medical treatment would result in 18.5 additional pregnancy losses for each case of toxoplasmosis avoided (12.1 additional pregnancy losses were estimated to occur if infected pregnancies underwent termination rather than treatment).[114]

When screening is performed or when a pregnant woman's clinical presentation leads the practitioner to suspect acute toxoplasmosis, the diagnosis may be established by serologic tests, amplification of specific nucleic acid sequences (using PCR), histologic demonstration of the parasite and/or its antigens (immunoperoxidase stain), or isolation of the organism. Ultrasound also has an important role in the evaluation of this infection.

Serologic Tests

The use of serologic tests for demonstration of specific antibody to *T. gondii* in maternal blood is the initial and primary method of diagnosis. IgG antibodies usually appear within 1 to 2 weeks of acquisition of an infection,

peak within 1 to 2 months, decline at various rates, and usually persist for life. The most common methods of measurement of IgG include the Sabin-Feldman dye test, the ELISA, the immunofluorescence assay (IFA), and the modified direct agglutination test.[115] IgM antibodies, on the other hand, may appear earlier and decline more rapidly than IgG antibodies. They are measured by ELISA, IFA, and the immunosorbent agglutination assay.[115] False-positive results for the presence of IgM may occur when rheumatoid factor or antinuclear antibodies are present. Commercial kits often have low specificity, and positive results must be interpreted with great caution. Although IgM antibodies usually decline rapidly after the onset of infection, they may persist for years in some individuals, further complicating the interpretation of a positive serologic test.

A combination of serologic tests is usually required to establish whether an individual has most likely been infected in the distant past (which should pose minimal to no risk to an ongoing pregnancy) or has been recently infected. The traditional acute and convalescent titers of IgM and IgG are most helpful when either both are negative in two samples 3 or more weeks apart (no acute or chronic infection) or IgG is positive and IgM is negative in both samples (distant infection but no acute infection). When IgM is positive in either (especially when titers are drawn after the first trimester of pregnancy), or when IgG is negative in the first and positive in the second (or with a greater than fourfold rise in IgG antibody titer from the first sample) with or without positive IgM, concern about a recent infection must be raised. A combination of tests that has demonstrated value in pregnancy to distinguish acute from chronic infection includes the Sabin-Feldman dye test (for the presence of IgG antibodies), double sandwich IgM ELISA, IgA ELISA, IgE ELISA, and differential agglutination test.[116] IgA antibodies may be detected in the sera of acutely infected adults and congenitally infected infants, and IgE antibodies have a briefer duration in the sera than IgM or IgA. The differential agglutination test uses the differential amount of agglutination that occurs when fixing Toxoplasma organisms with acetone and with formalin and reacting those antigens to sera that contains IgM antibodies and allows the laboratory to distinguish IgM antibodies that are acute from those that are chronic. An example of results from sera of a patient infected in the distant past would include a positive dye test; negative IgM, IgA, and IgE; and a chronic pattern in the differential agglutination test. On the other hand, an acute infection should be suspected with high titers of the dye test; positive IgM, IgA, and IgE; and an acute pattern with the differential agglutination test. Because indeterminate results may occur even with this combination, follow-up samples may be required. Ideally, when duplicate samples of these or any acute and convalescent titers are requested, they should be run by the same laboratory in parallel with the earlier sample for greatest accuracy in interpretation. When done by an appropriate reference laboratory, this combination of tests allows great precision in differentiating acute from chronic infections. Another recently reported means by which acute and chronic infections may be distinguished is by measuring the binding strength of specific IgG antibodies to multivalent Toxoplasma antigen. This binding strength, or IgG avidity, increases as the duration of infection lengthens. Thus, higher IgG avidity indicates a more long-standing infection and may be useful in early pregnancy when other tests are inconclusive.[117]

PCR

Polymerase chain reaction amplification for detection of T. gondii DNA in amniotic fluid has been used to accurately and rapidly diagnose intrauterine infection with the parasite. The sensitivity is high (81% to 88%),[118,119] and the overall accuracy is comparable to or better than fetal blood testing by cordocentesis[118,119] with less risk to the fetus.

Histology

Demonstration of tachyzoites in amniotic fluid or placental tissue establishes the diagnosis of an acute infection. This is best accomplished with the immunoperoxidase technique with antisera to T. gondii.[120]

Isolation of T. gondii

Isolation of the organism from tissue or fluid establishes the infection as acute. Mouse inoculation coupled with PCR analysis of amniotic fluid has sensitivities of 91% to 94%.[118,121]

Ultrasound

Ultrasound findings of fetal infection with T. gondii are generally nonspecific; however, ventricular dilation (the most common finding), intracranial calcifications, increased placental thickness, hepatic enlargement, and ascites may be seen in over one-third of cases of fetal infection and may be useful in evaluation.[122] In highly suspicious cases in which serology or PCR is nonconclusive, follow-up ultrasound has been found to be valuable in confirming a diagnosis of congenital toxoplasmosis.[123]

Maternal and Fetal Risks

Maternal risks of toxoplasmosis in the immunocompetent gravida are minimal, and 90% of infections are asymptomatic and self-limited. Symptoms most commonly resemble infectious mononucleosis with posterior cervical or axillary lymphadenopathy that is discrete, nontender, and nonsuppurative. Other maternal symptoms may include malaise and muscle pain.

Fetal risks, on the other hand, vary widely, depending on the trimester of acquisition and presence or absence of maternal treatment. In general, the earlier the infection is acquired, the lower the risk of fetal transmission, but the greater the risk of serious sequelae to the fetus when congenital infection does develop.[124] Maternal seroconversion occurring at or before 5 weeks' gestation has been reported to have minimal to no risk of fetal infection, whereas seroconversion in the third trimester may result in congenital infections in as many as 60% of neonates.[125] As many as 85% of congenitally infected neonates have subclinical infections that will later surface as chorioretinitis, hearing loss, or developmental delays. Serious sequelae noted at or after birth, including intrauterine death, neurologic abnormalities, hydrocephalus and cerebral calcifications, and chorioretinal scars with or without severe visual impairment, may be reduced by the use of prenatal antibiotic therapy even though the rate of congenital infection may not change.[118,126]

Management Options

Prepregnancy

Preconception infection with toxoplasmosis generally conveys immunity to subsequent pregnancies against congenital toxoplasmosis. Reports exist describing preconception seroconversion and subsequent fetal infection, but these are extremely rare,[127] and gravidas with IgG positivity at the onset of pregnancy should be considered at low risk for subsequent congenital infection.

Prenatal

Prevention of acute infection during pregnancy is much preferred to treatment of toxoplasmosis.

Pregnant women, especially those determined to be IgG-negative during pregnancy, should be advised of appropriate preventive measures to use. When acute toxoplasmosis is suspected during pregnancy, appropriate laboratory testing is critical (see "Diagnosis"). If serologic testing confirms acute *maternal* toxoplasmosis, amniocentesis with PCR testing of amniotic fluid should be performed to document presence of *fetal* infection. Mouse inoculation may also be considered along with PCR testing of the fluid. Cordocentesis is no longer considered an essential component of the evaluation of fetal infection, having been replaced by PCR due to its simplicity and relative safety. Spiramycin 3 g/day should be administered as soon as maternal infection is documented, adding pyrimethamine/sulfadiazine if fetal infection is confirmed by PCR testing or mouse inoculation studies of amniotic fluid. Doses and dosing schedules and the addition of folinic acid with pyrimethamine vary, taking into consideration the trimester and local preferences.[128,129] In the United States, spiramycin may be obtained from the Food and Drug Administration after confirmation of acute maternal infection by a reputable reference laboratory.

Labor and Delivery

Patients with ongoing or recent toxoplasmosis infection pose a transmission risk only to their fetus and do not require isolation for themselves or for their newborn. The pediatrician caring for the neonate should be alerted to the possibility of congenital toxoplasmosis so appropriate follow-up studies can be performed on the infant. Congenital infection can be excluded if IgG does not persist in the infant beyond age 12 months.

Postpartum

After delivery, the parturient may be managed routinely, again emphasizing to the healthcare team that neither she nor the newborn poses a risk of transmission to others.

SUMMARY OF MANAGEMENT OPTIONS
Toxoplasmosis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy Toxoplasmosis infection before conception (documented by the presence of IgG antibodies) conveys a relative immunity to the gravida and makes congenital infection extremely unlikely.	III	B	127
Prenatal–Prevention Teach patient to prevent *Toxoplasma* infection: • Cook meat to well done (industrial deep-freezing also seems to destroy parasites efficiently). • When handling raw meat, avoid touching mouth and eyes. • Wash hands thoroughly after handling raw meat or vegetables soiled by earth.	—	GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Toxoplasmosis *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal–Prevention *(Continued)*			
• Wash kitchen surfaces that come into contact with raw meat.			
• Wash fruit and vegetables before consumption.			
• Avoid contact with things that are potentially contaminated with cat feces.			
• Wear gloves when gardening or handling cat litter box.			
• Disinfect cat litter box for 5 min with boiling water.			
The policy of routine screening for toxoplasmosis varies between countries; it is not practiced universally in the United States.	III	B	114
Prenatal–Diagnosis			
Maternal infection should be confirmed by an appropriate lab using reliable testing, which may include Sabin-Feldman dye test for IgG and ELISA; testing for IgM, IgA, and IgE along with IgG avidity testing; or differential agglutination test for chronicity of infection.	III	B	116
IgM antibodies for toxoplasmosis are frequently false-positive or may represent chronic infection, and should *always* be confirmed by a reference lab.	IIb	B	116
Prenatal–Treatment			
When maternal infection is confirmed, begin spiramycin as soon as possible.	IIa	B	122,129
Fetal infection may be diagnosed by PCR testing of amniotic fluid, obviating the need for cordocentesis (though not possible to determine prognosis).	IIa	B	118,121
Documented fetal infection necessitates addition of pyrimethamine/sulfadiazine.	IIa	B	122,129
Serial ultrasound will give an identification of signs of fetal infection.	IIa	B	121,123
Labor and Delivery; Postpartum			
Neither the mother nor infant is infectious to the healthcare team and may be handled in routine fashion.	IV	C	120

CONCLUSIONS

LYME DISEASE

- The diagnosis of Lyme disease is based on history of a tick bite in an endemic area and characteristic clinical findings rather than isolation of the organism or serology.
- Observe skin after tick bites for up to 30 days for signs of infection.
- Prophylactic antibiotics are usually not warranted in the absence of Lyme disease infection.

TUBERCULOSIS

- Droplet nuclei, containing two to three *M. tuberculosis* organisms, are so small that air currents normally present in any indoor space can keep them airborne for long periods of time.
- Although experts disagree about the most appropriate management of pregnant patients with latent nonclinical TB, isoniazid 300 mg daily for 6 to 9 months with pyridoxine 50 mg daily and baseline and serial liver function tests is the preferred treatment.

MALARIA

- Although the major adverse effect of malaria in pregnancy on the mother is anemia, the risk of developing severe and complicated malaria is three times higher in pregnancy and that of developing hypoglycemia is seven times more likely.
- Use of pyrethroid-containing insect spray and permethrin-impregnated bednets with liberal use of DEET insect spray topically will reduce frequency of mosquito bites.
- Consult www.cdc.gov for appropriate chemoprophylaxis and therapy for malaria, because significant resistance exists in various regions of the world.
- Chloroquine is a safe, effective chemoprophylactic drug for susceptible strains of *Plasmodium*.
- Quinine, mefloquine, and clindamycin are also appropriate and safe therapies for malaria in pregnancy.
- Chemoprophylaxis for malaria should begin 2 weeks *before* travel and continue for 4 weeks *after* leaving the endemic area.

SYPHILIS

- Benzathine penicillin G is the treatment of choice for syphilis.
- If significant penicillin allergy is determined, the pregnant patient should be desensitized, because only penicillin will adequately treat the fetus.
- The Jarisch-Herxheimer reaction is a systemic reaction that occurs 1 to 2 hours after the initial treatment of syphilis with effective antibiotics. In addition to the abrupt onset of fever, chills, myalgias, headache, and other systemic symptoms, at or beyond 24 weeks' gestation the gravida may also experience uterine contractions and recurrent variable fetal heart rate decelerations.

TOXOPLASMOSIS

- Toxoplasmosis infection prior to conception (documented by the presence of IgG antibodies) conveys a relative immunity to the gravida and makes congenital infection extremely unlikely.
- False-positive serology for toxoplasmosis with IgM testing is frequent and must be confirmed with an appropriate reference laboratory.
- Fetal infection with toxoplasmosis may be confirmed by amniotic fluid testing with PCR or mouse inoculation, making cordocentesis unnecessary.
- Spiramycin for maternal toxoplasmosis infection and pyrimethamine/sulfadiazine for fetal infection will reduce neonatal sequelae of the disease.
- Neither the pregnant woman nor her fetus/neonate are infectious to the healthcare team and require no special handling during treatment.

SECTION FIVE

Late Prenatal—Maternal

Substance Abuse

James J. Walker / Ann Walker

INTRODUCTION AND OVERVIEW

Substance abuse during pregnancy is an increasing problem that is associated with significant maternal and fetal morbidity. The complication for the clinician is that the mother is the cause of the problem that potentially harms both herself and her unborn child. Abuse is often further complicated by associated legal, social, and environmental problems[1] that can interfere with both the provision of care and the patient's ability to care for her child after delivery. The aim of the obstetrician is to provide an environment that is nonjudgmental and supportive to minimize the risk to the mother and infant, not only during pregnancy and the neonatal period, but also in the long term. To achieve this goal, the caregivers must be multidisciplinary and tolerant.[2]

The aim of antenatal care is to reduce risk, but this does not necessarily mean that the mother must abstain from drug use. The ultimate goal is to keep her within the care system and encourage her to take responsibility for herself and her child. No one should be turned away or denied help; doing so ultimately is harmful to the mother and infant.

Because the care required includes support during pregnancy, preparation for labor and delivery and the neonatal period, and long-term follow-up and social support, the obstetrician needs help and support from others, including midwives, addiction counselors, social workers, neonatologists, and general practitioners. The structure of the health care system in the United Kingdom lends itself to this approach, but it is more difficult in other parts of the world, where health care provision is more fragmented. However, programs of comprehensive antenatal care that provide social and behavioral support along with medical care do not universally improve maternal health and pregnancy outcome.[3] The specifics of the care provided are probably less important than the quality of care given and the degree of engagement of the individual.[4]

Major life events, such as pregnancy, can be a turning point in a woman's life, allowing her to take control of her life to the benefit of herself and her infant. It is often the first time she has been given any responsibility. She may not be interested in harm reduction for herself, but she is likely to wish to protect her infant. Unfortunately, the associated social problems of poor hygiene, poor nutrition, and social deprivation are responsible for much of the risk, rather than the abuse itself. The use of drugs or alcohol is a symptom of these problems. Because most users abuse more than one substance and have multiple social complications, it is difficult to evaluate the risk of any given substance. However, this chapter will attempt to do this by discussing each one in turn.

TOBACCO SMOKING

Background

Smoking is a legal and socially tolerated form of substance abuse. Although it is accepted that smoking is harmful to general health and to pregnancy in particular, the incidence of smoking in the pregnant population has increased in recent decades to between 16.3% and 52%, depending on the characteristics of the patient group.[5-8] However, there is evidence that it is declining in some populations.[6,8] Smoking is more common in the socially deprived population and varies with race. It is also heavily dependent on family and partner influences.[9] The incidence of smoking in pregnancy is higher if the mother's mother smoked, suggesting a possible inherited factor. However, because the incidence is higher still if the patient's mother smoked during pregnancy, there is a potential intrauterine influence.[7] The incidence of smoking decreases throughout pregnancy because of voluntary cessation.[5]

Maternal and Fetal Risks

Maternal smoking increases almost all placental complications. These include placental abruption,[10,11] placental insufficiency,[12,13] placenta previa,[10,11] and low birth weight.[8,12,13] Many of these infants are admitted to the neonatal unit,[8] and they have a higher incidence of neonatal death and sudden infant death syndrome.[7,8] However, the increased risk is eliminated when women with proven placental pathology are excluded from data analysis, suggesting that smoking produces most of its effects through placental damage.[14]

Interestingly, smoking in pregnancy is a significant protective factor against preeclampsia, reducing the incidence by up to 50%[15]; however, the harmful consequences of smoking on pregnancy outcome far outweigh this risk reduction.[11] There is also an increased risk of preterm delivery, partly as a result of placental disease and also because of preterm premature rupture of the membranes.[11] Data on miscarriage are contradictory. Some studies suggest an increased incidence with smoking,[16] but recent large cohort studies found no link.[17,18] However, there is an increased risk of ectopic pregnancy.[11] There are also varied data on the role of smoking and cleft lip and palate, with some studies suggesting no effect[19]; others showing a possible effect, especially with heavy use[20]; and others showing a definite effect.[21] No evidence links maternal smoking to childhood cancer.[22]

The risk of growth restriction increases with the number of cigarettes smoked per day, and heavy smokers deliver babies up to 458 g lighter than nonsmokers.[23] The effect of smoking on birth weight also increases with maternal age. Passive smoking produces risks similar to those seen in women who smoke 1 to 5 cigarettes/day. Women who stop smoking during pregnancy deliver babies that are, on average, 120 g larger than babies of those who do not stop smoking, although these infants are still 39 g smaller than infants of those who never smoked. The difference in birth weight between infants of those who never smoked and infants of those who are still smoking is 153 g.[24] The main effect of smoking appears to occur in the latter part of pregnancy, presenting a compelling argument for smoking cessation interventions that emphasizes the risk of smoking late in pregnancy.

Complications do not stop at delivery, with neonatal neurobehavioral abnormalities[25] and reduced arousal reflexes seen in infants of mothers who smoke, which may explain the increase in sudden infant death syndrome in these infants. There is evidence that children whose mothers smoked during pregnancy have early neurodevelopmental impairment and behavioral problems,[26] but these effects appear to decrease with age.[27] However, some long-term effects remain, with maternal smoking increasing the risk of conduct disorders and criminal behavior in male offspring.[28] This effect can be alleviated if the mother is responsive to the child in infancy,[29] suggesting that at least some of these changes depend on the social environment and not just the effect of intrauterine exposure to smoking.

Management Options

Prepregnancy and Prenatal

Although the strategy appears simple, it can work only if the women are aware of the risks to the unborn child and willing to stop smoking. These women need support from their partners and caregivers. This was shown in a study in England in which a mass media campaign on smoking and pregnancy was targeted at high risk women.[30] After the campaign, more people understood the risks to the unborn child, but there was no significant change in smoking prevalence or consumption. Therefore, information itself does little to change practice, and more active intervention is required.

Few centers appear to offer specific programs to reduce smoking. A mail survey in Australia showed that although smoking advice was rated an essential activity at the first antenatal visit by 69% of caregivers, only 12% of clinics offered relevant staff training and only 4% had written policies.[31] A narrow array of strategies to promote cessation was used, and almost one third of respondents said that they advised smokers to cut down rather than stop smoking completely. Some of this lack of effort comes from skepticism about the success of intervention programs.

Various studies of the role of a specially designed self-help manual to help stop smoking show that some women had already stopped before recruitment. Although there was an increase in the number of those stopping and reducing smoking compared with a control group, the percentages of patients who stopped were small, ranging from 10% to 20%.[32,33] Better results (38%) occurred with a more intensive program. Therefore, although smoking cessation is beneficial, intervention programs have limited effect because some women do not comply,[34] partly because of environmental factors.[35]

These studies used patient histories to assess smoking habits. If smoking status in pregnancy is determined by a serum cotinine assay, the rate correlates well with declared smoking.[36] However, in studies in which the percentage of self-reported quitting was higher with intervention programs compared with control groups, cotinine-verified quit rates were not significantly different. These results suggest that biochemical verification of quitting is essential to evaluate smoking cessation interventions because self-reported cessation is overstated[37] and that previously reported successful intervention programs may have overrated the number of quitters.

In a high risk group of working mothers attending a large public hospital in Valencia, Spain, 62% smoked before pregnancy. Of these, 28% gave up smoking during pregnancy. Cessation was more common among women 26 to 30 years of age, those with secondary education,

and those who were originally lighter smokers.[38] This and other studies suggest that approximately 25% of women stop smoking voluntarily during pregnancy. However, these women are usually lighter smokers from a higher socioeconomic group and therefore at lower risk for complications.[35,39] If smoking cessation programs are going to be cost-effective, it is in the high risk group of heavy smokers where most benefits can be achieved, but where intervention programs appear to fail.

Pregnant women are less able to quit smoking than nonpregnant women, possibly because pregnant women cannot use nicotine replacement therapy.[40] However, recent studies suggest that this therapy may be safe because the amount of nicotine transferred to the baby may be reduced compared with smoking itself,[41] and the FDA no longer states pregnancy as a contraindication to its use.[42] However, it should still be used with caution because studies in nonpregnant patients show that cessation rates may still be only 17%,[40] which is similar to that achieved by existing pregnancy smoking cessation programs. Despite the obvious difficulties and relatively low success rates, smoking cessation programs should be encouraged. Evidence shows increased long-term cessation. This benefits future pregnancies because cessation before conception has the greatest effect.[43]

If people stop smoking, what is the relapse rate? In a randomized trial, fewer women in the intervention group (8.8%) reported restarting smoking by 36 weeks compared with the usual care group (16.9%), a nonsignificant difference. Similarly, no significant difference in relapse rates was observed with urinary cotinine-to-creatinine ratios, but these rates, 29.5% and 27.9%, respectively, were substantially higher than those based on self-reporting. Long-term postpartum relapse rates were not significantly different, 50.9% and 50.0%, respectively. However, individual smoking relapse prevention counseling increased the interval to relapse. No particular advice appears to prevent smoking relapse during pregnancy, but repeated support and encouragement provided to women who quit early in pregnancy may be beneficial.[44] The effect of family and peer pressure is important, with increasing success occurring when there is family or peer support.[45]

Because randomized trials of antismoking advice did not affect the outcome of pregnancy compared with stud-ies of women who stopped voluntarily, maternal smoking may merely be an index of another factor that retards growth, such as social deprivation. Greater benefits may be achieved by programs to prevent nicotine addiction among adolescent girls or by encouraging cessation before pregnancy, when cessation is easier. There is evidence that this is occurring because smoking in pregnancy appears to be decreasing.[46]

Labor and Delivery

Women who smoke are more likely to have preterm premature rupture of the membranes and premature delivery, possibly because of increased oxytocin sensitivity,[47] but there is no difference in treatment. Because the risk of placental insufficiency is increased, the infant may have growth restriction, with an increased possibility of fetal distress. Therefore, close vigilance in labor is recommended, with assessment of the fetal heart rate on admission and again near the end of labor, when the risks to the fetus are greatest. Interestingly, because of the effect on fetal growth, smoking is protective against macrosomia.

If a general anesthetic is required, women who smoke are at increased risk. Normally, smokers are asked to stop at least 24 hours before the anesthetic is administered, but labor is not predictable. Women should be told not to smoke once contractions have started.

Postnatal

Cigarette smoking during pregnancy is a significant health risk to the fetus, but most women continue to smoke during pregnancy, and most who quit relapse postpartum. This can have a significant effect on the future health of the child as well as on subsequent pregnancies.[9] Smoking cessation is easier in the nonpregnant state, but cessation appears to be more closely related to environmental and social factors than to any medical intervention. Failure to stop smoking also has a detrimental effect on long-term maternal health. A follow-up study in northern Finland showed that the mortality ratio, adjusted for age, place of residence, years of education, and marital status, in women who smoked during pregnancy was more than twice that in nonsmokers. The difference was related to an increase in expected smoking-related diseases.[48]

ALCOHOL

Background

Alcohol is a natural substance with body enzymes designed to metabolize it. Therefore, it is unlikely that alcohol is in itself toxic. However, the consumption of excessive amounts of alcohol is detrimental. After many historical references to the harmful effects of alcohol consumption in pregnancy, Lemoine and colleagues[49] described defects in fetal growth and development associated with maternal alcohol abuse in 1968. Further studies described the range of fetotoxicity attributed to both heavy and social maternal alcohol consumption.[50] Although the risk depends on the level and frequency of alcohol use, therapy is dependent on the degree of maternal dependency. In women who are not dependent, there is a high success rate with simple educational and motivational methods.[51] However, those who are dependent need greater supportive input and often require pharmacologic intervention.[52]

Maternal and Fetal Risks

Excessive Consumption

Jones and Smith[53] were the first to coin the phrase "fetal alcohol syndrome" to describe the features associated with heavy maternal alcohol consumption, but the signs had been described before.[54] The main features include the following:

- Growth deficiency, both prenatally and postnatally
- Central nervous system disturbance that affects intellect and behavior

- Abnormal facial characteristics, particularly low-set, unparallel ears; a short, flattened philtrum; an elongated midface; a small head; and a short, upturned nose
- Malformation of major organs, especially the heart, and skeletal deformities

Newborns with the syndrome may be irritable, with hypotonia, severe tremors, and withdrawal symptoms. The main physical and cerebral signs are usually apparent at birth. Mild mental retardation, the most common and serious deficit, and other anomalies may accompany fetal alcohol syndrome, and the degree of facial abnormality is directly related to the long-term physical and intellectual deficits.[55] Sensory deficits include optic nerve hypoplasia, poor visual acuity, hearing loss, and receptive and expressive language delays. Atrial and ventricular septal defects as well as renal hypoplasia, bladder diverticula, and other genitourinary tract abnormalities may occur. Only complete abstinence during pregnancy is considered safe. Alcohol consumption in each trimester is associated with abnormalities, and the lowest innocuous dose of alcohol is not known.[56] However, abnormal facial features are apparent only at the highest levels of exposure.[56]

Fetal alcohol syndrome is relatively rare, with an incidence of less than 1 in 1000 live births, increasing to 4.3% among "heavy" drinkers. The general incidence is more than 20 times higher in the United States (1.95 in 1000) compared with Europe and other countries (0.08 in 1000).[57] Relatively few women who drink alcohol during pregnancy give birth to children with fetal alcohol syndrome, and various theories have been suggested.[58] In the United States, the incidence is higher in lower socioeconomic groups, suggesting that the problem is

multifactorial and includes genetic factors, social deprivation, nutritional deficiencies, and tobacco and other drug abuse.[58]

Intrauterine growth restriction is also more frequent in women who drink alcohol during pregnancy. This effect is aggravated by maternal smoking.[56] Maternal alcohol intake of more than 20 g/day is associated with an increase in preterm delivery and neonatal jaundice.[59] Excessive consumption, especially when accompanied by a poor diet and smoking, can lead to significant fetal effects.

Social Alcohol Consumption

The evidence against more moderate consumption is controversial. Although effects are seen at all intake levels, the results are not conclusive.[60] Approximately 50% of women consume alcohol on a moderate and occasional basis during pregnancy, although more abstain in the first trimester.[61] This behavior is socially acceptable and considered normal. The consequences on pregnancy are difficult to assess because quantification of alcohol consumption is difficult to assess accurately. In addition, there are confounding factors, particularly socioeconomic group and tobacco consumption.

Far more studies have reported no significant effects of mild alcohol intake than have reported problems. The effect of smoking on birth weight is three times greater than the effect of alcohol.[56] When data are stratified by smoking status, moderate maternal alcohol consumption usually has no significant effect on birth weight in nonsmokers, but among smokers, there is a significant linear trend, with a threshold for decreased birth weight at an average of approximately two drinks per day (14 units/wk).[62] Lower consumption levels are associated with an increase in birth weight, suggesting an inverted J-shaped function between drinking during pregnancy and birth weight.[63] On its own, moderate intake of alcohol during pregnancy of less than 12 to 14 units/wk has no apparent detrimental effect on fetal growth.[63]

Although some studies show that children exposed to alcohol prenatally had significantly lower weight, height, head circumference, and palpebral fissure width at 6 years,[64] most show that the effect on growth is transient and the differences are not measurable after 8 months of age.[65]

Although most studies suggest that low alcohol intake in pregnancy does not have a substantial effect on child development, there is concern about the long-term neurodevelopment of exposed offspring. Dose-dependent effects on neurobehavioral function from birth to 14 years have been established and are described as fetal alcohol effects.[66] Specific problems include attention deficit, slower information processing, and learning problems, especially with arithmetic,[67] as well as slower reaction times, suggesting an alcohol-related deficit in "speed of central processing." Reaction time deficits were dose-dependent,[68] as were attention and memory

deficits. The number of drinks per occasion was the strongest predictor of deficits. Fluctuating attention states, problems with response inhibition, and spatial learning also showed a strong association.[67] The higher the average number of drinks per occasion, the poorer the performance of the adolescent offspring on tasks believed to underlie numeric problem-solving and reading proficiency.[69] As with fetal alcohol syndrome, not all exposed offspring studied showed neurodevelopmental deficits. The effects appear to increase with advancing maternal age.[70]

Management Options

Prepregnancy and Prenatal

Because most women are not addicted to alcohol, they often take a "better safe than sorry" approach and reduce or stop drinking in pregnancy.[61] A successful previous pregnancy experience or a previous alcohol-related problem can influence this decision.[71] However, it is not the social drinker who concerns the obstetrician because these patients are relatively easily educated about risks and tend to reduce their intake.[61] The few heavy drinkers, either dependent or binge drinkers, are more likely to harm their unborn child and are difficult to manage. Smokers and older women are particularly at risk because of the associated additive effects.

Formalized questionnaires on alcohol use can be used to screen either the entire population or targeted at-risk groups. The T-ACE questionnaire has been validated and appears to be accurate in detecting women who drink more than 1 oz absolute alcohol/day (approximately 25 g, or 2.5 units). Screening is most sensitive during the first 15 weeks of pregnancy.[72]

T-ACE is an acronym for the following:

- T: TOLERANCE

  How many drinks does it take to make you feel "high"?

- A: ANNOYED

  Have people ANNOYED you by criticizing your drinking?

- C: CUT DOWN

  Have you felt you should CUT DOWN on your drinking?

- E: EYE OPENER

  Have you ever had a drink first thing in the morning?

Scoring of the test is straightforward. If the answer to the tolerance question is more than 2, a score of 2 is given. A score of 1 is assigned to a positive answer to all of the other questions. A total score of more than 2 is considered positive for problem drinking, and this score correctly identifies more than 70% of women who drink

heavily during pregnancy. Although this questionnaire is better than traditional alcohol questionnaires, its sensitivity can be improved with the use of a further test.[73]

An alternative is the Leeds Dependence Questionnaire, which is a 10-item, self-completion questionnaire designed to measure dependence on a variety of substances. It is understood by users of alcohol and opiates. The questionnaire is sensitive to changes over time from severe to mild dependence. Test–retest reliability is 0.95.[74]

Biochemical markers, such as blood γ-glutamyltransferase, alcohol concentration, thiocyanate, and mean corpuscular volume, can be used as surrogates of excessive alcohol consumption, but they are not accurate and can be used only to identify potential at-risk women. Abnormalities of liver enzymes in women who drink heavily should be taken into account if these tests are used during pregnancy to monitor other diseases, such as preeclampsia.

As with smoking, studies show that approximately one third of women who drink alcohol before pregnancy stop drinking during pregnancy and those who continue to drink tend to reduce their consumption.[61] A few women continue high levels of alcohol intake, and if they can be identified, preventive efforts should be focused on this group.[75] In contrast to smoking, many of these women are in higher socioeconomic groups.[76]

Adults have a significantly higher average daily intake of alcohol than adolescents. However, adults are more likely to reduce their intake in pregnancy and have a reduced incidence of binge drinking during the first trimester, which puts the offspring of adolescents at greater risk.[77]

If intervention programs are established, help from outside agencies, such as the local addiction unit, is invaluable. As with smoking, these programs are more likely to be successful in women who want to stop and when supportive care is provided. Motivational intervention with close monitoring of alcohol consumption with a planned reduction program is of benefit, often with the help of friends, family, and organizations such as Alcoholics Anonymous, with their 12-step program.[78] Because the effects of alcohol are associated with dietary deficiencies, the importance of a good diet and vitamin supplementation should be discussed.[79] Many complications of alcohol abuse may be attenuated by these measures.

If there is continued dependent drinking and the patient is motivated to stop, planned detoxification should be considered, possibly with hospitalization or regular daily monitoring of withdrawal symptoms. Sudden withdrawal can lead to acute maternal symptoms, including convulsions, which may be detrimental to the fetus. Detoxification is normally undertaken with benzodiazepines, such as chlordiazepoxide, with the possible addition of phenobarbitone, if required, to manage convulsions.[80] These are given by reducing the regimen over 7 to 10 days. Benzodiazepines given in the first trimester may be associated with cleft palate abnormalities.[81] However, the benefits of stopping alcohol use outweigh this risk because alcohol is by far the greater teratogen. If delivery is likely within the next few days, benzodiazepines should be given with care because neonatal sedation and "floppy baby syndrome" can occur.[82] Disulfiram (Antabuse) should not be used because it is considered a potential teratogen, although the evidence is conflicting.[83] These patients should also be given vitamin B supplementation.

Labor and Delivery

There are no problems with labor and delivery, except for the occasional need for higher levels of opiate analgesia or problems with general anesthesia because of induced liver enzymes. Alcohol withdrawal occurs after 48 hours and may be a problem postnatally. Appropriate sedation can be used with vitamin, particularly thiamine, supplementation. Symptoms subside after a few days. Women may appear agitated and have difficulty caring for the infant during this time.

If alcohol abuse continues after delivery, breastfeeding should be discouraged. Alcohol crosses over to the baby, and there may be continued effects of alcohol on the neonate.[56] Alcohol abuse during breastfeeding can cause drowsiness in the baby and may aggravate existing nutritional problems, increasing the need for dietary supplementation. However, alcohol may interfere with milk production, necessitating artificial feeding.

Postnatal

In most follow-up studies, a significant percentage of women relapsed. In one study of adolescents, more than 30% reported using alcohol within 3 months of delivery. These women are more depressed, are under greater stress, and report a greater need for social support. Therefore, the use of alcohol, as with other drugs of abuse, may be a marker for other problems that would benefit from intervention.

There is increasing concern about children of parents who abuse alcohol. These children have a higher risk of psychiatric disorders, cognitive deficits, and substance abuse that may be genetic or a long-term effect of in utero alcohol exposure.[84] Significant alcohol use affects family functioning, and children of alcohol-abusing parents are at risk for abuse and neglect.[85] Family drinking patterns are associated with adolescent alcohol abuse.[84] Children of alcohol-abusing parents have a higher incidence of emotional and behavioral disturbances and are at risk for future adult morbidity other than alcoholism. Therefore, women who abuse alcohol during pregnancy require careful follow-up from the appropriate agencies.

DRUG ABUSE: GENERAL

The effects of maternal drug abuse on the mother and infant are controversial. Much of the research comes from the United States and involves low-income women with multiple drug use and social problems.[86] When matched for social factors, mothers who use heroin have similar birth outcomes to non-drug-using mothers.[2] Therefore, many effects attributed to maternal drug abuse may be related to socioeconomic deprivation or associated factors, such as smoking, rather than to in utero drug exposure. The only effects that can be definitely blamed on drug abuse are neonatal withdrawal. However, specific complications are associated with particular substances (discussed later).

The social factors are made worse by the fact that the drugs used are illegal. The women often live in a subculture of illegal behavior, including theft and prostitution.[87] Many mothers attempt to hide their lifestyle and claim fictitious support. They are often reluctant to be honest and may fear criticism, legal action, or removal of the child. They may resist antenatal care and must believe that the care is beneficial.[88] The service must be flexible and understanding enough to cope with these problems. In Glasgow, Scotland, a multidisciplinary approach was used to provide economic, social, and antenatal care during pregnancy.[2] This model has been copied elsewhere.[89] Because these problems persist after delivery, support for issues related to social problems and substance misuse must be continued after pregnancy to maximize the outcome for the mother and infant. This requires close collaboration with local addiction services.[90]

Care programs that have been developed attempt to modify the external influences as much as possible to stabilize the mother's substance misuse.[89] Some women can stabilize their habit, detoxify, leave the drug culture, become healthy and responsible, and keep and care for their infant. However, others struggle to stay within the system, and care should be directed at the best possible outcome for each individual rather than optimal outcome. These care systems may change the pattern of abuse, but not necessarily the neonatal outcome.[91]

The systems that work best are multidisciplinary, with input from obstetricians, midwives, pediatricians, community-based health workers, social workers, drug abuse counselors, and others who can offer support.[2,89]

Caregivers should not be judgmental, although they must establish boundaries and maintain discipline. It is important to keep the trust of women and encourage them to obtain care, regardless of whether they are using drugs. A system based on rewards structure is better than one based on punishment. The ultimate reward is being able to keep and care for the infant after delivery. Care programs are more successful when friends and family are supportive.[92]

It is difficult to believe addicts, and urine screening is beneficial to assess program compliance.[93] Inpatient care can be useful to detoxify the patient; remove her from an unhealthy, stressful street environment; and provide adequate nutrition. However, these patients may be disruptive, cause stress in other patients, and continue to abuse substances. In an attempt to overcome these problems, some hospitals have a segregated area for the care of addicts.[94] However, in Leeds, we believe that it is important to treat them as normally as possible and to house

them in the regular areas.[89,90] Protocols must be in place and sympathetic staff available.

Establishing a Special Clinical Service for the Pregnant Addict

In Leeds, a special pregnancy addiction service was set up within an antenatal clinic.[90] This allows patients to have all of their needs met at a single site. The clinic is coordinated by a liaison midwife with an obstetrician and an addiction worker. This ensures access to necessary antenatal care and addiction advice. The service provides a regular clinic that is available by appointment as well as on a drop-in basis. Providing care at a single site avoids the potential stigma of a separate clinic as well as possible loss of confidentiality. The availability of the service is promoted in health centers, hospitals, and local relevant organizations.

To achieve this, a close working relationship was developed between the obstetric and addiction services, with links with community midwives, general practitioners, pediatricians, health visitors, child protection services, social services, and general support services, such as housing, probation, and community care projects. With so many individuals involved, regular monthly meetings are held to exchange information and discuss concerns. Treatment protocols are available for all staff, particularly those who share responsibility with other services.

Regular reviews of the women are important. The Standing Conference on Drug Addiction guidelines are followed.* An initial assessment is performed at presentation, and a full review of progress made and work outstanding is completed at 32 weeks. By that time, a plan should be in place to deal with outstanding issues. Other professionals, usually social services or housing authorities, can be contacted at that time. This process occurs with the consent of the woman, unless the infant is considered "at risk." In this case, authorities must be involved, even without the mother's consent. When significant concern is present, a full prebirth assessment by social services may be needed. A postnatal review at 3 months is scheduled to assess the progress of the mother and infant.

*Standing Conference on Drug Abuse (SCODA) 1997 "Drug using parents: Policy Guidelines for Inter-Agency working." Local government forum and association, United Kingdom.

Labor and Delivery

The labor and delivery unit must be prepared to provide the care required at delivery. As with alcohol, problems include issues of drug withdrawal and complications with analgesia, but also include the possibility of HIV and hepatitis infection. Specific problems depend on the drugs used.

Postnatal

The neonatal unit should be ready to care for an infant with withdrawal symptoms. The incidence and severity of these symptoms are related largely to the type and amount of drug used. In the past, babies of drug-using women were usually admitted routinely to the special care nursery and often treated for, or in anticipation of, withdrawal symptoms. These symptoms are a source of distress to the mother, but separation can cause further distress. In the United Kingdom, most infants do not require admission to a neonatal unit and can be cared for in a transitional care area, where the mother is directly involved.[89]

Drug abuse was formerly considered incompatible with adequate child care, but it is now realized that drug cessation and postnatal abstinence is largely unachievable. An attempt to enforce drug cessation is likely to drive the women away from the supportive environment that was carefully established during pregnancy. However, harm reduction and stabilization should be the goal, and this goal is compatible with maternal and child health. In the United Kingdom, methadone maintenance is the main treatment for opiate addicts who are unable or unwilling to stop using drugs.[90] This approach may allow the women to live a reasonably stable life and care for her children. Many studies show that infants who remain with their biologic parents do better than those who do not.[95] To achieve these outcomes, a good working relationship with the local addiction unit is necessary to ensure that adequate follow-up and support is available.[89,90]

The success of these policies is varied. More than 50% of women who stop abusing drugs resume drug use within 6 months of delivery. Many of their infants are cared for by extended family members on a voluntary basis, and others enter foster care or are adopted. This outcome may be upsetting to staff working in this area, but one success can lead to long-term benefit to at least two people (i.e., the mother and her child), and even a temporary success may reduce the long-term effects on the infant.

HEROIN ADDICTION: SPECIFIC PROBLEMS

Background

Heroin is processed from morphine, a naturally occurring substance extracted from the seedpod of the Asian poppy plant. Heroin usually appears as a white or brown powder. Street names for heroin include "smack," "H," "skag," and "junk." Other names refer to types of heroin produced in a specific geographic area, such as "Mexican black tar."

Heroin is a highly physically addictive drug, and its use is a serious worldwide problem. It can be injected, snorted, or smoked, and like many drugs of abuse, the ritual of preparation is an important part of the attraction. After heroin injection, there is a surge of euphoria ("rush") accompanied by warm flushing of the skin, dry mouth, and a heavy sensation of the extremities. A drowsy state occurs, and mental functioning becomes clouded as a result of central nervous system depression. This leads to a lack of motivation and reduced social interaction.

The management approaches discussed earlier are particularly relevant to the care of the patient who uses heroin in pregnancy. Outcome of the mother and infant is greatly enhanced by her attendance at an appropriate support clinic. The mother must know the risks of heroin addiction to her infant, particularly the risks of street heroin, which is of variable strength and quality and produces unpredictable results. The benefits of methadone maintenance or detoxification should be emphasized.[90,96] This support, including methadone maintenance treatment, should be provided within a multidisciplinary clinic, with regular follow-up.[90,96] In this environment, there is a reduction in supplementary drug use and an associated reduction in harm. Although the doses of methadone used in the United States tend to be higher than those used in the United Kingdom, the success of maintenance therapy is largely independent of either methadone dose or plasma concentration and relates to the degree of ongoing support.[93]

Maternal and Fetal Risks

The main clinical problems related to heroin use are direct drug effects on the fetus and neonate and the reduced ability of the mother to care for the child.[95] Opiates are not teratogenic.[97] However, their use is associated with intrauterine growth restriction and premature delivery,[95,98] a higher incidence of fetal distress, and a greater need for neonatal care.[99] Although other factors, such as poor antenatal attendance, poor nutrition, mixed drug use, and cigarette smoking, are undoubtedly involved, it is important to realize that these pregnancies are at risk, regardless of whether the drug is primarily responsible. Longitudinal studies found an increased incidence of deficits in cognitive development and more behavioral problems but no differences in motor development. It is difficult to separate the effects of in utero exposure to heroin from the problems of deficient child care.[100] Children who are adopted at an early age into nurturing families develop normally, suggesting that there is no inherent problem in these babies, and if the mother is stabilized and succeeds in changing her lifestyle, the long-term outcome for the infant can be good. However, these mothers have child care problems, and there is an increased risk of sudden infant death syndrome, with a risk ratio of nearly 3.[101] Pregnancy care is only the starting point, and there is a need for ongoing support after delivery, requiring collaboration with addiction services.[90]

Management Options

Prepregnancy and Prenatal

The main aim of care for the pregnant drug-abusing woman is engagement. With this, the rest of the care follows. She can be cared for by a multidisciplinary team (including addiction service), with the goal of risk reduction.[89,90] The core of risk reduction is the drug substitution program; methadone is the therapy most often used.

METHADONE USE IN PREGNANCY

Methadone use in pregnancy varies. In the United States, higher doses are used to block opiate receptors and reduce cravings, whereas in the United Kingdom, the approach is often to find the lowest dose to prevent withdrawal symptoms. Studies show that reducing the dose to a minimum improves birth weight and prolongs gestation.[102] It is difficult to determine whether these benefits result from the use of methadone, the reduction of other drug use, an improved lifestyle, or a combination of these factors.[102] However, the risk and severity of neonatal abstinence syndrome (NAS) appear to be increased by methadone compared with heroin,[103] but methadone stabilization has considerable overall benefits for the mother and infant. The purpose of substitution therapy is to reduce illegal heroin use as well as the crime, disease, and other consequences of street use. Reducing intravenous injection has the added benefit of reducing the risk of HIV infection and hepatitis B and C infection and well as other health risks. Because methadone, at therapeutic levels, does not create euphoria, sedation, or analgesia and has no adverse effects on motor skills, mental capability, or employability, it is compatible with a reasonably normal lifestyle. Therefore, it is suitable for stabilization during pregnancy and for short- to medium-term use after delivery to maintain stability. Although many patients reduce their opiate use, only a few (10%–25%) become drug-free,[97,98] and many of these return to heroin use after delivery.

The amount of methadone required should be assessed in the usual way. Women who are not regular (daily) users do not need substitution therapy. Those who are given methadone should have a clear history of daily use, withdrawal symptoms, and positive urine toxicology findings. The amount of methadone required can be assessed by the declared amount of heroin used or the amount of money spent per day. However, because the cost and purity of street heroin vary considerably, this guidance can only be approximate. Dosage is then titrated against withdrawal scores until stabilization is achieved. The aim is to find the lowest dose of methadone that is compatible with an absence of withdrawal symptoms or cravings. The dosage regimens in pregnancy are the same as those used in the nonpregnant user. The maximum dose of methadone used in the Leeds service is 80 mg/day. Because the metabolism of methadone is increased in pregnancy, leading to a shorter half-life, the dose may need to be split into a twice-daily dose in later pregnancy to maintain a satisfactory steady state.[104] This dosing can increase compliance without the need to increase the total dose.[105] Methadone maintenance treatment is more successful within a supportive environment and is largely independent of methadone dose or plasma concentration.[93] Therefore, the supportive nature of the service is more important than the drug regimen used.[87]

Once stabilization is achieved and lifestyle issues are addressed, if the woman is motivated, gradual dose reduction can begin. The main goal is stability. Because of the danger of miscarriage, this is more safely carried out between 12 and 30 weeks' gestation. After this point, it is better simply to stabilize the patient at the lowest possible dose in preparation for labor and delivery. Because of the changes in maternal metabolism, the maintenance dose may need to be increased to sustain maternal stability. Reduction should be done slowly, by decreasing the daily dosage by 5 mg, no more often than every 2 weeks, and then, from 20 mg/day, by 2 mg every 2 weeks, to achieve the lowest sustainable dose without the mother resorting to street heroin or suffering withdrawal symptoms.[102] It is important to aim for the lowest maternal dose to reduce the possibility of NAS. Although not strictly dose-related, a dose of less than 20 mg is not usually associated with significant NAS, unless there is concurrent street drug use. Regular urine toxicology testing allows accurate assessment of the success of the treatment program and assists in the planning of dose adjustments.[93]

ALTERNATIVES TO METHADONE

Because of the well-recognized limitations of methadone treatment, alternatives have been sought. Buprenorphine appears to be a potential option,[106] but the safety to the fetus is unknown. Early studies showed that stabilization is possible, and the risk of NAS appeared low.[107,108] However, more recent studies show that NAS occurs in 40% to 60% of cases, usually within 12 to 48 hours, peaks at approximately 72 to 96 hours, and lasts for 5 to 7 days.[109,110] However, NAS appears to be of less duration and severity than methadone and is related to polydrug use in at least 40% of cases.[110] The children are followed closely, with regular monitoring of physical and psychological development. So far, no clear detrimental effects have been found. Buprenorphine taken at the time of conception has been reported with no teratogenic effects.[107] If these results are confirmed by randomized trials, buprenorphine would offer a real alternative to methadone, with a reduced risk profile.

Labor and Delivery

The attendant staff must be trained in the care of pregnant drug users and treat them in the same way as other women in labor. On admission, a history of recent drug use (i.e., before admission) must be obtained. Many

mothers use heroin before hospital admission to help them tolerate labor.

No specific problems are associated with labor or delivery, except for maternal analgesia. Methadone should be continued, with additional opiate analgesia as required. Because high doses of narcotic analgesia may be necessary, epidural analgesia has advantages. At delivery, the infant should not be given naloxone (Narcan) because it causes a severe withdrawal reaction.

Postnatal

After delivery, normal support should be continued, ideally in a transitional unit. This allows the mother and infant to be together, which is important for bonding and establishment of parenting skills. This is the ideal time for staff to promote support and assess possible risk.

The incidence and severity of NAS are partially related to the type and amount of drug used.[111,112] However, polydrug use can influence this, particularly street heroin, benzodiazepines, and cocaine.[111] Both benzodiazepines and cocaine delay the onset of NAS, but cocaine also appears to reduce the severity of symptoms.[112] The pediatric unit should be alerted to the potential clinical problems and involved in the case discussion and the development of management protocols.

In Leeds, a modified Finnegan scale is used to monitor the infant for signs of NAS.[113] This is initially carried out every 4 hours and monitoring is reduced when appropriate. Three scores of 8 or more should be used for the diagnosis. It is useful for the mother to be involved in these assessments because many drug-using mothers have strong feelings of guilt and want to feel that they can make a useful contribution. They can also improve the continuity of assessment. Withdrawal from heroin occurs over 1 to 3 days, whereas methadone has a longer clearance time, and symptoms in the newborn may not occur for up to 7 days after delivery. Assessment should last at least 7 days, although some centers advocate earlier discharge if there are no signs by 72 hours.[114] The classic symptoms are restlessness, jitteriness, failure to feed, tremors, a high-pitched cry, arching of the back, yawning, sneezing, and sweating.[113] Convulsions may also occur. Narcotics, either morphine or methadone, are the best drugs for the treatment of NAS, although phenobarbitone may be required if convulsions occur.[114,115] Although most babies show some withdrawal symptoms, fewer than 50% require treatment and most can be safely cared for in a transitional unit.[89,114] Of 200 babies born in Glasgow in the 1980s and early 1990s to mothers using illicit drugs or legal methadone, only 7% required treatment for withdrawal and even fewer required admission to the special care nursery.[94] However, other centers, including more recent figures from Glasgow, quote incidences of 10% to 80% of cases, depending on the amount of antenatal drug used and the success of the clinic maintenance program.[99,111,112,114]

Continuing supportive care, including methadone maintenance, may allow the new mother to live a reasonably stable life and care for her child, which is the best outcome for the child.[95] This requires a continued good working relationship with general practitioners, health visitors, community pediatricians, and the local addiction service. However, many babies are eventually cared for by extended family members, placed in foster care, or released for adoption.[116]

BREASTFEEDING

If the mother is stable on methadone, is not supplementing with street drugs, and is believed to be HIV-negative, breastfeeding should be encouraged. The secretion of methadone in breast milk is variable,[117] but it may help to reduce withdrawal symptoms.[118] A stable lifestyle helps successful breastfeeding. However, if the mother is still injecting street heroin, is known to be or is at risk for being HIV-positive, or is using other street drugs (e.g., cocaine), breastfeeding is not advisable.

HIV AND OTHER INFECTIOUS DISEASES

HIV infection is associated with drug abuse because of needle sharing and heterosexual spread from associated prostitution. The danger, particularly in the United Kingdom, has been overstated, although in some areas, the incidence of HIV infection is particularly high. In Edinburgh, in 290 at-risk pregnancies, 93 (32%) of the women were HIV-positive. However, of these 93 pregnancies, only 8 (8.7%) resulted in an HIV-infected child.[119] Since then, the prevalence of HIV has declined from 0.5% of all pregnancies in 1986 to 0.1% in 1992. This figure has not changed.[120] The risk of vertical transmission has been significantly reduced by the use of antiviral drugs and obstetric intervention.[121] However, although the incidence is decreasing in Scotland, the medical authorities knew most of the HIV-positive women in 1990, but by 1992, only 30% were identified.[122,123] This makes the targeting of antiviral treatment more difficult.

Because many HIV-positive patients are not known to the service, single-tier management of all pregnant women is important to minimize the risk of transmission to health care workers. This also helps to reduce discrimination against substance-misusing women. In the United Kingdom, HIV testing is offered to all pregnant women after appropriate counseling. The benefits of testing must be explained to the mother. Current therapy improves maternal health and significantly reduces vertical transmission to the baby.[121]

Intravenous drug users are also at risk for hepatitis B and C infection, and screening is routinely offered. The most common infection found is hepatitis C, which is found in approximately 40% to 60% of women who abuse intravenous drugs. Evidence suggests that hepatitis C does not adversely affect the pregnancy and the pregnancy does not worsen the viral load or prognosis of the

disease, although many women have a slight rise in alanine aminotransferase levels postpartum.[124] Vertical transmission of hepatitis C infection occurs in approximately 1% to 6% of cases and is partly dependent on maternal viral load and concurrent HIV infection.[125,126] Transmission is also increased in longer labors, but breastfeeding does not influence it because hepatitis C virus RNA is not detected in breast milk. Infants who are hepatitis C virus-positive should be followed up for at least 1 year because some become seronegative and others have hepatitis. No treatment or vaccination is available.

Less frequently, women are hepatitis B-positive. Pregnancy does not appear to affect the course of the disease in the mother, but the rate of vertical transmission without intervention is 80% to 90%.[127] Of these patients, more than 85% become clinical carriers of the virus. Infection in the baby usually occurs at or directly after delivery, so the babies are candidates for postexposure prophylaxis. An at-risk infant should be given HepB immunoglobulin within 12 hours of delivery while concurrently being given the first dose of HepB vaccination.[128] This should be completed with follow-up vaccinations at 1 month and at 6 months. This intervention is safe and provides 90% protection against infection. One study suggested that maternal lamivudine treatment may also help to reduce neonatal infection.[129]

COCAINE ADDICTION: SPECIFIC PROBLEMS

Background

Cocaine is a vasoactive drug and can cause specific problems in the baby as a result of placental damage[130] and direct fetal vascular effects. Unlike alcohol, cocaine has no specific associated syndrome or cluster of signs.[131] Its effects are varied and may be more closely related to other drug use and associated social problems.[130,132]

It comes in the following two forms:

- Pure cocaine, or "coke," which is a white powder that is generally snorted through the nasal mucosa.
- "Crack," which is more addictive and dangerous. Crack is produced by mixing cocaine crystal or powder with water and baking soda or sodium bicarbonate. The mixture is boiled until the water evaporates, leaving brown and white rocks. It is usually smoked with special glass pipes or silver foil, although it can be injected after a solution is made with water.

Cocaine is absorbed rapidly into the bloodstream, producing a high in approximately 6 to 8 minutes. Unlike the physical addiction of heroin, cocaine addiction is more psychological. Cocaine and crack users are difficult to identify and treat. There are no suitable substitute drugs.

Many studies, particularly in the United States, found higher rates of cocaine abuse than of heroin abuse, with an incidence of 0.8% to 16%.[130,133,134] Radioimmunoassay of hair samples obtained immediately postpartum show much underreporting of cocaine use. Underreporting is more common among women who are unmarried, African American, and multiparous.[135,136]

Maternal and Fetal Risks

Cocaine users often do not eat or sleep while under the influence of the drug and often become dehydrated. Although these effects may not present problems with occasional use, heavy use may be associated with exhaustion, dehydration, and poor nutrition. Some people use heroin to "come down" from cocaine highs, further complicating the medical problems. Because crack can be smoked, it can affect other people nearby; this has implications for children and babies in the room with a user.

Heavy usage of cocaine is associated with an increase in preterm delivery, low birth weight, the need for resuscitation at birth, and prolonged postnatal stay.[99,137] The effect of cocaine on birth weight may be related to shorter gestation and poor maternal nutrition. Women who use cocaine use prenatal care less often, smoke more cigarettes, and drink more alcohol, all of which are associated with poor growth.[138] When these variables are excluded, identifiable differences in birth weight between cocaine-using mothers and control subjects are no longer present.[132] However, peripartum exposure to cocaine is associated with an increased frequency of abruptio placentae; thick, meconium-stained amniotic fluid; and premature rupture of the membranes.[130] There is also an association with fetal abnormalities, including genitourinary anomalies and abdominal wall defects.[130]

Cocaine-exposed infants with very low birth weight had an increased incidence of mild intraventricular hemorrhage. However, the incidence of developmental delay was significantly higher, even after controlling for the effects of intraventricular hemorrhage and gestational age.[139] Cocaine-exposed infants with very low birth weight were also more likely to be living with relatives or in foster homes, which further affects their development.[139] Long-term assessment showed reduced head circumference, low Stanford-Binet Intelligence Scale (SBIS) verbal reasoning, and low SBIS abstract/visual reasoning. These children were also more aggressive.[140] These findings are similar to those associated with alcohol.

Binge cycles are a particular problem and reflect the chaotic lifestyle of many drug abusers. Binges range from 26.4 to 34.4 hours.[141] Bingeing is associated with premature delivery and an increased incidence of acute problems, such as vaginal bleeding (21.8%), abruptio placentae (14.3%), and stillbirth (20.5%). Erratic use of cocaine or crack results in perinatal complications that are as severe as those occurring with daily use.[141]

Like heroin, maternal cocaine exposure during pregnancy is associated with acceleration of amniotic fluid and fetal lung maturity, which may reflect increased fetal stress.[142]

Not all substance-exposed children have the same poor prognosis, suggesting that maternal and environmental factors modify the damage.[140] Surveys show that most cocaine users also use alcohol.[138] Comparison with alcohol shows that alcohol is the more potent teratogen. Those who use both agents are more likely to have troubled backgrounds, indulge in antisocial behavior, and drop out of treatment programs than those who use only alcohol. Good nutrition is very important in preventing congenital anomalies and fetal death, and cocaine use during pregnancy is more dangerous to the street person who uses multiple drugs and alcohol than to the middle-class woman who takes antenatal vitamins.[143]

ANIMAL STUDIES

Animal studies have been used to assess the direct effect of cocaine in pregnancy. Rhesus monkeys that were exposed to cocaine during pregnancy were compared with matched nonexposed control subjects. There was no difference in infant outcome, as measured by body weight, overall length, crown–rump length, rump–heel length, biparietal diameter, and crown circumference.[144]

Pregnant Sprague-Dawley rats were fed diets with differing protein content and exposed to cocaine. Cocaine was associated with reduced food intake, and this difference was greater in the group with low protein intake. This diet affected weight gain in pregnancy as well as skeletal maturation of the pups. Litter size was significantly reduced with higher doses of cocaine across all diet groups, suggesting a fetotoxic effect. Gestation length was unaffected. Therefore, cocaine may produce poor fetal growth by reducing dietary intake.[145]

Animal studies suggest that cocaine can cause functional problems. Perinatal cocaine exposure led to decreased responsiveness to inotropic drugs during the early neonatal period in rats[146] as well as to cognitive impairment in some male offspring, without apparent postnatal physical abnormalities or adverse effects on maternal health.[147]

In pregnant baboons, intravenous cocaine increased plasma oxytocin concentrations.[148] A similar study in rats produced a marked increase in uterine activity and arterial blood pressure.[149] These studies suggest that cocaine use may increase uterine activity in pregnancy and may increase the risk of premature labor. This may explain the chemically observed relationship between acute cocaine use and abruptio placentae.

Management Options

Prepregnancy and Prenatal

Again, the basis of care is trust between the woman and her caregivers. The true nature of cocaine or crack abuse may not be easily divulged, and support may be rejected. The risk to the fetus must be made clear and the particular risk of binge use emphasized. No substitute drug is available to help with stabilization in pregnancy. However, sudden cessation is not associated with adverse fetal effects. Although the desire for a healthy baby may be an incentive to stop using cocaine, success is rare because psychological addiction is usually strong. If a woman wishes to stop using cocaine or crack, hospital admission may be beneficial to remove her from her usual environment. Constant social support and encouragement increases the chance of success. If use is stopped at any time during pregnancy, the outcome is improved.

Labor and Delivery

There is no major problem with labor or delivery, other than an increased need for narcotic analgesia. There can be specific problems in anesthetizing a patient who uses cocaine or crack.[150] As noted earlier, drug-related hypertension may mimic preeclampsia. Excessive uterine activity may result in fetal compromise or acute separation of the placenta.

Postnatal

After delivery, the symptoms of fetal cocaine withdrawal may not reach a peak until 3 days of life, and they may persist for 2 to 3 weeks. Many babies are discharged home before symptoms occur, so community midwives should be vigilant. Common signs are irritability, tremulousness, mood alterations, and hypertonia; in addition, the infants may be difficult to console.

As with heroin, relapse to drug abuse may occur in the postpartum period. Close community support from the relevant agencies can help women to stay drug-free and develop parenting skills.

CANNABIS: SPECIFIC PROBLEMS

Background

Marijuana is the most prevalent illicit drug used in pregnancy (4%–30%).[134,151,152] Despite this, there are few reports on fetal effects.

Maternal and Fetal Risks

Studies suggest that there is no increase in the rate of morphologic anomalies, low birth weight, preterm delivery, or abruptio placentae.[64,99,134,153]

A study in Jamaica assessed newborns exposed to marijuana antenatally in a blinded fashion and compared them with nonexposed babies from socioeconomically matched mothers. At 1 month, marijuana-exposed infants scored higher on autonomic stability, reflexes, general irritability, and weight. No ill effects from

marijuana were found, and there may have been dose-related positive effects. The Jamaican mothers reported that cannabis increased their appetite during pregnancy and relieved pregnancy-related nausea.[134]

Therefore, the use of marijuana is not a problem and may even be beneficial in pregnancy. However, some may see marijuana as a gateway drug that potentially leads to harder drugs because of its association with the drug culture. Users should be warned against progression to drugs that are more harmful.

Management Options

No management problems are specifically associated with cannabis use.

BENZODIAZEPINES: SPECIFIC PROBLEMS

Background

Benzodiazepines are commonly used as anxiolytics and sedatives.[154] Their legitimate use in pregnancy has varied over the years, including the management of preeclampsia.[155] However, because of the fear of harmful effects, many women and their physicians recommend stopping their medication acutely, often with adverse maternal effects.[156] There are no apparent fetal effects, although the fetus may be at risk if the mother has a convulsion. These substances are also taken as part of polydrug abuse,[157] making assessment of their risk difficult.

Maternal and Fetal Risks

Large epidemiologic studies show no teratogenic effects and no obvious problems related to withdrawal from various benzodiazepines.[158,159] However, some abnormalities, particularly cleft palate,[81] are associated with its use. This finding is not conclusive, and other studies found no link.[160] Further, cleft palate is a common abnormality that occurs with other drug use.[161] However, there is evidence of hypotonia and problems with feeding because of its sedative effect when taken immediately before delivery.[82]

Management Options

No specific management in pregnancy is needed, except to discourage its use or stabilize the patient to the lowest level tolerated. Further reduction and cessation is possible in motivated patients. Stopping suddenly can produce maternal side effects, but is safe for the baby, apart from the risk of maternal convulsion. Benzodiazepines are excreted in breast milk, but the levels are low and should not cause neonatal problems.[82]

AMPHETAMINES: SPECIFIC PROBLEMS

Amphetamines are synthetic amines that are similar to the body's own adrenaline (epinephrine). They exaggerate the normal reaction to emergency or stress. Common slang terms for amphetamines include "speed," "wizz," "crystal," "meth," "bennies," "dexies," "A," "uppers," "pep pills," "diet pills," "jolly beans," "truck drivers," "co-pilots," "eye openers," "wake-ups," "hearts," and "footballs." The stimulating effects of amphetamines have been widely used to counteract fatigue. These drugs are also used by athletes to increase performance and by others for general stimulation, pleasure, or fun. Their use in pregnancy varies but is usually less than 1%.[162] In the younger age group, approximately 9% describe past use.[152]

The drug is usually taken orally but can be injected or sniffed. It is sometimes used interchangeably with cocaine. Because amphetamine use produces undesirable personality changes, "speed freaks" are highly unpopular with other addicts. They may be aggressive and violent. Most drug users consider amphetamines extremely dangerous and do not use them.

After continued administration of moderate doses, recovery is associated with fatigue, drowsiness, and often depression. The increased energy produced by the drug merely postpones the need for rest. Regular users rely on the drug when fatigued and often do not get proper rest for long periods. Near the end of such a "run" (usually <1 week), toxic symptoms dominate and the effects become intolerable. If the drug is discontinued, fatigue sets in and prolonged sleep follows, sometimes lasting days. After wakening, the user feels lethargic, sometimes depressed, and extremely hungry. These effects can be overcome by further drug use, which restarts the cycle. To stop runs, "downers" or opiates are sometimes used. Amphetamines do not produce a physical dependence, and psychological and environmental factors appear to be the motivating factors in the addiction.

Maternal and Fetal Risks

The effect on the baby is not well documented, but it appears to be associated with congenital abnormalities, particularly an increased occurrence of cleft palate.[163] Because amphetamine use is associated with hypertension, the incidence of preeclampsia and convulsions is also increased, with associated intrauterine growth restriction and death. Premature labor is also more common, but this may be due to associated lifestyle factors. The long-term growth of infants born to mothers who were addicted to amphetamines during pregnancy was found to be impaired.[164] This reduction appeared to be global, suggesting symmetrical growth impairment, which is usually associated with direct

injury to the developing fetus rather than placental insufficiency.

Management Options

Amphetamines are dangerous and should be discontinued. There is no drug substitute. Success in stopping the use of this drug is poor, and these addicts are probably the most difficult and problematic to treat. They value their sick appearance and often claim that they will die. Death as a result of amphetamine use is relatively rare. The best approach is to provide close, supportive care and constant encouragement to stop using the drug. The problem is that stopping is relatively easy, but so is restarting.

LSD: SPECIFIC PROBLEMS

Background

D-lysergic acid diethylamide-25 is an unusual, controversial drug better known as "LSD" or simply "acid." It is usually taken orally but may be sniffed or injected. LSD is one of the most potent biologically active substances known. It is well absorbed from the gastrointestinal tract, is distributed in the blood, easily diffuses into the brain, and crosses the placental barrier.

The psychological effects are not predictable and are affected by the user's personality and current thoughts. However, its use is compatible with a reasonably normal life and is not necessarily associated with the normal drug culture. In the younger age group, approximately 7% describe past use.[152]

Maternal and Fetal Risks and Management Options

High doses of LSD given to pregnant animals produce deformities in the offspring of some species and not others[165,166] There are little data on LSD use in human pregnancy.[167] Until more information is known, the most sensible approach is to recommend that pregnant women avoid LSD use. No other particular care is required.

BARBITURATES: SPECIFIC PROBLEMS

Background

The incidence of barbiturate use in pregnancy is relatively low.[168] There do not appear to be specific fetal effects, except for fetal dependence. Acute withdrawal during pregnancy can affect the fetus in utero and is not recommended, although the precise risk is unknown.

Gradual withdrawal can be achieved with reducing doses of short-acting barbiturates, such as pentobarbitone.

Maternal and Fetal Risks

The main risk to the mother and neonate is associated with withdrawal. This can be alleviated with a gradually reducing regimen that includes supplementary drugs. Acute withdrawal is associated with seizures and mental instability, usually occurring approximately 48 hours after the last dose. The neonate may take longer to show symptoms because the clearance of barbiturates is slower in the newborn.

Management Options

Slow reduction and cessation of drug use is the mainstay of management.

SOLVENT ABUSE: SPECIFIC PROBLEMS

Background

Solvent abuse is extremely common, and up to 19% of schoolchildren in parts of the United States have used them. Along with alcohol, marijuana, and tobacco, they are considered gateway drugs. There are many types of inhalants, including spray paint, liquid correction fluid, hair spray, nail polish remover, paint thinners, felt-tip markers, air fresheners, octane booster, glues and adhesives, fabric protectors, acetone products, carburetor cleaner, gasoline, propane gas, gas inside Ping-Pong balls, VCR head cleaner, and vegetable cooking sprays. Other examples are butyl nitrates, called "locker room" or "rush," and amyl nitrate capsules, called "snappers" or "poppers."

Maternal and Fetal Risks

Solvent abuse produces clinical signs, such as irritation and sores around the mouth and nose, nausea and headache, coughing, memory loss, lack of concentration and coordination, and odd behavior or irritability.

Sniffing leads to rapid entry of the drugs into the brain and organ systems, producing a high that lasts 15 to 45 minutes. Inhaling from a plastic or paper bag ("bagging") or inhaling from a soaked rag placed in the mouth ("huffing") greatly increases these effects. Damage can occur to the brain, liver, kidneys, blood, and bone marrow, and unconsciousness is common. In a study in pregnant solvent users, renal tubular acidosis was diagnosed in 5.3%, and 3.6% had adverse neurologic sequelae. One patient was diagnosed with brain damage, including expressive aphasia. The incidence of premature delivery was 21.4%.

The substances in solvents can cross the placenta and enter the fetal bloodstream. In the same study, 16.1% of infants had major anomalies. Most of these had facial abnormalities similar to those seen in fetal alcohol syndrome, and a further 10.7% had hearing loss.[169]

In another study of infants exposed to toluene, there was a 10% incidence of neonatal death as well as an increased incidence of prematurity (42%), low birth weight (52%), and microcephaly (32%). In addition, some infants had craniofacial features similar to those seen in fetal alcohol syndrome as well as other minor anomalies.[170]

Management Options

Solvent use is associated with erratic behavior, is dangerous for the mother and fetus, and should be strongly discouraged. Close observation and monitoring is required because of the high incidence of premature delivery and intrauterine growth restriction. Because there is evidence of neonatal abnormalities similar to those seen with alcohol and there may be developmental problems, the babies require close long-term follow-up.

SUMMARY OF MANAGEMENT OPTIONS
Specific Drugs of Abuse (e.g., heroin, cocaine, barbiturates)

Management Options	Quality of Evidence	Strength of Recommendation	References
Use a multidisciplinary approach.	IIb	B	93,181
Explain the risks of low birth weight, intrauterine growth restriction, and preterm delivery, and the need for neonatal care, especially if withdrawal symptoms occur.	III	B	99
Explain the risk of developmental abnormality in infants.	III	B	95
	IIb	B	184
In women using heroin, encourage detoxification or substitution with methadone or buprenorphine.	III	B	95
Encourage cessation with cocaine and amphetamines.	IIb	B	184
Solvent abuse produces effects similar to those of alcohol.	III	B	170
Screen for fetal abnormality, growth, and well-being.	III	B	99
The patient may need an increased dose of narcotic analgesia (an epidural is preferable).	IV	C	185
Provide fetal monitoring if intrauterine growth restriction occurs.	–	GPP	–
If the patient is HIV-positive or is still injecting, discourage breastfeeding.	IV	C	121
Watch for symptoms of withdrawal in the infant (starting at 3 days with heroin, cocaine, and solvents; 7 days with methadone, barbiturates, and amphetamines)	IV	C	114, 186
Provide follow-up by an addiction team.	IV	C	187, 188

CONCLUSIONS

- Of all abused substances, tobacco has the greatest effect on fetal growth and development.
- Alcohol is the worst teratogen of all abused substances.
- Women who abuse recreational drugs are probably at increased risk because of social and environmental factors.
- Substance abuse is as much a sign of risk as the cause of the risk itself.
- A multidisciplinary team approach is required.
- Pregnancy is a life event that may give a woman the opportunity and motivation to change her lifestyle for hers and the baby's long-term benefit.

Medication

Bertis B. Little

INTRODUCTION

The safety of approximately one half of medications for the mother and embryo or fetus remains unknown. Most pregnant women (40%–90%) are exposed to medications during gestation. These medications include a range of agents, such as vitamins, minerals, antibiotics, laxatives, antiemetics, sedatives, antacids, diuretics, and antihistamines (Table 35–1).[1,2] Medications are frequently used without a physician's advice or before pregnancy is recognized. In a small fraction of pregnant women, medications are needed to treat serious or life-threatening medical conditions, making it necessary to formulate a clinical plan to manage the chronic disease and the acute physiology of pregnancy. Pharmacokinetics are profoundly affected by pregnancy-associated physiologic changes (e.g., renal clearance, metabolism, blood volume, cardiac output), and dose adjustments are usually needed to optimize the clinical outcome.[3]

FREQUENCY OF MEDICATION USE IN PREGNANCY

Many women use medications during gestation. In studies, approximately 90% to 97% of pregnant women took medications prescribed by their physician, and two thirds took over-the-counter medications without medical advice.[4,5] The percentage of pregnant women who used medication during gestation appeared considerably lower in the United Kingdom compared with the United States (e.g., fewer than 10% of pregnant women in the United Kingdom used medications other than prenatal vitamins and iron supplements during the first trimester).[6]

DRUGS THAT ARE POTENTIALLY HARMFUL TO THE EMBRYO OR FETUS

An unborn child may be harmed by medications through either teratogenic or fetal effects, depending on the timing of exposure. Teratogenic effects are traditionally considered to occur during the period of organogenesis (embryonic period), with vulnerability encompassing the second through eighth weeks after conception by embryonic age. Embryonic age is estimated from the day of conception. Menstrual age is approximately 2 weeks greater than embryonic age because the former is calculated from the first day of the last menstrual period. A teratogen may cause a malformation in the unborn child when given during the embryonal period (organogenesis).[2] The fetal period is classically counted from 9 weeks after conception to delivery. Fetal effects are alterations in the structure or function of organ systems that are normally formed during organogenesis or organ systems that develop during the fetal period.[2] Medications with suspected or known teratogenic effects are listed in Table 35–2.

Thalidomide

Thalidomide is a sedative and hypnotic agent that is also used to treat leprosy, tuberculosis, and HIV. It is the most notorious of all human teratogens. Thalidomide taken between 27 and 42 days after conception produced phocomelia (absence of the long bones from the upper or lower limbs).[7] Other congenital anomalies were observed when the drug was taken outside the critical period for limb formation, including defects of the external ear and heart. Thalidomide is commercially available for use, as in South America, to treat leprosy. It is also used to treat tuberculosis and HIV. Alternate antituberculosis and antileprosy drug regimens are indicated for the treatment of women of reproductive age. In the mid- to late 1990s, another epidemic of thalidomide embryopathy was reported in South America that continues unabated.[8]

Retinoids

Vitamin A is an essential nutrient that is the lipid-soluble parent compound of retinoic acids (retinoids). Nutritional

Quinine
Radioiodine
Thalidomide
Trimethoprim

guidelines recommend that pregnant women consume approximately 10,000 IU vitamin A daily, through a combination of dietary intake and nutritional supplementation. A recent study showed that higher intake, including dietary intake and nutritional supplementation, is associated with an increased risk of malformations, beginning at 15,000 IU daily.[9]

Isotretinoin and etretinate are synthetic derivatives of retinoic acid (vitamin A). Isotretinoin (Accutane) is the primary medical therapy for intractable cystic acne, a dermatologic disorder that is common in women of reproductive age. Despite the serious warning in the manufacturer's package insert that isotretinoin use during pregnancy is a known cause of very severe congenital anomalies of the brain, ears, heart, and thymus, clinicians who provide health care for pregnant women are likely to encounter use of this medication during early pregnancy. Scientific studies support the manufacturer's warning that isotretinoin is a very harmful teratogen that causes serious congenital anomalies (Table 35-3). Among nearly 100 fetuses exposed to isotretinoin during early pregnancy, one third had an adverse outcome.[2,9-16] Nineteen percent had spontaneous abortion, and 28% had malformations.[16,17] Mental retardation occurred in more than 85% of children who did not have major congenital anomalies.[18] Isotretinoin has a terminal half-life of approximately 96 hours, but even if the medication is discontinued within days before conception, the risk of congenital anomalies is still increased.[19]

Etretinate (Tegison) is used to treat psoriasis and is associated with central nervous system, craniofacial, and skeletal anomalies in progeny of pregnant women who received this medication before or during pregnancy.[17,20] This medication has an unusually long half-life. Newborns with central nervous system and craniofacial abnormalities were born to women who discontinued etretinate use up to 12 months before conception, according to several published reports.[21,22] Serum etretinate levels persist in the therapeutic range for more than 5 years after the cessation of therapy (personal communication from the manufacturer). Psoriasis is not common during pregnancy and usually does not require systemic therapy. Topical agents should be used to treat psoriasis

in pregnant women and probably women of reproductive age because these medications are poorly absorbed and are primarily metabolized in the skin (i.e., topical therapy with steroids or retinoids results in insignificant serum concentrations).

Acitretin is an active metabolite of etretinate and is another retinoid that is given systemically to treat dermatologic conditions. The terminal half-life of acitretin is only a few days (approximately 3) compared with the parent compound etretinate, whose terminal half-life is putatively 3 months or longer. Two cases of human malformation (one electively terminated fetus, one liveborn infant) were reported with acitretin exposure during the first trimester, but exposure to acitretin before conception does not seem to be associated with an increased frequency of congenital anomalies. No congenital anomalies occurred among 52 infants born to women who discontinued acitretin therapy more than 14 days before conception.[20]

Antineoplastics

Most antineoplastics are teratogenic in humans because the medications usually impede or halt cell replication (see Table 35-2). Folate antagonists (e.g., aminopterin, methotrexate) have long been recognized as potent human teratogens. Aminopterin and methotrexate are also used as abortifacients. Congenital anomalies associated with fetal aminopterin syndrome are summarized in Table 35-4.[2,23-25] Similar congenital anomalies were observed when methotrexate was used during the first trimester.[26,27]

Busulfan (Myleran) is an alkylating agent used to treat some forms of leukemia. One infant whose mother received this antineoplastic during the first trimester had fetal growth retardation, cleft palate, and eye defects.[27] These findings were similar to defects reported in animal teratology studies.[2] Another alkylating agent, cyclophosphamide (Cytoxan), is used to treat certain forms of leukemia and other forms of cancer (ovarian, cervical, endometrial, and breast carcinomas). First-trimester cyclophosphamide use is associated with cleft palate, absence of digits (thumbs, great toes), imperforate anus, and fetal growth retardation.[28,29] Nonhuman primates whose mothers were given this cyclophosphamide during organogenesis had craniofacial anomalies[30] similar to those observed in exposed human fetuses.[31]

Available anecdotal data are not sufficient to quantitate the teratogenic risk of alkylating agents to the human fetus. Fourteen percent of offspring exposed to alkylating agents in the first trimester had major congenital anomalies,[32] and the other 86% were apparently normal.

Anticonvulsants

Anticonvulsant agents (phenytoin, trimethadione, carbamazepine, and valproic acid) are associated with an increased risk of congenital anomalies.[2] Hydantoin agents, phenytoin (Dilantin, Diphenylan), ethotoin (Peganone), and mephenytoin (Mesantoin) are teratogens long recognized for their association with a constellation of congenital anomalies known as fetal hydantoin syndrome (Table 35-5).[33] In a summary of studies that included more than 450 infants born to women who received hydantoin anticonvulsants during pregnancy, approximately 10% of infants exposed to phenytoin during gestation had major congenital anomalies (cardiac defects, cleft lip or palate), and one third had minor anomalies (craniofacial and digital).[34]

Paramethadione (Paradione) and trimethadione (Tridione) are known as dione anticonvulsants and are primarily used to treat petit mal seizures. Fetal dione syndrome has long been recognized. Its constellation of abnormalities is strikingly similar to fetal hydantoin syndrome.[35]

Carbamazepine (Tegretol) was considered relatively safe for use during pregnancy. It was the drug of choice to treat pregnant women with seizure disorders,[36] supported in part by one report that the frequency of congenital anomalies was not increased among fewer than 100 infants born to women who took carbamazepine during early pregnancy.[37] In 1989, however, it was reported that carbamazepine use during early pregnancy was associated with a pattern of malformations very similar to that caused by phenytoin (i.e., craniofacial abnormalities, minor limb defects, growth retardation, mental retardation) as well as with neural tube defects.[38] A 1991 U.S. Food and Drug Administration (FDA) report warned that the risk of neural tube defects is approximately 1% among carbamazepine-exposed offspring, compared with approximately 1 in 1000 in the general population.

A major difficulty with ascribing a specific risk of birth defects to anticonvulsant therapy is that epilepsy per se is a risk factor for congenital anomalies. Hence, it is unclear whether the anticonvulsant medication, the disease being treated (epilepsy), or a combination of factors causes the birth defects.[36] Pharmacogenetic evidence shows that deficits in maternal epoxide hydrolase enzyme activity are probably associated with birth defects, whereas normal enzyme activity is associated with normal infants after gestational phenytoin exposure.[39,40] This enzyme is essential for the elimination of a toxic phenytoin epoxide metabolite that is believed to be responsible for the teratogenicity of several anticonvulsant medications that share this metabolic pathway.[39,41]

Valproic acid (Depakene) is the most commonly prescribed medication for petit mal seizures. It is associated with a 1% to 2% risk of neural tube defects, which is 8 to 10 times greater than that in the general population.[42,43] Fetal valproate syndrome is a constellation of facial and digital anomalies associated with the use of valproic acid in early pregnancy.[44–46]

Anticoagulants

Warfarin is a coumarin anticoagulant. It is a small molecule that readily crosses the placenta.[36] Warfarin embryopathy is a distinct pattern of anomalies and occurs among 15% to 25% of infants and children whose mothers used warfarin during the first trimester.[47,48] Nasal hypoplasia and stippling of the epiphyses or malformed vertebral bodies are the most common features; other features also occur (Table 35–6).[47] When used during the second or third trimester, warfarin and other coumarin anticoagulants are associated with adverse fetal effects, including intracerebral hemorrhage, microcephaly, cataracts, blindness, and mental retardation.[47]

Hormones

Androgen therapy (i.e., testosterone) during pregnancy resulted in virilized external genitalia of female fetuses, including clitoromegaly and labioscrotal fusion.[49] Most hormone-induced fetal defects, short of actual fusion, usually resolve spontaneously during infant growth and development. Hormone-induced genital tract abnormalities that persist can be surgically corrected, and normal female pubertal development can be anticipated.[2]

Danazol, a drug used to treat endometriosis, is a testosterone derivative with weak androgenic activity. Female fetal exposure in utero may result in clitoromegaly or labial fusion.[50–53] However, the exact risk of this complication is unknown, and no apparent adverse effects were seen in male fetuses.

Diethylstilbestrol (DES), a nonsteroidal synthetic estrogen, causes vaginal clear cell adenocarcinoma in the progeny of women exposed to the drug during late embryogenesis.[54] The number of pregnant women actually exposed to this hormone during gestation is unknown. Other nonmalignant anomalies were also reported in female and male offspring of mothers exposed to this agent during early pregnancy (Table 35–7).[2,54–64] Women whose mothers used DES during pregnancy had an increased frequency of preterm labor, spontaneous abortion, and ectopic pregnancy.[59] Importantly, DES-exposed female progeny are in the reproductive or postreproductive years in 2004. DES is clearly contraindicated during pregnancy.

Antibiotics

The only antibacterial agents with known teratogenic effects are tetracyclines, and the effect is cosmetic and transient. The adverse effect caused by tetracyclines is yellow-brown discoloration of the deciduous teeth. The permanent teeth, the frequency of dental caries, and bone growth are unaffected by tetracycline exposure.[65–67] Tetracycline use during pregnancy is not associated with an increased frequency of structural congenital anomalies.[68–70] Tetracyclines should be given during pregnancy to treat life-threatening infections (e.g., syphilis) in patients who are allergic to penicillin. Otherwise, tetracyclines are not recommended for use during pregnancy because of the adverse effects on the deciduous teeth.

Psychotropics

Lithium is used to treat affective mental disorders.[36] An increased risk of cardiovascular anomalies is observed in offspring born to women who used lithium during early gestation.[71] A meta-analysis of published data indicated that previous estimates of the association of lithium exposure and Ebstein's anomaly (3%–12%) were too high.[72] Ebstein's anomaly occurs in approximately 1 in 20,000 live births. Although the exact risk of cardiovascular anomalies as a result of maternal exposure to lithium during embryogenesis is unknown,[36,71] data show that 1% of infants exposed to lithium during gestation may have Ebstein's anomaly. In addition, the risk of noncardiovascular congenital anomalies does not appear to be increased substantially above background rates.[72] Prenatal diagnosis (fetal echocardiogram) is indicated to evaluate possible fetal tricuspid valve regurgitation. Possible secondary complications of lithium use during the second and third trimesters include polyhydramnios and fetal diabetes insipidus. If possible, first-trimester exposure to this agent should be avoided. Patients who use lithium during the second and third trimesters should be routinely evaluated for increased amniotic fluid volume.

Other Drugs

Penicillamine is used to treat rheumatoid arthritis and cystinuria.[2] It is also used as a chelating agent for heavy metal poisoning (e.g., lead). Penicillamine is putatively associated with connective tissue disorders in the offspring of exposed mothers,[73] although the risk is quantitatively unknown.[74] Therefore, penicillamine is contraindicated during pregnancy.

USE OF OTHER MEDICATIONS DURING PREGNANCY

Most currently available medications are not proven to be human teratogens, although fewer than 50% have been adequately studied for use in human pregnancy. Further, in the last 20 years, few advances in clinical teratology have occurred.[75] The use of medications during pregnancy is discussed later in the context of medical indications for their use. It is important to remember that absence of evidence is not evidence of absence.

Dermatologic Drugs

Tretinoin (Retin-A) is a retinoic acid analogue used topically to treat acne. Minimal systemic absorption occurs because tretinoin is poorly absorbed from the skin and partly metabolized by the skin. The frequency of congenital anomalies was not increased in two studies in which 212 and 86 infants were exposed to tretinoin during the first trimester.[76,77]

Anticonvulsants

Anticonvulsants long recognized to be associated with teratogenic effects (i.e., phenytoin, carbamazepine, valproic acid, trimethadione) were discussed earlier. The benefits of anticonvulsant therapy during pregnancy often outweigh the risks, such as birth defects and other adverse effects. A major confounder is that seizure activity in the pregnant patient with untreated epilepsy may itself be teratogenic (e.g., from hypoxia). Therefore, continuation of anticonvulsant therapy is usually recommended, as necessary, to control seizures in pregnant patients with epilepsy.

Some anticonvulsant agents (i.e., hydantoins and barbiturates) may cause hemorrhage as a result of drug-induced vitamin K deficiency. The need for vitamin K supplementation is controversial in pregnant women who take these medications and possibly in their newborns. Phenobarbital and ethosuximide are two anticonvulsants that were not discussed previously.

Phenobarbital

Scientific data are not clear on the potential teratogenicity of phenobarbital. In more than 1000 mother–infant pairs in which phenobarbital was used during the first trimester, there was no increased frequency of malformations detected at birth compared with control subjects.[69] However, a recent review of clinical teratology indicated that facial clefts, congenital heart disease, and nail hypoplasia were more common in infants of women who took phenobarbital in pregnancy.[75,78,79] Phenobarbital was not associated with an increased frequency of congenital anomalies when taken for nonseizure indications during pregnancy.

Ethosuximide

Ethosuximide (Zarontin) is a succinimide anticonvulsant used primarily to treat petit mal seizures. Ethosuximide was studied in 57 pregnancies exposed in the first trimester, and the frequency (2, or 3.5%) of congenital anomalies was not increased over the background risk.[80] However, a recent review classified ethosuximide as a teratogen.[75]

Antimicrobials

Health-threatening infections are common during pregnancy, and antimicrobial agents often must be prescribed. These include antibacterials, antifungals, antivirals, and antiparasitics.

Antibacterials

The third most frequently prescribed medication during pregnancy is antimicrobials, and the most frequently prescribed antimicrobials are antibacterial agents. Most antimicrobials are safe for use during pregnancy.

Antibiotics associated with adverse fetal effects are summarized in Table 35–8. Except for patients who are allergic to penicillin-based antibiotics, all penicillins are safe for use during pregnancy. The use of amoxicillin, penicillin, and ampicillin was studied. Congenital anomalies and other adverse effects were not increased in frequency with exposure during pregnancy. More recently developed broad-spectrum penicillins (e.g., piperacillin, mezlocillin) and those combined with the β-lactamase inhibitors, such as clavulanic acid (Timentin, Augmentin) and sulbactam (Unasyn), are not adequately studied during pregnancy, although a significant risk for adverse effects seems unlikely. Maternal serum levels of all penicillins are significantly lower in pregnant women compared with nonpregnant patients because the volume of distribution is increased during pregnancy (i.e., blood volume is increased approximately 40% during pregnancy).[79] In addition, renal clearance is increased during pregnancy, which contributes to lower serum drug levels.[81] All penicillins cross the placenta and result in fetal levels near adult therapeutic levels, as summarized in Table 35–9.[82,83] Therefore, the penicillin family of drugs is the first-line maternal therapy for syphilis during pregnancy and for prevention of congenital syphilis. In contrast, erythromycin does not cross the placenta in sufficient quantity to treat or protect the fetus in cases of maternal syphilis.

The three major classes of cephalosporins are first-, second-, and third-generation derivatives. Cephalosporins cross the placenta to achieve fetal levels similar to those in the mother.[81–83] No controlled scientific studies of cephalosporin use during pregnancy and congenital anomalies are published, but many pregnant women were prescribed these drugs to treat serious conditions. A theoretical risk of second- and third-generation cephalosporins is testicular hypoplasia in experimental animals exposed to the drugs during gestation.[84] Second- and third-generation cephalosporins contain the *N*-methylthiotetrazole side chain, which is putatively the

TABLE 35–9

Ratio of Cord Blood to Maternal Blood for Some Penicillins and Cephalosporins

DRUG	RATIO
Ampicillin	0.7
Mezlocillin	0.4

Ampicillin plus sulbactam	1.0

(Adapted in part from Gilstrap LC, Little BB, Cunningham FG: Medication use during pregnancy: Part 2. Special considerations. In Cunning G, Mac Donald P, Grant N (eds.). Williams Obstetrics, 18th ed, Appleton and Lange; Norwalk, CT. Supplement 11, 1991.)

cause of testicular hypoplasia in newborn animals,[84] but this finding has not been reported in humans. Cefoxitin, a second-generation cephalosporin that does not contain this side chain, appears to be the rational choice when broad-spectrum cephalosporin therapy is indicated during pregnancy.

Erythromycin is a macrolide antibiotic. It does not cross the placenta in quantities great enough to reach therapeutic levels in the fetal compartment. Erythromycin is not associated with adverse fetal effects or congenital anomalies, except when the drug is used to treat the fetus. For example, congenital syphilis was reported among the offspring of penicillin-allergic mothers who received erythromycin for syphilis during pregnancy.[85] An efficacious strategy for the treatment of penicillin-allergic pregnant women is to desensitize those who are infected with syphilis and treat the mother and fetus with penicillin. A less desirable approach is to treat pregnant women with syphilis with tetracycline, but many clinicians may not choose this strategy because of the risk of discoloration of the deciduous teeth.[86,87]

Azithromycin is used to treat bacterial and chlamydial infections. No information was published on its use during pregnancy, but it is closely related to erythromycin (discussed earlier). Clarithromycin is used to treat respiratory tract and other infections. More than 100 infants were born after first-trimester exposure to clarithromycin, and the frequency of congenital anomalies was not increased. Azithromycin and clarithromycin are probably safe for use during pregnancy because of their well-studied "cousin," erythromycin.

Aminoglycosides cross the placenta[82,88,89] and reach nearly therapeutic levels in the fetal compartment. Streptomycin, an aminoglycoside, was associated with eighth cranial nerve damage (sensorineural deafness) in fetuses whose mothers were exposed to multiple, high doses during pregnancy.[90,91] The risk of fetal ototoxicity from aminoglycosides is not known but appears to be 1% to 2%, a frequency approximately 20-fold greater than the background risk for sensorineural hearing loss.

Aztreonam (Azactam) is a monobactam antibiotic with a spectrum of activity similar to that of the aminoglyco-

TABLE 35–8

sides. No well-controlled studies are published on its use during pregnancy, but the U.S. FDA granted it risk category B status. Unlike the aminoglycosides, monobactam antibiotics are not associated with renal toxicity or ototoxicity in adults,[36] but it is important to remember that absence of evidence is not evidence of absence.

Clindamycin is used to treat anaerobic infections. It crosses the placenta sufficiently to reach therapeutic levels in the fetal compartment.[88] There are no scientific studies of its use during the first trimester. Its use in pregnant women is rarely indicated, and the effect of clindamycin on the developing conceptus is virtually unknown.

Chloramphenicol crosses the placenta and reaches higher than therapeutic concentrations in the fetus, causing perinatal complications. Evidence is not sufficient to exclude chloramphenicol as a human teratogen,[36] but its teratogenic potential seems very unlikely. Adverse neonatal effects with high doses administered to the mother near the time of delivery include the risk of maternal aplastic anemia and "gray baby syndrome" in the newborn. Because less potentially harmful medications are available, chloramphenicol is rarely used.

Sulfonamides and trimethoprim are often used in combination, primarily to treat urinary tract infections. Sulfonamides cross the placenta, and in the fetus, they compete with bilirubin for binding in the fetus. If given during late gestation, they may cause neonatal hyperbilirubinemia.[81] Trimethoprim is a weak folate antagonist. Despite reassurances from an early study that included more than 200 infants whose mothers used trimethoprim during the first trimester with no increased frequency of birth defects,[92] three recent studies presented evidence to the contrary. In these studies, the absolute risk of neural tube defects associated with folate deficiency or folate antagonist medications was estimated to be 1%,[93–95] approximately 10-fold greater than the risk for the general population.

Nitrofurantoin is used primarily to treat urinary tract infections, some of which occur during pregnancy. Its use during pregnancy was not associated with an increased risk of congenital anomalies in one small study, and there are no reports of adverse effects after its use in pregnancy.[36,96] The U.S. FDA gave nitrofurantoin a risk category rating of B based on limited information, and it seems unlikely to pose a risk when used as medically indicated during pregnancy.

Fluoroquinolones (ciprofloxacin and norfloxacin) are antibiotics that are frequently used to treat urinary tract infections in women who are not pregnant. In six studies of data from teratogen and manufacturer registries, the overall frequency of congenital anomalies was not increased in more than 300 infants whose mothers took these drugs during pregnancy.[97–102] The manufacturer reported that these agents were associated with irreversible arthropathy in dogs whose mothers were given the drug during pregnancy,[36] but other studies in rats, mice, and rabbits did not replicate these findings.[103] Moreover, the teratogen registry study data did not find a pattern of congenital anomalies or a consistently increased frequency of any class of congenital anomalies.

Antituberculotics (rifampin, isoniazid, ethambutol) were not associated with an increased frequency of congenital anomalies in summarized case reports[104] or among the offspring of 85 women who took isoniazid during pregnancy.[69] In a smaller study of fewer than 50 infants whose mothers used isoniazid during the first trimester, the frequency of congenital anomalies appeared increased, but the birth defects were so heterogeneous that no conclusions can be drawn about causality.[105]

Among 320 infants whose mothers used ethambutol during the first trimester, malformations were not increased in frequency.[104] No controlled epidemiologic studies are published of the use of antituberculotics during pregnancy, and many case series involved polydrug therapy. In life-threatening diseases, therapeutic agents often have benefits that outweigh any theoretical risk, depending on the stage of disease.

Antifungals

Medications prescribed to treat fungal infections during pregnancy include clotrimazole, miconazole, and nystatin. In infants born to women who used these drugs during pregnancy, the frequency of congenital anomalies was not increased above that in the general population in two large studies.[70,106] No epidemiologic studies of congenital anomalies in infants whose mothers took butoconazole during pregnancy were published, but the U.S. FDA assigned this drug a pregnancy risk category rating of C.

Fluconazole is used to treat mycotic infections and is given either parenterally or orally. Fluconazole requires special mention because high-dose parenteral administration during pregnancy was associated with a distinct pattern of birth defects (brachycephaly, abnormal facies and calvarial development, cleft palate, and congenital heart disease).[107–109] In contrast, oral doses do not appear to be associated with an increased frequency of congenital anomalies or with a pattern of birth defects among more than 500 infants exposed during the first trimester.[110–112]

Amphotericin B is used to treat systemic mycotic infections.[36] In one study, it was not associated with an increased frequency of malformations in infants whose mothers used the drug during pregnancy.[113] The little information available on the use of amphotericin B during pregnancy is confounded because this drug is part of a polydrug regimen (e.g., with flucytosine). Flucytosine is an antifungal used to treat severe systemic mycotic infections, and there is no information available on its use during pregnancy. Griseofulvin is also used to treat mycotic infections of the skin and nails. No scientific studies of griseofulvin use during human pregnancy are published. However, there are reports of increased frequency of

central nervous system and skeletal anomalies in animal studies.[30,36] One case report implicated griseofulvin use during early pregnancy with conjoined twinning,[114] but a Hungarian case–control study of 86 conjoined twins did not confirm this anecdotal finding.[2]

Antivirals

Frequently prescribed antiviral agents include zidovudine, acyclovir, amantadine, rimantadine, ribavirin, idoxuridine, and vidarabine. Other antiviral agents include citreoviridin, ganciclovir, indinavir, saquinavir, valacyclovir, viridofulvin, lamivudine, nevirapine, and trifluridine.

Zidovudine is the primary agent used to treat HIV infection. In one large epidemiologic study that included more than 1800 infants, the frequency of congenital anomalies after first-trimester exposure was not increased.[115] In more than 470 infants exposed to zidovudine during the first trimester who were examined prospectively, the frequency of congenital anomalies was not increased.[116] In 10 infants whose mothers took zidovudine in the first trimester, there were no birth defects.[117] It is reasonable to conclude that the benefits of its use to treat the fatal disease caused by this virus, AIDS, far outweigh any theoretical risks. Importantly, this drug may prevent congenital HIV infection because it significantly reduces the HIV titer and decreases the risk of vertical infection.[118]

Acyclovir is the drug of choice in the treatment of herpes viruses, such as primary genital herpes and varicella. The registry maintained by the manufacturer of acyclovir indicates no increase in the frequency of congenital anomalies or adverse fetal effects in almost 600 pregnancies with first-trimester exposure.[119] Acyclovir is recommended for routine use in pregnant women with active genital herpes. It is also effective in treating overwhelming varicella infection. Topical acyclovir resulted in negligible systemic concentrations of the drug and poses no known risks of adverse effects in the developing embryo or fetus. Valacyclovir is an acyclovir analogue designed to lengthen the half-life. Although no studies are available on its use during pregnancy, its close relationship to acyclovir may reassure patients. Unpublished drug registry data include 14 normal infants born after first-trimester exposure.

Amantadine was not associated with an increased frequency of congenital anomalies in one anecdotal uncontrolled report of 20 patients who used the drug during early pregnancy.[36] Similarly, in 64 infants born to women who took amantadine during the first trimester, five malformations occurred (7.8%). This rate is slightly higher than expected (5%).[119] There are no reports of amantadine use during pregnancy.

Ribavirin is administered as an aerosol to treat respiratory syncytial viral infections in infants, and systemic regimens are available. No human studies are published on the use of this agent during pregnancy, but it was terato-

genic in animals. It seems to be a potent teratogen because a high frequency of a constellation of malformations occurred among the offspring of rodents given the drug at human therapeutic doses and several times the human therapeutic dose during embryogenesis.[120] Therefore, it should not be prescribed for use during pregnancy. Inadvertent occupational exposure is probably not a clinically significant risk factor because the amount absorbed is so small. If the patient requests prenatal diagnosis for the limited reassurance it can provide, routine screening should assess central nervous system, craniofacial, eye, body wall, and skeletal development.

No scientific studies of the use of idoxuridine, vidarabine, citreoviridin, ganciclovir, indinavir, saquinavir, viridofulvin, lamivudine, nevirapine, or trifluridine during human pregnancy have been undertaken.

Antiparasitics

A commonly prescribed antiparasitic agent is metronidazole, a nitroimidazole. Metronidazole is prescribed primarily as an antiparasitic agent to treat vaginal trichomoniasis. This drug was not teratogenic in more than 60 offspring of women who took it during the first trimester.[36,121] Among more than 9000 infants exposed to metronidazole during the first trimester, the frequency of congenital anomalies was not increased.[122] In a case–control study of more than 20,000 infants, the frequency of congenital anomalies was not increased in those exposed to metronidazole.[123] Although the drug is carcinogenic in rats and mutagenic in certain bacteria, it appears safe for use during pregnancy.

Lindane is a topical agent indicated for the treatment of *Pediculosis pubis* and scabies. No epidemiologic studies of its use during human pregnancy were published, but it was not teratogenic in experiments of pregnant animals.[36] Toxicity of the central nervous system may occur if this agent is absorbed systemically. Some clinicians recommend a combination of pyrethrins and piperonyl butoxide as an alternative to lindane for the initial treatment of *P. pubis* during pregnancy. Topical application of lindane over limited skin surface areas apparently results in minimal systemic absorption.

Chloroquine is a first-line antimalarial agent. When used for chemoprophylaxis against malaria in pregnant women who travel to areas where malaria is endemic, the risk of congenital anomalies was not increased.[124] Prophylactic low-dose weekly use of chloroquine for malaria appears to pose no teratogenic risk.[36] Quinine is the prototypical antimalarial agent and is used to treat chloroquine-resistant *Plasmodium falciparum* malaria. No epidemiologic studies of the use of this agent during pregnancy were published. One report suggested an increased risk of congenital anomalies with the use of quinine in large doses as an abortifacient, but there is little information on its use in therapeutic doses.[125] Anecdotal data suggest that large doses may cause

otolithic agenesis, eye defects, and vestibular abnormalities in infants born to mothers who took therapeutic, large doses during the first trimester.[2]

Pyrimethamine is an antiparasitic agent that is effective in the treatment of malaria and toxoplasmosis. This drug is a folic acid antagonist, although in one report of 64 offspring of women who took this drug in early pregnancy, the frequency of malformations was not increased.[126] However, special precautions should be taken. Concurrent dietary supplementation with folinic acid (*not* folic acid)[127] should be administered with pyrimethamine. Two other agents, spiramycin and sulfadiazine, are used to treat toxoplasmosis. No studies of the effect of spiramycin on the developing embryo have been published. Sulfadiazine was not associated with an increased frequency of congenital anomalies among more than 90 infants whose mothers took the drug during the first trimester.[128]

Mebendazole is an antiparasitic agent that is used primarily to treat helminthic infections, including enterobiasis (pinworms), trichuriasis (whipworm), ascariasis (roundworm), and necatoriasis (hookworm). Mebendazole is teratogenic in laboratory animals given the drug during gestation at many times the human therapeutic dose.[36] The frequency of congenital anomalies was not increased in more than 400 infants whose mothers took mebendazole during the first trimester.[129] Thiabendazole is another antihelminthic agent, but no human studies of its use during pregnancy have been published. Findings in animal studies were equivocal, with dose-related effects occurring in mice but not in three other experimental animal species. Pyrantel pamoate is another antihelminthic agent that is used to treat ascariasis and enterobiasis. The drug was not teratogenic in animal studies, and no human studies have been published. The relevance, if any, of animal teratology studies to human exposure is unknown.

Cardiovascular Drugs

Approximately 3% to 5% of pregnant women have cardiovascular disease. Many pregnant women require cardiovascular drugs for the treatment of life-threatening disorders. With few exceptions, cardiovascular medications may be given during pregnancy with minimal risk to the fetus. Cardiovascular agents with potentially adverse embryonic or fetal effects are summarized in Table 35–10 and were discussed earlier.[47,130–147]

Anticoagulants

Fetal warfarin syndrome, caused by the use of coumarin anticoagulants during gestation, was discussed previously (see Table 35–6).

High-molecular-weight heparin does not cross the placenta.[36] Heparin use during pregnancy is not associated with an increased frequency of congenital anomalies. Protracted use of this drug is associated with

osteoporosis and thrombocytopenia in adults, including pregnant women. Calcium supplements should be given to patients who require long-term heparin therapy. Low-molecular-weight heparin does not cross the placenta but is associated with maternal complications similar to those of high-molecular-weight heparin.

Antihypertensives

Methyldopa (Aldomet) is used to treat chronic hypertension in pregnant women. No studies of congenital anomalies and the use of this agent during early pregnancy were published. Hydralazine (Apresoline) is another antihypertensive agent that is commonly used to treat pregnant women. Most clinical experience with this drug has been with its use during the latter half of pregnancy to treat acute, severe, pregnancy-induced hypertension; it is not usually prescribed for chronic hypertension. First-trimester experience is limited to eight patients.

Many β-adrenergic-blocking agents are commercially available to treat hypertension. β-Blockers commonly prescribed for use during pregnancy include propranolol (Inderal), labetalol (Normodyne, Trandate), metoprolol (Lopressor), nadolol (Corgard), and atenolol (Tenormin). No epidemiologic studies of congenital anomalies in infants whose mothers took any of these agents during pregnancy are published in peer-reviewed journals. However, reports of Franz Rosa's research (see preface, Briggs GG et al. Drugs in Pregnancy and Lactation, Fifth edition) in unreviewed book format suggest that the frequency of congenital anomalies was not increased in infants exposed to β-blockers during early pregnancy. Although some investigators reported an increased frequency of fetal growth retardation among infants born to

TABLE 35–10
Cardiovascular Agents with Possible Adverse Fetal Effects*

AGENT	POTENTIAL ADVERSE EFFECTS
Warfarin (see Table 35–6)	Fetal warfarin syndrome
Verapamil and other calcium channel blockers	Decrease in uterine blood flow, myocardial depression and fetal cardiac arrest
Propranolol and other β-adrenergic blockers	Intrauterine growth retardation, bradycardia, respiratory depression, and hypoglycemia
Diazoxide	Alopecia and abnormalities of body hair, and hyperglycemia
Sodium nitroprusside	Cyanide toxicity in animals
Furosemide	Decrease in uterine blood flow, hyperbilirubinemia
Spironolactone	Feminization of male animal genitalia
Thiazide diuretics	Neonatal thrombocytopenia
Angiotensin-converting enzyme inhibitors	Anuria and renal malformations, hypocalvaria

*Some of these effects have been described only in animals and are theorized to occur in humans.

women who used these agents on a long-term basis during pregnancy,[132,148] others reported no association.[149] However, the effect of the drug is difficult to differentiate from that of the disease state, pregnancy-induced hypertension, which causes fetal growth retardation. Previously observed adverse fetal or neonatal effects include transient bradycardia, respiratory depression, and hypoglycemia.[132–135] Based on available data, the benefits of β-adrenergic blockers appear to outweigh any theoretical risks associated with their use during pregnancy.

Clonidine (Catapres) is an α-adrenergic blocker antihypertensive that has been given to pregnant women without apparent adverse fetal effects.[150,151] However, no epidemiologic studies of the frequency of congenital anomalies in infants whose mothers used the drug during the first trimester were published.

Diazoxide (Hyperstat), a thiazide, is used as both an antihypertensive and a tocolytic agent. No epidemiologic studies of congenital anomalies among infants born to women who took this drug during the first trimester were published. Thiazide use during pregnancy is associated with body hair abnormalities (alopecia) and transient neonatal hypoglycemia.[136,137]

Sodium nitroprusside (Nipride, Nitropress) is a potent antihypertensive that is used to treat serious, life-threatening hypertension. In experimental animals, this agent caused fetal cyanide toxicity.[138] However, the human fetus does not appear to be at risk for this complication when therapeutic doses are used.[152] Nonetheless, it is prudent to avoid this drug during pregnancy unless it is needed to treat a life-threatening condition in which other medications have not proven effective.

Captopril (Capoten) and enalapril (Vasotec) are angiotensin-converting enzyme (ACE) inhibitors. No human studies of the use of these agents during pregnancy were published. However, highly convincing case series and case reports show an association of oligohydramnios, neonatal anuria, congenital hypocalvaria, renal anomalies, and nephrotoxicity with ACE inhibitor use during the second and third trimesters.[143–147] Therefore, ACE inhibitors are contraindicated during pregnancy and are considered human teratogens.

Diuretics

Diuretics are used to treat chronic hypertension and pulmonary edema associated with heart disease in pregnant women. The major classes of diuretics are thiazides, loop diuretics, potassium-sparing diuretics, and carbonic anhydrase inhibitors.

Thiazide diuretics are most commonly prescribed to pregnant women. Chlorothiazide (Diuril) and hydrochlorothiazide (HydroDIURIL, Esidrix, Hydro-Chlor) were not associated with an increased frequency of congenital anomalies among fewer than 70 exposed infants.[69] However, thiazides pose a risk of transient neonatal thrombocytopenia.[142] In the latter half of pregnancy,

these drugs may also be associated with reduced maternal blood volume and decreased uteroplacental perfusion.

The use of loop diuretics, such as ethacrynic acid (Edecrin) and furosemide (Lasix, Myrosemide), during pregnancy has not been studied to identify an increased risk of congenital anomalies. Unreviewed data on furosemide from the Franz Rosa database suggested no increased risk of congenital anomalies among 350 infants whose mothers took the drug during the first trimester. Loop diuretics may interfere with the normal pregnancy-associated expansion of blood volume and may decrease placental perfusion. In addition, maternal use of furosemide seems to displace bilirubin from albumin, possibly causing neonatal hyperbilirubinemia.[140]

Spironolactone (Aldactone), a potassium-sparing diuretic, acts as a competitive inhibitor of aldosterone. Its effect on the developing human conceptus has not been studied, but it has mild antiandrogenic effects and was associated with feminization of male rat fetuses born to mothers given large doses of this drug during gestation.[141] For this reason, spironolactone is not recommended for use during pregnancy. However, two case reports suggest normal virilization of male infants whose mothers took the drug throughout pregnancy.

Acetazolamide is a carbonic anhydrase inhibitor diuretic. Inadequate data are published to allow an evaluation of possible human teratogenic effects. However, it is associated with a characteristic and replicable pattern of limb abnormalities in animals born to mothers given the drug during pregnancy.[153] Therefore, this diuretic should be avoided during pregnancy.

Antiarrhythmics

The cardiac glycoside digoxin is used as an antiarrhythmic agent to treat atrial fibrillation and flutter and to treat congestive heart failure. In more than 190 infants, the frequency of congenital anomalies was not increased after first-trimester exposure.[68,69] It has also been successfully used to treat fetal cardiac arrhythmias because it readily crosses the placenta.[154,155]

Quinidine is another agent that is commonly used to treat arrhythmias (supraventricular tachycardia and ventricular arrhythmia). No epidemiologic studies were published on the use of quinidine during pregnancy. Some clinicians believe that it is probably relatively safe for use during pregnancy,[156] but this opinion is not based on evidence.

Many local anesthetics are used as antiarrhythmic agents. The best known are probably lidocaine (Xylocaine), also known as lignocaine in the United Kingdom, and procainamide (Pronestyl, Rhthmin, Promine). Related agents include encainide (Enkaid), flecainide (Tambocor), tocainide (Tonocard), and mexiletine (Mexitil). These agents probably cross the placenta to an appreciable degree, but maternal concentrations from local administration are low. In one study, the frequency of

congenital anomalies was not increased in 293 offspring of mothers who were given lidocaine for acute illness in early pregnancy.[6] However, a distinction must be made between short-term use of the drug as a local anesthetic and long-term use to treat cardiac arrhythmias. No studies have reported the possible association of malformations with the use of related agents during pregnancy. However, in most cases, the benefit of their use clearly outweighs any theoretical risk because cardiac arrhythmias may be life-threatening.

Disopyramide (Norpace) is an antiarrhythmic whose action is similar to that of quinidine. It is used to treat supraventricular and ventricular arrhythmias.[157] No studies of its use during human pregnancy and the frequency of congenital anomalies were published. However, the drug caused uterine contractions when administered during the third trimester.[155,156] Therefore, other treatment regimens should be used during gestation.

Bretylium (Bretylol) is used to treat ventricular tachycardia and fibrillation. The risk of congenital anomalies after its use in human pregnancy is unknown because no studies have been published. If this agent is clearly indicated for the treatment of life-threatening arrhythmias when other agents have been ineffective, it should be used, regardless of the stage of pregnancy.

Amiodarone (Cordarone) is another agent used to treat life-threatening arrhythmias, ventricular tachycardia, and fibrillation. Case reports are the only data available on the use of this agent,[158] and no published epidemiologic studies of its use during pregnancy are available. As with bretylium, it seems reasonable to use this agent during pregnancy, if indicated, to treat serious ventricular arrhythmias, when other agents have not been effective. Based on case reports, neonatal thyroid dysfunction or goiter is a risk associated with amiodarone therapy after 10 weeks' gestation because of the iodine content of the drug.[159,160] In addition, learning deficits were associated with its use during pregnancy.[161]

Antianginals

Organic nitrites are the most commonly used antianginal agents and include nitroglycerin, amyl nitrate, erythrityl tetranitrate (Cardilate), isosorbide dinitrate (Isordil, Sorbitrate), and pentaerythritol tetranitrate (Pentritol, Peritrate). Nitroglycerin has also been used to "blunt" the hypertensive effect of intubation during general anesthesia in the pregnant patient with hypertension or cardiac disease. No epidemiologic studies of the use of organic nitrites during human pregnancy have been published, but it is prudent to use these agents in patients with life-threatening conditions.

A variety of calcium-channel-blocking agents have antianginal effects. Some of these agents are also used to treat supraventricular tachycardia and hypertension. Verapamil (Clan, Isoptin) is the best known of this group of drugs. It has been given to many pregnant women without apparent adverse fetal effects, but it was associated with decreased uterine blood flow in experimental animals.[130] In addition, it may cause cardiac depression or even cardiac arrest in neonates whose mothers received it peripartum for supraventricular tachycardia associated with heart failure.[131] Theoretically, other calcium antagonists may be associated with similar adverse effects. As a group, calcium-channel-blocking agents are indicated for use during pregnancy only when life-threatening conditions exist and other therapeutic agents have been ineffective.

Dipyridamole (Persantine) is a selective coronary vasodilator that inhibits platelet aggregation. It is used as an adjunct to prevent thromboembolism, myocardial infarction, and transient ischemic events. The frequency of congenital anomalies was not increased in more than 190 infants whose mothers were treated with dipyridamole during the last two trimesters.[162–164] According to the manufacturer, dipyridamole was not teratogenic in animal studies, but the relevance of this finding to humans is unknown.

Asthma Drugs

Approximately 1% to 4% of pregnant women have clinically diagnosed asthma.[36] The two major classes of medications used to treat asthma, bronchodilators and immunosuppressants, seem to be safe for use during pregnancy.

Bronchodilators

Theophylline salts are the most frequently prescribed bronchodilators for treating both pregnant and nonpregnant patients with asthma. Aminophylline is the parenteral form, and numerous oral forms are available. This agent has been used extensively in pregnant women without apparent adverse effects.

Epinephrine is another bronchodilator that is reserved for the treatment of acute asthmatic attacks and is usually given at a dose of 0.3 to 0.5 mL subcutaneously in a 1:1000 dilution.[36] An increased frequency of heterogeneous, nonmajor malformations was reported in the Collaborative Perinatal Project.[69] However, it is unclear whether the effects were related to the maternal illness or to the drug itself. It seems very unlikely that epinephrine is a human teratogen. However, its use should be reserved for treatment of acute asthma attacks, and it should not be given on a long-term basis. Another agent, terbutaline (Brethaire, Brethine, Bricanyl) has significant activity as a bronchodilator. No reports have been published on congenital anomalies in infants whose mothers used this agent during early pregnancy. In one study of protracted maternal use of terbutaline during the second and third trimesters, no adverse effects were noted among offspring.[165] In 149 women, terbutaline use was reported during the first trimester, and the frequency of

congenital anomalies was not increased.[166] However, these data were not reported in a peer-reviewed journal.

Albuterol (Proventil, Ventolin) and metaproterenol (Alupent, Metaprel) are β-adrenergic-blocking bronchodilators that are self-administered inhalation aerosols. Systemic concentrations resulting from inhalation are small. In a non-peer-reviewed publication, the frequency of congenital anomalies was not increased in more than 1000 infants who were exposed to albuterol during the first trimester.[166] These agents are commonly used to treat asthma in pregnant patients.

Immunosuppressants

Cromolyn sodium (Nasalcrom, Rynacrom) is an agent that inhibits mast cell histamine release and is given through nasal insufflation. It has little benefit during an acute asthmatic attack and is used primarily for prophylaxis in chronic asthma.[36] Among more than 350 infants born to women who used cromolyn during pregnancy, the frequency of congenital anomalies was not increased.[167,168] According to the manufacturer, this drug was not teratogenic in several animal species given several times the usual human dose during gestation.

Several glucocorticoids are used to treat pregnant women with asthma. The most commonly used agents are beclomethasone, betamethasone, cortisone, and prednisone. Therapeutic doses of these glucocorticoids for the treatment of asthma are unlikely to be associated with an increased frequency of congenital anomalies. Beclomethasone (Vanceril, Beclovent) is used primarily as an inhalational aerosol or nasally. Dexamethasone (Decadron, Respihaler, Turbinaire) is also used in this fashion. In some pregnant women, it is occasionally necessary to use large doses of parenterally administered corticosteroids to treat a life-threatening acute asthmatic attack. Some women may also need long-term steroid maintenance therapy to prevent exacerbation of respiratory symptoms.

An acute asthmatic attack may be life-threatening. These agents should be used because the potential risks are clearly outweighed by the potential benefit of saving the mother's life.

The American College of Obstetrics and Gynecology recommendations[169] for the treatment of asthma are outlined in Table 35-11.

Psychotropics

Psychiatric illnesses occur in approximately 1% to 2% of pregnant women, but some studies estimate much higher prevalences.[170] Treatment of most psychiatric disorders should continue during pregnancy for the benefit of the patient. Abrupt discontinuation of psychotropic therapy may have adverse effects, including suicide attempts.

Sedatives, Hypnotics, and Tranquilizers

A variety of sedatives, hypnotics, and tranquilizers are available and belong to several pharmacologic categories. Common agents include phenobarbital, secobarbital, butalbital, diazepam, chlordiazepoxide, chloral hydrate, and meprobamate.

Phenobarbital was implicated when used with other anticonvulsant agents in causing congenital anomalies.[36] It is unclear whether the anticonvulsant medication, the seizure disorder, or a combination of both was associated with an increased risk of congenital anomalies, as previously discussed. Phenobarbital has been prescribed to pregnant women as a sedative, and recent evidence suggests that it is teratogenic when used for this indication.[75] Among more than 1000 offspring exposed to this agent during the first trimester, the frequency of malformations

TABLE 35-11

ACAAI-ACOG Recommendations for the Pharmacologic Step Therapy of Chronic Asthma During Pregnancy

CATEGORY	STEP THERAPY
Mild intermittent	Inhaled beta-2 agonists as needed. (For all categories, most published human data obtained with albuterol, metaproterenol, or terbutaline)
Mild persistent	Inhaled cromolyn; continue inhaled nedocromil in patients showed a response before pregnancy; substitute inhaled corticosteroids if above treatment is not adequate.
Moderate persistent	Inhaled corticosteroids; beclomethasone or budesonide if treatment is initiated during pregnancy; continue the original inhaled corticosteroid if the patient was well controlled before pregnancy; consider budesonide if the patient requires high-dose inhaled corticosteroids for adequate control. Continue inhaled salmeterol in patients who showed a very good response before pregnancy. Add oral theophylline or inhaled salmeterol for patients who do not achieve adequate control with medium-dose inhaled corticosteroids.
Severe persistent	Above, plus oral corticosteroids (burst for active symptoms, alternate-day or daily therapy if necessary) [Anon, 2000].

From American College of Obstetrics and Gynecology, 2000; American College of Allergy, Asthma, and Immunology, 2000.
(Adapted from ACAAI-ACOG Recommendations for the Pharmacologic Step Therapy of Chronic Asthma During Pregnancy. American College of Obstetrics and Gynecology, 2000.)

was not increased.[69] However, recent information suggests that phenobarbital use during organogenesis was associated with facial clefting, congenital heart defects, facial dysmorphism, nail hypoplasia, learning deficits, and mental retardation.[78,79] Another risk associated with barbiturates is maternal drug dependence and possible transient neonatal withdrawal.

Secobarbital (Seconal) is a short-acting barbiturate given primarily as a sleep medication. There is no scientific evidence that this agent is teratogenic in humans. It seems to be relatively safe for use during pregnancy, based on the findings in more than 370 infants whose mothers used it during the first trimester and 4200 whose mothers used it throughout pregnancy.

Butalbital is a short-acting barbiturate that is found in combination with a variety of other medications, such as aspirin (e.g., Fiorinal), acetaminophen (e.g., Fioricet, Rogesic), and codeine. Among more than 100 pregnant women exposed to this agent during the first trimester, the frequency of malformations among exposed offspring was not statistically increased compared with control subjects.[69]

Diazepam (Valium, Vazepam, Meval) and chlordiazepoxide (Librium, Librax, Lipoxide, Medilium, Novopoxide) are benzodiazepines commonly used as minor tranquilizers and sedatives. Diazepam is also used as an amnesic and anticonvulsant. In the 1970s, diazepam was believed to be associated with an increased risk of facial clefts.[171–173] However, this finding was not confirmed in several other large studies,[174–176] some of which were a reanalysis of previously reported data. In addition, there are reports of an association of maternal diazepam and cardiovascular anomalies in offspring exposed in utero,[177,178] but these findings were not confirmed in subsequent studies.[179,180] Available information does not support the idea that diazepam is a human teratogen. However, it may cause transient hypotonia, hypothermia, and respiratory depression ("floppy infant syndrome") in neonates chronically exposed to diazepam near delivery. These symptoms are not life-threatening when managed medically.

Chlordiazepoxide was associated with an increase in congenital anomalies in one study,[181] although this association was not confirmed in a much larger study of more than 250 offspring whose mothers used the drug during early pregnancy.[69] Similarly, the frequency of malformations was not increased in several other studies of infants whose mothers used the drug in the first trimester.[182–184]

Meprobamate (e.g., Equanil, Miltown) is a minor tranquilizer and muscle relaxant. Whether it is causally associated with congenital anomalies is controversial. Two groups of investigators reported an association of congenital anomalies with the use of this drug during gestation,[70,181] but a third group did not show this effect.[69] In one study of more than 350 offspring, meprobamate exposure during pregnancy was not associated with an

increased frequency of malformations.[69] It is prudent to avoid prescribing this agent during all stages of pregnancy because of inconsistencies in the available data. However, if a patient has inadvertent exposure, the reassurance provided by an ultrasound study targeting the lip and palate is appropriate.

Chloral hydrate is a minor sedative that is sometimes prescribed as a sleep medication. The frequency of congenital anomalies in the offspring of 71 pregnant women who took chloral hydrate in early pregnancy was not increased compared with control subjects.[69] The chance of this agent being causally associated with congenital anomalies is remote.

Antidepressants

Antidepressants are generally divided into tricyclic and nontricyclic agents. Tricyclic antidepressants were the most commonly used agents until fluoxetine (Prozac) was introduced. These agents are summarized in Table 35–12.

Although limb-reduction defects have been reported with one of the tricyclic agents, amitriptyline,[185,186] during early pregnancy, this association was not confirmed by other studies.[69,187,188] This risk seems very unlikely. No information on the safety of other tricyclic antidepressants during pregnancy was published, but several are metabolites of amitriptyline. Therefore, their risks may be assumed to be similar to those of amitriptyline (i.e., negligible).

Tranylcypromine (Parnate), isocarboxazid (Marplan), and phenelzine (Nardil) are monoamine oxidase inhibitors that are used as antidepressants. No information was published on the safety of these agents for use during pregnancy.

Fluoxetine is one of the most frequently prescribed antidepressants. In one report by the manufacturer that included 485 offspring born to mothers who took this drug during pregnancy,[189] the frequency of congenital anomalies was not increased above the expected or background risk of congenital anomalies in humans (28 of 483, or 5.8%). In another study, the frequency of congenital anomalies was not increased among 98 infants whose mothers took the drug throughout pregnancy.[190] In a third study, the frequency of congenital anomalies

TABLE 35–12
Commonly Used Tricyclic Antidepressants
Imipramine (Tofranil, Janimine, Tipramine)
Amitriptyline (Amitril, Elavil, Endep, Emitrip, Enovil)
Desipramine (Norpramin, Pertofrane)
Doxepin (Adapin, Sinequan)
Nortriptyline (Aventyl, Pamelor)
Protriptyline (Vivactil)
Amoxapine (Asendin)
Clomipramine (Anafranil)

was not increased among 101 infants whose mothers took fluoxetine during the first trimester.[191]

Sertraline (Zoloft) is a popular antidepressant. Among 150, 112, and 28 infants born to women whose mothers took sertraline during pregnancy, the frequency of congenital anomalies was not increased.[192-194]

Antipsychotics

Phenothiazines are the largest pharmacologic class of antipsychotics. Several phenothiazines are also prescribed as antiemetics during pregnancy (chlorpromazine, perphenazine, prochlorperazine, and triflupromazine).

For several decades, chlorpromazine (Thorazine) has been prescribed to pregnant women as an antipsychotic. This agent was not associated with an increased risk of congenital anomalies in two studies of more than 4000 patients who took the drug during the first trimester for various indications.[69,195] Two of the most common side effects in adults are hypotension and extrapyramidal tract symptoms. Similar transient effects were seen in neonates exposed to the drug during late gestation.

Among more than 800 infants born to women who took prochlorperazine (Compazine) during early pregnancy, as reported in the Collaborative Perinatal Project,[69] the frequency of congenital anomalies was not increased above the background risk. Likewise, no increase in the frequency of malformations was found in the offspring of 63 pregnant women who took perphenazine (Trilafon) during the first trimester compared with control subjects.[69]

There are no epidemiologic studies of the safety of the use of thioridazine (Mellaril) or trifluoperazine (Stelazine) during pregnancy. Maternal use of thioridazine during the first trimester was reported in 23 infants who had no congenital anomalies, but there was no control group.[196] The frequency of congenital anomalies was not increased in 42 infants born to women who used trifluoperazine during the first trimester.[69]

Other antipsychotic drugs include haloperidol (Haldol, Decanoate), thiothixene (Navane), loxapine (Loxitane, Daxolin), clozapine (Clozaril), molindone (Moban, Lidone), and chlorprothixene (Taractan). The frequency of congenital anomalies was not increased in 90 infants whose mothers took haloperidol during the first trimester.[197] First-trimester exposure to thiothixene was not associated with an increased risk of congenital anomalies in 38 infants, but this was not a peer-reviewed study.[117] There is no relevant scientific information on the safety of the other agents during pregnancy.

Analgesics

Analgesics are the medications that are most commonly prescribed to pregnant women. Most analgesics can be administered to pregnant women with relative safety.

Nonsteroidal Anti-inflammatory Drugs

A variety of nonsteroidal anti-inflammatory drugs (NSAIDs) are commercially available for use as analgesics. Frequently prescribed NSAIDs are summarized in Table 35–13. Indomethacin is a commonly used NSAID that also acts as a tocolytic in perceived premature labor.[198] The frequency of congenital anomalies was not increased in one study of 50 patients who received this agent during the first trimester.[68] The major concern with NSAIDs is the possible association with premature closure of the ductus arteriosus when given during the latter half of pregnancy. There have been reports of fetal and newborn premature ductal arteriosus closure and subsequent pulmonary hypertension as a result of maternal use of these agents,[199-201] although other studies did not confirm this association.[198,202] These agents are also associated with decreased amniotic fluid volume.[203] NSAIDs usually are not recommended for use in pregnant women after 34 weeks' gestation because of the theoretical risk of these adverse effects. These agents are probably safe if used before this gestational age, especially for short-term use.

Salicylates and Acetaminophen

Salicylates and acetaminophen are non-narcotic analgesics that are commonly used by pregnant women. In one report of more than 1500 pregnant women, approximately half used aspirin and 41% used acetaminophen.[204]

Aspirin is also an NSAID and has been available for more than a century. Although there are reports of an association with malformations in humans,[205] this association was not confirmed in other studies.[206,207] Like other NSAIDs, aspirin is a prostaglandin synthetase inhibitor and is associated with premature closure of the ductus arteriosus and pulmonary hypertension in the newborn[201,208] as well as with oligohydramnios.[208] Large doses of aspirin may also be associated with hemorrhagic disorders in both mother and fetus as a result of reduced platelet activity. Low-dose adult aspirin probably poses little risk to the fetus. However, this drug should be avoided in late pregnancy because safer medications are available (i.e., acetaminophen).

TABLE 35–13

Commonly Used Nonsteroidal Anti-inflammatory Drugs

Indomethacin (Indocin)
Ibuprofen (Advil, Motrin)
Fenoprofen (Fenoproten, Nalfon)
Meclofenamate (Meclamen)
Naproxen (Naprosyn, Anaprox)
Tolmentin (Tolectin)
   Diflunisal (Dolobid)
   COX-2 inhibitors

Acetaminophen is the preferred analgesic for use in pregnancy. In one report of more than 300 offspring born to mothers who took this agent during pregnancy, the frequency of malformations was not increased.[68] Findings were similar in more than 200 offspring included in the Collaborative Perinatal Project database.[69] However, this analgesic may result in fetal liver toxicity when used in excessive amounts (e.g., attempted suicide late in pregnancy).[209] Acetaminophen apparently is not associated with premature ductal closure or oligohydramnios.

None of the selective COX-2 inhibitors have been studied for possible adverse effects in pregnancy. Hence, the risks associated with them are unknown, despite their widespread use.

Narcotic Analgesics

Many narcotic analgesic agents are available. Narcotic analgesics may be abused, and this section discusses only use according to therapeutic guidelines. Frequently prescribed drugs in this class include codeine, meperidine (Demerol), morphine, pentazocine (Talwin), butorphanol (Stadol), hydrocodone (Vicodin), nalbuphine (Nubain), hydromorphone (Dilaudid), and propoxyphene (Darvon).

Meperidine and morphine, as with all opioid narcotic agents, may cause a transient withdrawal syndrome in the newborn when used on a long-term basis during pregnancy. However, none of these analgesics was associated with an increased frequency of malformations in offspring after maternal use in early pregnancy.[69] Morphine in particular may be associated with newborn respiratory depression when given in large doses near the time of delivery. Codeine was not teratogenic in one study of more than 500 patients with first-trimester exposure.[69] Similarly, the frequency of malformations was not increased compared with unexposed control subjects in more than 700 newborns whose mothers used propoxyphene during early pregnancy.[69,70] There have been isolated case reports of malformations associated with propoxyphene use. The association was probably serendipitous and not causal.[36] Similarly, pentazocine use in early pregnancy was not associated with an increased frequency of congenital anomalies.[36]

Forty infants born to women who used hydrocodone during the first trimester had no increased frequency of congenital anomalies.[210] No epidemiologic studies of congenital anomalies in infants whose mothers used butorphanol or hydromorphone during the first trimester were published, although these drugs are potentially associated with neonatal withdrawal if abused or used for a protracted period during late pregnancy.

Thyroid Drugs

Hypothyroidism rarely occurs during pregnancy, but it is common to encounter pregnant women who received thyroid replacement therapy before pregnancy was recognized. Hyperthyroidism is infrequent during pregnancy.[36]

Thyroid Deplacement Drugs

Thyroxine does not cross the placenta measurably[36] and is not associated with congenital anomalies.[62]

Antithyroid Drugs

Agents used to treat hyperthyroidism include propylthiouracil (Propyl-Thyracil), methimazole (Tapazole), potassium iodide, and propranolol. Propranolol use during pregnancy was discussed previously.

The other three antithyroid agents readily cross the placenta. Propylthiouracil may result in fetal hypothyroidism and goiter formation, although clinically significant effects are uncommon with the usual therapeutic regimens. There is no firm scientific evidence that propylthiouracil is related to an increased risk of malformations, although the data are largely inconclusive. Methimazole was associated with scalp defects in the offspring of mothers who used this agent,[211,212] but other studies during pregnancy have not confirmed this association.[213,214]

Potassium iodide and sodium iodide block the release of thyroid hormone. Long-term use may result in fetal hypothyroidism and goiter formation. It is highly unlikely that short-term use of iodide medication results in such adverse effects when given to treat thyroid crisis ("thyroid storm") with intravenous sodium iodide or when used for prophylaxis before thyroid surgery (oral potassium iodide). Most adverse effects result from long-term iodine therapy.

Antineoplastics

Malignancy occurs in approximately 0.1% of pregnant women.[215] Breast carcinoma, melanoma, and Hodgkin's lymphoma are the most common malignancies in pregnant women.[215–218]

Chemotherapeutic agents can be grouped into alkylating, antimetabolite, plant alkaloid, antibiotic, and miscellaneous types. Antineoplastics are often associated with fetal growth retardation and congenital anomalies, and causality seems plausible because most chemotherapeutic agents are designed to impede cell division and growth.

When used after the first trimester, most chemotherapeutic agents are not associated with significant fetal risk, except for growth retardation. The potential life-saving benefits of these therapies always outweigh the fetal risk. Some conditions, such as acute leukemia, mandate chemotherapy immediately on confirmation of the diagnosis, even during the first trimester.

Alkylating Agents

Common alkylating agents include busulfan (Myleran), cyclophosphamide (Cytoxan), chlorambucil (Leukeran), melphalan (Alkeran), trimethylene thiophosphoramide (Thiotepa), and carmustine (BCNU).

There are no epidemiologic studies of congenital anomalies or fetal effects in infants whose mothers used melphalan, trimethylene thiophosphoramide, or carmustine during pregnancy. Based on the mode of pharmacologic action, these agents should be considered teratogenic.

Busulfan and cyclophosphamide were discussed earlier and are associated with an increased risk of congenital anomalies. In a report of 44 infants whose mothers received one of several alkylating agents during pregnancy, 6 (14%) had a major congenital anomaly, indicating an apparently increased risk of malformation.[219]

Antimetabolites

Antimetabolites used to treat neoplasia include methotrexate (Folex, Mexate), mercaptopurine (Purinethol), thioguanine, cytarabine (Cytosan), and fluorouracil (Efudex, Fluoroplex). Methotrexate was discussed earlier and is associated with an increased risk of congenital anomalies, similar to those associated with another folate antagonist, aminopterin.[23–27] Although there are only case reports of the possible association of congenital anomalies with the use of other antimetabolites during early pregnancy, common mechanisms of action suggest that the case reports represent a causal relationship. In a review by Doll and associates,[219] 15 of 77 offspring (19%) exposed to antimetabolites in utero had major congenital anomalies. Of these 15 infants, 13 were exposed to folate antagonists. Obviously, these agents should be avoided during pregnancy if possible, especially in the first trimester.

Plant Alkaloids

The two major plant alkaloids are vinblastine (Velban, Velsan) and vincristine (Oncovin, Vincasar, Vincrex). Although there are reports of a possible association of malformations with first-trimester exposure,[220] there are also reports of normal infants born to women who used this class of drugs during pregnancy.[221,222] In a review by Doll and associates,[223] 1 of 14 infants (7%) exposed to this group of agents had a major congenital anomaly. These agents are used to treat life-threatening malignancies (i.e., acute leukemia), and should be given when indicated, even during the first trimester.

Antibiotics

Antineoplastic antibiotics include daunorubicin (Cerubidine), doxorubicin (Adriamycin), bleomycin (Blenoxane), and dactinomycin (Cosmegen). No epidemiologic studies of the use of any of these agents during pregnancy have been published. However, anthracycline antibiotics (daunorubicin and doxorubicin) may be needed during the first trimester to treat acute leukemia because potentially life-saving therapy should not be withheld.

Miscellaneous Antineoplastics

Agents in this category include cisplatin (Platinol), procarbazine, and hydroxyurea (Hydrea). No controlled studies in human pregnancies involving any of these agents have been published. Treatment with these agents should ideally be avoided during the first trimester, but should not be withheld when clearly needed to treat life-threatening conditions.

Immunosuppressants

Immunosuppressants are used to treat autoimmune diseases (rheumatoid arthritis, systemic lupus) and for maintenance therapy in organ transplant recipients. The most frequently prescribed agents include glucocorticoids, azathioprine (Imuran), and cyclosporine (Sandimmune). Glucocorticoids were discussed earlier.

Azathioprine

A derivative of 6-mercaptopurine, azathioprine is given as an adjunct in the suppression of cell-mediated immunity. There are no controlled studies of the use of this agent in pregnant women. However, in two case series involving a total of 154 pregnant women who took azathioprine and prednisone throughout pregnancy,[221,224,225] malformations were reported in 11 infants (7.1%). It is impossible to differentiate the effects of monotherapy with this agent from the effects of multiple immunosuppressant medications and from the disease process itself. In one case series of 33 infants born to women who received azathioprine during the first trimester, the frequency of congenital anomalies was not increased.[226] Azathioprine is usually given to prevent organ rejection (a life-threatening condition) in renal transplant recipients. It should not be withheld from the pregnant patient.

Cyclosporine

Cyclosporine is used primarily to treat and prevent allograft rejection. Six hundred infants have been born after exposure to cyclosporine during gestation; however, it is unknown how many were exposed during organogenesis.[227] It should be used when indicated, even in pregnant women, because it is usually prescribed for potentially life-threatening conditions.

Antihistamines and Decongestants

Allergic disorders (rhinitis, hay fever, nasal congestion), upper respiratory infections, and sinusitis occur frequently during pregnancy. The "common cold" is the most common respiratory disorder in pregnant women and the most frequent reason for antihistamine, decongestant, or expectorant use.[228] No effective therapy

against rhinoviruses exists, but the symptoms can be treated while the illness runs its course.

A wide selection of antihistamines is available, and many are used in combination with a sympathomimetic amine (e.g., pseudoephedrine) that is a decongestant. These drugs are used for symptomatic relief in pregnant women. Some commonly prescribed agents are discussed later. An important aspect of prescribing these medications is dose and systemic effects. Intranasal administration is as effective as oral administration and more effective in some instances. Intranasal administration dramatically reduces the dose delivered to the fetus and treats the symptoms effectively.[228]

Decongestants

PSEUDOEPHEDRINE

Pseudoephedrine hydrochloride is the preferred decongestant for pregnant women.[228] It is one of the most frequently used sympathomimetic decongestants used to treat "common cold" or "sinus" symptoms. In more than 1000 women who used this drug in the first trimester, the risk of congenital anomalies among offspring was not increased.[68–70]

PHENYLEPHRINE AND PHENYLPROPANOLAMINE

Phenylephrine and phenylpropanolamine are decongestants that are used in combination with antihistamines. The manufacturer cautions that these agents may interfere with uterine blood flow and should be avoided in pregnant women with conditions associated with decreased uterine blood flow (e.g., hypertension), but no reports in the peer-reviewed literature substantiate this claim. A weak association of phenylephrine and phenylpropanolamine with congenital anomalies was found in 1249 and 726 pregnancies, respectively,[69] but it was likely not causal. In more than 225 infants exposed to phenylephrine during the first trimester, the risk of congenital anomalies was not increased.[68,70] Phenylephrine (Neo-Synephrine, 4-Way) is also used in popular nasal sprays.

OXYMETAZOLINE, XYLOMETAZOLINE, AND NAPHAZOLINE

Oxymetazoline, xylometazoline, and naphazoline are sympathomimetic decongestants found in long-acting nasal sprays (Afrin, Allerest, Dristan, 4-Way). The frequency of congenital anomalies was not increased in more than 250 infants whose mothers used oxymetazoline during the first trimester[68,70] or in 432 infants whose mothers used xylometazoline in the first trimester.[68,70] No published studies were available on the use of naphazoline during pregnancy.

Antihistamines

Antihistamines act primarily by competing with histamine for H_1 receptors and are chemically related to local anesthetics. Effects of some older antihistamines include sedation, antiemesis, anti-motion sickness, and antidyskinesia. For convenience of discussion, antihistamines are best grouped according to their chemical derivation.

One report suggested that antihistamines may be associated with increased frequency of retrolental fibroplasia in premature infants.[229] This effect was substantiated in 2004.

PROPYLAMINE DERIVATIVES

Propylamine derivatives include brompheniramine, chlorpheniramine, dexchlorpheniramine, and triprolidine. Brompheniramine was weakly, and likely not causatively, associated with birth defects in a small sample of 65 offspring with first-trimester exposure.[69] The risk of congenital anomalies was not increased in 270 infants born after first-trimester exposure.[68,70] A summary meta-analysis of all data on brompheniramine strongly suggests that it is not a human teratogen.[233]

Chlorpheniramine and dexchlorpheniramine were not associated with an increased frequency of congenital anomalies after first-trimester exposure in two large epidemiologic studies.[69,70]

Similarly, triprolidine was not associated with an increased frequency of birth defects in offspring of 628 women who took this drug in the first trimester.[68,70]

ETHANOLAMINE AND ETHYLAMINE DERIVATIVES

No human epidemiologic studies of first-trimester use of bromodiphenhydramine, carbinoxamine, and clemastine were published. First-trimester diphenhydramine use was not associated with an increased frequency of congenital anomalies in 865 pregnancies.[69,70] No large epidemiologic studies of bromodiphenhydramine use during pregnancy were published, but no malformations occurred in 10 children whose mothers were exposed to bromodiphenhydramine during the first trimester.[69] Caution should be exercised with parenteral use of ethylamine derivatives because these drugs are reported to have oxytocic effects.[230–232]

Doxylamine has received considerable attention because it was one of the main components of the popular antinausea drug Bendectin (along with pyridoxine and dicyclomine). Reports of an association of Bendectin use and diaphragmatic hernias,[234] congenital heart disease, and pyloric stenosis[68,235] were published. Other studies of thousands of infants found no such association. Millions of women used Bendectin during the first trimester without scientific evidence of adverse fetal effects. The U.S. FDA concluded that either doxylamine or another component of this medication was a human teratogen. Unfortunately, it appears that the Bendectin component was a significant "litogen" (i.e., lawsuit-inducing agent).[236] It is well established that doxylamine is a safe drug for use during pregnancy. Bendectin will be reintroduced for the treatment of nausea after the U.S. FDA republishes its findings that the drug was not a teratogen.[237]

PIPERIDINE DERIVATIVES

No studies of the risk of congenital anomalies in the offspring of mothers who took azatadine, cyproheptadine, or diphenylpyraline during pregnancy were published.

ETHYLENEDIAMINE DERIVATIVES

Tripelennamine exposure during the first trimester was not associated with an increased frequency of congenital anomalies in 100 infants. Similarly, the risk of birth defects was not increased in 112 infants born to mothers who used pyrilamine during the first trimester.[69]

BUTYROPHENONE DERIVATIVES

First-trimester terfenadine (Seldane) exposure was not associated with an increased risk of birth defects in 134 infants.[238] According to the manufacturer, terfenadine is not recommended for use by nursing mothers because it was associated with decreased pup weight in rats.

PIPERAZINE DERIVATIVES

Cyclizine, buclizine, and meclizine have antihistamine actions, but are used primarily as antiemetics. Meclizine use by mothers during the third trimester was not associated with an increased frequency of fetal effects among exposed infants.[69] In more than 1000 offspring whose mothers used meclizine in the first trimester, the risk of birth defects was not increased. Further information indicating that meclizine is not teratogenic in humans was published in one cohort study and three case–control studies.[239–242] Similarly, in 111 infants with first-trimester exposure to cyclizine, the risk of congenital anomalies was not increased.[241]

PHENINDAMINE

No animal or human studies of the risk of congenital anomalies with phenindamine exposure during pregnancy were published. However, phenindamine is closely related to chlorpheniramine, which was studied during pregnancy and did not increase the risk of birth defects after exposure during organogenesis.

Nonsedating Antihistamines

Recently marketed nonsedating antihistamines include loratadine (Claritin), cetirizine (Zyrtec), Fexofenadine (Allegra), astemizole (Astemizol, which is not available in the United States), cromolyn (Intal), and ebastine (Ebast, Ebastel, Kestine). All but one of these agents, cromolyn, is a H_1 receptor antagonist.

LORATADINE

No studies of loratadine use during pregnancy were published that adequately address its safety. In one small study of fewer than 20 infants born to women who took loratadine during pregnancy, no congenital anomalies

were observed.[243] However, the clinical and epidemiologic significance of this case series is questionable.

CETIRIZINE

Cetirizine is an oral H_1 antihistamine that is used to treat allergies. In 49 infants whose mothers took cetirizine during pregnancy, the frequency of congenital anomalies was not increased.[243,244] The data are tenuous, but suggest that the risk of congenital anomalies with this drug is low.

FEXOFENADINE

Fexofenadine is an oral H_1 receptor antagonist that is used to treat seasonal allergies and rhinitis. Although no studies of the risk of congenital anomalies in infants born to women who used fexofenadine during pregnancy were published, terfenadine is metabolized to fexofenadine. Terfenadine is not associated with an increased risk of birth defects after first-trimester exposure.

ASTEMIZOLE

Astemizole, a long-acting H_1 receptor antagonist, is used to treat allergic conditions. It is not available in the United States, but is available in Europe, Canada, and Mexico. It may be obtained by international mail order in the United States. In more than 100 infants exposed to astemizole during the first trimester, the risk of birth defects was not increased above background levels.[245]

CROMOLYN SODIUM

Cromolyn sodium is a mast cell inhibitor that is used prophylactically to treat chronic allergic conditions. In more than 440 infants whose mothers used cromolyn during the first trimester, the risk of congenital anomalies was not increased.[246,247]

IPRATROPIUM BROMIDE

No studies of first-trimester human exposure to ipratropium were published. One animal study found no increased frequency of congenital anomalies after exposure during organogenesis. However, this finding may be irrelevant to the risk of birth defects in humans.

EBASTINE

No studies of ebastine exposure during the first trimester of human pregnancy were published. In one animal study of exposure during organogenesis, the frequency of congenital anomalies was not increased. However, the relevance of these findings to the risk in humans is unknown.

Expectorants and Antitussives

Expectorants

Guaifenesin is the leading expectorant in current use and is a major component of most cough medications, both prescribed and over the counter. The risk of birth defects

was not increased in more than 1000 infants born after first-trimester exposure.[68–70] Other mucolytic or expectorant medications contain iodide (potassium iodide, iodinated glycerol), and should not be used after 10 weeks' gestation. Iodide in iodide-containing medications crosses the placenta and may cause fetal goiter. Therefore, iodide-containing agents are contraindicated during pregnancy after formation of the fetal thyroid.

Antitussives

Dextromethorphan is available by prescription and over the counter as an antitussive. Among 300 infants born to women who used dextromethorphan during the first trimester, the frequency of congenital anomalies was not increased.[69] Several narcotics are used in cough preparations, such as codeine, hydrocodone, and hydromorphone. Long-term use, tantamount to abuse, of narcotic-containing antitussives may result in neonatal addiction, withdrawal, and respiratory depression. However, the risk of congenital anomalies is not increased by the narcotics commonly used in these formulations. Opiates were discussed previously.

Benzonatate (Tessalon) is an antitussive that anesthetizes stretch receptors in the respiratory smooth muscle. No human studies were published with which to assess the risk of birth defects or adverse fetal effects after exposure during gestation.

Many cough preparations contain alcohol (ethanol). The alcohol content of typical cough preparations is 15% to 26%. It is unlikely that short-term use is associated with a significant risk. However, according to case reports, long-term abuse of alcohol-containing cough medicines is associated with fetal alcohol syndrome.

Gastrointestinal Drugs

Gastrointestinal disorders occur frequently during pregnancy. Nausea, with or without vomiting, is the most common gastrointestinal disorder of early pregnancy. In the extreme form (i.e., hyperemesis gravidarum), vomiting may cause significant weight loss and dehydration. Another common gastrointestinal disorder in pregnancy is pyrosis, or "heartburn," which is related to increased gastroesophageal reflux as a result of decreased muscular tone in the lower esophagus and hypersecretion of gastric acid. Medications used to treat gastrointestinal disorders include antacids, histamine H_2 receptor antagonists, proton pump inhibitors, antiemetics, and corticosteroids (discussed earlier).

Antacids

Antacids are divided into five categories based on their metal salt content: aluminum, calcium, magnesium, magaldrate, sodium bicarbonate, and combinations of these. Antacids are the most frequently used over-the-counter and prescribed gastrointestinal medications among pregnant women. Aluminum hydroxide and magnesium hydroxide combinations are used in many commercial preparations, including Maalox, Mylanta, Riopan, and Gelusil. Calcium carbonate is a very popular antacid and is contained in such proprietary preparations such as Tums, Titralac, Rolaids, and Chooz.[103]

No teratology studies were published on antacids. Antacids are believed to be associated with little significant risk when used in moderation during pregnancy. However, long-term, high-dose use may be associated with adverse effects, such as maternal or fetal hypercalcemia, hypermagnesemia, or hypocalcemia.

H₂ Receptor Antagonists

H_2 receptor antagonists reduce gastric acidity through systemic action on histamine H_2 receptors. Time for absorption and distribution is needed before the patient experiences relief. Preparations include cimetidine, famotidine, nizatidine, and ranitidine. These agents are used as prophylaxis against aspiration and are given before general anesthesia. Long-term administration of systemic antacids is used to treat peptic ulcer disease, an uncommon ailment in pregnant women, and gastroesophageal reflux disease that is unresponsive to the usual antacids, such as the calcium and other metal salts mentioned earlier. These agents cross the placenta.[248,249]

Among more than 400 infants born to women treated with various histamine H_2 receptor antagonists during the first trimester, the risk of congenital anomalies was not increased.[250–252] The frequency of congenital anomalies in 237 infants whose mothers used cimetidine during the first trimester was not increased above that in control subjects.[253] The risk of congenital anomalies was not increased in 58 infants born to women who took famotidine during the first trimester.[252] No studies of nizatidine use during human pregnancy were published when this topic was researched in 2004. In more than 500 infants born to mothers who used ranitidine during the first trimester, the frequency of congenital anomalies was not increased above the expected background rate.[252,253]

Findings suggest that first-trimester use of histamine H_2 antagonists is not associated with an increased risk of congenital anomalies. Data on ranitidine are compelling because the sample sizes are large. Data on famotidine are less compelling because the sample size is much smaller.[254] Little information was published about nizatidine use during human pregnancy. In the latter half of pregnancy, histamine H_2 antagonists apparently can be used safely. No adverse maternal or fetal effects were noted.

Proton Pump Inhibitors

Proton pump inhibitors were recently developed to treat gastric hyperacidity. They act systemically by directly inhibiting the production of H^+,K^+-ATPase and related ions.[254]

OMEPRAZOLE

The first proton pump inhibitor used to treat ulcers and gastric reflux was omeprazole (Prilosec). This agent blocks the production and secretion of gastric acid. It has been used during organogenesis and the fetal periods of pregnancy. The frequency of major congenital anomalies was no greater than expected. In 91 infants of women who were treated with omeprazole during the first trimester, the frequency of congenital anomalies was not increased above the rate expected for the general population.[255] No adverse effects on newborns were noted when women were given omeprazole in preparation for delivery by elective cesarean section.[256,257]

ESOMEPRAZOLE

There are no epidemiologic studies of esomeprazole use during pregnancy. Esomeprazole is the sinister racemate of omeprazole. The clinical advantage of esomeprazole compared with omeprazole is that the sinister racemate isomer is cleared from the body more slowly, decreasing dose periodicity.[258] It is tempting to assume that esomeprazole is safe because a closely related drug (omeprazole) is apparently safe based on fewer than 100 first-trimester exposures. However, an isomer of thalidomide, the most notorious human teratogen ever discovered, was not associated with birth defects.

Antiemetics

Most pregnant women experience nausea during the first trimester. Most are managed comfortably without medication. However, some patients who have nausea and emesis require therapy because of protracted or health-threatening vomiting that causes dehydration. In serious cases of protracted vomiting during pregnancy, or hyperemesis gravidarum, inpatient treatment may be necessary.

PHENOTHIAZINES

Phenothiazines are used for several indications, including nausea and vomiting, psychotic disorders, and mild pain. They are also used as antidyskinetics and mild sedatives. The phenothiazine derivatives prochlorperazine, chlorpromazine, and promethazine are the most commonly used agents for the treatment of nausea and vomiting during pregnancy. Phenothiazine use during pregnancy may be associated with extrapyramidal symptoms in the mother and fetus, but these adverse effects are rare.[259,260] Phenothiazine use during gestation is not associated with an increased frequency of congenital anomalies.

PROMETHAZINE

Promethazine is marketed under many trade names. Phenergan is the most well known to obstetricians. It is also used as an adjuvant to meperidine during labor and for pain relief after cesarean delivery. In more than 100 infants born to women who took promethazine in the first trimester, the frequency of birth defects was not increased.[69] Similarly, the risk of congenital anomalies was not increased in two other studies that included several hundred women who used the drug during the first trimester[68,195] and later in pregnancy.[195] When promethazine was used to treat hyperemesis, the frequency of congenital anomalies was lower than expected.[195]

CHLORPROMAZINE

The risk of congenital anomalies was not increased in the offspring of more than 400 women who took this drug during the first trimester.[69,195]

PROCHLORPERAZINE

In more than 1000 infants whose mothers took prochlorperazine during the first trimester, the frequency of congenital anomalies was not increased above the background risk. In addition, in more than 2000 women who used prochlorperazine during the second and third trimesters, no adverse maternal or fetal adverse effects were observed.[69,70,241,261]

PIPERAZINE DERIVATIVES

Cyclizine, buclizine, and meclizine are piperazine derivatives that are used as antiemetics and antihistamines. The risk of congenital anomalies was not increased in several hundred infants whose mothers used piperazine derivatives during the first trimester[69] or in more than 100 infants whose mothers used cyclizine during the first trimester.[241]

DOXYLAMINE-PYRIDOXINE

Doxylamine-pyridoxine (Bendectin) was wrongly classified as a teratogen more than 20 years ago. Until it was taken off the market, Bendectin was the most commonly prescribed antiemetic for hyperemesis during pregnancy. It was reportedly very efficacious. After the drug combination was withdrawn from the market, many obstetricians prescribed the components of Bendectin separately to be taken concomitantly. Flawed studies associated Bendectin use with diaphragmatic hernias, congenital heart disease, and pyloric stenosis. Better-designed studies refuted the association of Bendectin with birth defects. Epidemiologic studies of first-trimester use of the individual components of Bendectin also show the safety of the drug combination.

Millions of women used Bendectin during the first trimester, and by chance alone, 3.5% would be expected to have infants with birth defects. In 2002, it was clear that Bendectin was not a teratogen. The U.S. FDA elected to republish its exonerative findings, and Brent reported that the drug would become available again.[237] Unfortunately, it appears that Bendectin was a significant "litogen" (i.e., capable of inducing nonmeritorious lawsuits).[236,262,263] Until Bendectin is reintroduced, obstetricians will likely prescribe doxylamine and pyri-

doxine under separate labels to be taken together as an antinauseant.

5-HT₃ RECEPTOR AGONISTS

Ondansetron. Ondansetron (Zofran) is a $5\text{-}HT_3$ receptor agonist and a very potent antiemetic. It is most often used for severe nausea and vomiting associated with chemotherapy. It has also been used successfully to treat severe hyperemesis gravidarum. No human epidemiologic studies have been published, but this agent was not teratogenic in animal studies, according to its manufacturer. It is classified as U.S. FDA risk category B, although, as noted earlier, this classification does not provide reliable reassurance.

Prokinetic Agents. Prokinetic agents stimulate motility of the upper gastrointestinal tract. They are used primarily to treat gastrointestinal reflux disease. Metoclopramide (Reglan) is also used as an antiemetic, especially for postoperative nausea. No adequate human reproduction studies of cisapride (Propulsid) or metoclopramide were published. Neither drug was teratogenic in animal studies. Cisapride is listed as U.S. FDA risk category C, and metoclopramide is listed as U.S. FDA risk category B.

MANAGEMENT OF THE PREGNANT PATIENT WITH MEDICATION EXPOSURE

Management of the pregnant patient who has been exposed to medication during pregnancy, especially during the critical period of organogenesis, is a challenge. Several important questions must be answered. Is the medication or substance a known teratogen? Are there potential adverse fetal or neonatal effects? What is the risk to the mother if the medication is used or withheld? Are there other important factors to consider, such as the disease being treated? What are the available sources of information about medication use during pregnancy? How should the patient be counseled?

Etiology of Malformations

In most cases of congenital malformations (65%–70%) the cause is unknown. It was estimated that 20% to 25% are caused by genetic abnormalities 3% to 5% are caused by intrauterine infection and 4% are associated with maternal diseases, such as diabetes mellitus, phenylketonuria, or epilepsy.[264] Fewer than 1% of cases are causally related to prescribed medications. However, many patients, physicians, and lawyers often suspect that a medication caused a malformation in an exposed infant.[265]

Evaluating Risk

Few medications are known human teratogens. However, for most medications, perhaps more than 60%, inadequate data are available to allow an assessment of the risks of congenital anomalies or adverse fetal effects.

Sources of Information

Where can this information be found? Several major textbooks can provide a starting point. In addition, computerized databases, such as TERIS,[2] provide useful information for the assessment of potential risks (Table 35–14). Ultimately, referral to a tertiary care center with a clinical teratologist on staff is the preferred approach.

U.S. Food and Drug Administration Fetal Risk Categories

In 1979, the U.S. FDA established a risk category system to classify drugs with potential adverse fetal effects.[1,2,266] Category A drugs are considered relatively safe for use during pregnancy. Category B drugs have no known risks, but there are no controlled human studies. Category C agents are those for which little or no information is available. Most new drugs are placed in this category. Category D agents have a definite risk, but may be deemed necessary for use during pregnancy based on a risk–benefit assessment (i.e., anticonvulsants). Category X drugs pose a definite risk. Their use during pregnancy is contraindicated because the potential risks outweigh the benefits. Few medications are listed as category A (e.g., some prenatal vitamins). Ampicillin is an example of a category B drug (i.e., no controlled human studies). Isotretinoin (Accutane) is a category X drug. These categories usually do not reflect current scientific information on the potential teratogenic risk of a specific medication.[267] Therefore, they should not be considered primary directives for prescribing medication during pregnancy.

Counseling the Patient

It is important to take a detailed medical history and to perform a physical examination before counseling the patient and her family. The history should include gestational dating criteria, such as the date of the last menstrual period. In addition, detailed information should be obtained about drug exposure (class, dose, route of administration, timing, disease being treated). It is important to obtain information on concomitant medication use and ionizing radiation exposure as well as a detailed family history and genetic pedigree. Finally, it is necessary to review other medical conditions that may affect the risk of malformations.[2]

Determining the gestational age and the timing of exposure is of paramount importance. Ultrasound evaluation for dates should be done if the gestational age is questionable or is not confirmed by the findings on physical examination. If it can be determined that a medication was taken before conception or after organogenesis, for most medications, counseling may consist of simply reassuring the patient. Perhaps the most important information obtained during the counseling session is the gestational age at which exposure occurred. It is important to differentiate between embryonic age and menstrual age because menstrual age includes 2 weeks when the patient was not actually

pregnant. It is important to determine whether the specific agent is absorbed from the maternal gastrointestinal tract, which may result in significant serum levels in the mother and possibly in the fetus. Some agents, such as stool softeners, have a local effect with no systemic absorption. These agents are expected to cause negligible embryonic or fetal exposure.

It is also necessary to determine whether significant amounts of a specific agent cross the placenta. For example, both low-molecular-weight and high-molecular-weight forms of heparin cross the placenta poorly and have no known direct adverse fetal effects. However, most drugs (99%) cross the placenta.

For known teratogens, such as isotretinoin, with reasonably established risk figures, the patient can be counseled that there are definite risks associated with exposure during a given gestational period. Therapeutic options include pregnancy termination. After the appropriate information is gathered during a cordial clinical interview, all counseling sessions should begin with an explanation of the background risk of congenital anomalies in the general population (3%–5%). The age-associated risk of chromosomal abnormalities should be elucidated if the patient is 35 years old or older.

No scientific studies on the use of approximately half of the currently available agents during pregnancy are available. Polifka and Friedman[75] point out that during the last 20 years research in clinical teratology has slowed significantly. When data are available, the counselor may explain the risk as follows: "Although a small risk cannot be 'ruled out,' the risk of spontaneous anomalies (3%–5%) is probably greater than any risk that can be estimated from available information for most medications that have been studied."[265] The counselor might continue to say: "For certain medical illnesses, such as diabetes or seizure disorders, the risk of the condition itself, especially if untreated, generally far outweighs any known or theoretical risk of medications to the fetus. These medications should not be withheld from a woman because she is pregnant." Obviously, preconception counseling is preferred, but this opportunity is rare.

Finally, when medications are being considered for a woman who is already pregnant, it is important to consider whether the initiation of therapy can be delayed until after the completion of the first trimester (i.e., embryogenesis). If a delay is unsafe, treatment should be initiated when needed, even if risk is involved. For example, chemotherapy for acute leukemia should be initiated as soon as the diagnosis is confirmed, regardless of gestational age.

CONCLUSIONS

- During pregnancy, many women take medication not all of which is prescribed.
- A detailed medication history should be taken at the beginning of pregnancy.
- Most drugs do not have proven adverse fetal effects, but they should be avoided in the first trimester, if possible.
- Medication should be used or continued in pregnancy only if the benefits outweigh the risks.
- When counseling patients about drug exposure in pregnancy, whether intended or inadvertent, it is important to obtain comprehensive and up-to-date data about known risks.

SUMMARY OF MANAGEMENT OPTIONS
Medication During Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Inadvertent Exposure to Medication			
Obtain accurate details about exposure, especially gestational age	–	GPP	–
Check for confounding family or medical history	–	GPP	–
Obtain up-to-date information about published risks of the specific drug in humans	–	GPP	–
Emphasize "background" risks in counseling	–	GPP	–
Be clear about what is known, but do not assume that absence of data means no risk	–	GPP	–
Considering Initiating or Continuing Medication			
Medication should be used only if the expected benefits (usually to mother) are greater than the risks (usually to fetus)	–	GPP	–
Try to avoid first-trimester use	–	GPP	–
Use drugs that have been used extensively in pregnancy rather than new or untried drugs	–	GPP	–
Use the minimum dose to obtain the desired effect	–	GPP	–
Absence of data does not imply safety	–	GPP	–
Medications Known or Suspected to Be Human Teratogens or to Have Serious Adverse Fetal Effects (see Table 35–2)			
Retinoids			
High-dose vitamin A	IV	C	9
Isotretinoin (see Table 35–3)	III	B	19
Etretinate	IV	C	20
Acitretin	III	B	21
Hormones			
Danazol	III	B	50–53
Androgens	III	B	49
Diethylstilbestrol (see Table 35–7)	IIa	B	57
Anticoagulants			
Warfarin and other coumarin anticoagulants (see Table 35–6)	III	B	47
Antineoplastics			
Aminopterin and methylaminopterin (see Table 35–4)	IV	C	23–25
Methotrexate	IV	C	23–25

Medication During Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Busulfan	IV	C	27
Cyclophosphamide	IV	C	28,29
Anticonvulsants			
Phenytoin and other hydantoins (see Table 35–5)	III	B	33,34
Carbamazepine	III	B	38
Valproic acid	III	B	44–46
Trimethadione and paramethadione	III	B	35
Primidone	III	B	35
Phenobarbital	III	B	75,78,79
Antibiotics (see also Table 35–8)			
Tetracycline	III	B	65–67
Aminoglycosides	III	B	90,91
Fluconazole administered parenterally (not orally)	III	B	107–109
Others			
Cocaine	IV	C	22
Lithium	III	B	71,72
Penicillamine	III	B	73,74
Thalidomide	III	B	7
Angiotensin-converting enzyme inhibitors	IIa	B	143–147
Amiodarone	IV	C	158–161
Nonsteroidal anti-inflammatory drugs	III	B	198–202

Hypertension

Asnat Walfisch / Mordechai Hallak

INTRODUCTION

Hypertensive disorders of pregnancy are responsible for significant maternal and perinatal morbidity and are the second leading cause, after embolism, of maternal mortality.[1] Kaunitz and associates[2] reviewed the causes of maternal mortality in the United States and found that 421 (20%) of 2067 maternal deaths between 1974 and 1978 were related to hypertensive diseases. The clinical course of gestational hypertension is progressive and is characterized by continuous deterioration that is ultimately stopped only by delivery. Early detection and appropriate management of the pregnancy may improve the outcome for both the mother and the fetus.

Hypertensive disorders of pregnancy complicate approximately 12% to 22% of all pregnancies[3,4] and are directly responsible for 17.6% of maternal deaths in the United States. Gestational hypertension, which includes preeclampsia and eclampsia, is responsible for 70% of cases, whereas chronic hypertension represents 30% of hypertensive disorders in pregnancy.[5] Gestational hypertension is mainly a disease of young primigravidae, and accordingly, its incidence is higher in this group. The exact incidence of preeclampsia is unknown, but is approximately 5% to 8%.[6,7] The incidence was 14.1% in primigravidae versus 5.7% in multiparas among 2434 singleton pregnancies reported by Long and Oats.[8] The increased incidence of gestational hypertension in patients older than 35 years probably reflects undiagnosed chronic hypertension with superimposed gestational hypertension. The incidence of gestational hypertension is also increased in patients pregnant with twins (25.9%)[8] and in patients who had gestational hypertension in a previous pregnancy.[9] Other risk factors include pregestational diabetes, vascular or connective tissue disease, nephropathy, antiphospholipid antibody syndrome, obesity, positive family history, and African American race.[6,10–14]

The etiology of gestational hypertension is unknown, despite intensive research worldwide, and there is confusion about its classification, diagnosis, and treatment. More than 100 names have been given to the disease.[15] However, great advances in the understanding of the pathophysiology of gestational hypertension allow clinicians to better evaluate and manage patients. This progress is primarily responsible for the recent decline in maternal and perinatal mortality and morbidity rates.[16] This chapter emphasizes the most widely accepted knowledge about maternal and fetal risks and the management of the pregnant patient with hypertension.

DEFINITIONS

Several systems of classification of hypertensive disorders of pregnancy are used around the world. In 1972, the Committee on Terminology of the American College of Obstetricians and Gynecologists prepared a classification and definitions.[17] Table 36–1 shows a slight modification of this classification.[18] The modifications include eliminating edema from the diagnostic criteria and abandoning the use of changes in blood pressure as diagnostic.[19] Korotkoff phase V (disappearance), as opposed to phase IV (muffling), was chosen to determine the diastolic blood pressure because substantial data support its use.[20] The following definitions are proposed[19]:

Hypertension

Hypertension is defined as diastolic blood pressure of at least 90 mm Hg or systolic pressure of at least 140 mm Hg. Diastolic blood pressure is the pressure at which the sound disappears (Korotkoff phase V). These blood pressures must be recorded on at least two occasions 6 hours or more apart. Elevation of more than 30 mm Hg systolic

TABLE 36-1

Classification of Hypertensive Disorders in Pregnancy

Gestational hypertension
  Preeclampsia
    Mild
    Severe
  Eclampsia
Chronic hypertension before pregnancy (any etiology)
Chronic hypertension (any etiology) with superimposed gestational hypertension
  Superimposed preeclampsia
  Superimposed eclampsia

or more than 15 mm Hg diastolic above the patient's baseline is no longer part of the criteria and has not proved to be a good prognostic indicator.

Preeclampsia

Preeclampsia is defined as the development of hypertension, proteinuria, or both, after week 20 in a woman with previously normal blood pressure. It may be associated with many other signs and symptoms, such as edema, visual disturbances, headache, and epigastric pain. Preeclampsia may develop before week 20 in patients with extensive hydatidiform changes in the chorionic villi or in the presence of lupus anticoagulant. The following two types are recognized:

- Mild preeclampsia. No criterion for severe preeclampsia is present.
- Severe preeclampsia. One or more of the criteria shown in Table 36–2 are present.

Proteinuria

Proteinuria is defined as the presence of 300 mg/L or more protein in a 24-hour urine specimen. This finding

TABLE 36-2

Criteria for Severe Preeclampsia

Blood pressure reading, with the patient at rest, of at least 160 mm Hg systolic or 110 mm Hg diastolic pressure on two occasions at least 6 hours apart. In practice, after a diastolic pressure reading of 110 mm Hg, the clinician should not wait 6 hours for diagnosis and treatment.
Proteinuria levels of at least 5 g in 24-hour urine collection or 3+ to 4+ on semiquantitative assay collected at least 4 hours apart
Oliguria. 24-hour urinary output of less than 500 mL
Cerebral or visual disturbances, altered consciousness, headache, scotomata, or blurred vision
Pulmonary edema or cyanosis
Epigastric or right upper quadrant pain caused by stretching of Glisson's capsule. Occasionally, pain precedes hepatic rupture.
Impaired liver function of unclear etiology
Thrombocytopenia (postulated to be caused by platelet adherence to collagen exposed at sites of disrupted vascular endothelium)
Intrauterine growth restriction

usually correlates with a finding of +1 or greater, but should be confirmed with a random urine dipstick evaluation and 24-hour urine collection.

Eclampsia

Eclampsia is defined as new-onset grand mal seizures in a woman whose condition also meets the criteria for preeclampsia when a coincidental neurologic disease, such as epilepsy, does not cause the convulsions.

Chronic Hypertension

Chronic hypertension is defined as persistent hypertension, of any cause, before week 20 in the absence of hydatidiform mole or persistent hypertension beyond 6 weeks postpartum.

Superimposed Preeclampsia or Eclampsia

Superimposed preeclampsia or eclampsia is defined as new-onset proteinuria in a woman with hypertension before 20 weeks' gestation. Other criteria include a sudden increase in proteinuria (if already present), a sudden increase in hypertension, and the development of hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome in a woman with chronic hypertensive vascular or renal disease. Women with chronic hypertension who have headache, scotomata, or epigastric pain also may have superimposed preeclampsia.

PREECLAMPSIA AND ECLAMPSIA

Pathophysiology and Maternal and Fetal Risks

Although the etiology of preeclampsia is unknown, much of the literature focused on the degree of trophoblastic invasion by the placenta, which appears to be incomplete in preeclampsia.[21-23]

Cardiovascular System

The main feature of preeclampsia and eclampsia is hypertension. Blood pressure is a product of cardiac output and total peripheral resistance. Cardiac output increases in the first trimester of normal pregnancy, reaching a peak of 30% to 50% above the nonpregnant level. This increased output is maintained for the rest of the pregnancy.[24,25] This increase is maintained and rises further in patients with preeclampsia.[26,27] During normal pregnancy, total peripheral resistance decreases by 25%,[25,28] whereas in gestational hypertension, it increases.[26,27] This increase in peripheral vascular resistance appears to be the main cause of the elevation in blood pressure that is seen in gestational hypertension. Table 36–3 shows a comparison of the hemodynamic

TABLE 36–3

Comparison of the Hemodynamic Profile of Normal Nonpregnant Patients, Normal Pregnant (36–38 Weeks' Gestation) Patients, and Patients with Severe Pregnancy-Induced Hypertension (Mean, 35.4 Weeks' Gestation)

PARAMETER	NONPREGNANT PATIENT $N = 10$ MEAN (± SD)	% CHANGE	PREGNANT PATIENT $N = 10$ MEAN (± SD)	% CHANGE	SEVERE PIH $N = 45$ MEAN (± SD)
Heart rate (beats/min)	71 (10)	+17	83 (10)	+14	95 (13.4)
Cardiac output (L/min)	4.3 (0.9)	+43	6.2 (1)	+21	7.5 (1.5)
Mean arterial pressure (mm Hg)	86.4 (7.5)	NS	90.3 (5.8)	+53	138 (20)
Central venous pressure (mm Hg)	3.7 (2.6)	NS	3.6 (2.5)	NS	4 (6.7)
Pulmonary capillary wedge pressure (mmHg)	6.3 (2.1)	NS	7.5 (1.8)	+33	10 (6.7)
Colloid oncotic pressure (mm Hg)	20.8 (1)	−14	18 (1.5)	NS	19 (3.3)
Systemic vascular resistance (dyne × cm × sec^{-5})	1530 (520)	−21	1210 (266)	+24	1496 (428)
Pulmonary vascular resistance (dyne × cm × sec^{-5})	119 (47)	−34	78 (22)	NS	70 (33)
Left ventricular stroke work index (gm × m^{-2})	41 (8)	NS	48 (6)	+68	81 (13)

(The % change is significant at $p < 0.05$ in all values except when indicated as NS.)

profile of normal nonpregnant and pregnant women and patients with severe gestational hypertension, as measured by pulmonary artery catheterization.[25,26] Hemoconcentration, in addition to hypertension, is a significant vascular change because women with preeclampsia or eclampsia may not have the normal hypervolemia associated with pregnancy.[29]

Endocrine System

Alterations in vascular sensitivity to endogenous hormones (angiotensin II, catecholamines, and vasopressin) may have an important role in the increase in vascular resistance and elevated blood pressure seen in preeclampsia. In normal pregnancy, there is refractoriness to the pressor effect of angiotensin II.[30] Increased vascular reactivity to these pressor hormones is seen in patients with preeclampsia.[31,32] The abnormal sensitivity is acquired between week 17 and the clinical onset of gestational hypertension. Gant and colleagues[33] showed that loss of refractoriness to angiotensin II occurs 8 to 12 weeks before the appearance of the clinical manifestations of gestational hypertension.

The control of vascular tone and blood pressure achieved by angiotensin II is probably mediated by vascular endothelial synthesis of prostaglandins. The vascular response to angiotensin II is decreased by the use of prostaglandin inhibitors, indomethacin, and aspirin.[34,35] During normal pregnancy, production of prostacyclin and thromboxane A_2 increases, with a delicate balance that favors prostacyclin.[36] Prostacyclin, which is produced by the vascular endothelium, is a potent vasodilator and antiplatelet aggregant. Thromboxane A_2, which is produced by platelets and trophoblasts, is a potent vasoconstrictor and platelet aggregator. In preeclampsia, the ratio of thromboxane A_2 to prostacyclin is increased, with significantly decreased placental production of prostacyclin

and significantly increased production of thromboxane A_2.[37] In addition, in gestational hypertension, a decreased amount of the prostacyclin metabolite 6-keto-prostaglandin $F_{1\alpha}$ was seen in maternal, placental, and umbilical vessels.[38,39] In patients with gestational hypertension, damaged endothelial cells may lead to decreased prostacyclin production in vessel walls and increased platelet activation, which in turn releases thromboxane A_2. This may result in an increased ratio of thromboxane A_2 to prostacyclin and may increase vascular tone and elevate blood pressure.

Hematologic System

During normal pregnancy, total blood volume increases by 50% by the end of the second trimester.[29] More of the increase is caused by the expansion of plasma than by erythrocytes, leading to the physiologic anemia of pregnancy. In gestational hypertension, the expansion in blood volume is reduced (16%).[29] The hemoconcentration seen in gestational hypertension can result in decreased regional perfusion. In these patients, in the absence of hemorrhage, the intravascular compartment is not underfilled because of the increase in vascular tone and vasospasm. Clinically, hematocrit increases with increased severity of gestational hypertension.[29] Vasospasm and subsequent hemoconcentration are associated with contraction of the intravascular space. Attempts to expand the intravascular space with fluid therapy may increase pulmonary wedge pressure and cause pulmonary edema as a result of associated capillary leak.[40]

The vasospasm that is part of the pathophysiology of gestational hypertension is likely to result in endothelial injury. Dadak and associates[41] found marked damage to the endothelium of the umbilical arteries of mothers with gestational hypertension. The injury to the endothelium

could be the cause of the microangiopathic hemolysis that accompanies gestational hypertension. It causes thrombocytopenia, anemia, and fragmentation of red blood cells.

Gestational hypertension is also associated with high levels of fibronectin, low levels of antithrombin III, and low levels of α_2-antiplasmin.[42,43] These changes may reflect endothelial damage (high fibronectin levels),[44] clotting (low antithrombin III levels), and fibrinolysis (low α_2- antiplasmin levels). Changes in the levels of these factors can aid in the diagnosis of preeclampsia and help to differentiate it from chronic hypertension.[45–47]

Thrombocytopenia and hemolysis may occur as part of the HELLP syndrome. Thus, interpretation of hematocrit levels should take this into consideration. Lactate dehydrogenase is present in erythrocytes in high concentration, and when elevated, may be a sign of hemolysis.

Kidney

Renal blood flow and the glomerular filtration rate increase considerably during normal pregnancy. In women with gestational hypertension, renal perfusion decreases by an average of 20% and the glomerular filtration rate decreases by an average of 32% compared with normal pregnant women near term.[48] Oliguria, commonly defined as less than 500 mL in 24 hours, may occur as a result of hemoconcentration and decreased renal blood flow. Rarely, persistent oliguria reflects acute tubular necrosis.

Some consider the microscopic changes seen in renal biopsy specimens from women with preeclampsia to be pathognomonic of the disease. Characteristic changes include glomerular capillary endothelial swelling accompanied by deposits of fibrinogen derivatives within and under the endothelial cells.[49] This constellation of lesions was designated by Spargo and colleagues[50] as glomerular capillary endotheliosis. The swollen endothelial cells block the capillary lumens. Resolution of the glomerular changes occurs within several weeks postpartum.

Liver

In preeclampsia accompanied by HELLP syndrome, an elevation in liver function test results is noted. Alanine aminotransferase and aspartate aminotransferase levels may be elevated. Hyperbilirubinemia may occur, especially in the presence of hemolysis. Periportal hemorrhagic necrosis in the periphery of the liver lobule is probably the lesion that causes elevated serum liver enzyme levels. Bleeding from these lesions or from the liver capsule can lead to subcapsular hematomas. Hemorrhage under the liver capsule can be so severe that the capsule ruptures and causes life-threatening intraperitoneal bleeding. In this case, laparotomy with packing and drainage may prove lifesaving.[51]

Brain

Cerebral blood flow and cerebral oxygen metabolism are usually unaltered by gestational hypertension, whereas cerebral vascular resistance is significantly increased in gestational hypertension compared with normal pregnancy.[52] Cerebral blood volume response, measured noninvasively by near-infrared spectroscopy, provided additional evidence of altered cerebral hemodynamics in women with preeclampsia.[53] Approximately one-third of patients who died of eclampsia had cerebral hemorrhage, ranging from petechiae to large hematomas.[54] Sibai and associates[55] reported nonspecific, transient abnormal electroencephalographic findings in 75% of patients after eclamptic convulsion. Hypodense cortical areas corresponding to hemorrhages and local edema were the most common findings in computed topographic head scans of patients with eclampsia.[56] Although it is uncommon, temporary, and even permanent,[57] blindness may accompany severe preeclampsia.[58] Other central nervous system manifestations include headache, blurred vision, and hyper-reflexia.

Uteroplacental Circulation

In normal human pregnancy, the spiral arteries in the placental bed progressively lose their musculoelastic tissue by migration of trophoblasts into their walls. These trophoblast-induced changes involve the entire length of the spiral artery, from the intervillous space to its origin in the inner third of the myometrium. This process widens the spiral arteries and creates a low-resistance, low-pressure, high-flow system that allows the increased blood supply to reach the pregnant uterus.[59] The first stage of these changes may involve the decidual part of the spiral arteries and occurs in the first trimester. The second stage starts at 16 weeks' gestation, and the process progresses to the myometrium.[59]

In women with gestational hypertension, small-for-gestational-age fetuses, and diabetes mellitus, trophoblast-induced changes are restricted to the decidual arteries. Myometrial segments of the spiral arteries are left with their musculoelastic architecture, which make them sensitive to vasomotor influences.[59] This process may account for the twofold to threefold decrease in uteroplacental perfusion seen in hypertensive patients compared with normotensive women.[60]

Some histologic changes in the uteroplacental vessels that are seen in gestational hypertension are considered pathognomonic and termed "acute atherosis."[61] Microscopic vascular findings include endothelial cell damage, basement membrane disruption, platelet deposition, mural thrombi, fibrinoid necrosis, proliferation of intimal cells and myointimal hyperplasia, hyperplasia of smooth muscle cells, extensive lipid necrosis of myointimal and smooth muscle cells, and an increase in smooth muscle cells with vasospasm that leads to a decreased vessel lumen.[61–63]

Perinatal Mortality

The perinatal mortality rate is increased in preeclampsia, especially in patients with severe preeclampsia. Individual contributing factors include preterm delivery, uteroplacental insufficiency, abruptio placentae, and unexplained fetal death.

Preterm delivery is often necessitated because definitive treatment of preeclampsia mandates termination of pregnancy, regardless of gestational age. The uteroplacental bed is not spared the vasoconstrictive effects of preeclampsia. Therefore, this decrease in perfusion can result in fetal growth restriction, reduced amniotic fluid volume, and an inability to tolerate the in utero environment. Abruptio placentae also may occur. This complication is more common in pregnancies complicated by severe preeclampsia, HELLP syndrome, and superimposed preeclampsia.[64]

Management Options

Prenatal

PREDICTION

Many clinical and laboratory parameters have been used to predict preeclampsia, with varying degrees of success. The ideal predictive test should be simple, noninvasive, rapid, inexpensive, easy to perform early in pregnancy, and reproducible, with high sensitivity and predictive value. No single screening test for preeclampsia is reliable and cost-effective.[65–67] The "rollover" test was introduced more than 20 years ago to predict the development of preeclampsia as early as 28 to 32 weeks, but it did not have high specificity.[68] Increased vascular reactivity to intravenous infusion of angiotensin II, as shown by an increased pressure response, is predictive as early as 26 weeks' gestation.[33,69] In the 1980s, high plasma cellular fibronectin levels showed promise, but the test has not developed into a useful clinical tool.[70–72] Increased platelet angiotensin II receptors,[73] increased platelet intracellular calcium levels when exposed to arginine vasopressin,[74] decreased urinary calcium excretion,[75] higher fasting insulin levels,[76] increased mean arterial pressure early in pregnancy,[77] positive isometric exercise testing,[78] microalbuminuria, decreased platelet count, elevated hematocrit,[79–81] high second-trimester plasma homocysteine concentrations,[82] and low maternal serum pregnancy-associated plasma protein A (PAPP-A) or β human chorionic gonadotropin (βhCG)[83] have been used to predict preeclampsia. Increased serum uric acid level[84] is one of the most commonly used tests, but has a positive predictive value of only 33%.[85] Campbell and associates[86] reported that Doppler velocimetry of the uterine and umbilical vessels can predict preeclampsia as early as 18 weeks. Patients with preeclampsia had a characteristic notching of the diastolic waveform, suggesting increased peripheral vascular resistance. Doppler may be useful to monitor the course of hypertensive disorders of pregnancy and the treatment effect, but is not useful for screening pregnant women at low risk.[65,87] None of these predictive tests is used in clinical practice, primarily because they do not meet the criteria for a good predictor.

PREVENTION

The lack of understanding of the underlying pathophysiology of preeclampsia impeded attempts at prevention. Several empiric approaches have been studied, with varying degrees of success. These include dietary supplementation, antioxidants, diuretics, antihypertensives, and low-dose aspirin.

Manipulations of sodium, magnesium, and calcium intake have received interest. However, prospective trials have not produced consistent results. Supplementation with calcium, the best studied cation, shows the most promise. Epidemiologic data show an inverse relationship between calcium intake and eclampsia.[88] Animal and human data suggest that calcium supplementation can significantly reduce blood pressure. Studies in pregnant women are limited, but suggest that calcium can lower blood pressure and reduce the incidence of preeclampsia.[89] A meta-analysis of several small trials of calcium supplementation showed a significant reduction in the incidence of preeclampsia.[90] Calcium supplementation given in pregnancy to high-risk nulliparas (angiotensin II-sensitive patients) reduced the incidence of pregnancy-induced hypertension in a double-blind trial.[91] However, calcium did not prevent preeclampsia in healthy nulliparas in a prospective study of 4589 patients.[92] Additional data and reliable predictive tests are needed before calcium can be recommended to prevent preeclampsia in a high-risk population.

Recently, antioxidant therapy with vitamin C 1000 mg/day and vitamin E 400 mg/day showed promise in preventing preeclampsia.[93] These results need confirmation in larger randomized trials. Prophylactic administration of diuretics or antihypertensives did not prevent preeclampsia.[94] However, one report showed a decreased incidence of proteinuria in hypertensive gravidas treated with atenolol.[95] This preliminary finding requires additional study. A meta-analysis of randomized studies of antihypertensives given to women with chronic hypertension showed no effect on the incidence of superimposed preeclampsia.[96]

Aspirin inhibits the enzyme cyclooxygenase, which is essential for the synthesis of prostaglandins, such as thromboxane A_2 and prostacyclin.[97] Low-dose aspirin (60–80 mg/day) selectively inhibits platelet thromboxane A_2 release, but does not affect endothelial cell production of prostacyclin. On this basis, recent clinical trials focused on low-dose aspirin as a preventive agent.

Several large randomized multicenter clinical trials evaluated the safety and effectiveness of low-dose aspirin in preventing preeclampsia. The National Institute of

Health sponsored the Maternal-Fetal Medicine Network study of 2985 healthy, normotensive, nulliparous women who were randomized to receive aspirin versus placebo at 13 to 26 weeks' gestation.[98] The results showed a decreased incidence of preeclampsia in nulliparous patients (by 26%), no decrease in perinatal morbidity, and an increased risk of abruptio placentae. The authors recommended against the routine use of low-dose aspirin in healthy nulliparous women. In a recent study, the same group concluded that aspirin therapy did not reduce the incidence of preeclampsia in high-risk women.[99] The CLASP study included 9364 patients in 213 centers located in 16 countries, including patients at risk for preeclampsia.[100] The findings did not support the routine prophylactic or therapeutic use of low-dose aspirin to all women at increased risk for preeclampsia. The current literature does not support the routine use of low-dose aspirin to prevent preeclampsia. However, a recent randomized double-blind placebo-controlled trial showed some benefit of low-dose aspirin in reducing the incidence of preeclampsia in women with bilateral uterine artery notching.[101]

DIAGNOSIS

Signs.

BLOOD PRESSURE. High blood pressure is the hallmark of gestational hypertension. Blood pressure is taken with the patient in an upright position, after a 10-minute rest period. A mercury sphygmomanometer is preferred.[3] Sibai[4] suggested that blood pressure should be taken in a sitting position in ambulatory patients and in a semireclining position in hospitalized patients. The right arm should be used for the measurement, and the arm should be placed in a horizontal position at heart level. The increase in blood pressure reflects the arteriolar vasospasm that is basic to preeclampsia.

PROTEINURIA. In early preeclampsia, proteinuria is minimal. Proteinuria develops as the disease progresses and usually occurs after the development of hypertension and weight gain.[102,103] However, proteinuria accompanied by hypertension is the most reliable indicator of fetal morbidity and mortality.[104] Urine protein levels are affected by several factors and fluctuate in the same patient from hour to hour.[4] Therefore, a semiquantitative assay is unreliable, and a definitive diagnosis of proteinuria depends on the total amount of protein excreted in a 24-hour urine collection period.

EDEMA. Edema is an early, nonspecific sign of preeclampsia. Rapid weight gain of 5 pounds or more in 1 week is considered a warning sign.[18] However, edema occurs in 35% of normotensive patients.[105] Chesley[106] reviewed the literature and concluded that most women with rapid weight gain do not have preeclampsia and that preeclampsia occurs in the absence of this finding. Moreover, in one series, rapid weight gain of 5 pounds or more in 1 week occurred in only 10% of patients with eclampsia.[106] Therefore, only generalized edema that

involves the body and face after 12 hours of bed rest is considered clearly abnormal.[18] Some investigators preclude edema as a prerequisite for the diagnosis of preeclampsia.[4]

DEEP TENDON REFLEXES. Hyper-reflexia is not considered a sign of preeclampsia or eclampsia. Although normal women may have hyper-reflexia and eclamptic seizures can occur in the absence of hyper-reflexia,[107] it is a common clinical impression that increased reflexes and clonus are signs of imminent eclampsia.

RETINAL CHANGES. Spasm of the retinal arterioles is the physical finding that correlates best with the renal biopsy changes associated with preeclampsia.[108] It occurred in 85% of patients reported by Pollak and Nettles.[108] Segmental arteriolar spasm or generalized narrowing is usually seen.

Symptoms.

CEREBRAL. Headache, dizziness, tinnitus, drowsiness, and altered consciousness are common in severe preeclampsia and almost invariably precede an eclamptic convulsion. These symptoms indicate poor cerebral perfusion.

VISUAL. Symptoms may include blurred vision, diplopia, scotomata, blindness as a result of retinal arterial spasm, edema, and retinal detachment. The pathophysiology of these symptoms can also be vasospasm, ischemia, and hemorrhage in the occipital cortex.[56]

GASTROINTESTINAL. Nausea, vomiting, and epigastric or right upper quadrant pain and hematemesis are caused by distention of Glisson's capsule by edema and hemorrhage. These are symptoms of severe preeclampsia and can precede hepatic rupture and convulsions.

RENAL. Oliguria, anuria, and hematuria are symptoms of severe preeclampsia that may be caused by renal artery vasospasm.

Laboratory Findings and Clinical Tests.

RENAL FUNCTION. Creatinine clearance is used to detect changes in glomerular filtration. Creatinine clearance decreases as the severity of preeclampsia increases. The serum uric acid concentration also predicts preeclampsia and perinatal outcome.[109] Serum creatinine concentration and blood urea nitrogen are also valuable tests to evaluate renal function.

LIVER FUNCTION. Serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and lactate dehydrogenase (LDH) levels are increased in severe gestational hypertension and HELLP syndrome.[110,111] Elevated liver function test results may also indicate subcapsular hematoma and imminent liver rupture.

HEMATOLOGIC FINDINGS AND HEMOSTASIS. As the severity of gestational hypertension increases, hemoconcentration and hypoalbuminemia develop. The serum fibrinogen level, prothrombin time, and partial thromboplastin time are usually normal. Fibrinogen degradation products are increased, and thrombin time is usually prolonged. Thrombocytopenia is another sign of severe

preeclampsia.[18] A decreased platelet count (<100,000/mm³) is also part of HELLP syndrome.[110] Intravascular hemolysis is another feature of HELLP syndrome and is detected by evaluation of the peripheral smear and by elevated bilirubin, SGOT, and LDH levels.

ROLLOVER TEST. A positive rollover test result is defined as an increase in diastolic blood pressure of 20 mm Hg or more when measured 5 minutes after a gravida is "rolled" from the lateral to the supine position between 28 and 32 weeks' gestation.[68] Gant found that 93% of primigravid women with a positive rollover test result later had gestational hypertension and 91% of women who had a negative test result did not have hypertension during that pregnancy.[68] However, the value of this test as a clinical screening tool is debatable. In a study by Phelan and colleagues,[112] the rollover test predicted gestational hypertension in 78% of patients who subsequently had the disease, but the false-positive rate was 60%. Andersen[113] studied 191 patients and concluded that the test is not sufficiently reliable, sensitive, or specific for clinical use as a screening test.

ANGIOTENSIN II TEST. A normal pregnant patient requires mean angiotensin II doses of 13.5 to 14.9 ng/kg/minute to increase diastolic blood pressure by 20 mm Hg. Ninety-one percent of women who require more than 8 ng/kg/minute to achieve this blood pressure elevation remained normotensive throughout pregnancy.[38] Conversely, normotensive primigravidae who later had gestational hypertension responded at doses of less than 8 ng/kg/minute as early as 28 to 32 weeks' gestation. Ninety percent of these patients later had overt gestational hypertension.[38]

DIFFERENTIAL DIAGNOSIS

Patients with preeclampsia, liver involvement, and epigastric or right upper quadrant abdominal pain can be misdiagnosed. Alternative diagnoses include hepatitis, gallbladder disease, peptic ulcer, gastroenteritis, pyelonephritis, nephrolithiasis, Reye's syndrome, acute fatty liver of pregnancy (AFLP), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS).

TTP is an uncommon entity characterized by fever, neurologic and renal abnormalities, thrombocytopenia, and hemolytic anemia.[114] The patient may have abnormal bleeding from mucous membranes, headache, visual disturbances, seizures, syncope, paresis, altered consciousness, other neurologic symptoms, jaundice, and fever.[114] The peripheral blood smear indicates microangiopathic hemolysis that includes anemia, with fragmented erythrocytes, reticulocytosis, and thrombocytopenia. These changes lead to elevation of indirect serum bilirubin and LDH levels as well as slight elevation of serum blood urea nitrogen and creatinine concentrations. Differentiating between TTP in pregnancy and the postpartum period and preeclampsia or eclampsia is difficult. Some investigators suggest that every case

should be treated as preeclampsia unless the diagnosis of TTP was made before pregnancy or there is no evidence of pregnancy-induced hypertension.[115] New treatment modalities for TTP that include plasmapheresis or plasma infusion can be given during pregnancy and the postpartum period when the diagnosis of TTP is secure.[116] When the differential diagnosis between TTP and severe preeclampsia or eclampsia is difficult, it is reasonable to use both plasmapheresis and standard preeclampsia treatment. However, with available data, this approach cannot be recommended with certainty.

Microangiopathic hemolysis, thrombocytopenia, renal failure, and altered consciousness and seizures are also hallmarks of HUS (see also Chapters 41 and 80). However, these patients usually have a history of viral or bacterial gastrointestinal infection. Renal failure occurs early in the course of disease and is usually severe, whereas thrombocytopenia and bleeding are less severe than in TTP. The neurologic symptoms are less remarkable and usually correlate with the severity of renal failure and hypertensive encephalopathy. HUS is more common in children, although cases during pregnancy and postpartum are reported.[117] Finally, because HUS is being treated with plasma exchange, in the same way as TTP, the absolute diagnosis is less important and the same considerations should be applied in pregnancy and the postpartum period.[118]

AFLP (see Chapter 48) is an uncommon, potentially fatal disorder that may complicate the third trimester.[119] If it is unrecognized or untreated, AFLP may progress to fulminant hepatic failure, with jaundice, encephalopathy, disseminated intravascular coagulation, uncontrollable gastrointestinal and uterine bleeding, and death.[120] Early recognition of the disorder, rapid termination of pregnancy once the diagnosis was made, and intensive supportive treatment decreased fetal and maternal mortality rates considerably.[120] The differentiation of gestational hypertension with liver involvement from AFLP is difficult and sometimes impossible, and some investigators wonder whether these conditions are variants of the same disease.

Both conditions occur in primigravidae, mostly in the third trimester. They are common in twin gestations, improve with delivery, and include liver involvement, with elevated serum transaminase levels, low platelet counts, coagulopathy, hyperuricemia, hypoglycemia, and low antithrombin III levels. The elevated blood pressure and proteinuria that characterize preeclampsia may be present in patients with AFLP, and the liver histology is similar in some patients.[121,122] The management of severe preeclampsia with liver involvement is similar to the management of AFLP, making the differentiation between the two less important. Both conditions require prompt delivery and maternal supportive care.[119]

Acute cholecystitis, choledocholithiasis, and cholangitis may occur in pregnancy, leading to right upper quadrant pain, but are not associated with hepatic failure, coagulopathy, or other signs and symptoms of gestational

hypertension. Ultrasonography of the right upper quadrant detects gallstones and a dilated bile duct.

Viral hepatitis[123] is the most common cause of hepatic dysfunction in pregnancy,[124] but is not usually associated with liver failure, disseminated intravascular coagulation, or hypertension and proteinuria. Acute hepatitis can be diagnosed by serologic tests. Fulminant viral hepatitis, which can cause hypoglycemia, disseminated intravascular coagulation,[125] and encephalopathy, may be difficult to distinguish from severe preeclampsia and AFLP.[123] Peak levels of SGOT and SGPT vary from 400 to 4000 IU; much lower levels are seen in pregnancy-induced hypertension.[126] The absence of thrombocytopenia and hyperuricemia, which coexist with pregnancy-induced hypertension, can also help with the differential diagnosis. Drug-induced hepatitis is usually identified from the clinical history. Drugs that are associated with hepatitis include halothane, diphenylhydantoin, α-methyldopa, isoniazid, and chlorothiazide. Tetracycline can also cause fatty liver syndrome.[127]

Reye's syndrome also causes fatty liver and hepatic encephalopathy, but it usually occurs in children. Twelve cases were reported in adults.[128] These patients had hypouricemia, and their hepatic histologic features differed from those in patients with gestational hypertension.[128]

Patients with peptic ulcer disease, gastroenteritis, pyelonephritis, and nephrolithiasis may have epigastric or abdominal pain, but the absence of other signs of gestational hypertension should help with the differential diagnosis.

Management Options

The goals of therapy are the following:

- Prevent convulsions
- Prevent complications, such as cerebrovascular hemorrhage, pulmonary edema, renal failure, abruptio placentae, and fetal death
- Deliver a surviving child with minimal trauma to the mother

Prenatal

Management of the patient with mild gestational hypertension is shown in Table 36–4. Induction of labor is reserved for patients who have reached 37 weeks' gestation when the fetus is mature and the cervical condition is favorable.[18] If the cervix is unfavorable, results of fetal evaluation are normal, and maternal blood pressure is stable, the patient may be followed beyond 37 weeks. For an immature fetus, watchful observation may be indicated until fetal maturity is documented and the cervix is favorable. If observation is indicated for pregnancy-induced hypertension, several parameters should be evaluated because their deterioration may be an indication

for delivery (Table 36–5). No randomized controlled trials have shown the best test for fetal evaluation.

Several antihypertensive drugs are used to treat the preterm patient with mild preeclampsia in an attempt to prolong the pregnancy and improve neonatal outcome. These include β-blockers, including β_1-selective and nonselective agents; α_1-antagonists, α_2-agonists; calcium channel blockers; vasodilators; and diuretics.[4] The use of

TABLE 36–5

Parameters That Indicate Delivery in a Patient with Gestational Hypertension

PARAMETER	INDICATION FOR DELIVERY
Maternal	
Blood pressure	≥160/110 mm Hg
Platelet count	<100,000 mm³
Serum fibrinogen	<150 mg/dL
Serum glutamic-oxaloacetic transaminase, Serum glutamic pyruvic transaminase	Any elevation
Blood urea nitrogen	≥30 mg/dL
Creatinine	≥1.2 mg/dL
Creatinine clearance	<50 mL/min
Fetal	
Nonstress test, oxytocin challenge test, BPP (weekly or twice weekly for suspected intrauterine growth restriction or oligohydramnios)	Nonreactive nonstress test with positive oxytocin challenge test or abnormal BPP
Ultrasonic biometry (every 3 wks)	Severe intrauterine growth restriction

BPP, biophysical profile.

these drugs for the preterm patient with mild preeclampsia is controversial. However, studies of perinatal outcome in hospitalized patients with or without treatment show no advantage of long-term antihypertensive therapy in preeclampsia.[129]

Hospitalization is often initially recommended for women with new-onset preeclampsia. After the initial assessment, subsequent management of mild gestational hypertension or preeclampsia remote from term may be continued in an outpatient setting or at home. If this management is selected, it should include frequent maternal and fetal evaluation and access to health care providers. Admission to an outpatient unit instead of hospitalization for nonproteinuric hypertension reduces the time spent in the hospital and the proportion of women with induced labor.[130] If the patient's condition worsens, hospitalization is indicated. Management of the patient with severe gestational hypertension is best accomplished in a tertiary care setting (Table 36–6). Controversy surrounds the treatment of the patient with severe gestational hypertension when the fetus is immature but is not growth-restricted or in jeopardy. Some institutions follow the mother and fetus conservatively until maturity is achieved or maternal or fetal jeopardy develops. However, the perinatal and maternal outcome of these pregnancies is extremely poor.[131,132] Jenkins and associates[133] retrospectively reviewed maternal and neonatal outcome in patients with severe preeclampsia before 25 weeks' gestation. They concluded that delivery was associated with minimal short-term maternal morbidity, although the rates of neonatal morbidity and death were appreciable (only 10% survival, all with severe handicaps).

Labor and Delivery

FLUID THERAPY

During labor, patients with preeclampsia should remain in the left lateral position, with continuous electronic fetal heart rate monitoring. After rupture of the membranes, a scalp electrode and an internal uterine pressure catheter should be placed. Intravenous fluids, consisting of a balanced salt solution, should be infused at a rate of 75 to 125 mL/hour. Strict attention should be paid to urine output, and a Foley catheter may be needed, especially if preeclampsia is severe.

Oliguria is defined as less than 0.5 mL/kg/hour over 2 consecutive hours. Oliguria is usually treated by prompt delivery. Under controlled conditions, a bolus of 500 to 1000 mL balanced salt solution can be administered. Careful attention is given to symptoms and signs of pulmonary edema. It may be necessary to follow blood oxygen saturation with a pulse oximeter when a fluid challenge is initiated without invasive monitoring to predict and prevent incipient pulmonary edema.

A fluid bolus of 1000 mL should be given at the time of vasodilator therapy. This results in a smoother and more gradual reduction in blood pressure and prevents the abrupt and profound drops in blood pressure that may be seen with vasodilator therapy in hypovolemic patients.[134] If a marked intake–output imbalance is noted, restriction of fluids to 50 mL/hour is advisable.

PREVENTION OF CONVULSIONS WITH MAGNESIUM SULFATE

Magnesium sulfate is considered the standard agent for the prevention and treatment of eclamptic convulsions in North America. The American College of Obstetricians and Gynecologists recommends the use of magnesium sulfate in every woman with a diagnosis of preeclampsia or eclampsia during labor and the postpartum period.[18] Although there is no unanimity of opinion on the prophylactic use of magnesium sulfate to prevent seizures in women with mild preeclampsia or gestational hypertension, a significant body of evidence attests to its efficacy in severe preeclampsia and eclampsia.[135–138] Two accepted regimens for parenteral magnesium sulfate therapy are shown in Table 36–7. Magnesium sulfate has a dual action. It interferes with transmission at the neuromuscular junction and also affects the central nervous system. Magnesium sulfate had central anticonvulsant

TABLE 36–6

Management of Severe Preeclampsia

MATURE FETUS OR IMMATURE FETUS WITH GROWTH RETARDATION OR FETAL JEOPARDY

Definitive Management
Prevent convulsions (magnesium sulfate)
Control blood pressure (hydralazine)
Deliver by vaginal or cesarean birth, depending on fetal and maternal conditions

---

TABLE 36–7

Prevention and Treatment of Convulsions with Magnesium Sulfate

Pritchard Protocol
Loading Dose
Give 4 g (20 mL of 20%) IV over 4 minutes (only in severe preeclampsia or eclampsia), immediately followed by 10 g (20 mL of 50%) IM, 5 g in each buttock
If convulsions persist after 15 minutes, give 2 g (10 mL of 20%) IV over 2 minutes (if the woman is large, give 4 g)
Maintenance
Give 5 g (10 mL of 50%) IM every 4 hours, on alternate sides

Sibai Protocol
Loading Dose
Give 6 g IV over 20 minutes
Maintenance
Give 2–3 g/hr IV
At the time of convulsion, give 2 to 4 g by IV bolus over 5 minutes
If convulsion recurs, give amobarbital sodium 250 mg IV over 3 minutes
As a last measure, give a paralyzing agent and perform intubation

activity in an animal model, inhibiting the N-methyl-D-aspartate receptor in the brain.[139–142] These objective data and a vast amount of clinical experience support the use of magnesium sulfate for seizure prophylaxis.

The hypotensive effect of magnesium sulfate is transient and related to bolus administration and rapid infusion.[143] Continuous infusion does not maintain hypotension, and the dosages used for gestational hypertension do not depress myocardial work. Therefore, they do not usually contribute to myocardial compromise.[143–145]

To continue magnesium sulfate treatment, the patient should have a patellar reflex, urine flow greater than 30 mL/hour, respiratory rate greater than 12 beats/minute, and magnesium blood levels of 4 to 8 mg/dL, if obtained.[18] Table 36–8 shows the relationship between blood levels of magnesium sulfate and symptoms and signs. Magnesium toxicity can be reversed by slow intravenous administration of 10% calcium gluconate and nasal administration of oxygen. If toxicity is not reversed, respirations must be supported until plasma magnesium levels decrease.

Alternative anticonvulsant drugs have been recommended. Recently, phenytoin was mentioned as the drug of choice, but its safety and efficacy in eclampsia are not proven.[144] In the United States, magnesium sulfate is the standard drug used to treat and prevent eclamptic convulsions.

CONTROL OF HYPERTENSION

Careful control of hypertension must be achieved to prevent complications, such as maternal cerebrovascular accidents and placental abruption. Although no large randomized clinical trials compared treatment with placebo, antihypertensive therapy is usually recommended when systolic blood pressure exceeds 180 mm Hg or diastolic blood pressure exceeds 110 mm Hg.[6,19,145,146] A recent meta-analysis investigated the benefits of oral antihypertensives for mild to moderate gestational hypertension and concluded that treatment-induced decreases in maternal blood pressure may adversely affect fetal growth. Therefore, this treatment should be used cautiously.[147] Although many antihypertensive agents are available, this discussion focuses on the agents that are most commonly used to treat acute hypertensive crises in pregnancy. Hydralazine is the most widely accepted drug to treat hypertension in severe preeclampsia.[18] A method

of administration is shown in Table 36–9.[148] Hydralazine increases heart rate and cardiac output and decreases mean arterial pressure and systemic vascular resistance.[134] Hydralazine carries the risk of a potentially harmful effect on the fetoplacental unit in the face of hypovolemia. It causes abrupt, profound decreases in blood pressure unless a fluid bolus is administered concomitantly.[139] Hypertension refractory to hydralazine therapy warrants central hemodynamic monitoring and the use of more potent antihypertensive agents.[149,150]

Labetalol is a combined α- and β-adrenoreceptor antagonist that may be used to induce a controlled, rapid decrease in blood pressure through decreased systemic vascular resistance in patients with severe hypertension. Reports on the efficacy and safety of labetalol in the treatment of hypertension during pregnancy are favorable.[151–154] Mabie and colleagues[152] compared bolus intravenous labetalol with intravenous hydralazine in the acute treatment of severe hypertension and found that labetalol had a more rapid onset of action and did not result in reflex tachycardia. Labetalol may exert a positive effect on early fetal lung maturation in patients with severe hypertension who are remote from term.[151] Lunell and associates[153] studied the effects of labetalol on uteroplacental perfusion in pregnant women with hypertension and noted increased uteroplacental perfusion and decreased uterine vascular resistance.

Labetalol can be administered parenterally by repeated intravenous injection or slow continuous infusion. An initial dose of 20 mg is administered, followed by additional doses of 40 or 80 mg at 10-minute intervals, until the desired effect is achieved or a total of 220 mg has been given. If a continuous infusion is used, labetalol is initiated at a dose of 2 mg/minute. Maximum effect is seen approximately 5 minutes after intravenous administration. Oral dosage of labetalol begins at 100 mg twice daily and can be increased to a maximum of 2400 mg/day.

Sodium nitroprusside is another potent antihypertensive agent that may be used to control severe hypertension. A dilute solution may be started at 0.25 mg/kg/minute and titrated to the desired effect by increasing the dose by 0.25 mg/kg/minute every 5 minutes. The solution is light-sensitive and should be covered in foil and changed every 24 hours. Arterial blood gases should be monitored to watch for developing metabolic acidosis, which may be an early sign of cyanide toxicity. Treatment

TABLE 36–8

Magnesium Sulfate Blood Levels

BLOOD LEVELS	SYMPTOMS AND SIGNS
4–8 mg/dL	Therapeutic
9–12 mg/dL	Nausea, warmth, flushing, somnolence, double vision, slurred speech, weakness, loss of patellar reflexes
15–17 mg/dL	Muscular paralysis and respiratory arrest
30–35 mg/dL	Cardiac arrest

TABLE 36–9

Control of Blood Pressure with Hydralazine

Give hydralazine intermittently as a bolus to patients with diastolic blood pressure greater than 110 mm Hg

Give 5 to 10 mg as an intravenous bolus with dosage intervals no less than every 20 minutes until blood pressure is controlled

Monitor blood pressure every 2 to 5 minutes

The goal of therapy is to decrease diastolic blood pressure to 90 to 100 mm Hg

time should be limited because of the potential for fetal cyanide toxicity.[155] Hypovolemia must be corrected before the initiation of nitroprusside infusion to avoid abrupt and often profound decreases in blood pressure.

Nifedipine is administered at an initial oral dose of 10 mg, which may be repeated after 30 minutes, if necessary, for the acute management of severe hypertension; then 10 to 20 mg may be administered orally every 6 to 8 hours, as needed. Care must be taken when nifedipine is administered to patients who are receiving concomitant magnesium sulfate because an exaggerated hypotensive response may occur.[156] Nifedipine appears safe for the treatment of hypertensive crisis in pregnancy, but further controlled clinical trials are needed before the drug is accepted for general clinical use.

Nitroglycerin relaxes predominantly venous, but also arterial, vascular smooth muscle. It decreases preload at low doses and afterload in high doses. It is a rapidly acting, potent antihypertensive agent with a very short hemodynamic half-life. Using invasive hemodynamic monitoring, Cotton and associates[150] noted that the ability to control blood pressure precisely was dependent on volume status. Nitroglycerin is administered through an infusion pump at an initial rate of 10 mg/minute and titrated to the desired pressure by doubling the dose every 5 minutes. Methemoglobinemia may result from high-dose (>7 mg/kg/minute) intravenous infusion. Patients with normal arterial oxygen saturation who appear cyanotic should be evaluated for toxicity, which is defined as a methemoglobin level greater than 3%.[157]

MODE OF DELIVERY

A patient with preeclampsia at term whose intake and output are balanced and whose blood pressure is controlled should have a trial of vaginal delivery. No randomized clinical trials have evaluated the optimal method of delivery for women with severe preeclampsia or eclampsia. Cesarean section is reserved for cases in which the maternal and fetal conditions are adverse and deteriorating and for patients with preterm gestation and an unripe cervix. Nevertheless, in retrospective studies comparing induction of labor with cesarean delivery in women with severe preeclampsia remote from term, induction was a reasonable alternative.[158,159] Therefore, the decision to perform cesarean delivery should be individualized. If cesarean delivery is performed, the clinician should inspect and gently palpate the liver, especially if liver enzyme abnormalities are present, to exclude liver hematoma.[51] Regional anesthesia is the preferred technique for both labor and delivery in women with severe preeclampsia or eclampsia.[19] It provides superior pain relief compared with intravenous analgesia but apparently no additional therapeutic benefits.[160] General anesthesia carries more risk to pregnant women than does regional anesthesia.[161] However, regional anesthesia is generally contraindicated in the

presence of coagulopathy. If general endotracheal anesthesia is used, then antihypertensive therapy should be used before intubation to prevent further increases in blood pressure during intubation. Agents used by anesthesiologists include hydralazine, nitroprusside, nitroglycerin, trimethaphan, fentanyl-droperidol, and labetalol.[143,162–165]

CONTROVERSIES IN THE MANAGEMENT OF SEVERE PREECLAMPSIA

Role of Invasive Monitoring. The American College of Obstetricians and Gynecologists[166] does not list severe preeclampsia or eclampsia as an indication for pulmonary artery catheterization. Others recommend invasive monitoring in patients with severe preeclampsia because of associated hypovolemia.[167] No prospective studies validated the use of invasive monitoring in severe pregnancy-induced hypertension. Invasive hemodynamic monitoring may be helpful in patients with pulmonary edema of uncertain etiology,[166] oliguria that is unresponsive to initial fluid challenge,[166] hypertension that is refractory to hydralazine, and other medical indications for hemodynamic monitoring.[166] The range of values obtained from invasive hemodynamic monitoring studies in normal nonpregnant patients, normal pregnant patients, and patients with pregnancy-induced hypertension are listed in Table 36–3.[25,26] There are several clinical recommendations for treatment in invasively monitored patients. They include maintaining pulmonary capillary wedge pressure between 10 and 15 mm Hg with discrete fluid challenges, vasodilators, or diuretics; treating oliguria on the basis of the patient's hemodynamic findings[168]; restricting fluids to 75 to 125 mL/hour and treating hypovolemia with 500- to 1000-mL boluses; and correcting colloid osmotic pressure only when the patient has a prolonged negative colloid osmotic pressure–pulmonary capillary wedge pressure gradient or a colloid osmotic pressure of 12 mm Hg or less.[169]

Conduction Anesthesia. The use of conduction anesthesia in preeclampsia is controversial. Decreases in blood pressure that lead to late decelerations in fetal heart rate can occur if volume contraction is not corrected before epidural placement.[102,170,171] Patients with gestational hypertension and associated hypovolemia are even more susceptible to hypotension during epidural anesthesia. Moore and associates[172] studied the safety of epidural anesthesia in patients with pregnancy-induced hypertension. They compared fetal and maternal outcomes in 285 patients with gestational hypertension delivered with epidural, general, or local anesthesia and found that continuous lumbar epidural anesthesia was safe and effective for patients with pregnancy-induced hypertension and also for their fetuses. Epidural anesthesia avoids the dramatic increase in blood pressure and central pressures seen with general anesthesia.[173] If volume loading is used, fetal well-being is evident, and the maternal coagulation profile is normal, in many studies, conduction anesthesia appears to be safe and efficacious.[172,174,175]

Postnatal

Magnesium sulfate should be continued postpartum for 24 hours while the patient is closely observed in the recovery area. Close monitoring and treatment with magnesium sulfate may continue beyond 24 hours postpartum in the patient with severe preeclampsia who is not improving or the patient with HELLP syndrome who continues to deteriorate. Efforts should be made to prevent pulmonary edema as a result of fluid shifts in patients with impaired renal function. If central hemodynamic monitoring was used intrapartum, it is continued until diuresis occurs.

If blood pressure remains greater than 150/100 mm Hg 2 to 3 days postpartum, oral antihypertensive therapy is usually initiated. Calcium channel blockers are most commonly used; however, α-methyldopa, hydralazine, or β-blockers may also be considered. Blood pressure is monitored one to two times per week. If hypertension persists beyond 6 weeks postpartum, the patient is classified as having chronic hypertension[18] and referred to a specialist.

HELLP SYNDROME

General

HELLP syndrome is considered a complication of severe preeclampsia and eclampsia. Weinstein,[111,176] who gave the syndrome its current name, specified that it should be considered an additional independent criterion for severe preeclampsia. The incidence of HELLP syndrome was 9.7% among 1153 pregnancies complicated by preeclampsia or eclampsia.[110] Martin and associates[177] reported an overall recurrence risk of 25% among 94 liveborn infants.

In another study, HELLP syndrome occurred in approximately 20% of women with severe preeclampsia.[178] HELLP syndrome develops antepartum in 70% of patients and after delivery in the rest.[4] As with severe preeclampsia, HELLP syndrome is associated with an increased risk of many adverse outcomes, including placental abruption, renal failure, preterm delivery, and maternal or infant death.[178,182]

The diagnosis of HELLP syndrome is based on laboratory findings and includes the following:

- Hemolysis. Microangiopathic hemolytic anemia is characterized by burr cells, schistocytes, and polychromasia on the peripheral smear. An increased bilirubin level, most of it indirect (>1.2 mg/dL), and an increased LDH level (>600 IU/L) confirm the diagnosis.
- Elevated liver enzyme levels. Levels of SGOT, SGPT, and LDH are increased. Right upper quadrant pain may be associated with hepatic cell damage, which also

causes an elevation in liver enzymes. The hepatic lesion is parenchymal necrosis, in which deposits of fibrin-like material are seen in the sinusoids. In severe parenchymal necrosis, bleeding can extend to the subcapsular region, leading to a hematoma that stretches Glisson's capsule and eventually may rupture.
- Low platelet count. The platelet count is less than 100,000/mm^3.

According to Weinstein[111] and Sibai and colleagues,[110] the signs and symptoms, by incidence, are as follows:

- Right upper quadrant or epigastric pain (86%–90%)
- Nausea or vomiting (45%–84%)
- Headache (50%)
- Right upper quadrant tenderness on palpation (86%)
- Diastolic blood pressure greater than 110 mm Hg (67%)
- Proteinuria greater than 2+ on dipstick (85%–96%)
- Edema (55%–67%)

Management Options

Management of the patient with HELLP syndrome includes the same principles of treatment as management of severe preeclampsia or eclampsia. The first step is assessing and correcting maternal coagulation abnormalities. Platelets should be transfused when the platelet count is less than 20,000/mm^3, and blood products should be given if hypovolemia and coagulopathy must be corrected. Because of continued hemolysis in the postpartum period, packed red blood cell transfusions are often necessary.[111] Fetal status should be also evaluated. Maternal and fetal status should be considered to decide whether to pursue immediate delivery by cesarean section or attempt vaginal delivery. Patients who meet the criteria for HELLP syndrome should be delivered at any gestational age. Patients with overt HELLP syndrome and an immature fetus rarely benefit from steroid injections and delayed delivery. The patient should be monitored very closely before delivery with repeated clinical and laboratory studies. Conservative approaches to the treatment of gestational hypertension associated with HELLP syndrome have been reported.[111,183,184] These include plasma exchange transfusions and antithrombin III transfusions. Although reports are encouraging, this mode of treatment is considered experimental.

Expectant management before 32 weeks' gestation is undertaken only in tertiary care centers or as part of randomized clinical trials with appropriate safeguards and consent.[19]

The time between delivery and recovery was as long as 11 days in severely affected patients with HELLP syndrome.[185] These patients should be followed with repeated measurements of platelet count and LDH serum concentration, until the platelet count is increased

to more than 100,000/mm^3 and effective diuresis is achieved. Neiger and associates[186] found that most patients with preeclampsia and thrombocytopenia reached nadir levels 27 hours after delivery. The mean time required for the platelet count to return to greater than 100,000/mm^3 was 60 hours; recovery time was inversely related to the severity of thrombocytopenia.

ECLAMPSIA

General

Eclampsia is defined as the occurrence of convulsions, not caused by coincidental neurologic disease (e.g., epilepsy), in a woman whose condition meets the criteria for preeclampsia.[18] The incidence of eclampsia is approximately 1 in 1600 pregnancies.[4] Eclampsia is much more common as term approaches; approximately 50% of cases develop before delivery.[4,187] The remaining 50% of cases are divided equally between the intrapartum and postpartum periods.[4,187] When the first convulsion occurs more than 48 hours postpartum, other causes should be excluded.[102]

Clinical Course

The initial presentation of the patient with preeclampsia is similar to that of the patient with preeclampsia. Sibai[188] reported that only 40% of patients with eclampsia had severe hypertension, and 20% had systolic blood pressure less than 140 mm Hg or diastolic blood pressure less than 90 mm Hg. The presence of edema and proteinuria among patients with eclampsia is variable. The signs and symptoms of severe preeclampsia may precede convulsions; however, they are not necessary for the development of convulsions.[189] Laboratory findings in patients with eclampsia are similar to those in patients with preeclampsia of varying degrees of severity.

Differential Diagnosis

When convulsions occur during pregnancy, delivery, or the puerperium, the diagnosis of eclampsia is made until proven otherwise. Other conditions that can cause convulsions and coma should be considered. These include epilepsy, intracranial hemorrhage and thrombosis, rupture of a cerebral aneurysm, meningitis, encephalitis, cerebral tumors, and hyperventilation syndrome.[102]

Management Options

Definitive treatment of eclampsia includes the following:

- Controlling convulsions and preventing their recurrence with magnesium sulfate

- Providing ventilation and correcting hypoxia and acidosis
- Using hydralazine to control diastolic blood pressure to 90 to 100 mm Hg to prevent maternal cerebrovascular accidents and congestive heart failure
- Prompt delivery of the fetus and placenta

Sibai[4] recommends cesarean delivery for patients with an unripe cervix at less than 32 weeks' gestation because of the high incidence of intrapartum complications in these patients. Pritchard and colleagues[29] advocate delivery as soon as the convulsions are controlled and the patient is conscious, certainly within 48 hours of the onset of seizures. Some investigators advocate more conservative management attempts to achieve fetal lung maturity before delivery.[190] This approach, if confirmed to be safe, applies only to the rare patient with eclampsia. No specific contraindications to labor induction are associated with eclampsia. Indications for cesarean delivery are based on obstetric issues, if the patient's condition is not rapidly deteriorating. The rate of cesarean delivery in patients with eclampsia is 11% to 57%.[191]

Most women with severe preeclampsia can be managed without invasive hemodynamic monitoring. No randomized controlled trials support the routine use of pulmonary artery catheters, although this approach may benefit women with severe cardiac or renal disease, oliguria, or pulmonary edema.[6,192–194]

Prognosis

Severe preeclampsia and eclampsia are responsible for considerable maternal morbidity and mortality. Maternal morbidity includes severe bleeding from abruptio placentae, with resultant coagulopathy, pulmonary edema, aspiration pneumonia, acute renal failure, cerebrovascular hemorrhage, liver rupture, and retinal detachment. The maternal mortality rate is 2% to 4% in patients with HELLP syndrome and 10% in patients with pulmonary edema.[195] The maternal mortality rate associated with eclampsia is still 0.4% to 5.8%, even in institutions with much experience.[4,29,196] Transient hypertension only, without the development of preeclampsia, does not appear to alter maternal or fetal outcome and is of limited clinical significance.[197]

The recurrence rate of pregnancy-induced hypertension in future pregnancies and the chance of later development of chronic hypertension are unclear from the literature. Chesley[198] reviewed several of these reports and concluded that the incidence of recurrent eclampsia is 10.3% (range, 0%–21%) and the average chance of a hypertensive disorder in a subsequent pregnancy is 33%. The incidence of chronic hypertension is highly variable in different reports and ranged from 0% to 78%, with an average of 23.8%.

CHRONIC HYPERTENSION

General

Chronic hypertension is defined as persistent elevation in blood pressure of 140/90 mm Hg or greater before 20 weeks' gestation or persistent hypertension beyond 6 weeks postpartum. Because of the physiologic decrease in blood pressure that is seen in midpregnancy, patients with chronic hypertension may have pressures in the normotensive range for a good portion of pregnancy. This makes the diagnosis difficult in those with little prenatal care.

In chronic hypertension, elevated blood pressure is the cardinal pathophysiologic feature, whereas in preeclampsia, increased blood pressure is a sign of the underlying disorder. Thus, the effects of the two conditions on the mother and the fetus are different, and management differs as well.

The literature on chronic hypertension in pregnancy is clouded by inconsistencies in the criteria used to select study patients. Americans tend to use the definition given earlier, whereas Europeans and Australians tend to include patients with all forms of hypertension. Classification schemes also vary. In this chapter, patients with mild chronic hypertension include those with systolic blood pressure between 140 and 159 mm Hg and diastolic pressure between 90 and 109, whereas those with systolic blood pressure 160 mm Hg or greater or diastolic pressure 110 mm Hg or greater are classified as having severe chronic hypertension.

Depending on the population studied and the criteria used, the incidence of chronic hypertension in pregnancy is 0.5% to 3%. Essential hypertension is responsible for 90% of cases of chronic hypertension associated with pregnancy. Causes of secondary hypertension include renal disease (glomerulonephritis, nephropathy, renovascular disease), endocrinologic disorders (diabetes with

vascular involvement, thyrotoxicosis, pheochromocy-toma), and collagen vascular disease (systemic lupus ery-thematosus, scleroderma).

Maternal and Fetal Risks

Maternal and perinatal morbidity and mortality rates are not generally increased for patients with uncomplicated mild chronic hypertension. However, risks to the mother and fetus increase dramatically when the pregnancy is complicated by severe disease or superimposed preeclampsia. Other risk factors include maternal age older than 40 years, hypertension lasing longer than 15 years, blood pressure greater than 160/110 mm Hg early in pregnancy, diabetes classes B through F, renal disease, cardiomyopathy, connective tissue disease, and coarcta-tion of the aorta.[199]

Maternal risks include exacerbation of hypertension, superimposed preeclampsia, congestive heart failure, intracerebral hemorrhage, acute renal failure, abruptio placentae with disseminated intravascular coagulation (DIC), and death as a result of any of these. Of these, superimposed preeclampsia and abruptio placentae are the two most common complications. Superimposed preeclampsia complicates approximately 5% to 50% of pregnancies of women with chronic hypertension, depending on whether the diagnosis of preeclampsia was made simply on the basis of exacerbation of hypertension or if significant proteinuria was included. In patients with risk factors, the incidence of superimposed preeclampsia is 25% to 50%. The incidence of abruptio placentae is 0.5% to 2% in patients with mild, uncomplicated hyper-tension and 3% to 10% in those with severe hyperten-sion. The incidence of superimposed preeclampsia or abruption is not affected by antihypertensives.[199]

Fetal morbidity and mortality rates are directly related to the severity of hypertension. They are particularly high in patients with superimposed preeclampsia and abruptio placentae. Decreased uteroplacental per-fusion can lead to fetal growth restriction. Spontaneous or intentional interruption of pregnancy adds the com-pounding complications of prematurity. The risk of midtrimester death in utero is higher in patients with chronic hypertension, especially those who do not receive prenatal care. Perinatal complications are not increased in those with mild, uncomplicated hypertension.

Management Options

Prepregnancy

Women with severe hypertension who desire pregnancy should be encouraged to receive prepregnancy care. The cause and severity of chronic hypertension should be established, if possible. Antihypertensives with potential adverse effects on the fetus, such as angiotensin-converting enzyme inhibitors and diuretics, should be discontinued under strict physician supervision. At times, these medications are continued into pregnancy, despite

the potential fetal risk, because of difficulty controlling hypertension otherwise. Adequate time must be allowed preconceptionally to gauge the patient's response to new medications to control hypertension. Renal function should be assessed in more severe cases by measuring serum creatinine and performing 24-hour urine collec-tion to determine creatinine clearance and protein con-centrations. Once conception occurs, early prenatal care in an appropriate setting is important.

Prenatal

Early and frequent prenatal care is essential to optimize perinatal outcome in patients with hypertension. During the initial visits, a detailed evaluation of the etiology and severity of chronic hypertension should be made. Careful attention must be given to a history of cardiac or renal disease, diabetes, or thyroid disease and to the outcome of previous pregnancies. Baseline laboratory studies eval-uating organ systems that are likely to be affected include urinalysis and culture; measurement of electrolytes, uric acid, and blood sugar; and 24-hour urine collection to measure creatinine clearance and protein concentrations. Patients with severe hypertension or proteinuria in the first trimester should have a chest x-ray, electrocardio-gram, antinuclear antibody testing, and when indicated, serum complement studies. In those with severe, long-standing hypertension, an echocardiogram should be performed to evaluate cardiac function. Those with recurrent pregnancy loss or recent thromboembolic dis-ease should be evaluated for lupus anticoagulant and anticardiolipin antibodies.

Women who are at low risk (those with mild, chronic hypertension and none of the listed risk factors) should be seen every 2 to 4 weeks in the first two trimesters, and then weekly. Sibai and colleagues[200] recommend discon-tinuation of all antihypertensives at the first prenatal visit in low-risk women. Only half require subsequent med-ication; treatment of patients who need antihypertensives can be tailored to their individual needs. Fetal evaluation includes serial ultrasound examinations to document ade-quate fetal growth and weekly antepartum fetal testing, beginning at approximately 34 weeks' gestation. If there is no superimposed preeclampsia or if fetal well-being cannot be documented, routine induction of labor before 41 weeks' gestation probably is not warranted.

Pregnancy in women with hypertension and additional risk factors is associated with increased maternal and perinatal complications. These pregnancies should be managed in consultation with appropriate specialists (e.g., maternal–fetal medicine, nephrology). Very close monitoring is essential, and multiple hospitalizations may be necessary to control maternal hypertension and asso-ciated medical complications. Severe hypertension man-dates an aggressive pharmacologic approach. Carefully selected antihypertensives may benefit those with mild hypertension who have additional complicating factors, such as diabetes, renal disease, or cardiac dysfunction.

Intensive fetal surveillance is critical to optimize fetal outcome. Serial ultrasonography for fetal growth and weekly (or more frequent, depending on the fetal condition) antepartum fetal testing, beginning as early as 26 weeks, should be used. The pregnancy may be continued until term, until the onset of superimposed preeclampsia, or until fetal growth restriction or other signs of fetal decompensation occur. The development of severe, superimposed preeclampsia places the patient at highest risk for maternal and perinatal complications. This development after 28 weeks is an indication for delivery. Before 28 weeks, the pregnancy may be followed conservatively in a tertiary center with daily evaluation of the maternal and fetal condition, although this approach is controversial.[201]

Although the maternal and fetal benefits of antihypertensives are well documented in the treatment of pregnancies complicated by severe hypertension, the benefits of these drugs in pregnant patients with mild, uncomplicated hypertension is much less clear. There are no randomized trials of the treatment of severe hypertension. However, the general consensus is to start therapy when diastolic blood pressure reaches 110 mm Hg, to prevent cerebrovascular accident, the largest cause of maternal death in patients with hypertension. In the United States, methyldopa is the first-line agent because of the extensive experience with its use and the lack of known fetal effects. Labetalol, which was first popularized in European studies, is a reasonable second-line antihypertensive for use in these women.[200, 202]

The treatment of gravidas with mild to moderate chronic hypertension is more controversial. The many reports of antihypertensive use in this group of patients are difficult to evaluate because of differences in definitions, populations, and treatments. The trials are more limited by sample size, selection bias, and frequent initiation of therapy late in the second or third trimester. Nevertheless, a few generalizations can be made.[200,202] The use of methyldopa or labetalol in women with mild, uncomplicated hypertension does not significantly improve gestational age at delivery, birth weight, rates of intrauterine growth retardation, or the perinatal death rate over these measures in women who were untreated or received placebo. Trials comparing the efficacy of methyldopa with a β-blocker in mild hypertension showed few significant differences.[152,203,204] The use of these agents does not reduce the incidence of superimposed preeclampsia or abruptio placentae, the conditions responsible for most adverse perinatal outcomes in patients with mild, chronic hypertension.

Labor and Delivery

The goal of intrapartum management is to avoid acute maternal and fetal complications. Maternal blood pressure can be controlled with oral or intravenous hydralazine or labetalol (see). Judicious use of intravenous fluids and close attention to noninvasive hemodynamic parameters (e.g., blood pressure, pulse oximetry) are crucial. Fetuses may be compromised by long-standing growth restriction and hypoxemia before the onset of labor. Therefore, continuous electronic fetal monitoring and intermittent fetal scalp pH sampling, as needed, are important to assess the ability of the fetus to tolerate labor.

Postnatal

High risk patients with chronic hypertension should be monitored closely for at least 48 hours after delivery because they are at risk for hypertensive encephalopathy, pulmonary edema, and renal failure. Oral or intravenous hydralazine, methyldopa, labetalol, or calcium channel blockers can be used to control severe hypertension. Diuretic therapy is used in patients with evidence of circulatory congestion or pulmonary edema. These women must be evaluated after the postpartum period to detect deterioration in cardiac or renal function and to adjust antihypertensive medication.

After delivery, oral antihypertensives usually must be continued to control hypertension. Minute amounts of all antihypertensives are found in breast milk. Limited data suggest that there are no short-term effects on breastfeeding infants who are exposed to methyldopa, hydralazine, β-blockers, or calcium channel blockers.[205] However, thiazide diuretics inhibit adequate breast milk production.[206]

SUMMARY OF MANAGEMENT OPTIONS			
Chronic Hypertension			
Management Option	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Establish the cause and severity of hypertension	–	GPP	–
Evaluate renal function	–	GPP	–
In those with mild to moderate hypertension, stop medication or switch to medication with few fetal side effects	–	GPP	–

Chronic Hypertension *(Continued)*

Management Option	Quality of Evidence	Strength of Recommendation	References
Prepregnancy *(Continued)*			
In those with severe or difficult-to-control hypertension, medication may be needed despite the potential fetal risks	–	GPP	–
Encourage early prenatal care in an appropriate setting	–	GPP	–
Prenatal			
Early and frequent prenatal care	IV	C	230
Discontinue antihypertensive medication unless maternal diastolic pressure exceeds 100 to 110 mm Hg	Ia	A	212
Use oral medication in severe hypertension (methyldopa, hydralazine, calcium channel blockers) and in those with mild hypertension complicated by risk factors	Ia	A	224
Laboratory studies (where appropriate):	–	GPP	–
• 24-hr collection for creatinine clearance and protein			
• Uric acid			
• Platelet count and clotting studies			
• Electrolytes			
• Antinuclear and antiphospholipid antibodies and serum complement			
• Blood sugar			
Fetal surveillance with serial ultrasound for growth, umbilical artery Doppler, and biophysical profile testing:	IV	C	230
• Start at 26 weeks in women with severe hypertension or risk factors			
• Start later in women with mild, uncomplicated hypertension			
Maintain vigilance for superimposed preeclampsia	IV	C	230
Labor and Delivery			
Continuous electronic fetal monitoring	IV	C	230
Use antihypertensives to maintain blood pressure below 160/110 mm Hg	Ia	A	225
Monitor for potential complications (e.g., abruption, superimposed preeclampsia)	IV	C	230
Postnatal			
Monitor closely in the first 48 hours to anticipate hypertensive encephalopathy, pulmonary edema, or renal failure	IV	C	230
Use oral or intravenous medication to control hypertension	IV	C	230
Evaluate for deterioration in cardiac or renal status	IV	C	230
Most patients with hypertension are safe during lactation; avoid thiazide diuretics	IV	C	230

CONCLUSIONS

- Hypertensive disorders complicate approximately 12%–22% of all pregnancies.
- Established criteria are available to classify and differentiate preexisting hypertension, preeclampsia, and superimposed preeclampsia.
- Although the etiology of preeclampsia is undetermined, the maternal and fetal consequences of this condition have been thoroughly studied and documented.
- Preeclampsia cannot be accurately predicted. Prevention strategies are currently suboptimal.
- Management goals of preeclampsia focus on prevention of convulsions, minimization of adverse events, and, if possible, delivery of a surviving and intact child.
- The complications of HELLP syndrome and eclampsia generally require rapid stabilization of the mother and prompt delivery of the fetus.
- Complications and adverse events related to chronic hypertension in pregnancy can be minimized by careful blood pressure management, observation for evidence of superimposed preeclampsia, and diligent fetal surveillance.

Cardiac Disease

Mark W. Tomlinson

INTRODUCTION

Maternal and Fetal Risks

Serious maternal cardiac disease complicating pregnancy is relatively uncommon; however, it can have a significant adverse effect on maternal and fetal outcomes, despite modern cardiac care. The overall incidence of serious heart disease complicating pregnancy is approximately 1%.[1,2] With a decrease in maternal death as a result of the classic causes of hemorrhage, hypertension, and infection, the relative importance of cardiac disease increased.[1–3] During the last few decades, the etiology of heart disease changed from primarily rheumatic to predominately congenital.[1,2,4]

Despite the potential for significant maternal morbidity, in most patients with cardiac disease, a satisfactory outcome can be expected with careful antenatal, intrapartum, and postpartum management.[1,2,4,5] Serious complications during pregnancy and the postpartum period include congestive heart failure, arrhythmias, and stroke. In a series reported by Siu and associates,[5] of 221 women with either congenital or acquired conditions, 18% of patients had one of these complications. No maternal deaths occurred. The rate of complications was related to several factors, including maternal functional status, myocardial dysfunction, significant aortic or mitral valve stenosis, and history of arrhythmias or a cardiac event.

Although maternal mortality is uncommon, several conditions are associated with a high risk of maternal death. Table 37–1 shows the estimated qualitative risk of maternal mortality associated with various cardiac conditions. Contemporary literature quantifying the risk of maternal mortality is limited for a number of reasons. Most congenital lesions are diagnosed early, allowing appropriate surgical repair. The significant decrease in the incidence of rheumatic heart disease limits the number of patients with acquired lesions who are seen for the first time because of the physiologic

---

TABLE 37–1

Risk of Maternal Morbidity and Mortality Associated with Pregnancy

Low Risk

Atrial and ventricular septal defect previously repaired or without pulmonary hypertension
Pulmonic or tricuspid disease
Mitral valve prolapse
Patent ductus arteriosus
Corrected congenital heart disease without residual cardiac dysfunction
Mitral stenosis: New York Heart Association Class I or II

Moderate Risk

Mitral stenosis with atrial fibrillation
Aortic stenosis
Artificial valve
Moderate to severe systemic ventricular dysfunction
History of peripartum cardiomyopathy with no residual ventricular dysfunction
Coarctation of the aorta
Tetralogy of Fallot; uncorrected or with residual disease
Previous myocardial infarction
Marfan's syndrome with normal aorta

High Risk

Pulmonary hypertension
Coarctation of the aorta, complicated
Marfan's syndrome with aortic involvement
Any condition with New York Heart Association class III or IV
History of peripartum cardiomyopathy with residual ventricular dysfunction

---

stresses of pregnancy. Patients who are at greatest risk for cardiac decompensation are offered sterilization or termination.

Normal physiologic changes that occur during pregnancy can aggravate underlying cardiac disease, leading to the associated morbidity and mortality. Beginning in early pregnancy, total body water increases progressively by 6 to 8 L because an additional 500 to 900 mEq sodium is retained.[6–8] As a result, plasma volume increases steadily throughout the first two trimesters and into the

early third trimester, reaching a plateau at approximately 32 weeks.[9] In a singleton pregnancy at term, plasma volume is nearly 50% greater than that seen in nonpregnant women.[10] Maternal cardiac output starts to increase at approximately 10 weeks and reaches a plateau near the end of the second trimester, at levels 30% to 50% above nonpregnant values.[11–15] This increased output results from increases in stroke volume and heart rate. The increase in heart rate peaks in the third trimester, at 10 to 15 beats/minute over baseline.[15,16] These physiologic changes increase the demand on the already compromised heart.

The pregnancy-related decrease in blood pressure may offset some of the increased work resulting from increased plasma volume. In some cases, a significant decrease may be deleterious. Normally, systolic and diastolic pressures fall throughout the first two trimesters, reaching a nadir between 24 and 28 weeks, before increasing to nonpregnant levels at term.[17] Systolic pressure decreases an average of 5 to 10 mm Hg, and diastolic pressure decreases 10 to 15 mm Hg.[18] Blood pressure and cardiac output may be further affected by maternal posture. Late in pregnancy, the gravid uterus may mechanically obstruct the aorta and vena cava in the supine position, leading to hypotension.[19,20] In addition, changes in cardiac output and blood pressure cause an initial decrease in systemic vascular resistance, followed by an increase toward nonpregnant values near term.[17]

Colloid oncotic pressure is another important variable that is affected by pregnancy. Both plasma and interstitial colloid oncotic pressure decrease throughout gestation, with the latter decreasing to a greater extent.[21] There is an accompanying increase in capillary hydrostatic pressure.[22] An increase in hydrostatic pressure or a decrease in plasma colloid oncotic pressure may overcome the delicate balance that favors edema formation, especially in late pregnancy. After delivery, a further decrease in plasma colloid oncotic pressure occurs, reaching a nadir between 6 and 16 hours, with a return toward intrapartum levels after 24 hours.[23,24] These changes can lead to the dependent edema that is commonly seen in normal pregnant patients, thus complicating the diagnosis of cardiac decompensation.

Fetal complications in pregnancies complicated by maternal cardiac disease commonly include growth restriction and prematurity. Despite the risk of low birth weight, overall perinatal mortality is not significantly greater than that in the general population. When a pregnant patient has congenital heart disease, the fetus is at increased risk for this disease. The incidence is 0% to 10%, depending on the specific lesion. When the fetus is affected, approximately 50% have the same anomaly as the mother.[2,25] The risk of a cardiac lesion in the fetus is also increased when other first-degree family members have a congenital heart lesion.[26,27]

Management Options

Prepregnancy

Ideally, in patients with significant heart disease, pregnancy is a planned event. This assumes regular and reliable use of an effective contraceptive method. Before discontinuation of contraception, preconception evaluation and counseling should take place. The patient's cardiologist should be an active participant in this process. Maternal disease status should be determined. An echocardiogram can be used not only to define the cardiac anatomy, but also to describe ventricular function and estimate intracardiac pressure gradients.[28] Nuclear medicine scans, although helpful in the nonpregnant state, should be avoided during pregnancy.

A careful history is obtained to identify previous cardiac complications, including arrhythmias. The patient's functional status should also be established. The New York Heart Association (NYHA) functional classification system[29] (Table 37–2) is commonly used. Ninety percent or more of patients are categorized as having class I or II disease.[4] Outcomes are favorable in these two groups, but deterioration may occur. The reported frequency of adverse cardiac events varies, depending on patient selection, from 13% to 79%.[1,4,5] Although few patients have class III or IV disease, historically, nearly 85% of maternal deaths occur in these groups.[30]

The risk of maternal cardiac complications during pregnancy was quantified by Siu and colleagues[5] with a combination of five echocardiographic and historical factors that could be obtained and evaluated at the initial evaluation. The complications studied include pulmonary edema, symptomatic arrhythmias, and stroke or transient ischemic attack of cardiac origin. The five predictive indicators were NYHA classification greater than II or cyanosis, left ventricular obstruction, cardiac dysfunction, previous arrhythmia, and previous cardiac complication. Left ventricular outflow obstruction was defined as aortic valve stenosis with a valve area less than 1.5 cm^2, mitral stenosis with a valve area of 2.0 cm^2, or a

TABLE 37–2	
New York Heart Association Cardiac Functional Classification	
Class I	No limitations of physical activity; ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain
Class II	Slight limitation of physical activity; ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain
Class III	Marked limitation of physical activity; less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain
Class IV	Inability to perform any physical activity without discomfort; symptoms of cardiac insufficiency or anginal syndrome may be present, even at rest; any physical activity increases discomfort

peak left ventricular outflow tract gradient greater than 30 mm Hg. Myocardial dysfunction was defined as an ejection fraction less than 40%, restrictive or hypertrophic cardiomyopathy, or complex congenital heart disease. A significant history of arrhythmia was defined as symptomatic bradyarrhythmia or tachyarrhythmia requiring therapy. If no predictive factors were present at the beginning of pregnancy, only 3% of patients had a cardiac complication. When one factor was present, 30% of patients had a complication, and when two or more predictors were present, 66% of patients had a complication. This information can be useful in counseling patients.

Medical management of the patient's cardiac condition should be optimized. During maternal drug therapy, potential fetal effects must be considered. Table 37–3 shows a fetal risk factor classification scheme that is helpful when choosing optimal medical therapy.[31] The corresponding risk factor category is listed, with medications discussed in the next section. Coexisting conditions that may aggravate preexisting heart disease, such as anemia, arrhythmias, and hypertension, should be appropriately treated and controlled. Ideally, necessary cardiac surgery is carried out before conception.

Prenatal

Few patients are seen for prepregnancy evaluation. Therefore, evaluation and counseling should be initiated at the first prenatal visit. Cardiac surgery, although not contraindicated, is usually not required during pregnancy.[2] If possible, it is best delayed until postpartum. When the maternal mortality rate is excessive, as in Eisenmenger's syndrome, termination should be discussed.

During prenatal care, the patient should be routinely questioned and examined for signs or symptoms of cardiac failure. Vital signs and weight gain should be closely monitored. When there is an increased risk of intrauterine growth restriction, serial ultrasound examinations every 2 to 4 weeks in the third trimester allow assessment of interval fetal growth. Antenatal testing may begin at 32 to 34 weeks unless earlier surveillance is indicated because of compromised maternal or fetal status. Future fertility desires and contraceptive plans should be addressed in the antepartum period. Topics should include a discussion of sterilization, depending on future fertility desires, the maternal risk of pregnancy, and the long-term prognosis.

Labor and Delivery

Labor should proceed with the patient in the lateral position to avoid aortocaval compression and possible hypotension. Intrapartum fluid balance should be followed closely. Continuous electrocardiographic monitoring may be used, as necessary, to detect arrhythmias. Invasive hemodynamic monitoring with a pulmonary artery catheter (PAC) and an arterial line may be considered in particularly high risk conditions or in patients with deteriorating cardiovascular status. Although its use has not been rigorously evaluated during pregnancy, some question the safety and utility of the PAC in critically ill and high risk surgical patients.[32–34] Until more information is available on its safety and efficacy, a PAC should be used cautiously during pregnancy. Close fetal surveillance is needed throughout labor. Operative vaginal delivery is indicated in some patients to shorten the second stage of labor and avoid blood pressure changes associated with pushing. Cesarean delivery is usually reserved for obstetric indications.

An understanding of the principles of and indications for bacterial endocarditis antibiotic prophylaxis in pregnant patients is important. In patients with an uncomplicated labor and delivery, bacterial endocarditis is rare. In two series with a total of 906 pregnant women with cardiac disease, routine prophylactic antibiotics were not used and no cases of bacterial endocarditis were identified.[1,2]

TABLE 37–3		
Classification System for Fetal Risk Associated with Medications used During Pregnancy		
Category A	Controlled studies in women show no risk to the fetus in the first trimester (and no evidence of risk in later trimesters); the possibility of fetal harm appears remote	
Category B	Either animal reproduction studies show no fetal risk but there are no controlled studies in pregnant women or animal reproduction studies show an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters)	
Category C	Either studies in animals show adverse fetal effects (teratogenic, embryocidal, or other) and there are no controlled studies in women or studies in women and animals are not available; drugs should be given only if the potential benefit justifies the potential risk to the fetus	
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective)	
Category X	Studies in animals or humans show fetal abnormalities or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit; the drug is contraindicated in women who are or may become pregnant	

American Heart Association Recommendations for Endocarditis Prophylaxis

Cardiac Conditions

Endocarditis prophylaxis recommended

High risk

Prosthetic cardiac valves, including bioprosthetic and homograft valves

Previous bacterial endocarditis

Complex cyanotic congenital heart disease (e.g., single ventricle states, transposition of the great arteries, tetralogy of Fallot)

Surgically constructed systemic pulmonary shunts or conduits

Moderate risk

Most other congenital cardiac malformations (other than those listed above and below)

Acquired valvar dysfunction (e.g., rheumatic heart disease)

Hypertrophic cardiomyopathy

Mitral valve prolapse with valvar regurgitation or thickened leaflets

Endocarditis prophylaxis not recommended

Negligible risk (no greater risk than in the general population)

Isolated secundum atrial septal defect

Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 months)

Previous coronary artery bypass graft surgery

Mitral valve prolapse without valvar regurgitation

Physiologic, functional, or innocent heart murmur

Previous Kawasaki disease without valvar dysfunction

Previous rheumatic fever without valvar dysfunction

Cardiac pacemaker (intravascular and epicardial) or implanted defibrillator

Surgical Procedures

Endocarditis prophylaxis not recommended

Genitourinary tract

Vaginal hysterectomy

Vaginal delivery*

Cesarean section

In uninfected tissue

Urethral catheterization

Uterine dilation and curettage

Therapeutic abortion

Sterilization procedure

Insertion or removal of intrauterine device

*Prophylaxis is optional for high-risk patients.

Adapted from Dajani AS, Taubert KA, Wilson, W, et al: Prevention of bacterial endocarditis: Recommendations of the American Heart Association. JAMA 1997;277:1794-1801.

Recommended Antibiotic Regimens for Genitourinary Procedures

American Heart Association Recommendations

High-risk patients

Ampicillin 2.0 g IM or IV plus gentamicin 1.5 mg/kg (not to exceed 120 mg) within 30 minutes of starting the procedure: 6 hours later, ampicillin 1 g orally

Ampicillin-, amoxicillin-, or penicillin-allergic patient regimen

Vancomycin 1.0 g IV over 1 to 2 hr plus gentamicin 1.5 mg/kg IV or IM (not to exceed 120 mg); complete injection or infusion within 30 minutes of starting the procedure

Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy Recommendations

Patients who are not allergic to penicillin and who have not had penicillin more than once in the previous month

1 g amoxycillin IM in 2 to 5 mL 1% lignocaine hydrochloride plus 120 mg gentamicin IM just before induction, then 0.5 g amoxycillin orally 6 hours later

Patients who are allergic to penicillin or who have had penicillin more than once in the previous month

Vancomycin 1.0 g by slow IV infusion over 60 minutes followed by gentamicin 120 mg IV just before induction or 15 minutes before the surgical procedure

Adapted from Dajani AS, Taubert KA, Wilson, W, et al: Prevention of bacterial endocarditis: Recommendations of the American Heart Association. JAMA 1997;277:1794-1801.

tal procedures, in which positive blood cultures are obtained in 60% to 90% of patients, depending on the procedure.[36] The American Heart Association[37] guidelines for endocarditis prophylaxis are shown in Table 37–4. The Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy[38] recommends antibiotic prophylaxis during obstetric and gynecologic procedures only for patients with prosthetic heart valves. Table 37–5 shows the drug regimens recommended by the American Heart Association[37] and the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy.[38]

Postnatal

In the postpartum period, fluid balance must be monitored carefully. During the first 24 to 72 hours, significant fluid shifts occur and can lead to congestive heart failure in patients with cardiac disease. Careful attention should be paid to patients who do not have brisk spontaneous diuresis. In these patients, progressive reduction in oxygen saturation monitored by pulse oximetry often heralds the onset of clinical pulmonary edema. Previously developed contraceptive plans should be reviewed and implemented.

Prophylactic antibiotics are not necessary in all patients with cardiac disease. Prophylaxis is indicated when the cardiac condition puts the patient at risk for endocarditis or when the planned procedure is likely to produce bacteremia with an organism that can cause endocarditis. The incidence of positive blood cultures is low after uncomplicated vaginal delivery, with a reported range of 1% to 5%.[35] Bacteremia is more common with den-

CARDIAC MURMUR

Maternal and Fetal Risks

Cardiac murmurs result from turbulent blood flow that causes vibration of the cardiac structures. Systolic murmurs are very common during pregnancy, with the reported incidence exceeding 90%.[39,40] Typically, the murmur is early to midsystolic and soft (grade I–II). The left sternal border area is usually the area of maximal intensity, followed by the aortic and pulmonic areas.[41] These murmurs are rarely associated with cardiac pathology and are likely secondary to the increased intravascular volume and cardiac output.

Echocardiographic studies of pregnant patients who are referred for evaluation of nonspecific systolic murmurs show normal structure and function in more than 90% of examinations. Most patients had the clinical characteristics of a benign flow murmur.[41–45] Most abnormalities were mild and were associated with a history suggesting pathology.[41–44] Clinically significant murmurs differ from the typical benign flow murmur. Systolic murmurs that are "loud or long" are suspicious and are more frequently associated with cardiac pathology. Late systolic, pansystolic, and diastolic murmurs are abnormal and require further evaluation.[42]

Management Options

Echocardiography adds little to the clinical evaluation of nonspecific systolic murmurs, because most significant cardiac conditions seen during pregnancy are diagnosed before conception. Unsuspected mild cardiac disease may initially present during pregnancy or the puerperium. A common benign flow murmur must be differentiated from a pathologic condition. Unfortunately, the accuracy of clinical evaluation of systolic murmurs by noncardiologists is unknown.[45] A history that suggests cardiac disease or a pathologic murmur (late systolic, pansystolic, or diastolic) heard on physical examination should prompt evaluation with echocardiography. When a suspicious systolic murmur is noted, either a cardiologist's clinical examination or echocardiogram can reliably identify significant pathology.[45] The method of choice depends on institutional resources.

MITRAL VALVE PROLAPSE

Maternal and Fetal Risks

Mitral valve prolapse (MVP) represents a range of valvular abnormalities that allow one or both mitral valve leaflets to extend above the plane that separates the atria and ventricle. The condition is common, with a prevalence of 2% to 4% in the general population.[46–48] There is a wide range in the reported prevalence, however, depending on the method of diagnosis, the diagnostic criteria, and the population studied. Females are affected twice as often as males. The condition is most common in women of reproductive age, with prevalence rates as high as 21%.[46]

Auscultation or echocardiography may be used to diagnose MVP. A midsystolic click, with or without a midsystolic to late systolic murmur, is the clinical hallmark. With M-mode or two-dimensional echocardiography, the diagnosis is made when the mitral valve is seen prolapsing into the left atrium.[47] Postural maneuvers are sometimes used to aid in the auscultatory diagnosis. Activities that decrease left ventricular volume increase the degree of prolapse. Hydration affects the auscultatory findings of MVP.[49] Pregnancy may have similar effects, with changes in the timing of the click and shortening or softening of the murmur. Serial echocardiograms during pregnancy showed disappearance of MVP during pregnancy in a significant number of patients.[50]

Palpitations, arrhythmias, chest pain, syncope, fatigue, and panic attacks are reported in association with MVP. Together they comprise MVP syndrome,[47] although the existence of a distinct syndrome has been questioned. The symptoms associated with MVP syndrome are very common and are seen with near equal frequency in patients with and without an echocardiographic diagnosis of MVP.[48,51]

Severe mitral regurgitation requiring surgery, infective endocarditis, cerebral ischemia, and sudden death are serious complications associated with MVP. Of the risk factors associated with these complications, only a holosystolic mitral regurgitant murmur is likely to be seen in pregnant patients.[52,53] Even mitral regurgitation is more likely to be seen in males and patients older than 45 years of age than in women of reproductive age.[54] In an examination of offspring of the Framingham Heart Study participants, with an average age of 54 years, the occurrence of severe complications in association with MVP was only minimally greater than that in those without the diagnosis.[48] The risk of serious complications in women younger than 45 years of age with uncomplicated MVP is estimated to be 0.2% per year.[53]

Management Options

Prepregnancy

Prepregnancy management should document associated mitral regurgitation by either echocardiography or evaluation by a cardiologist.

Prenatal

Patients should be observed for cardiac arrhythmias, particularly supraventricular tachycardia. Although these occur very infrequently, the patient should be counseled to avoid caffeine, alcohol, tobacco, and betamimetic drugs.

When necessary, digoxin (category C) or β-blockers (most category C) may be used.[47]

Labor and Delivery and Postnatal

In addition to continued observation for arrhythmias, some recommend endocarditis prophylaxis for high risk procedures in patients with MVP and associated mitral regurgitation.[47]

CONGENITAL HEART DEFECTS

Atrial Septal Defect

Maternal and Fetal Risks

Ostium secundum atrial defect is one of the most common congenital heart defects seen in pregnancy, and women are more commonly affected than men. Pregnancy is generally well tolerated and uncomplicated, especially in patients with normal systolic function shown by echocardiography and NYHA functional class I or II.[55] Significant complications can be associated with uncorrected atrial septal defect (ASD), but these are uncommon before 40 years of age.[56] Supraventricular arrhythmias are more frequent with advancing age and may aggravate right-sided heart failure. Paradoxical emboli from the venous to the systemic circulation can follow right-sided heart failure as a result of increased peripheral edema and venous stasis. Pulmonary hypertension is uncommonly associated with ASD and is typically found in older patients.[56] In fetuses born to mothers with an ASD, the risk of congenital heart disease is 3% to 10%.[25,27,56]

Management Options

PREPREGNANCY

The goal of preconception management is to identify secondary complications, such as supraventricular arrhythmias or pulmonary hypertension. Pregnancy should be discouraged and effective contraception initiated when significant pulmonary hypertension is present.

PRENATAL

Prenatal care is routine in the absence of supraventricular arrhythmias, right-sided heart failure, and pulmonary hypertension.

LABOR AND DELIVERY

Labor is generally well tolerated. Patients are monitored for arrhythmias. Blood pressure is carefully monitored, and fluid is restricted. Use of a PAC is considered only in the presence of pulmonary hypertension. In addition to pain control, epidural anesthesia reduces systemic vascular resistance and may reduce the left-to-right shunt.

POSTNATAL

In patients without secondary complications, postpartum management is routine. Postpartum management encourages ambulation to decrease the risk of deep venous thrombosis and paradoxical embolization.

Ventricular Septal Defect

Maternal and Fetal Risks

Ventricular septal defects (VSDs) are uncommon in adults. Small defects either close spontaneously or are corrected in childhood. Maternal morbidity is related to the size of the VSD and the presence of pulmonary hypertension. Small defects and those that are repaired in childhood usually present no problem during pregnancy. Some asymptomatic patients with a repaired VSD have significant, but unrecognized, pulmonary hypertension, which is manifested clinically in association with the hemodynamic stresses of pregnancy.[57,58] As with ASD, however, patients with good functional status and normal systolic ventricular function usually have a normal outcome.[55] Occasionally, an uncorrected VSD is complicated by congestive heart failure during pregnancy.[26] These patients are at risk for paradoxical systemic emboli. Infants born to mothers with a VSD have a 6% to 10% risk of congenital heart disease.[26,56]

Management Options

PREPREGNANCY

Before pregnancy, patients with a VSD (corrected or uncorrected) should be evaluated for pulmonary hypertension. Pregnancy is discouraged in patients with pulmonary hypertension. In the absence of pulmonary hypertension, repair of uncorrected lesions should be considered. Patients should be counseled about the increased risk of congenital heart disease in their offspring.

PRENATAL

Patients should be evaluated and followed with serial echocardiography. The size of the lesion, the degree of the shunt, and the presence of pulmonary hypertension should be determined. Termination should be offered to patients with pulmonary hypertension.

LABOR AND DELIVERY

Hypotension should be avoided to prevent shunt reversal. Endocarditis prophylaxis is indicated in patients with infection or a complicated delivery.

POSTNATAL

Volume status should be monitored during the postpartum period because of fluid shifts and the potential for congestive heart failure. Ambulation is encouraged to

avoid the risk of deep venous thrombosis and paradoxical embolization.

Pulmonary Hypertension

Maternal and Fetal Risks

Pulmonary hypertension associated with pregnancy is a grave condition, and the maternal mortality rate is as high as 50%.[59] Primary pulmonary hypertension is an idiopathic disease of the pulmonary vasculature that is seen primarily in women. Secondary pulmonary hypertension can result from long-standing increases in pulmonary pressure as a result of underlying cardiac disease, such as ASD or VSD, mitral stenosis, or patent ductus arteriosus (PDA).[60]

With primary pulmonary hypertension, the most dangerous times are labor, delivery, and the early postpartum period. Intravascular volume changes are not well tolerated because of the fixed pulmonary vascular resistance. Increases in cardiac output during labor or as a result of postpartum fluid shifts may lead to sudden right-sided heart failure. At delivery, excessive blood loss decreases preload, resulting in an inability to overcome high pulmonary vascular resistance. Both situations lead to a decrease in left ventricular preload and a dramatic decrease in left ventricular output. A direct consequence is myocardial ischemia, leading to arrhythmias, ventricular failure, and sudden death. Pulmonary thromboembolic events are usually fatal. Even small thrombi in the lungs can dramatically aggravate pulmonary hypertension.[60] In the fetus, chronic maternal hypoxia can lead to intrauterine growth restriction. Despite this, the neonatal survival rate is nearly 90%.[59]

Management Options

PREPREGNANCY

Despite improvements in maternal outcome with a comprehensive team approach,[60] maternal morbidity and mortality are significant risks. As a result, pregnancy should be discouraged and permanent sterilization should be considered.

PRENATAL

If pregnancy occurs, termination should be offered because of maternal risks. If pregnancy is discovered in the second trimester and termination is chosen, dilation and evacuation is preferred over induction. In a continuing pregnancy, the cardiologist, critical care specialist, and obstetrician must work closely together. An obstetric anesthesiologist should be consulted early in the pregnancy. The use of calcium channel blockers is reported in some patients, with improvement in maternal cardiac output and successful pregnancy outcome. Nifedipine in doses of 90 to 120 mg daily was used.[61] Heparin (category C) thromboembolism prophylaxis is initiated early, with doses of 5000 to 10,000 units given subcutaneously twice daily. Patients with more severe disease, manifested by chest pain or oxygen saturation of 80% or less, are at higher risk and full heparin anticoagulation has been used. In the early third trimester, in-hospital bed rest with oxygen therapy (up to an FiO_2 of 0.4) and frequent monitoring with pulse oximetry is advocated. Late diagnosis and late admission to the hospital were associated with an increased risk of maternal mortality.[59] Lack of improvement in SaO_2 with oxygen suggests further increased maternal risk.[60]

LABOR AND DELIVERY

Close monitoring during labor is essential to achieve a good outcome. Spontaneous labor is preferred to prevent the increased risk of cesarean section associated with induction. When indicated, however, Pitocin or E series prostaglandins can safely be used for induction. Oxygen flow is increased to 5 to 6 L/minute. Oxygen saturation is monitored continuously with pulse oximetry. A radial artery line is placed to allow continuous blood pressure monitoring and facilitate frequent blood gas sampling. Maintenance of stable blood pressure is important. Adequate preload is essential to maintain cardiac output. Routine use of a pulmonary artery catheter (PAC) is discouraged.[59] An alternative is to place a central venous pressure (CVP) catheter early in labor. Arguments against the use of a PAC stem from the fact that information from the right side of the heart can be obtained from the CVP line. Left-sided heart pressure may not be accurately reflected due to elevated pulmonary artery pressures. Potential complications, such as arrhythmias, thrombosis, and pulmonary artery rupture, must be considered when deciding on PAC use. Despite these concerns, in some patients, cardiac output data obtained from a PAC is useful. The decision to use invasive hemodynamic monitoring should be made on an individual basis, after the risks and benefits are considered.

Several case reports described the use of intravenous prostacyclin or inhaled nitric oxide therapy during labor.[62-64] Both drugs cause vascular dilation and inhibit platelet aggregation, leading to improved oxygenation, decreased pulmonary vascular resistance, and a decreased risk of thromboembolism. Improvement in pulmonary hypertension is similar between the two drugs in nonpregnant patients, and there seems to be no added benefit to a combination of the two agents. Inhaled nitric oxide avoids systemic hemodynamic changes, is easy to administer, and may cost less than other agents. Nitric oxide is typically used at a dose of 5 to 20 ppm. Elevated methemoglobin levels are a potential toxicity, but this effect has not been reported at these doses.[65]

An epidural catheter is placed early in labor and carefully activated when contractions become painful, to avoid hypotension. Intrathecal narcotics can be added to decrease the hypotensive effect of local anesthetics. During labor and delivery, the patient is placed in the left lateral position to avoid supine hypotension. Vaginal

delivery, with shortening of the second stage with forceps or a vacuum to decrease the need for pushing, is desirable. Blood loss at delivery is carefully monitored. Crystalloid solution can be used to replace volume and maintain preload if blood loss is greater than normal. Cesarean delivery is associated with increased maternal morbidity and mortality and should be reserved for obstetric indications.[59,60]

POSTNATAL

Antepartum and intrapartum management principles are continued into the postpartum period. Thromboembolism prophylaxis and oxygen therapy are continued. Excessive blood loss or right-sided heart failure as a result of fluid shifts can lead to sudden death. The patient must be monitored closely during the first 48 to 72 hours. During this time, nitric oxide is slowly weaned.[64] If prostacyclin is used, long-term therapy can continue, if necessary, through a central venous catheter.[63] Controlled diuresis is important during postpartum fluid mobilization to control preload and prevent worsening right-sided heart function.[61] Pulmonary edema may develop rapidly in patients who do not have brisk spontaneous diuresis. Permanent sterilization should be considered in patients with severe pulmonary hypertension.

Eisenmenger's Syndrome

Maternal and Fetal Risks

Eisenmenger's syndrome is defined as pulmonary hypertension as a result of uncorrected left-to-right shunt of a VSD, ASD, or PDA, with subsequent shunt reversal and cyanosis. Pulmonary hypertension is defined as mean pulmonary artery pressure greater than 25 mm Hg. The increase in blood volume and decrease in systemic vascular resistance can lead to right ventricular failure, with a decrease in cardiac output and sudden death. Maternal mortality with Eisenmenger's syndrome is as high as 40% in pregnancies that continue past the first trimester.[59,66] In contrast, the 15-year survival rate is more than 75% in nonpregnant patients.[67] Postoperative fluid shifts associated with cesarean delivery pose an even greater risk, with mortality rates approaching 70%. Although maternal risk remains high, a recent report emphasizing a team approach, with close follow-up and careful attention to detail, achieved a more optimistic outcome.[60] Intrauterine growth restriction is a common fetal complication. Preterm delivery is also frequent, occurring in up to 85% of pregnancies.[66] Despite the maternal and fetal complications, the neonatal survival rate approaches 90%.[59]

Management Options

PREPREGNANCY

Pregnancy should be discouraged and reliable contraception, preferably permanent sterilization, advised because of the extreme maternal risk associated with pregnancy.

Even first-trimester termination is associated with a maternal mortality rate of 5% to 10%.[60]

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

Echocardiography is helpful in evaluating shunting, right ventricular function, and pulmonary hypertension. Cardiac catheterization may be necessary to quantify pulmonary hypertension. Pregnancy complications and outcome are related to the degree of pulmonary hypertension. Management of pulmonary hypertension associated with Eisenmenger's syndrome follows the same principles discussed in the section on pulmonary hypertension. Nitric oxide use is described in two case reports that showed improvement in pulmonary hypertension and maternal oxygenation during labor and delivery. Unfortunately, despite continued use, progressive deterioration occurred postpartum, and neither patient survived.[68,69] In one case, doses as high as 80 ppm were used, and an elevated methemoglobin level occurred.[68]

Coarctation of the Aorta

Maternal and Fetal Risks

Coarctation of the aorta complicating pregnancy is relatively uncommon, accounting for only 6% to 11% of cases of congenital heart disease in pregnant patients in older series. Most of these lesions were corrected before pregnancy.[1,2,4] When the lesions are corrected, maternal and fetal outcomes are not significantly different from those in the general obstetric population.[70] Several cardiovascular anomalies are associated with coarctation of the aorta. Aneurysms of the circle of Willis, intercostal arteries, and distal aorta may be present. Bicuspid aortic valve is also seen.[71] Although most patients complete pregnancy without complication, the risk of significant maternal morbidity exists, particularly if other anomalies are present. Surgical repair can reduce, but not eliminate, the risk of aortic rupture or dissection.[72] Bicuspid aortic valve increases the risk of bacterial endocarditis.[56] Aneurysms may rupture, with those involving the circle of Willis resulting in subarachnoid hemorrhage. Maternal hypertension is common, particularly if the lesion is not repaired.[72] In these patients, the risk of fetal congenital heart disease is 4% to 7%.[27,56,72]

Management Options

PREPREGNANCY

Coarctation of the aorta should be repaired before conception. Appropriate imaging studies should be done to identify aneurysms or aortic valve disease. If they are identified, elective surgical management should be considered.

PRENATAL

Termination may be considered in patients with uncorrected coarctation of the aorta, especially if it is

associated with other anomalies, because of the increase in maternal morbidity and mortality.

LABOR AND DELIVERY AND POSTNATAL

Hypertension should be controlled in both the intrapartum and postpartum periods. Epidural anesthesia is encouraged because it effectively controls pain and decreases systemic vascular resistance.[73] Endocarditis prophylaxis is indicated for complicated deliveries with coexisting aortic valvular disease.

Tetralogy of Fallot

Maternal and Fetal Risks

Tetralogy of Fallot is a complex cyanotic heart disease that consists of VSD, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy. Although survival to adulthood is possible, uncorrected tetralogy of Fallot is rarely seen in pregnancy for several reasons. Most patients undergo surgical correction early in life. In those who do not have surgery, life expectancy is shortened and fertility is impaired. After surgical correction, cardiac arrhythmias are seen in some patients, although these are not usually a severe problem.[4,74] Patients without residual defects who have normal functional status after surgical correction tolerate pregnancy well.[55,74,75]

In patients with uncorrected tetralogy of Fallot, pregnancy presents serious risks, including maternal mortality (see Table 37–1). Preexisting pulmonary hypertension is a concern.[74] In addition, increased cardiac output leads to increased venous return to the hypertrophic right ventricle. These changes, together with decreased systemic vascular resistance, increase the right-to-left shunt. Oxygenation decreases, hematocrit increases, and cyanosis worsens, further stressing an already compromised system.[56] Risk factors that worsen the prognosis include prepregnancy hematocrit exceeding 65%, a history of congestive heart failure or syncope, cardiomegaly, right ventricular pressure exceeding 120 mm Hg or strain pattern on electrocardiogram, or oxygen saturation less than 80%.[76]

A good neonatal outcome can be expected in patients with corrected tetralogy of Fallot and no residual defects.[74,75] Neonatal outcome is often poor in patients with an uncorrected lesion because of increased rates of spontaneous abortion, prematurity, and intrauterine growth restriction. Congenital heart disease affects approximately 5% of infants of mothers with tetralogy of Fallot.[25]

Management Options

PREPREGNANCY

Surgery is advocated for patients with uncorrected lesions. Patients who underwent previous corrective surgery should be evaluated for residual defects, such as VSD. If defects are found, repair should be considered.[75]

PRENATAL

After surgical correction, activity is restricted only to the point of preventing fatigue. Patients with uncorrected tetralogy of Fallot should be offered termination. Hematocrit should be followed. Supplemental oxygen may be of benefit. Serial obstetric ultrasound examinations are used to detect intrauterine growth restriction. Antenatal testing is started during the third trimester, as indicated.

LABOR AND DELIVERY

In patients with uncorrected defects, careful fluid management and maintenance of blood pressure are the main features of intrapartum care. Central hemodynamic monitoring may be used, but there is a risk of exacerbating arrhythmias. Hypotension should be prevented to avoid shunt reversal. Epidural anesthesia can be used if the patient is adequately hydrated and it is carefully administered. To prevent decreases in venous return with bearing down, operative vaginal delivery may be used to shorten the second stage of labor. This strategy is often applied in patients with corrected tetralogy of Fallot, although it probably is not necessary.[74,75]

POSTNATAL

In patients with uncorrected tetralogy of Fallot, volume status should be monitored during the early postpartum period. A reliable contraceptive plan should be made, with permanent sterilization a good alternative.

Transposition of the Great Arteries

Maternal and Fetal Risks

Transposition of the great arteries is a congenital heart disease consisting of discordance between the ventricles and the great arteries, in which the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle. Two types exist, depending on the concordance of the ventricles and the atria. In the first type, complete transposition, there is atrial concordance. Two parallel circulations exist. The systemic venous return enters the right atrium, proceeds to the right ventricle, and exits through the aorta, bypassing the pulmonary circulation. The pulmonary venous return enters the left atrium, continues into the left ventricle, and returns to the lungs through the pulmonary artery. Thus, no oxygenated blood reaches the systemic circulation. Without an additional congenital shunt lesion or a surgical procedure to redirect blood flow more appropriately, this condition is not compatible with life. Although several procedures are used to repair the condition, an atrial switch procedure, the Mustard operation, is most commonly used. In this procedure, a baffle is placed between the right and left atria. Systemic venous return is redirected to the left side of

the heart and to the lungs, whereas the oxygenated pulmonary venous blood is shunted to the right ventricle and on to the systemic circulation. Surgery allowed these patients to reach adulthood and contemplate pregnancy.

The second type is congenitally corrected transposition. Both arterioventricular and atrioventricular discordance are present. The right atrium empties its systemic venous blood into the morphologic left ventricle. Oxygenated pulmonary venous blood returns to the left atrium and empties into the morphologic right ventricle. Additional cardiac anomalies are often present, including VSD, pulmonary stenosis, and valve abnormalities.[77,78] Patients with congenitally corrected transposition and no associated anomalies may be completely asymptomatic and remain undiagnosed into adulthood.[78]

The major concern in both types of transposition is the ability of the morphologic right ventricle to continue to support the systemic circulation as well as the increased cardiac output occurring during gestation. Several small series and case reports described the outcome of pregnancy in women with both complete[4,79–82] and congenitally corrected transposition of the great vessels.[4,77,78,83,84] In these patients, maternal mortality was rare, with only one death noted in the 78 patients who were followed. Morbidity was common, however, occurring in approximately 30% of patients. Not surprisingly, heart failure was seen most often. Other complications included arrhythmias, worsening cyanosis, cerebrovascular accident, and left atrioventricular (AV) valve regurgitation.

The incidence of miscarriage was high, approaching 40%. The increased risk was primarily related to maternal cyanosis.[83,84] The rate of preterm birth was 10% to 20%, and the incidence of growth restriction was infrequently reported. The risk of congenital heart disease in offspring of these women does not appear to be increased above that in the general population, although the number of patients evaluated was small.[25,82]

Management Options

PREPREGNANCY

As with all cardiac conditions in pregnancy, it is important to determine the patient's functional status. Echocardiography to evaluate the function of the systemic right ventricle is necessary. The patient should also be evaluated for arrhythmias. A cardiologist with experience in treating congenital heart disease in adults should be included in the initial evaluation and throughout pregnancy. Often, this role is filled by the patient's pediatric cardiologist because these physicians often follow patients into adulthood.

PRENATAL

Decreased activity is advised to minimize further stress on the right ventricle. Patients should have serial echocardiography to evaluate cardiac function. Symptoms of congestive heart failure should be evaluated quickly and treated with diuretics and digoxin, as indicated. An anesthesiologist should evaluate the patient before labor.

LABOR, DELIVERY, AND POSTNATAL

Maternal cardiac monitoring is used to detect arrhythmias. Supplemental oxygen is given, as necessary. Volume overload should be avoided during labor and throughout the postpartum period. Adequate analgesia is important and can be provided with an epidural. Shortening of the second stage with forceps or a vacuum should be considered. Cesarean delivery is reserved for the usual obstetric indications.

Patent Ductus Arteriosus

Maternal and Fetal Risks

Surgical correction of PDA is usually accomplished in childhood. Uncorrected lesions have traditionally accounted for fewer than 5% of pregnancies complicated by congenital heart disease.[1,2] Maternal complications depend on the size of the ductus. Asymptomatic patients with a small PDA generally tolerate pregnancy without difficulty. Left-to-right shunting may decrease during pregnancy as a result of decreased systemic vascular resistance. A large lesion with a long-standing left-to-right shunt can lead to pulmonary hypertension.[85] In this situation, the normal decrease in systemic vascular resistance during pregnancy can cause shunt reversal, with an increase in maternal mortality.[56] The risk of congenital heart disease in the fetus is approximately 4%.[56]

Management Options

PREPREGNANCY

Before pregnancy, evaluation includes echocardiography to determine the size of the PDA and identify pulmonary hypertension.

PRENATAL

Antenatal management consists of echocardiography to detect pulmonary hypertension. If pulmonary hypertension develops, bed rest and supplemental oxygen should be instituted.

LABOR, DELIVERY, AND POSTNATAL

Intrapartum volume status should be monitored with care to avoid hypotension, which can result in shunt reversal. Use of a PAC may be indicated in patients with pulmonary hypertension. Endocarditis prophylaxis is indicated, except in uncomplicated deliveries. Careful attention to volume status should continue through the postpartum period.

RHEUMATIC HEART DISEASE: GENERAL

Maternal and Fetal Risks

Over the last several decades, a significant decline in the incidence and severity of rheumatic heart disease occurred in developed countries. A similar pattern was seen with rheumatic heart disease complicating pregnancy.[2,86] In a recent multicenter report of 562 women with heart disease managed during pregnancy, only 14% had acquired valvular lesions.[4] The changes were attributed in part to improved socioeconomic conditions. In many parts of the world, rheumatic heart disease is a significant public health problem. Asia, Africa, and South America have high prevalence rates.[87,88] Some positive trends were noted in developing nations. Sri Lanka, for example, saw an increase in the age at presentation and a decrease in the severity and resultant morbidity and mortality associated with mitral stenosis.[89] Despite the dramatic decline in developed countries, rheumatic heart disease will continue to be seen because of immigration from high-prevalence areas.[90]

Rheumatic heart disease is a complication of rheumatic fever. Cardiac valve damage results from an immunologic injury initiated by a group A β-hemolytic streptococcal infection.[91] During pregnancy, the increased maternal blood volume and heart rate can lead to heart failure and pulmonary edema. Arrhythmias also frequently complicate pregnancy. In a series of 64 women followed in Los Angeles, California, congestive heart failure occurred in 38% and arrhythmias occurred in 15%.[92] Not surprisingly, poor maternal functional class (NYHA class III or IV) is associated with worse maternal and fetal outcomes.[92] Rates of intrauterine growth retardation and prematurity are increased with complicated rheumatic heart disease.[92,93]

Management Options

General management principles for patients with rheumatic heart disease are aimed at preventing cardiac failure and bacterial endocarditis. Volume status is monitored, and activity should be limited. Antibiotics should be given in association with high-risk procedures (see Table 37–4). Specific valvular lesions are discussed individually.

Mitral Stenosis

Maternal and Fetal Risks

Mitral stenosis, either alone or in combination with other lesions, is the most common valvular disorder associated with rheumatic heart disease.[1,2,93] In a 12-year review of 486 pregnant patients in India through 1999, 63% of lesions affected a single valve. Mitral stenosis was the abnormality in 90% of these women.[93] Although in the past mitral stenosis was the most common rheumatic lesion associated with maternal mortality, death rarely occurs today.[1,2,89,94,95] Hemodynamically, mitral stenosis is a state of fixed cardiac output caused by left atrial outflow obstruction. Pressures in the left atrium and pulmonary vasculature are increased. Long-standing severe disease may be complicated by secondary pulmonary hypertension and atrial fibrillation. In pregnancy, the increased intravascular volume can further elevate pressures and lead to pulmonary edema and arrhythmias, even in previously asymptomatic patients.[95] Increased maternal heart rate and decreased left ventricular filling time may result in a decrease in cardiac output.[94] If maternal decompensation can be avoided, a good fetal outcome can be expected.[1,2,89,94]

Management Options

PREPREGNANCY

The goal of preconception care is to define the severity of cardiac compromise. Two-dimensional echocardiography and color flow Doppler are used to determine cardiac function and the degree of stenosis. Together, these modalities allow noninvasive evaluation of these patients and decrease the need for cardiac catheterization.[96] In symptomatic patients or those with severely stenotic valves, surgical correction should take place before conception. Surgical commissurotomy is the traditional treatment modality. Recently, percutaneous mitral valve commissurotomy emerged as an alternative. The percutaneous method is safe and as effective as the surgical approach. In addition, it is less invasive, less expensive, and even preferred as first-line therapy in some patients.[90,97] Satisfactory results persisted beyond 5 years in these reports, delaying and potentially avoiding the risks associated with prosthetic valves.[98]

PRENATAL

The goal of prenatal care is to avoid cardiac decompensation. Special attention should be paid to volume status. Weight gain should be closely monitored. Symptoms or physical findings associated with heart failure should be reported and evaluated promptly. Maternal tachycardia should be avoided to prevent a decrease in cardiac output. Restriction of physical activity can aid in this objective. β-Blockade may be used to control heart rate. It is used empirically in mitral stenosis during pregnancy to prevent the development of tachycardia, with good maternal and fetal outcome.[99] Atrial fibrillation can be managed with digoxin (category C) or cardioversion, as necessary.

Serial echocardiography is indicated to follow cardiac function objectively. Cardiac catheterization may be necessary to further evaluate and even treat patients with refractory pulmonary edema, despite optimal medical management. Several series showed successful treatment and good maternal and neonatal outcome in patients managed with balloon valvulotomy for severe symptomatic mitral stenosis during pregnancy.[100–103]

LABOR AND DELIVERY

During the intrapartum and postpartum periods, volume status and cardiac output are critical concerns. In patients with NYHA class III or IV disease, central hemodynamic monitoring may be considered. Pulmonary pressures and cardiac output can be measured reliably. Although pulmonary capillary wedge pressure (PCWP) can warn of the potential for pulmonary edema, it does not accurately reflect left ventricular preload. The pressure gradient across the stenotic valve may necessitate a high normal or even elevated PCWP to allow adequate left ventricular filling and maintain cardiac output. To prevent pulmonary edema after delivery as a result of postpartum fluid shifts, PCWP should be maintained as low as possible without compromising cardiac output. Fluid restriction or careful diuresis, with attention to cardiac output, may be used to obtain desirable pressures. Decreased diastolic filling time associated with tachycardia may also decrease cardiac output. Careful intravenous administration of β-blockers (most category C) may be necessary to control heart rate and maintain cardiac output during labor.[94]

Similar considerations accompany analgesia and anesthesia during labor and delivery. Epidural analgesia is both safe and effective. Careful administration of the anesthetic agent is necessary to avoid hypotension. Control of labor pain removes a stimulus for tachycardia. The increased venous capacitance can also moderate postpartum fluid shifts. Drugs such as atropine, pancuronium, and meperidine can cause tachycardia and should be avoided.

Cesarean delivery is reserved for obstetric indications. If abdominal delivery is necessary, epidural is the anesthetic method of choice. Although forceps delivery is advocated to shorten the second stage of labor and reduce bearing down, it is not always required.[94] Endocarditis antibiotic prophylaxis should be given when a complicated delivery is anticipated. Because these deliveries cannot always be predicted, routine antibiotic prophylaxis is recommended.[104]

POSTNATAL

Postpartum fluid shifts increase the risk of pulmonary edema. Clark and colleagues[94] noted a mean increase in PCWP of 10 mm Hg between the second stage of labor and the postpartum period in eight patients with functionally severe mitral stenosis. Because frank pulmonary edema is unlikely at a PCWP of less than 30 mm Hg, maintaining the PCWP at 14 mm Hg or lower should prevent this complication.[94]

Mitral Regurgitation

Maternal and Fetal Risks

Although mitral stenosis is almost exclusively caused by rheumatic heart disease, mitral regurgitation has several causes. In addition to rheumatic disease, floppy mitral valves in association with MVP, papillary muscle dysfunction, and ruptured chordae tendineae can result in mitral regurgitation.[105] In women of reproductive age, however, rheumatic heart disease is the most common cause of hemodynamically significant regurgitation. It is the dominant lesion in approximately one-third of patients with rheumatic heart disease, but it is often associated with mitral stenosis.[1,2] In patients without severe mitral regurgitation or ventricular dysfunction, pregnancy is generally well tolerated. The decrease in systemic vascular resistance associated with pregnancy has a beneficial effect. Atrial fibrillation may develop because of the effect of increased volume on a dilated atrium.

Management Options

PREPREGNANCY

NYHA functional status should be determined (see Table 37–2). The degree of regurgitation, atrial size, and ventricular function should be established with echocardiography. If required, digoxin (category C) therapy should be optimized. Although uncommon, if valve replacement is necessary, surgery should be performed before pregnancy. Valve replacement is indicated in asymptomatic patients with mild to moderate ventricular dysfunction and in those with atrial fibrillation, pulmonary hypertension, or symptoms such as dyspnea at rest or orthopnea.[106]

PRENATAL

In patients with NYHA class I or II disease, restriction of activity to prevent fatigue should be all that is required. In patients who have symptoms, serial echocardiography is indicated. Digoxin, diuresis, and afterload reduction should be instituted if left ventricular failure develops.

If medical therapy is unsuccessful, cardiac surgery during pregnancy can proceed, if necessary. Although small case series suggested that maternal mortality is not increased compared with nonpregnant women,[107] a recent review of the literature suggests that surgery for valvular disease during pregnancy and the early postpartum period is associated with a mortality rate of approximately 9%, roughly four times that of the nonpregnant population.[108] The fetal survival rate typically exceeds 70%.[107,108] Factors that affected survival were gestational age at hospital admission and the degree of emergency necessitating the procedure. During cardiac bypass, fetal bradycardia and prolonged loss of fetal heart tones can occur as a result of maternal hypotension.[109] Fetal risks are minimized with high flow to maintain a mean maternal blood pressure greater than 70 mm Hg. Fetal heart rate can be monitored during the procedure and used as a guide to adjust flow rates. Hypothermia is also a concern and is associated with fetal bradycardia. Uterine contractions are common, further complicating fetal heart rate abnormalities. Perfusion temperatures greater than 30°C are generally well tolerated.[107] In the larger review, neonatal outcome was not related to the

evaluated variables associated with cardiac bypass, including duration of bypass, hypothermia versus normal temperature, and lowest temperature.[108]

Volume status should be monitored, and increases in blood pressure should be avoided to prevent worsening of regurgitant flow. When the left atrium is enlarged, cardiac monitoring may aid in the early identification of atrial fibrillation. Regional anesthesia is the method of choice for pain control during labor and delivery because of the decrease in systemic vascular resistance. Endocarditis prophylaxis should be used when indicated (see Table 37–4). Monitoring for congestive heart failure and atrial fibrillation should continue into the postpartum period.

Aortic Stenosis

Maternal and Fetal Risks

Aortic stenosis is the most common cardiac valve lesion in the United States. It can be congenital or rheumatic in origin, or it may be due to an age-related calcification of the aortic valve. All of these etiologies are uncommon in women of reproductive age. Both congenital aortic stenosis and age-related lesions more commonly affect men.[110] In addition, aortic stenosis of rheumatic origin is typically progressive and tends to be less severe in patients of reproductive age.[111] Aortic stenosis accounts for only 5% to 10% of cases of rheumatic heart disease in pregnancy and is usually seen in conjunction with mitral valve disease.[1,2]

The normal aortic valve area is 3 to 4 cm. The pressure gradient across the valve increases rapidly as the valve area is reduced to less than 2 cm, and this increase is associated with left ventricular outflow obstruction.[110] Mild to moderate stenosis (valve area >1 cm) is relatively well tolerated in pregnancy, with no cardiac complications reported in a recent case series of patients with congenital aortic stenosis. Even patients with severe aortic stenosis generally do well, with no maternal mortality and only a 10% rate of cardiac complications reported in the same series. During 2-year follow-up, 36% of patients had progression of the cardiac condition that required surgery.[112] In these patients, cardiac output is fixed. Increased left ventricular pressure leads to hypertrophy and subsequent atrial enlargement. Tachyarrhythmias may further complicate the condition. A decrease in cardiac output may result in inadequate coronary artery and cerebral perfusion, followed by sudden death. Patients with congenital stenosis are also at increased risk for endocarditis.[56] Despite the maternal risks, recent series reported a generally good outcome.[26,111,113,114] Decreased disease severity may be one factor.[111]

With severe stenosis, the fetus is at risk for intrauterine growth restriction. If maternal disease is congenital, the incidence of congenital heart disease in the fetus is 4% to 12%.[27]

Management Options

Before pregnancy, the severity of aortic stenosis should be determined by echocardiography and catheterization, if necessary. Severe disease should be corrected surgically before conception.

Physical activity should be limited. Patients should be observed for signs of congestive heart failure or arrhythmias. Serial fetal ultrasounds should be scheduled to detect evidence of growth restriction. Antenatal testing is initiated, as indicated.

Fluid management is the critical component of intrapartum care. Volume overload can lead to pulmonary edema. Of greater concern, however, is hypovolemia or hypotension, with decreased venous return and cardiac output. Use of a PAC may aid in monitoring volume status. Patients should labor and deliver in the lateral position to avoid aortocaval compression. Regional anesthesia is administered slowly and cautiously, after adequate volume loading, to avoid hypotension. A narcotic epidural can decrease the chance of hypotension. Blood loss should be monitored closely and replaced as necessary. If pulmonary edema develops, aggressive diuresis is avoided to prevent a decrease in preload. Oxygen, morphine (category B), and inotropic agents, such as dopamine (category C) or dobutamine (category C), are used to maintain cardiac output. Bacterial endocarditis prophylaxis is used, as indicated (see Table 37–4). Close monitoring of volume status is essential in the postpartum period.

Continued follow-up after the postpartum period is important because the condition is progressive. Many patients require surgical intervention within 2 years of pregnancy.[112]

Aortic Regurgitation

Maternal and Fetal Risks

Like aortic stenosis, aortic regurgitation is uncommon in women of childbearing age. Although it is most likely of rheumatic origin, aortic regurgitation is an infrequent rheumatic lesion. Less common etiologies include Marfan's syndrome and syphilitic aortitis. Regurgitation in both is a consequence of aortic root dilation.

With progressive aortic insufficiency, cardiac output is usually maintained by left ventricular dilation and hypertrophy as a result of increased preload and stroke volume. Because the condition is progressive, severe disease, with ventricular dilation, hypertrophy, and widened pulse pressure, is not likely to be seen in pregnancy.[115] The decreased

systemic vascular resistance and increased heart rate associated with pregnancy may improve the hemodynamics of aortic insufficiency because of decreased resistance to forward flow and decreased time for regurgitant flow to occur during diastole. As a result, pregnancy is generally well tolerated.[86]

Management Options

PREPREGNANCY

Preconceptually, the extent of disease should be defined by echocardiogram and catheterization, if necessary. In symptomatic patients, cardiac function should be optimized with digoxin (category C) and afterload reduction, as necessary. If indicated, valve replacement is done before pregnancy.

PRENATAL

Cardiac status should be optimized, as in the nonpregnant state, and patients should be followed for signs of congestive heart failure. If medical management is inadequate, valve replacement can be performed during pregnancy with relative safety.[107]

LABOR, DELIVERY, AND POSTNATAL

Volume status should be followed in the postpartum period while the patient is observed for congestive heart failure. Invasive hemodynamic monitoring is usually unnecessary unless other valvular disease is present. Pain control is best achieved with lumbar epidural anesthesia, which decreases regurgitant flow by reducing afterload.

PROSTHETIC HEART VALVES

Maternal and Fetal Risks

Surgical valve replacement allowed many patients with severe valvular heart disease to survive and lead near-normal lives. There are two broad categories of replacement valves, each with advantages and disadvantages. Mechanical valves are made of nonbiologic materials. Bioprosthetic valves are either heterografts, made of bovine or porcine valves or pericardium, or homografts, which are human aortic valves.[116] The different characteristics of these valves make the optimal choice in women of reproductive age difficult and controversial. Mechanical valves have the advantage of durability, but the risk of thrombosis requires long-term anticoagulation. Bioprosthetic valves do not require anticoagulation, but valve failure often occurs within 10 to 15 years.[116] To reduce the need for replacement, mechanical valves are recommended for young patients.[116] On the other hand, bioprosthetic valves are advocated to decrease the risk of thrombosis during pregnancy and the risk of bleeding complications as a result of anticoagulation. Bioprosthetic valves also eliminate the significant fetal risks associated with oral anticoagulants.[117]

The incidence of major thromboembolism in non-pregnant patients with mechanical valves averages 8%. Anticoagulation reduces this risk by 75%.[118] Valve thrombosis causes pulmonary congestion, poor perfusion, and systemic embolization. Rapid clinical deterioration often follows. Most embolization involves the cerebral vessels. Patients with atrial fibrillation or left ventricular dysfunction are at increased risk for embolic events. In addition, increased rates of pregnancy loss,[119,120] prematurity, and low birth weight[121] were reported in patients with mechanical valves compared with those with bioprosthetic valves.

Bioprosthetic valve dysfunction is often related to rupture or tearing of a leaflet. Progressive dyspnea and congestive heart failure suggest bioprosthetic valve deterioration. Failure in these valves is more common with a mitral valve prosthesis and in patients younger than 40 years old.[116] Pregnancy accelerated valve deterioration in one series,[119] although this finding was not confirmed by others.[122,123] In a recent report by Salazar and associates,[123] the need for bioprosthetic valve replacement was associated with the patient's age at the time of initial surgery and not with pregnancy. Bioprosthetic valve dysfunction occurred at a rate of 3.5% per patient-year in the pregnancy group compared with 3.4% per patient-year in the nonpregnant control group. Endocarditis complicates both types of prostheses equally. Reported rates vary from 3% to 6%[116] to as high as 10% to 22%.[122]

North and colleagues[122] reviewed their experience with valve replacement in a population of more than 230 patients 12 to 35 years of age, with nearly 1500 woman-years of follow-up. The report covered a 20-year period beginning in 1972. Of these women, 71 had a total of 132 pregnancies. Patients with bioprosthetic valves had a significantly lower incidence of thrombosis and bleeding complications as well as greater 10-year survival compared with those with mechanical valves. Not surprisingly, there was an increased need for replacement of the bioprosthetic valve within 10 years (Table 37–6).

In patients with mechanical valves, anticoagulation is required throughout pregnancy, and there is controversy about the method of choice. Heparin use was associated with an increased incidence of valve thrombosis compared with warfarin (category D).[120] This finding may be explained by inadequate heparin dosing.[124] On the other hand, warfarin is associated with increased risk in pregnancy, both early and late, compared with heparin.[120] In addition, a specific embryopathic pattern is seen when warfarin is used between weeks 6 and 9. Fetal warfarin syndrome is characterized by nasal hypoplasia and stippled epiphyses.[31] The incidence of fetal complications appears to be related to the warfarin dose, with a substantially increased risk noted in patients requiring more than 5 mg/day.[125] Because it crosses the placenta, warfarin can also cause fetal anticoagulation and bleeding, particularly if used within 2 weeks of labor.[124] Despite

TABLE 37–6

Comparison of Outcomes Associated with Mechanical and Prosthetic Valves in Young Women

OUTCOME	MECHANICAL (N = 178)	BIOPROSTHETIC (N = 73)	HOMOGRAFT (N = 72)	P
10-year survival (%)	70	84	96	0.12
Thrombotic complications (%)	45	13	1	<0.01
Bleeding complications (%)	15	4		0.05
10-year valve replacement (%)	29	82	28	<0.01

the potential fetal consequences associated with oral anticoagulation, a committee of the European Society of Cardiology Working Group on Valvular Heart Disease[126] advocates continued use of oral anticoagulation, with a switch to heparin (category C) during the final 2 to 3 weeks of gestation, as an acceptable treatment approach. Another acceptable regimen uses heparin during the first trimester, with a change to warfarin until 37 weeks, and a change back to heparin until after delivery. In both regimens, antenatal use of warfarin is advocated over heparin because of a decreased risk of valve thrombosis.[126] To prevent warfarin embryopathy, another option is to substitute heparin at therapeutic doses preconceptually or before week 6 and to continue its use until after delivery. This method is used successfully, with heparin given subcutaneously every 8 to 12 hours at a dose sufficient to maintain the activated partial thromboplastin time at greater than two times the control value.[116,124] The addition of low-dose aspirin was suggested as an adjunct to either heparin or warfarin to further reduce the risk of thrombosis; however, it is associated with a slight increase in the incidence of bleeding complications.[127] Osteoporosis and fractures are potential risks of long-term heparin therapy. Antiplatelet agents and low-dose heparin (5000 units given subcutaneously every 12 hours) do not adequately protect against thrombotic complications.[128]

The use of low-molecular-weight heparin for both prophylaxis and therapeutic anticoagulation during pregnancy increased in recent years. In 2002, Aventis issued a warning that enoxaparin should not be used for anticoagulation in patients with artificial heart valves because of reports of valve thrombosis associated with its use. Although this decision was criticized because of inadequate evidence,[127] until more data are available, it seems prudent not to use low-molecular-weight heparin for this purpose.

Management Options

Prepregnancy

As with other cardiac lesions, NYHA functional status is determined. Baseline echocardiography is indicated. Patients with bioprosthetic valves should be informed of the symptoms of valve deterioration, although the relationship with pregnancy is controversial. Warfarin embryopathy must be discussed with patients who have a mechanical valve. An informed decision about the potential use, timing, and duration of heparin treatment should be made.

Prenatal

Patients with bioprosthetic valves should be followed for signs of valve deterioration. Those with mechanical valves must maintain adequate anticoagulation. In patients who continue treatment with warfarin, the International Normalized Ratio is maintained between 2.0 and 4.9, depending on the valve type.[116,126] If heparin is used, the activated partial thromboplastin time is followed. Thrombocytopenia is associated with heparin therapy and has two types, early and late. The early type is seen during the first 5 days of therapy. Platelet counts usually return to normal within 72 hours.[129] Late-onset thrombocytopenia occurs after more than 5 days of heparin use and is associated with heparin-dependent immunoglobulin G antibodies. Immunoglobulins can cause platelet aggregation and activation, with subsequent paradoxical arterial or venous thrombosis.[129,130] A baseline platelet count should be obtained, and serial platelet counts are followed. The finding of late-onset thrombocytopenia requires heparin discontinuation. At term, if warfarin has been used, it is discontinued and heparin initiated.

Labor and Delivery

Clear recommendations for heparin use during labor and delivery are not available. Intravenous heparin at therapeutic doses may be given until 6 hours before delivery. This approach has the advantage of preventing thrombotic complications. The benefit is small, however, because the risk of valve thrombosis during the relatively short time of subtherapeutic anticoagulation is low.[118] If necessary, protamine can be used to reverse intravenous heparin anticoagulation at a dose of 1 mg/100 units heparin up to a maximum dose of 50 mg. The dose is decreased as the time since heparin withdrawal increases. Another approach is to give prophylactic doses of heparin (5000–7500 units every 12 hours) subcutaneously.

In some patients, endocarditis prophylaxis is indicated (see Tables 37–4 and 37–5). Patients with bioprosthetic valves may benefit from operative vaginal delivery to shorten the second stage of labor and avoid the additional hemodynamic stresses of pushing.

Postnatal

Warfarin is initiated in the postpartum period in patients with mechanical valves. Anticoagulation with intravenous heparin while awaiting therapeutic levels of warfarin is probably not warranted. The risk of bleeding, particularly after cesarean delivery, exceeds the risk of thrombotic complications.[118] Subcutaneous heparin in prophylactic doses may be used. Breast-feeding during anticoagulation with warfarin is not contraindicated.[131]

MARFAN'S SYNDROME

Maternal and Fetal Risks

Marfan's syndrome is a connective tissue disorder with characteristic findings in the skeletal, ocular, and cardiovascular systems. Cardiac manifestations include MVP and aortic root dilation. Aortic pathology is associated with increased morbidity and mortality. The pathophysiologic changes seen in the aorta result from decreased smooth muscle and abnormal connective tissue, leading to decreased distensibility.[132] Significant aortic root involvement is a particular problem because of the potential for aortic regurgitation, dissection, or rupture. In pregnant patients, morbidity and mortality rates increase when the aortic root diameter exceeds 40 mm.[133–135] With aortic root involvement, mortality rates as high as 25% to 50% are seen. Even with a normal aorta, significant maternal mortality is reported. The elevated risk seen in pregnancy may be related to the increased cardiac output, placing additional stress on the relatively stiff aorta. Pregnancy-associated hypertension may further aggravate the condition.[132] Recent reports suggested a better prognosis with minimal cardiovascular involvement. These patients had no increase in adverse maternal outcome and no accelerated dilation of the aorta compared with similar patients with Marfan's syndrome who did not become pregnant. Patients without aortic root dilation usually tolerate pregnancy well.[133–135] The syndrome is inherited by autosomal dominant transmission, so there is a 50% chance that the fetus may be affected.

Management Options

Prepregnancy

Genetic counseling is an essential part of family planning in Marfan's syndrome because of the 50% risk of transmission. If pregnancy is desired, echocardiographic evaluation of the aorta is performed to define maternal risk status. Pregnancy is discouraged in patients with significant aortic root dilation. Even when the aortic root size is normal, a risk-free pregnancy cannot be guaranteed.[135,136] If cardiac involvement is minimal, however, pregnancy may be cautiously planned. In this group of patients, initiation of β-blockade therapy should be considered if not already used. Although information on its use in pregnancy complicated by Marfan's syndrome is limited, long-term use outside of pregnancy slows the progression of aortic dilation.[137]

Prenatal

Serial echocardiography should be performed every 6 to 10 weeks throughout pregnancy to follow the aortic root size.[134] If not initiated preconceptually, the addition of β-blocker therapy should be considered. Little information is available to guide management in patients with progressive aortic root dilation during pregnancy. Patients should be kept at rest to minimize hemodynamic stresses. Hypertension should be avoided because of the increased risk of aortic dissection. Although it is best postponed until postpartum, prophylactic aortic root repair may be considered in extreme cases. In nonpregnant adults, 55 mm is the critical aortic root diameter at which prophylactic repair is undertaken.[137]

Prenatal diagnosis is available in some families through linkage analysis or mutation detection.[132]

Labor, Delivery, and Postnatal

Epidural anesthesia during labor should be considered. Adequate oxygenation must be maintained, and hypertension should be avoided. Vaginal delivery is desirable, with shortening of the second stage of labor with the use of a vacuum or forceps.[134] Some authors recommend elective cesarean delivery in patients who are at significant risk for aortic dissection.[135] Both patient and physician must remain vigilant because the risk of aortic dissection persists for 6 to 8 weeks postpartum.[134]

DILATED CARDIOMYOPATHY

Maternal and Fetal Risks

Dilated cardiomyopathy is uncommon in women of reproductive age. Peripartum cardiomyopathy is a subset of dilated cardiomyopathy that occurs in association with 1 in 1300 to 1 in 15,000 pregnancies.[138,139] Traditional diagnostic criteria include onset of heart failure in the last month of pregnancy or the first 5 months postpartum, with no other etiology of heart failure identified and no history of cardiac disease. A work group convened in 1997 by the National Institutes of Health and the National Heart Lung and Blood Institute added echocardiographic

evidence of left ventricular dysfunction to the diagnostic criteria. The dysfunction may be documented by a reduced ejection fraction or decreased fractional shortening.[140] Patients with peripartum heart failure are typically older than 30 years of age, multiparous, and of African descent.[138,141,142] The condition is also more common in patients with preeclampsia, gestational hypertension, and those pregnant with twins.[140] The existence of peripartum cardiomyopathy as a distinct pathologic entity is debated. Clustering of cases in late pregnancy and the puerperium suggests a unique condition.[138] Others argue that pregnancy leads to unmasking and decompensation of preexisting heart disease.[139] To minimize confounding by exacerbation of unrecognized preexisting heart disease, the National Institutes of Health work group emphasized the importance of limiting the diagnosis to heart failure occurring within the defined 6-month window.[140]

Regardless of the etiology, cardiomyopathy during pregnancy is associated with significant morbidity and mortality. Reported complication rates vary widely and likely reflect different patient populations and variations in diagnostic criteria. Persistent cardiac dysfunction is seen in 45% to 90% of patients.[141,142] Life-threatening arrhythmias may occur.[139] Embolic complications, either pulmonary or systemic, are seen in as many as 50% of patients.[138] Maternal mortality was reported in 4% to 80% of patients, with recent estimates near 20%.[141,143] Survivors often require cardiac transplant.[140,141] The rate of recurrence in subsequent pregnancies is as high as 85%.[140] Pregnancy is poorly tolerated in patients with persistent ventricular dilation and dysfunction.[138,141] In this group of patients, mortality rates are 20% to 60%. Those with normal cardiac function 6 to 12 months postpartum are at risk for heart failure and a recurrent decrease in ejection fraction that may not recover after pregnancy. Mortality rates in these patients are lower, ranging from 0% to 15%.[138,144] Patients whose cardiomyopathy clinically resolved had decreased contractile reserve with provocative testing.[142] This lack of reserve may cause cardiac decompensation as a result of the hemodynamic stress of a subsequent pregnancy and may contribute to the morbidity after a previous return to normal cardiac function.

Management Options

Prepregnancy

Pregnancy is strongly discouraged in patients with a history of peripartum cardiomyopathy, particularly those with residual cardiac dysfunction. In those with normal cardiac function, pregnancy may be attempted cautiously. The patient should be informed of the potential for worsening cardiac function during pregnancy, which may not completely resolve postpartum.[145] Reliable contraception should be provided, with permanent sterilization considered.

Prenatal

If pregnancy occurs, echocardiography should be performed to document ventricular size and function as well as the presence of mural thrombi. Termination should be offered, especially to patients who have persistent echocardiographic abnormalities because of the high associated maternal morbidity and mortality. If the pregnancy is continued, a multidisciplinary team, including a cardiologist, a perinatologist, an anesthesiologist, and a neonatologist, should collaborate to optimize outcome. Decreased activity and potentially bed rest are recommended, along with salt restriction. Diuretics, digoxin (category C), and afterload reduction with hydralazine (category B) should be used, as necessary. Because of the risk of embolic phenomena, heparin (category C) may be given. Both prophylactic and therapeutic doses are used.[141]

Labor and Delivery

Patients are watched closely for signs of heart failure and pulmonary edema. Cardiac monitoring is instituted early in labor. Fluids are restricted, and central hemodynamic monitoring should be available if decompensation occurs. If a flow-directed PAC is necessary, care must be taken during insertion. Positioning may be difficult because of dilated chambers and decreased ejection fraction. Arrhythmias may also be precipitated during insertion. Heparin can be discontinued during early labor and resumed in the early postpartum period. Adequate pain control is important, and epidural anesthesia works well. Patients with significant cardiac dysfunction may need to labor in a sitting position to reduce or prevent shortness of breath.

Postnatal

Monitoring of volume status must continue through the postpartum period, with fluid restriction as necessary. Diuretics may be used as necessary, and the patient should be given an angiotensin-converting enzyme inhibitor (category D) for afterload reduction.[140] A reliable and effective plan for contraception should be discussed. Although uncommonly performed, endomyocardial biopsy is recommended to exclude treatable causes of cardiomyopathy. Some patients with myocarditis found on biopsy respond favorably to immunosuppressive therapy.[140,143]

CARDIAC ARRHYTHMIAS

Maternal and Fetal Risks

Cardiac arrhythmias are relatively common during pregnancy. Most are benign and include sinus bradycardia, sinus tachycardia, and atrial and ventricular premature contractions. These patients are often asymptomatic, but

may have palpitations, although the correlation between symptoms and arrhythmia is poor. Shotan and associates[146] evaluated symptomatic pregnant patients who were referred to a cardiac clinic and compared them with asymptomatic pregnant patients who were referred for evaluation of a cardiac murmur. The incidence of premature atrial and ventricular contractions was 50% to 60% in each group. Although the frequency of arrhythmias was higher in symptomatic patients, only 10% of symptoms occurred in conjunction with arrhythmia. Healthy, asymptomatic patients without underlying pathology can often be managed with observation and rest.[147] Normal labor and delivery do not seem to increase the incidence or type of arrhythmias identified.[148]

Pregnancy may be associated with an increase in the incidence and severity of arrhythmias.[146,149,150] Supraventricular tachycardia is often seen in pregnancy. Ventricular tachycardia and multiform premature ventricular complexes are much less common but may be recognized for the first time during gestation. Atrial fibrillation is usually associated with underlying cardiac disease. An increase in cardiac complications as a result of long QT syndrome was noted, particularly during the postpartum period.[149] Serious maternal complications are rare, but include cardiac failure and sudden death. Fetal risk is primarily associated with exposure to drugs used for maternal therapy.

Management Options

Prepregnancy

All patients with a sustained arrhythmia should undergo a baseline electrocardiogram to determine whether the rhythm abnormality originates from the atrium or the ventricle. This is followed by a search for an underlying etiology. Patients with unexplained sinus tachycardia or premature atrial or ventricular contractions are questioned about tobacco, caffeine, and illicit drug use. They are also evaluated for anemia and hyperthyroidism. If a contributing factor is identified, behavior modification is attempted, as appropriate. Medical conditions should be treated before conception. Ambulatory monitoring is considered when patients have symptoms that suggest a rhythm disturbance but no objective evidence on examination. Patients who may benefit from ablative therapy should be identified and treated before conception.

Symptomatic and sustained arrhythmias often require appropriate antiarrhythmic therapy. Most antiarrhythmic agents are classified as category C, except when otherwise noted. β-Blockers can be used in patients with sinus tachycardia or frequent premature atrial or ventricular contractions when symptoms persist after conservative management.[150] In patients with long QT syndrome, β-blockers are continued to reduce the incidence of cardiac events.[149] Digoxin can be used safely to control the ventricular rate in atrial fibrillation and flutter and some

supraventricular tachycardias.[147] Adenosine has a rapid onset and very short duration of action. It is used during pregnancy to treat supraventricular tachycardia and is the drug of choice.[150–152] Esmolol and intravenous verapamil can be used intravenously in the acute management of supraventricular tachycardia. Quinidine is used for some atrial and ventricular arrhythmias, when clinically indicated. Lidocaine (category B) is used acutely to control ventricular arrhythmias. Procainamide is a second-line agent because of maternal side effects, including cardiac rhythm disturbances, lupus-like syndrome, and blood dyscrasia.[153] Amiodarone (category D) is used to treat life-threatening ventricular arrhythmias when first-line agents are unsuccessful. It is associated with neonatal hypothyroidism, hyperthyroidism, and possibly intrauterine growth restriction, fetal bradycardia, and neurologic abnormalities.[154]

Prenatal, Labor, Delivery, and Postnatal

Management during pregnancy consists of maintenance therapy to control arrhythmias. Drug levels should be monitored, as indicated, because of pregnancy-associated changes in volume of distribution and protein binding. Vagal maneuvers can be tried initially in tachyarrhythmias with first onset in pregnancy. Cardioversion can be used safely during pregnancy in unstable patients or when medical therapy is unsuccessful.[147] Continuous cardiac monitoring may be necessary intrapartum and postpartum for symptomatic or complex arrhythmias.

MYOCARDIAL INFARCTION

Maternal and Fetal Risks

Myocardial infarction is very uncommon in women of reproductive age.[155] Most events occur in the third trimester, with a maternal mortality rate of approximately 20%. Labor occurring within 2 weeks of an acute myocardial infarction increases the risk of maternal death.[156] A coronary thrombus, with or without associated atherosclerotic changes, is seen in no more than 50% of patients.[155] No cardiac risk factors are present in 40% of cases.[157] Nearly 30% of patients have normal coronary arteries.[156] Fetal outcome is related to maternal status and outcome.

Diagnosis is difficult because the index of suspicion is low. Physiologic changes of pregnancy may mimic the symptoms of myocardial infarction and delay the diagnosis. During labor, the diagnosis is further complicated by the fact that creatinine phosphokinase and the cardiac-specific MB fraction may be normally elevated.[158] Troponin I is a specific marker for cardiac injury that does not increase during normal labor and delivery, making it a potentially useful tool in the diagnosis of myocardial infarction in the pregnant woman.[159] A few case

reports described the utility of troponin I in the diagnosis of myocardial infarction during pregnancy.[160,161]

Management Options

Prepregnancy

Because the underlying condition is rare, pregnancy after myocardial infarction is uncommon. Unfortunately, it is even more uncommon for these patients to seek preconception counseling.[162] When possible, cardiac evaluation should be done, including stress testing and echocardiography. If the patient has no cardiac dysfunction, pregnancy can be planned cautiously.[162]

Prenatal

Patients should rest and avoid strenuous activity. They should also be monitored for evidence of arrhythmias or congestive heart failure. If a myocardial infarction occurs during pregnancy, management principles are similar to those for nonpregnant patients.[156,163,164] Most drugs used in the medical management of myocardial infarction are category C, except where otherwise noted. Nitroglycerin, oxygen supplementation, morphine (category B), heparin, and continuous cardiac monitoring are initiated. Lidocaine (category B), dopamine, calcium channel blockers, and β-blockers can be used, as indicated. Coronary angiography is also used during pregnancy.[163] Favorable pregnancy outcomes are reported after coronary angioplasty[164] and bypass surgery[165] during gestation. Pregnancy is a relative contraindication to thrombolytic therapy because of the theoretical increased risk of maternal and fetal bleeding.[156,163] However, safe and effective use is reported during pregnancy.[166]

In cases of cardiac arrest, cardiopulmonary resuscitation proceeds as in the nonpregnant patient, except that the gravid uterus is displaced laterally to prevent compression of the vena cava and improve venous return.[167] Successful cardioversion of ventricular fibrillation has been reported.[165] If initial attempts at resuscitation are unsuccessful, perimortem cesarean section is indicated to save the viable fetus. Optimal neonatal outcomes are seen when delivery occurs within 5 minutes of cardiac arrest. Alterations in maternal hemodynamics after delivery may improve maternal outcome.[167,168]

Labor and Delivery

External cardiac monitoring is necessary. Supplemental oxygen should be given, and epidural anesthesia is used for pain control. Operative vaginal delivery to shorten the second stage of labor is also advocated.[163,165,169] Labor can often be managed without invasive monitoring. Use of a PAC is reserved for unstable patients.

Cesarean delivery is empirically advocated in patients who start labor within 4 days of an acute myocardial infarction.[163,169]

Postnatal

Volume status is monitored in the postpartum period, and the patient should avoid exertion. A reliable plan for contraception should be made. Combination oral contraceptives are usually contraindicated. Although the risk of atherosclerosis is not increased, estrogen increases thrombotic risk, especially when other risk factors are present. If permanent sterilization is not desired, reasonable alternatives include long-acting progestins or an intrauterine device.[170,171]

HYPERTROPHIC CARDIOMYOPATHY

Maternal and Fetal Risks

Hypertrophic cardiomyopathy is an autosomal dominant condition characterized by left ventricular hypertrophy without chamber dilation or another etiology to explain the hypertrophy. It is classically associated with left ventricular outflow obstruction, but this is not found in most patients. As a result, older names for this condition, such as idiopathic hypertrophic subaortic stenosis and hypertrophic obstructive cardiomyopathy, have been generally replaced. In the general population, the frequency of this condition is approximately 1 in 500.[172]

The presentation and prognosis are clinically variable. Most patients have a normal life expectancy without limitations; however, hypertrophic cardiomyopathy is a common cause of sudden cardiac death in young people. The annual mortality rate is estimated at 1%, substantially less than the rate reported in older series, primarily because of the identification and inclusion of patients with more benign forms of the disease.[172,173] Clinical risk factors for sudden death include a family history of sudden cardiac death, previous syncope, and documented ventricular tachycardia. Maki and associates[173] identified an inadequate increase in systolic blood pressure associated with exercise, defined as less than 24 mm Hg on treadmill testing, as a risk factor in patients younger than 50 years of age. Left ventricular wall thickness greater than 30 mm may be a risk factor in young adults.[172] Implantable cardiac defibrillators are used successfully in high-risk patients and can be used in pregnant patients.[174]

Physiologic changes associated with pregnancy have variable effects on the condition. Adequate preload and systemic vascular resistance are important factors in maintaining end-diastolic volume and cardiac output. A decrease in end-diastolic volume increases outflow obstruction. The increased blood volume associated with

pregnancy has a beneficial effect, whereas the decrease in systemic vascular resistance can worsen outflow obstruction. The increased heart rate can also adversely affect maternal condition as a result of decreased diastolic filling time. Despite these concerns, maternal complications are uncommon and are confined primarily to women with specific risk factors.[175] The autosomal inheritance pattern gives the fetus a 50% chance of having the condition.

Management Options

Prepregnancy

Genetic counseling is indicated if either parent is affected. A careful history should be taken to identify patients with historical risk factors. An echocardiogram should be done. Patients should also be seen by a cardiologist who has experience with patients who have this condition to determine the need for exercise testing and the role of Holter monitoring.

Prenatal

Activity is limited to avoid tachycardia. Adequate hydration should be maintained. Although it is not necessary in all patients, β-blockade may be used in symptomatic patients.[172,176]

Labor, Delivery, and Postnatal

Volume status is monitored to avoid dehydration and hypotension during labor. Regional anesthesia may be used, but should be administered with care after adequate volume loading, again, to prevent hypotension. If tachycardia develops and the patient becomes symptomatic, β-blocking agents (mostly category C) may be used to control the heart rate. Esmolol, a short-acting β-blocker, is used successfully during labor to control symptoms.[176] Endocarditis prophylaxis is used, as indicated (see Table 37–4). The patient should be observed for excessive blood loss and tachycardia in the postpartum period. Volume replacement is given, as indicated.

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific

Management Options	Quality of Evidence	Strength of Recommendation	References
Cardiac Murmur			
Echocardiogram for patients with a significant history or a pathologic murmur (late systolic, pansystolic, diastolic)	III	B	42,43
Cardiology referral if an echocardiogram is abnormal	IIb	B	45
Mitral Valve Prolapse			
Cardiology and echocardiogram evaluation prenatally for mitral regurgitation	IV	C	47
Surveillance and treatment of arrhythmias in pregnancy	IV	C	47
Atrial Septal Defect			
Pregnancy			
Screen for arrhythmias or pulmonary hypertension; manage accordingly both before and during pregnancy (if undertaken)	III	B	55,56
Prenatal			
Routine unless the patient has arrhythmias or Pulmonary hypertension	III	B	55,56
Screen fetus for congenital heart defect	IIb	B	25
Labor and Delivery			
Screen for arrhythmias, monitor blood pressure, and avoid fluid overload	III	B	55,56
Postnatal			
Encourage early mobilization	III	B	55,56
Screen newborn for congenital heart defect	IIb	B	25

Cardiac Disease: Specific *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Ventricular Septal Defect			
Prepregnancy			
Screen for pulmonary hypertension and manage accordingly; consider repair of uncorrectedlesions and counseling about the risk of congenital heart disease	III	B	57,58
Prenatal			
Obtain serial echocardiograms, and manage accordingly	III	B	57,58
Screen fetus for congenital defect	IIb	B	25

Mitral Stenosis			
Prepregnancy			
Assess cardiac function, optimize medical therapy, and consider surgical correction.	III	B	96–98
Prenatal			
Avoid excess weight gain; provide tachycardia and serial echocardiography; treat tachycardia or arrhythmias; perform percutaneous commissurotomy or surgery for symptomatic severe disease; provide fetal surveillance.	III	B	99,100–103
Labor and Delivery			
Intensive care setting; consider central invasive monitoring, epidural analgesia, and antibiotic prophylaxis for complicated deliveries; provide fetal surveillance.	III	B	94
Mitral Regurgitation			
Prepregnancy			
As for stenosis	III	B	106
Prenatal			
Restrict activity; perform serial echocardiography; adjust medical control; consider surgery for symptomatic severe disease; perform fetal surveillance	III	B	106–108
Labor, Delivery, and Postnatal			
Avoid fluid overload and hypertension; provide maternal cardiac monitoring and endocarditis prophylaxis for complicated deliveries.	–	GPP	–
Aortic Stenosis			
Prepregnancy			
Determine severity by echocardiography and callretengation	III	B	110–114
Correct severe disease surgically before conception.	–	–	–
Prenatal			
Limit physical activity; maintain vigilance for heart failure and arrhythmias.	III	B	110–114
Fetal surveillance	–	–	–

Cardiac Disease: Specific *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Labor, Delivery, and Postnatal			
Avoid fluid overload, hypovolemia, and hypertension.	III	B	110–114
Some would use pulmonary artery catheter.	–	–	–
Implement prophylaxis for bacterial endocaditis	–	–	–
Cardiologic follow-up as risk of determination over the next 1–2 years.			
Aortic Regurgitation			
Prepregnancy			
As for mitral disease, i.e. echocardiography; cardiac catheterization; optimistic medical control (Digoxin); value replacement if indicated	III	B	115
Prenatal			
Surveillance for cardiac failure; surgery for failed medical therapy; fetal surveillance	III	B	107
Labor, Delivery, and Postnatal			
Avoid fluid overload; invasive monitoring is usually unnecessary; epidural is beneficial; provide fetal surveillance	III	B	115
Prosthetic Valves			
Prepregnancy			
Assess cardiac status; provide counseling about valve function and risks associated with warfarin	III	B	122
Prenatal			
If the patient has biosynthetic valves, provide vigilance for deterioration; if the patient has mechanical valves, provide adequate anticoagulation; vigilance for thrombocytopenia when using heparin	III	B	116,126,129
Labor and Delivery			
Adjust anticoagulation and provide endocarditis prophylaxis	III	B	122,126
Postnatal			
Readjust anticoagulation	III	B	122,126
Marfan's Syndrome			
Prepregnancy			
Genetic counseling, and echocardiography (especially aortic root); counsel against pregnancy	III	B	135–137
Prenatal			
Serial aortic root echocardiography; give β-blockers; avoid hypertension; encourage rest; surgery in extreme cases	III	B	132,134,137
Labor, Delivery, and Postnatal			
Epidural is beneficial; avoid hypertension; ensure adequate oxygenation; shorten the second stage of labor; maintain vigilance for aortic root dissection for at least 8 weeks postnatally	III	B	134,135
Dilated Cardiomyopathy			
Prepregnancy			
Counsel against pregnancy if the patient has a history of peripartum cardiomyopathy	III	B	145

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Echocardiography. Consider termination in patients with an abnormal echocardiogram; if the patient is symptomatic, provide medical therapy and anticoagulation	III	B	141,145
Multidiscliplinary team care			
Labor and Delivery			
Monitor for heart failure; avoid fluid overload; possibly use pulmonary artery catheter, vigilance for arrhythmias; adequate analgesia	III	B	141,143–145
Postnatal			
Avoid fluid overload; discuss contraception	III	B	141,143–145
Cardiac Arrhythmias			
Prepregnancy			
Investigate and treat	III	B	147,149–152
Prenatal, Labor, Delivery, and Postnatal			
Maintenance of therapy to control arrhythmia; cardioconversion can be used as indicated	III	B	147,149–152
Myocardial Infarction			
Prepregnancy			
Assess cardiac function (especially echocardiography and stress testing); counsel on the basis of results; give low-dose aspirin	III	B	162
Prenatal			
Avoid strenuous activity; provide surveillance for failure and arrhythmias; management as for a nonpregnant patient; surgery can be performed in pregnancy	III	B	156,163–165
Thrombolytic therapy has been used	III	B	156,163–165
Labor and Delivery			
Monitor electrocardiogram; provide supplementary oxygen; epidural is beneficial; consider cesarean section if labor occurs within 4 days of an acute myocardial infarction	III	B	156,165,169
Postnatal			
Avoid fluid overload and exertion; discuss contraception (avoid combination oral preparations)	III	B	165,170,171
Hypertrophic Cardiomyopathy			
Prepregnancy			
Genetic counseling; evaluate cardiac status with echocardiography	III	B	172
Prenatal			
Limit activity; give β-blockers for symptomatic patients	III	B	172,176
Labor, Delivery, and Postnatal			
Avoid dehydration or hypotension; give β-blockers for tachycardia and endocarditis prophylaxis for complicated deliveries	III	B	172,176

CONCLUSIONS

- Cardiac disease complicating pregnancy is not rare. Although both the incidence and the severity of rheumatic heart disease are decreasing, because of advances in cardiac surgery, more patients with repaired congenital heart disease are reaching reproductive age and choosing to become pregnant.
- The age at which women become pregnant is increasing, as is the incidence of diabetes and hypertension in the population, potentially leading to an increase in the incidence of ischemic heart disease during pregnancy.
- Physicians who treat these patients must understand the physiologic changes associated with pregnancy and their effect on specific cardiac conditions.
- With a complete diagnostic evaluation, optimization of cardiac function, and close follow-up throughout pregnancy and the puerperium, favorable maternal and fetal outcomes can be expected in most cases.

Respiratory Disease

Raymond Powrie

INTRODUCTION

A variety of biologic adaptations occur in the maternal respiratory system in pregnancy. Resting ventilation increases, oxygen consumption rises, and residual lung volume decreases. Generally, these physiologic changes are well tolerated by the pregnant woman. Their interrelationship with various pulmonary diseases is less well understood, despite the common occurrence of these conditions during pregnancy. It is advisable to include a respiratory physician, preferably one with particular interest in pregnancy, in the management of these disorders. This is critically important in acute severe asthma, the severity of which may be underestimated by both doctor and patient, in severe pneumonia, in cystic fibrosis, and in tuberculosis, where guidelines for therapy change frequently. Acute pulmonary edema is one of the more common reasons that pregnant or postpartum women are transferred to critical care facilities, and its management requires understanding and addressing of the underlying precipitating causes most commonly seen in pregnancy.

BREATHLESSNESS OF PREGNANCY

General

Pregnancy is associated with several significant changes in respiratory function. Pregnant women increase their minute ventilation by nearly 50% in pregnancy. This is achieved not by increasing respiratory rate but by increasing the volume of each breath. This increased "depth" of breathing is an effect of progesterone. Increased ventilation leads to a drop in arterial PCO_2 to 27 to 32 mmHg. PaO_2 is increased to 95 to 105 mmHg at sea level. A compensatory renal excretion of bicarbonate occurs in response to respiratory alkalosis, and serum bicarbonate decreases by 4 mEq/L.

Pulmonary function test results and peak expiratory flow rates (PEFR) remain largely unchanged in pregnancy. The main difference is a 20% drop in functional residual capacity (FRC, that portion of a breath that can still be exhaled after normal resting exhalation) due to a decrease in both expiratory reserve volume and residual volume.[1,2] Although the diaphragm will rise 4 cm above its usual position by term, this does not have a significant effect on respiratory function because diaphragmatic excursion is not altered.[3]

Breathlessness is a common symptom in normal pregnancy and therefore does not necessarily indicate cardiorespiratory disease. Up to 70% of pregnant women will report some level of dyspnea. The most typical description of this would be "air hunger."[2,4] This symptom can start during the late first or early second trimester. The peak gestation for the onset of breathlessness is 28 to 31 weeks. Often the breathlessness occurs spontaneously at rest and not in association with exertion. The etiology has not been clearly elucidated, although the hormonal effect of progesterone on ventilation and the associated fall in arterial carbon dioxide tension seem to be central features. It does not appear to be explained by increases in abdominal girth. Studies have suggested that the presence of dyspnea during pregnancy appears to correlate with a low PCO_2. Those women most likely to experience dyspnea during pregnancy appear to be those with a relatively high baseline nonpregnant PCO_2.[5,6]

Management Options

It can be difficult to differentiate benign breathlessness of pregnancy from the more serious causes of chronic dyspnea in pregnancy, such as asthma, pulmonary embolism, and cardiomyopathy. Initial evaluation should be based on a careful history and examination. A previous history of asthma, the presence of cough or wheezing, or an obstructive pattern on pulmonary function testing may point to asthma as a cause. Pulmonary

embolism is typically characterized by the sudden onset of dyspnea or chest pain. Dyspnea attributable to pregnancy is generally insidious in onset and should not be associated with any chest discomfort, cough, or sudden exacerbation. Cardiac disease in pregnancy may present as dyspnea. This may be due to previously existing cardiac conditions that have been unmasked by the increased cardiac work of pregnancy. It may also be due to new onset peripartum cardiomyopathy. Findings on physical examination of tachypnea, tachycardia, an elevated jugular venous pulse, a concerning murmur, respiratory crackles on auscultation, or an abnormal chest x-ray can point to a cardiac cause of dyspnea. Suspicion of a cardiac cause should lead to evaluation with transthoracic echocardiography.

History and physical examination can be supplemented with a complete blood count (CBC), oxygen saturation measurement (SaO_2) with exercise, and, if necessary, a chest x-ray. CBC can be used to identify those cases of dyspnea attributable to severe anemia. Measurement of SaO_2 (by pulse oximeter) with moderate exertion can be used to help rule out serious causes of dyspnea in pregnancy. If the SaO_2 remains normal (>95%) on exercise, it is unlikely that the patient has a major problem. Demonstrating to the patient that oxygenation is maintained despite the feeling of dyspnea can also help alleviate a patient's anxiety about her symptoms. Measurement of arterial blood gases (ABGs) will not be necessary in most patients presenting with a complaint of mild dyspnea of insidious onset in pregnancy.

When clinical evaluation leads the clinician to suspect that a patient's dyspnea is due to more than just the pregnancy, the clinician should be confident that all relevant diagnostic imaging procedures for investigating other causes of dyspnea can be safely performed during pregnancy. This includes chest x-rays, computed tomography (CT) scans of the chest, ventilation-perfusion scans, and pulmonary angiography.[7]

Most often, if other causes of dyspnea do not appear to be present, management of breathlessness in pregnancy is limited to educating the patient regarding these physiologic changes and providing reassurance.

CONCLUSIONS

BREATHLESSNESS

- Most breathlessness in pregnancy is common and is due to physiologic changes.
- A careful history and physical examination should be performed on all patients with this complaint, with specific emphasis on trying to identify evidence of thromboembolism, cardiac disease, or asthma.
- Specific concern should be focused on those patients who report dyspnea that is sudden in onset or occurs at rest.
- Investigate if pathologic cause suggested from clinical features; tests might include:
  - oxygen saturation at rest and with exercise (ABGs in severe cases)
  - hemoglobin
  - chest x-ray
  - ventilation-perfusion scan and/or CT angiogram
  - echocardiography

SUMMARY OF MANAGEMENT OPTIONS

Breathlessness in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Ask about wheezing, nocturnal worsening, and cough to distinguish from asthma.	IV	C	8
Ask about orthopnea and paroxysmal dyspnea, and perform cardiac exam to distinguish from heart failure.	IV	C	9
Ask about sudden onset of dyspnea, presence of chest pain, personal or family history of thrombosis and look for tachypnea and tachycardia to distinguish from pulmonary embolism. Consider lung scan if any of the above present.	IV	C	10

Breathlessness in Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Key investigations:	IV	C	6
• SaO$_2$ is the simplest, quickest test of oxygenation in presence of breathlessness (at rest and with exercise; ABGs in severe cases)			
• hemoglobin			
• chest x-ray			
• ventilation-perfusion scan or CT angiogram or MRI when pulmonary embolism suspected			
• echocardiography when cardiac causes suspected			

ASTHMA

General

Asthma is probably the most common potentially life-threatening medical disorder to occur in pregnancy. The worldwide prevalence of asthma has been steadily increasing such that it now occurs in approximately 1% to 4% of pregnant women.[8,11]

Asthma is defined as a chronic inflammatory disease of the airways that is manifest as a hyperresponsiveness of the airway to a wide variety of stimuli. It tends to be an episodic disease with exacerbations of reversible airway narrowing that are characterized clinically by coughing, wheezing, and shortness of breath. Precipitating factors for asthma exacerbations may include allergens, upper respiratory tract infections, medications (such as aspirin and beta blockers), environmental pollutants, occupational exposures, exercise, cold air, and emotional stress. The condition is more common in atopic individuals.

Maternal and Fetal Risks

Present data suggest that pregnancy does not have a consistent effect on the frequency or severity of asthma. In one prospective study of 330 asthmatic women, asthma was unchanged in 33%, improved in 28%, and worse in 35%.[12] Although it is not clear whether the severity of asthma before pregnancy predicts its course during pregnancy,[13] it does appear that women tend to have similar courses with their asthma in successive pregnancies.[14] Some investigators suggest that asthma tends to be less severe in the last 4 weeks of pregnancy and that if it does worsen, it tends to do so between 29 and 36 weeks' gestation.[15] Asthma exacerbations in labor appear to be very rare.

The usual reason asthmatic patients deteriorate in pregnancy is the mistaken belief that treatment for asthma is harmful to the fetus. Medical attendants as well as patients and their relatives are likely to promote this dangerous fallacy. A National Institutes of Health (NIH) Consensus Conference has concluded that "undertreatment of pregnant asthmatics, particularly because of unfounded fears of adverse pharmacologic effects on the developing fetus, remains the major problem in the management of asthma during pregnancy in the United States."[16] Other treatable reasons why asthma may worsen in pregnancy in individual women include pregnancy-related gastroesophageal reflux disease and pregnancy rhinitis. These precipitating factors should be considered and treated as possible contributors in pregnant women with difficult-to-control asthma.

In studies concerning the interaction between pregnancy and asthma, the only risks that are well established are those of preterm delivery [17,18] and maternal hypertension,[19] and even these risks have not been shown consistently.[20] Associations with hyperemesis, vaginal hemorrhage, complicated labor, neonatal mortality, placenta previa, prematurity and low birth weight infants have also been noted in some studies but not in others.[18,27] It is not clear if the possible relationship between asthma and these perinatal outcomes represents a direct effect of hypoxia and hypocapnia on the developing pregnancy, the effects of medication use, or a fundamental abnormality of smooth muscle in asthmatics manifest as increased contractile tone in the uterus, airways, and vasculature.[28] If indeed any of these associations exist, the effect is small. Asthma should in no way be considered a contraindication to pregnancy, and good asthma control may minimize the incidence of many of these complications.

The risk of the child developing asthma in later life varies between 6% and 30%, depending on whether or

not the mother is atopic and whether or not the father also is atopic and has asthma.[29]

Management Options

Prepregnancy

Pregnancy counseling should be given based on the preceding information. Overall it should be anticipated that pregnancy will be well tolerated. Patient education as to maintenance and rescue medications, peak expiratory flow rate (PEFR) use, proper use of inhalers, asthma prevention, and an asthma management plan as described in the following section is important before and during pregnancy. Pulmonary function testing is rarely needed in the management of established asthmatics. Patients should be educated not to stop necessary medications when they find out they are pregnant.

Prenatal

Ideally asthma care should be optimized before conception. Close monitoring of the patient's status and adjustment of treatment as necessary are essential to ensuring the best outcome for mother and child. It is worth reviewing here in some detail the present management of asthma in pregnancy.

ASTHMA MANAGEMENT: GENERAL PRINCIPLES

Present thinking emphasizes that asthma is a chronic inflammatory airway disease and treatment therefore focuses on avoidance of triggers and the use of inhaled corticosteroids to decrease the underlying airway inflammation that leads to symptoms. Use of bronchodilators continues but is perceived of as a method of obtaining symptomatic relief rather than disease control. The underlying principle for treatment of asthma during pregnancy is that, aside from a few exceptions, the same drugs and dosages that would be used outside pregnancy should be used in pregnancy for a given clinical situation.[30] Whenever possible, treatment should be by inhalation rather than oral agents, since this reduces systemic effects.[22,31] It also reduces any possible effects on the fetus.

ASTHMA MANAGEMENT: PREVENTION AND EDUCATION

Essential to the successful pharmacologic management of asthma is vigorous patient education. Against the background of this patient education, medication prescribing for asthma will be far more effective, and severe asthmatic exacerbations may be avoided. This education may be most effective if initiated before pregnancy. Key concepts emphasized by present clinical guidelines are as follows[32]:

- Patients should be taught to measure their PEFR twice daily to allow early detection of deterioration in pulmonary function before they become symptomatic. PEFR is best measured on awakening and approxi-

mately 12 hours later. PEFR can be especially helpful to pregnant asthmatic patients in determining if their dyspnea is due to breathlessness of pregnancy or an asthmatic exacerbation.

- Patients need to have proper inhaler use reviewed with them repeatedly. Proper use includes using a spacer to improve delivery of medication to the lungs, help avoid local side effects of inhaled steroids (such as oral thrush), and decrease unnecessary systemic absorption of medication through the buccal mucosa.

- All patients should be given a written asthma management plan that directs the patient in adjusting medication according to their PEFR and guides them about when to seek medical advice. In general action plans are based on the best PEFR that a patient has ever obtained. A typical action plan for a patient would tell her that if the PEFR drops transiently by 20% from her personal best that her therapy needs "stepping up"; the patient should have instructions at home as to how to do this. The patient should be told that sustained drops in PEFR of more than 20% from the previous personal best warrants a call to the physician. A PEFR drop >50% from the previous personal best warrants a trip to the emergency department (ED). Patients should be taught to avoid triggers. This advice includes the use of impermeable pillow and mattress covers to minimize contact with dust mites, removal of pets from the home (or at least the bedroom), removal of carpets in the bedroom, and avoidance of cigarette smoke.

- Patients should be clearly informed that present evidence suggests that well-controlled asthma does not appear to increase pregnancy risk but poorly controlled asthma does.[11,12,25] This information may help enhance compliance and alleviate the patient's fears about medication use in pregnancy.

ASTHMA MANAGEMENT: SPECIFIC ASTHMA MEDICATIONS

Asthma medications are classified as either rescue agents or maintenance agents. *Rescue agents* are those medications used to treat acute bronchospasm and provide symptomatic relief but do not treat the underlying inflammation that causes bronchospasm. Rescue agents include all the inhaled β_2 agonists and ipratropium. The data regarding their effectiveness and safety in pregnancy is reviewed in Table 38–1. *Maintenance agents* are those medications that help to control airway hyperreactivity and generally treat the underlying inflammation of the airway. The inhaled steroids are the keystones of present asthma maintenance. Other maintenance agents include systemic steroids, leukotriene antagonists, and cromolyn. The data regarding their effectiveness and safety in pregnancy is reviewed in Table 38–2.[16,40]

ASTHMA MANAGEMENT: DAILY ASTHMA MANAGEMENT WITH STEPWISE PLAN

Asthma medications are presently prescribed in a "stepwise" manner with adjustments in medication being

TABLE 38–1

Summary of Pregnancy Data on Rescue Agents Commonly Used to Treat Asthma[33–36]

CLASS	AGENT	EFFECT ON EMBRYO AND FETUS
Short-acting inhaled β₂-adrenergic agonists	albuterol, isoproterenol, isoetharine biltolterol, pirbuterol, metaproterenol, terbutaline	Published experience with these drugs in animals and humans suggests that β-sympathomimetics do not increase the risk of congenital anomalies.[37,38] Albuterol is the most studied of these agents. Metaproterenol is the second most studied.
Long-acting inhaled β₂-adrenergic agonists	salmeterol	Animal data about intravenously administered salmeterol have not been reassuring, but this agent is still felt to probably be safe in humans when administered by inhalation. However, no human data about this agent have been published at this point; therefore, its use should be reserved for patients who have failed low-potency steroids and/or cromolyn alone.
Inhaled anticholinergic	ipratropium	Reassuring animal studies but no published human data. Poorly absorbed by the bronchial mucosa so fetal exposure is likely minimal.[39] Efficacy in acute asthma attack presenting to the ED makes its short-term use seem justifiable, however.

From Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

made either upward or downward in intensity in response to the severity of the individual patient's asthma at that particular point in time. Table 38–3 reviews the criteria for classification of asthma into four separate classes of severity and summarizes the treatment recommended during pregnancy for each classification. This stepwise approach is recommended by both the United States National Asthma Education and Prevention Program[32] and the British Thoracic Society.[60]

Once control has been established and is maintained for several months, consideration of stepping down the treatment to a regimen appropriate for the next lower level of asthma severity should occur. However, if asthma fails to be controlled or worsens, stepping up a treatment level is advisable. In any class of asthma a rescue course of 5 to 10 days of oral prednisone may be used to gain control from a prolonged or severe exacerbation. This is particularly true in the setting of an asthma exacerbation secondary to the common cold. In pregnancy, gastroesophageal reflux disease,[61,62] vasomotor rhinitis of pregnancy, and noncompliance should always also be considered as possible causes of difficult-to-control asthma.

ASTHMA MANAGEMENT: TREATMENT OF ACUTE ASTHMA EXACERBATIONS

Patients with worsening asthma not improving on home management by the stepwise approach will need to be seen in an ED for evaluation. Treatment in the ED is reviewed in Table 38–4. Acute severe asthma (status asthmaticus) is a very dangerous condition that should be managed with a respiratory physician in an intensive care environment. High-dose intravenous steroids are the cornerstone of treatment for asthmatic exacerbations requiring admission to hospital. Even in the absence of

acute severe asthma, there should be a very low threshold for admission, because patients with asthma can deteriorate very quickly.[21] General guidelines for admission to hospital include a sustained drop in PEFR to less than 60% of baseline, a PO_2 <70 mmHg at sea level, a PCO_2 >35 mmHg, a heart rate of >120/minute, or a respiratory rate >22/minute. It is important to remember that a PCO_2 >40 mmHg in a pregnant women with an asthmatic exacerbation suggests impending respiratory failure, because the normal PCO_2 in pregnancy is 27 to 32 mmHg.

Clinical predictors of mortality from asthma include marked circadian variation in lung function, a large bronchodilator response, psychosocial instabilities, use of three or more medications, frequent visits to the ED, recurrent hospitalizations, and previous life-threatening attacks.

Asthma exacerbation is not an indication for elective delivery, though if there are other maternal or fetal problems, induction should not be withheld.

Labor and Delivery

Asthma exacerbations during labor are rare, presumably due to the natural outpouring of endogenous steroids and epinephrine associated with the stress of delivery. Exacerbations occurring at this time should always be approached with a differential diagnosis that includes pulmonary edema (from cardiac causes or noncardiac ones such as preeclampsia, tocolysis, and sepsis), pulmonary embolism, and aspiration. Although asthma is rarely a problem in labor, if readers wish to use a protocol for such cases, they are referred to the National Asthma Education Program Working Group on Asthma and Pregnancy guidelines.[30]

TABLE 38-2

Summary of Pregnancy Data on Maintenance Medications Commonly Used to Treat Asthma[38,41]

CLASS	AGENTS	PREGNANCY DATA
Inhaled corticosteroids	Low potency: beclomethasone dipropionate Medium potency: triamcinolone acetonide High potency: fluticasone propionate budesonide flunisolide mometasone furoate	Inhaled corticosteroids are the most important pharmacologic agents in maintaining asthma control in and out of pregnancy. Only 4% of 257 patients taking inhaled glucocorticoids from the start of pregnancy had acute attacks of asthma during pregnancy, in contrast with 17% of 177 patients who were not.[42] Beclomethasone[38,43,44] and budesonide are the most widely studied of the inhaled corticosteroids in pregnancy and should be considered the preferred inhaled steroids in pregnancy. Relatively little of these agents is absorbed, and human data have not suggested any teratogenic effects of these agents.[45–47] Triamcinolone is the next most studied inhaled steroid in pregnancy, with this limited experience suggesting no adverse pregnancy effects. Fluticasone has not been studied in pregnancy; however, its minimal systemic absorption and the safety of the other steroids in pregnancy make its use in pregnancy generally felt to be justifiable.[48]
Mast cell stabilizers	disodium cromoglycate (cromolyn) sodium nedocromil	Human and animal data suggest these agents are not teratogens. These agents are virtually not absorbed through mucosal surfaces, and the swallowed portion is largely excreted in the feces. These agents are best in mild cases of asthma in which the decision not to use inhaled steroids has been made. Cromolyn[38,43,49] has been better evaluated in human pregnancy than nedocromil and should be considered the preferred agent of this class.
Leukotriene antagonists	zileuton zafirlukast montelukast	The leukotriene antagonists represent an important exception to the general rule that asthma treatment is largely unchanged in pregnancy. Zafirlukast and montelukast both have favorable animal data, but data about their safety in human pregnancy are extremely limited at this point. Zileuton has concerning animal data. Their use should be limited in pregnancy to those unusual cases in which a woman has had significant improvement in asthma control with these medications before becoming pregnant, control that was not obtainable through other methods.
Sustained-release methylxanthines	theophylline	Theophylline and its intravenous form aminophylline do not appear to be human teratogens.[37,38,50] The safety of aminophylline therapy in the second and third trimester has been demonstrated in a large group of 212 gravidas in Finland.[50] The clearance of aminophylline is increased in pregnancy in a rather variable way.[51] Any patient who is taking more than 700 mg of aminophylline per day should have blood measurements made for optimal dosing. Their present role in treating asthma is generally felt to be as second- or third-line agents; they do not appear to be of benefit in an acute exacerbation.[52]
Systemic steroids	Oral: prednisone Intravenous: methylprednisolone hydrocortisone	Most data suggests that systemic steroids do not present a teratogenic risk in human pregnancy. In doses equivalent to prednisone 25 mg/day, they do not cross the placenta because of placental metabolism[53–55] (the same is not true for betamethasone or dexamethasone). Even in higher doses, the effect of hydrocortisone or prednisone on the fetus in terms of suppression of the hypothalmic-pituitary-adrenal axis is minimal. However, a recent case-control study found a significant association with first-trimester use and oral clefts (OR=6.55, 95% CI=1.44–29.76).[55,56] However, even if this association is real, the benefits of controlling a life-threatening disease make steroid use, when indicated, in the first trimester still generally justifiable.
Immunotherapy	Administering gradually increasing quantities of an allergen extract to an allergic subject to down-regulate response	Human data from small trials suggest safety of continuing immunotherapy in pregnancy, but present practice usually avoids initiation in pregnancy because of fear of provoking anaphylaxis.[57–59]

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

Prostaglandin E_2 compounds and oxytocin can be safely used in asthmatics. 15-Methyl prostaglandin $F_{2\alpha}$ should not be used in asthmatic patients because it can cause bronchoconstriction.[64,65] Ergonovine and other ergot derivatives should also not be used in asthmatics as they too have caused severe bronchospasm in asthmatic patients, particularly in association with general anesthesia. Although morphine and meperidine may theoretically cause bronchoconstriction through histamine release, in practice this is not generally a problem. Many asthmatic women will have been given morphine and meperidine in labor without harm. Nonetheless, some

TABLE 38–3

Classification of Asthma and Stepwise Management in Pregnancy[41]

CATEGORY	CRITERIA	STEP THERAPY
Mild intermittent	• Symptoms up to twice a week • Nighttime symptoms up to twice a month • Exacerbations last only hours to a few days • Asymptomatic between episodes • PEFR >80% predicted and day-to-day variability <20%	• No daily treatment necessary • Inhaled β_2-adrenergic agonists as needed
Mild persistent	• Symptoms more than twice a week but not daily • Nighttime symptoms more than twice a month • Exacerbations may affect activity • PEFR >80% predicted and day-to-day variability 20%–30%	• Inhaled β_2-adrenergic agonists as needed *and* • Daily treatment with inhaled cromolyn or nedocromil *or* inhaled low-dose corticosteroid (preferably beclomethasone or budesonide) *or* theophylline preparation
Moderate persistent	• Daily symptoms • Nighttime symptoms more than once a week • PEFR 60%–80% and day-to-day variability >30%	• Inhaled β_2-adrenergic agonists as needed *and* • Daily treatment with inhaled low- to medium-dose corticosteroid *and* • Daily treatment with salmeterol or theophylline preparation
Severe persistent	• Continual symptoms that limit activity • Frequent nighttime symptoms and acute exacerbations • PEFR <60% predicted and day-to-day variability >30%	• Inhaled β_2-adrenegic agonists as needed *and* • Daily treatment with inhaled high-dose corticosteroid *and* • Daily treatment with salmeterol or theophylline preparation *and* • Daily or alternate-day treatment with systemic prednisone

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

experts prefer to use butorphanol or fentanyl as alternatives in pregnant asthmatics because these agents are less likely to cause histamine release. If anesthesia is required, an epidural is preferable to general anesthesia because of the risks of chest infection and atelectasis with general anesthesia. For those patients who do require a general anesthetic, bronchodilatory agents such as ketamine and halogenated anesthetics are preferred.

It is known that daily doses of systemic steroids given for as little as several weeks may suppress the hypothalamic-pituitary-adrenal (HPA) axis for up to 1 year and thereby blunt the normal physiologic outpouring of adrenal corticosteroids that occurs with stressors such as illness, surgery, and labor. The practical significance of this in pregnancy remains unstudied. To avoid precipitating an adrenal crisis, many centers give empiric stress-dose steroids (hydrocortisone 100 mg IV every 8 hours on the day of delivery followed by 50 mg IV every 8 hours on day 1 after delivery and then back to the baseline dose) to any woman in labor who has received systemic steroids for longer than 2 to 4 weeks in the preceding year. Other centers will only do so if steroids have been used in the prior 4 weeks. Still other centers would advocate the use of a cosyntropin stimulation test to test the HPA axis prior to labor and delivery. If stress-dose steroids are not given, it is advisable to watch the patient for signs of adrenal insufficiency (anorexia, nausea, vomiting, weakness, hypotension, hyponatremia, and hyperkalemia) postpartum.

Postnatal

Patients should have their medications continued postpartum and their PEFR monitored in the days following delivery. Breastfeeding is not contraindicated in patients taking any form of asthma treatment, including oral prednisone. Indeed breastfeeding for between 1 and 6 months reduces the prevalence of atopy in 17-year-olds who were breastfed by about 30% to 50%.[66]

TABLE 38–4

Management of the Acute Asthma Exacerbation Presenting to the Emergency Department[41]

1. Place patient on oxygen to keep SaO_2 >95%.
2. Administer inhaled β_2-adrenergic agonist until improvement obtained or toxicity is noted; e.g., albuterol metered-dose inhaler (MDI) with spacer 3 to 4 puffs *or* albuterol nebulizer every 10–20 minutes.
3. Administer methylprednisolone 125 mg IV acutely and then 40–60 mg IV q6h *or* hydrocortisone 60–80 mg IV q6h. When the patient improves, she can be switched to a tapering oral regimen of prednisone (usually 60 mg once daily slowly reduced to nothing over the next 2 weeks).
4. Consider use of ipratropium MDI (2 puffs of 18 μg/spray q6h) or nebulizer (one 62.5-mL vial by nebulizer q6h) in first 24 hours after presentation.[63]
5. Avoid use of subcutaneous epinephrine in the pregnant asthmatic.

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

CONCLUSIONS

ASTHMA

- Optimal control of asthma with prevention and management of medications in a stepwise manner will help ensure the best possible outcome for mother and fetus.
- All patients with asthma should have a peak flow monitor and an asthma action plan and should be able to demonstrate good technique in the use of their inhaler with a spacer.
- Most commonly used asthma medications can be safely administered in pregnancy. Human data about the leukotriene inhibitors are limited, so their routine use as a first line agent in pregnancy is not recommended at this time.
- In labor, the use of prostaglandin $F_{2\alpha}$ and ergonovine should be avoided, and patients who received steroids for more than 2 weeks in the past year should receive stress-dose steroids with delivery.
- Breastfeeding will decrease the risk of atopy in the offspring of mothers with asthma.

SUMMARY OF MANAGEMENT OPTIONS
Asthma

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Adjust maintenance medication stepwise to optimize respiratory function.	IV	C	30,32,60
Educate patient to minimize precipitating factors, if possible by timing of pregnancy (seasonal) and avoidance of allergens.	IV	C	30,32,60
Educate patient about use of peak expiratory flow meters.	IV	C	30,32,60
Provide patient with asthma action plan.	IV	C	30,32,60
Advise early referral for prenatal care.	IV	C	30,32,60
Prenatal			
Use same drugs as outside pregnancy, especially steroids, beta-sympathomimetics, and theophylline.	IV / III	C / B	30,32,60 / 22, 31
Regulate peak flow with adjustment of asthma medication as needed to control symptomatology and minimize need for rescue therapy.	IV	C	30
Use inhalation therapy rather than oral.	IV	C	30,32,60
Ensure adequate fetal oxygenation with acute exacerbation by keeping SaO_2 >95%.	IV	C	30,32,60
If theophylline used, monitor blood levels, since blood volume expansion in pregnancy may mandate higher doses of the drugs.	IV	C	30,32,60
In the stable patient, antepartum nonstress testing is not necessary. If concerns over fetal well-being arise, begin antepartum testing in the late second or early third trimester.	IV	C	30,32,60
Seek anesthesiology consultation in preparation for delivery if general anesthesia is anticipated.	IV	C	30,32,60
Labor and Delivery			
Maintain adequate maternal oxygenation.	IV	C	30,32,60
Avoid prostaglandin $F_{2\alpha}$ and ergometrine.	Ib	A	64
Avoid general anesthesia if possible.	IV	C	30,32,60
Use parenteral stress-dose steroids for patients on chronic oral therapy or in those who have received more than 2 weeks of systemic steroids in the past year.	IV	C	30,32,60
Encourage respiratory therapy to minimize atelectasis.	IV	C	30,32,60
Continue maintenance drug therapy.	IV	C	30,32,60

Encourage breastfeeding.	IV	C	30,32,60

SARCOIDOSIS

General

Sarcoidosis is a noncaseating granulomatous condition typically affecting the lung with bilateral hilar adenopathy and/or pulmonary infiltrates. It is seen most commonly in women of reproductive age. It usually regresses spontaneously, although very occasionally lung disease is progressive.

The exact prevalence of sarcoidosis in the general population is difficult to establish because a large number of cases may be asymptomatic or go undiagnosed. The prevalence is estimated to be 10 to 20 per 100,000 population, with a lifetime risk of 0.85% among whites. It is three to four times more common in blacks.[67]

The etiology and pathogenesis of sarcoidosis remains unknown. The granulomas seen in this condition are focal chronic inflammatory reactions. Infectious agents such as mycobacterium or propionibacterium may produce this condition in genetically predisposed patients. Malignancy, tuberculosis, HIV infection, collagen vascular disease, and occupational lung disease should be ruled out before a diagnosis of sarcoidosis is made. Tissue biopsy should be obtained for all but the most classic presentations.

The lung is the most likely organ to be affected. Over one half of cases are detected incidentally on routine chest x-rays. When symptomatic, sarcoidosis may present as cough, dyspnea, chest pain, fatigue, malaise, weakness, fever, and weight loss. Chest x-ray may reveal the classic bilateral hilar adenopathy and/or interstitial or alveolar infiltrates. The classification of pulmonary involvement in sarcoidosis is based on the radiographic stage of disease. Stage I is defined by the presence of bilateral hilar adenopathy, which is often accompanied by right paratracheal node enlargement. Seventy-five percent of such patients will show spontaneous regression in 1 to 3 years. Stage II consists of bilateral hilar adenopathy and interstitial infiltrates. Two thirds of such patients undergo spontaneous resolution; the remainder either have progressive

disease or display little change over time. Stage III disease consists of interstitial disease with shrinking hilar nodes. Stage IV disease is defined by advanced fibrosis. Both stage III and IV disease are more likely to lead to progressive lung impairment without treatment.

Other organ systems that may be affected include skin (maculopapular eruptions, skin nodules, and erythema nodosum), lymphatic system (lymphadenopathy), eye (iridocyclitis, chorioretinitis, and keratoconjunctivitis), and liver. Fatigue is also a common complaint in patients with sarcoidosis. Less common manifestations can occur in the spleen (splenomegaly), the neurologic system, the salivary glands, the bone marrow, the ear nose and throat, heart, kidneys, bone, joint, or muscle.[68,69] Calcium homeostasis (hypercalciuria and hypercalcemia) can be also affected in sarcoidosis. The frequencies of different extrapulmonary manifestations of sarcoidosis seem to vary with ethnic origin and gender.

Treatment for sarcoidosis is reserved for those with significant symptoms or pulmonary compromise. Systemic steroids are the cornerstone of treatment for sarcoidosis. Two studies have shown that corticosteroid therapy is also of benefit in mild cases with chest x-ray evidence of parenchymal disease. The degree of improvement averaged 10%. Whether the risks of long-term corticosteroids are worth the modest benefit seen in these studies of asymptomatic patients remains unclear.[70,71] Chloroquine, hydroxychloroquine, methotrexate, azathioprine, pentoxifylline, thalidomide, cyclophosphamide, cyclosporine, and infliximab have all also been used to treat chronic or steroid-unresponsive sarcoidosis with variable success.[72]

Maternal Risks

Sarcoidosis rarely involves the female reproductive organs. However, sarcoidosis of the endometrium, ovary, and leiomyoma have all been reported.[73,74] Systemic sarcoidosis, in the absence of significant cardiopulmonary compromise, does not appear to affect fertility and does not increase the incidence of fetal or obstetrical complications.[75]

Although relatively few studies have been published about sarcoidosis in pregnancy, the general observation is that pregnancy does not influence the natural history of the disorder.[76] In some cases it will improve during pregnancy, possibly due to increases in maternal free cortisol.

Some patients with sarcoidosis develop progressive pulmonary fibrosis and hypoxemia and proceed to cor pulmonale and pulmonary hypertension. Pulmonary hypertension has a very poor prognosis in pregnancy, whatever the cause. Patients with evidence of moderate to severe pulmonary hypertension should be discouraged from proceeding with pregnancy because of the significant risk of maternal mortality (see Chapter 37).

Fetal Risks

There are no specific risks aside from the uncommon circumstance in which a mother has severe systemic disease that is a threat to maternal health and thereby leads to fetal compromise. Severe disease unresponsive to steroids may also lead to consideration of treatments with pharmacologic agents less well studied in pregnancy than steroids. Untreated maternal hypercalcemia could theoretically lead to neonatal hypocalcemia and tetany, although the hypercalcemia associated with sarcoidosis is usually mild and unlikely to cause neonatal problems. Sarcoid granulomas have been found in the placenta[77] but not in the fetus.

Management Options

Prepregnancy

Prepregnancy counseling can be given, incorporating the above information. It is generally advisable to obtain a baseline SaO_2 (both resting and with exercise), pulmonary function testing (including a diffusing capacity for carbon monoxide—DL_{CO}—as a measurement of gas exchange that is sensitive to the presence of interstitial lung disease), a chest x-ray, CBC, liver function tests, blood urea nitrogen, creatinine, and serum calcium. Patients with stage I or II disease and minor extrapulmonary manifestations should anticipate a good outcome. Patients with more severe disease should be warned that their disease progression and treatment may complicate the course of their pregnancy but will not usually have a direct adverse effect on the fetus.

Prenatal

Breathlessness is common in the normal pregnancy but can also be seen in stage II sarcoidosis. Obtaining the results of the baseline investigations listed will help in interpretation of additional testing if the patient with sarcoidosis reports new or worsening symptoms. Testing liver enzymes, creat-

inine, calcium, and CBC once a trimester can be helpful in identifying hypercalcemia before delivery and establishing a baseline that may help prevent the inappropriate attribution of abnormalities in creatinine or liver tests to preeclampsia later in pregnancy.

Complaints of increased dyspnea in women with known sarcoidosis will require evaluation with SaO_2 (both resting and with exercise), chest x-ray, and pulmonary function testing, including DL_{CO}. Distinguishing the normal dyspnea of pregnancy from progression of disease will be difficult without these objective tests. In some circumstances a high-resolution CT scan may be needed to define the extent of disease; there is no reason why this test cannot be carried out during pregnancy.

Painful joints and erythema nodosum are also manifestations of sarcoidosis that may be seen in normal pregnancies and need to be interpreted cautiously as a manifestation of disease progression in the setting of pregnancy.

Symptomatic disease attributable to sarcoidosis should generally be treated with systemic steroids under the supervision of a pulmonologist experienced in treating this disease. The safety of steroids in pregnancy is well established and is discussed in the preceding section on asthma. Symptomatic disease unresponsive to steroids may require treatment with other agents that are less well studied in pregnancy and will require careful consideration of both risk and potential benefits of treatment.

Patients with sarcoidosis can develop hypercalcemia, particularly in the setting of vitamin D supplementation.[78] Even in a patient with a normal serum calcium level, sarcoidosis-associated hypercalciuria can lead to nephrocalcinosis. Pregnant patients with sarcoidosis may do well to avoid both vitamin D and calcium supplementation. The contents of their prenatal vitamins should be reviewed to prevent unintended supplementation of both vitamin D and calcium.

The level of angiotensin-converting enzyme has been advocated by some experts as an index of disease activity in sarcoidosis. This may be invalid in pregnancy where angiotensin-converting enzyme levels seem to change independently of sarcoid activity.[79]

Labor and Delivery

If there is any degree of parenchymatous lung disease, an epidural block would be better than general anesthesia. Women who have been on steroids for more than 2 weeks of the preceding year should be given stress-dose steroids around the time of labor and delivery, as discussed in the preceding section on asthma.

Postnatal

No specific recommendations are needed for postpartum management of the parturient with sarcoidosis.

CONCLUSIONS

SARCOIDOSIS

- Sarcoidosis usually does not impact maternal or fetal outcome in pregnancy unless there is preexisting evidence of pulmonary fibrosis, hypoxemia, or pulmonary hypertension.
- Pulmonary function testing (with DLCO) and echocardiography can help assess severity of disease and the possibility of pulmonary hypertension.
- Women with sarcoidosis in pregnancy should be watched for signs and symptoms of progressive pulmonary disease. Steroid therapy should be instituted with evidence of significant disease advancement.
- Hypercalcemia can be a problem in sarcoidosis. Serum calcium should be checked periodically in women with sarcoidosis, and women with sarcoidosis should not take vitamin D supplementation. They should also not take a prenatal vitamin with vitamin D in it.

SUMMARY OF MANAGEMENT OPTIONS
Sarcoidosis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Reassure patient about benign nature of sarcoidosis during pregnancy (unless there is preexisting evidence of pulmonary fibrosis, hypoxemia, or pulmonary hypertension).	IV III	C B	75 76
Baseline pulmonary function studies may assist in the evaluation of the patient's lung status prior to pregnancy.	IV III	C B	75 76
If lung disease significant, evaluate by exam and echocardiogram for pulmonary hypertension. Discourage pregnancy in presence of pulmonary hypertension.	IV III	C B	75 76
Prenatal			
Avoid multivitamins containing vitamin D.	IV III	C B	75 76
Consider checking serum calcium once a trimester because of neonatal toxicities with maternal hypercalcemia.	IV III	C B	75 76
Watch for signs and symptoms of progressive pulmonary disease; institute steroid therapy with evidence of significant disease advancement.	IV III	C B	75 76
Labor and Delivery			
With substantial parenchymal disease, avoid inhalation anesthesia.	IV III	C B	75 76
Recognize that high block conduction anesthesia may cause significant respiratory compromise.	IV III	C B	75 76
Obtain early anesthesiology consultation in patients with severe disease.	IV III	C B	75 76
Use parenteral stress-dose steroids for patients on chronic oral therapy or in those who have received 2 weeks of systemic steroids in the past year.	IV III	C B	75 76
Postnatal			
Watch for neonatal tetany if mother has hypercalcemia.	IV	C	75
No other specific disease-related needs	III	B	76

TUBERCULOSIS

General

After a resurgence of tuberculosis (TB) in the western world in the early 1990s, the incidence of TB is once again declining in the resource-rich nations. In the year 2000, the United States reported the lowest rate of new TB infection in U.S. history, at 5.8 cases per 100,000 population.[80] However, there remain a large number of unidentified latent and active cases of TB in the western world.[81,82] This is particularly true among inner city minority populations and among immigrants from countries with a high prevalence of TB.

The global perspective on TB is much more daunting. It is estimated that one third of the world population has been infected with TB and that worldwide there are 8 million new cases of TB and 2 million deaths caused by TB each year.[81] Pregnancy offers a unique opportunity for identification and treatment of TB among young women to the benefit of a mother, her child, and the general public.

Maternal and Fetal Risks

Although pregnancy is not associated with an increased risk of tuberculosis, management of TB in pregnancy does require some additional considerations related to concerns about drug safety in pregnancy. In all cases, tubercular infections should be managed in conjunction with a physician specifically trained in the care of tubercular infections.

Maternal Risks

Tuberculosis used to have a sinister reputation in pregnancy,[83] but with the advent of modern chemotherapy, immunocompetent patients should make a complete recovery even if TB is first diagnosed in pregnancy.[84] Some concern exists that the hepatotoxicity of one of the key agents in antituberculous therapy—isoniazid—is increased in pregnancy and warrants increased monitoring.

Fetal Risks

Tuberculosis that is confined to the thorax or limited to lymphadenitis poses little risk to the fetus. Adverse fetal outcomes may be more frequent with extrapulmonary disease.[85] One small study that compared pregnancy outcomes in pregnant women with extrapulmonary TB versus healthy controls found significantly higher frequencies of low birth weight infants and infants with low Apgar scores among mothers with extrapulmonary TB.[86]

Tubercle bacilli very rarely cross the placenta,[87] though granulomata may be found in the placenta. True congenital infection is therefore exceptionally uncommon. Perhaps this is because congenital TB is almost invariably associated with genital tract TB, which in itself usually is a cause of infertility. Criteria for congenital TB have recently been re-evaluated and include a primary focus in the fetal liver.[88]

In practice the only risk to the fetus is the very questionable teratogenicity of antituberculous drugs. The neonate is only at risk of postnatally acquired infection if the mother still has active TB at the time of delivery. Then the risk is high.[89] Only under these most unusual circumstances should the mother be separated from her newborn. Any remote risks of neonatal infection may be reduced by giving the neonate bacille Calmette-Guérin (BCG) and prophylactic isoniazid.

Management Options

Prepregnancy

The main problem concerning the management of tuberculosis in pregnancy is the possible teratogenicity of some antituberculous drugs. Prepregnancy counseling may be given, incorporating the information on risks. Women undergoing treatment for active TB might consider delaying pregnancy until their treatment course is complete, but present data suggests that the most commonly used agents are safe in pregnancy. For those women who have completed an adequate course of chemotherapy, previous TB is no contraindication to pregnancy, and TB is no more likely to be reactivated in pregnancy than at any other time.

Prenatal

Screening is not justified in pregnancy except in high risk populations.[90] However, all pregnant women from populations at risk for tuberculosis (i.e., inner city minority populations and people who have recently emigrated from an area of the world with a high prevalence of TB) should undergo a tuberculin skin test (TST) unless documentation of recent TST status is available. TST is both safe and reasonably sensitive throughout pregnancy.[91,92] Positive skin test reactors (and women with symptoms suggestive of TB regardless of their TST results) should have a chest x-ray performed to look for active pulmonary TB.[93] If the chest x-ray is suggestive of TB, sputum examination for *Mycobacteria* should be performed and if positive (on smear, PCR testing, or culture), treatment should be initiated. Susceptibility testing for isoniazid, rifampin, and ethambutol should be performed on a positive initial culture. For all patients beginning antituberculous treatment, baseline measurements of serum aminotransferases, bilirubin, alkaline phosphatase, serum creatinine, and a platelet count should be obtained. Routine HIV testing of all patients with TB is also recommended. Testing of visual acuity and red-green color discrimination should be obtained when ethambutol is to be used.

Active tuberculosis can be treated successfully in pregnancy; the benefits of treatment dramatically outweigh any concerns about potential drug toxicity. Directly observed therapy, in which patients are observed to ingest each dose of antituberculous medications, is highly recommended because it helps maximize compliance. The current recommendation in the United Kingdom[93] and by the World Health Organization (WHO) and the International Union against Tuberculosis and Lung Disease (IUATLD) for uncomplicated TB in a pregnant individual is an initial phase of a 2-month course of ethambutol, pyrazinamide, rifampin, and isoniazid, followed by a continuation phase of a further 4 months of rifampin and isoniazid (i.e., a total of 6 months' treatment).[94] Such therapy can be given in various regimens.

The most commonly used regimens entail either 7 days a week therapy in both phases or a modified regimen of 5 days a week in the initial phase and 5 days a week (or even twice weekly) in the continuation phase. Less frequent dosing makes directly observed therapy more feasible. An initial four-drug regimen has become increasingly important as multidrug-resistant TB has become more common. Although this standard regimen is effective in most cases, treatment may need to be adjusted once formal antibacterial susceptibility patterns are established.

Pregnancy data about the commonly used antimycobacterial agents is reviewed in Table 38–5.[69,95–98] Among the commonly used antituberculous drugs, streptomycin is the only one that is clearly contraindicated in pregnancy. It has been shown to cause both

TABLE 38–5

Pregnancy Data Regarding Commonly Used Antimycobacterial Agents[41]

AGENT AND USUAL DOSE	ADVERSE EFFECTS IN GENERAL	PREGNANCY DATA	ADDITIONAL NOTES
Isoniazid (INH) • 5 mg/kg, up to a maximum of 300 mg daily • Dispensed in the USA as 50, 100, and 300 mg tabs and 50 mg/5 mL syrup	• Hepatitis • Peripheral neuropathy • Drug interaction with many agents, especially anticonvulsants • Cutaneous hypersensitivity	• FDA pregnancy classification C • High lipid solubility; easily passes into fetal circulation • Fair data to suggest this agent is safe in human pregnancy and any risk is outweighed by potential benefit. However, concerns about potential increase in INH hepatotoxicity in pregnancy make its routine use for prophylaxis in pregnancy in low risk cases not advisable.	• Always administer with 25–50 mg/day of pyridoxine (vitamin B_6) to decrease the risk of neurotoxicity in the mother. • Give vitamin K to mother near birth (10 mg PO daily from 36 weeks on) and infant at birth to decrease risk of postpartum hemorrhage and hemorrhagic disease of the newborn. • Check transaminases monthly while on the medication
Rifampin • 10 mg/kg, up to a maximum of 600 mg daily • Dispensed as 150 and 300 mg scored tablets in the USA	• Fever • Nausea • Hepatitis • Purpura • Flulike symptoms at high doses • Orange secretions • Increased metabolism of many agents	• FDA pregnancy classification C • Limited data suggest no adverse fetal effects.	• Give vitamin K to mother near birth (10 mg PO daily from 36 weeks on) and infant at birth to decrease risk of postpartum hemorrhage and hemorrhagic disease of the newborn.
Ethambutol • 15–25 mg/kg, up to a maximum of 2500 mg daily • Dispensed as 100 and 400 mg tablets in the USA	• Retrobulbar neuritis in 1% of patients • Peripheral neuropathy	• FDA pregnancy classification B • Limited data suggest no adverse fetal effects.	• At each monthly visit patients taking this agent should be questioned regarding possible visual disturbances, including blurred vision or scotomata; monthly testing of visual acuity and color discrimination is recommended for patients receiving the drug for longer than 2 months.
Pyrazinamide • 15–30 mg/kg PO daily, up to a maximum of 3000 mg daily	• Thrombocytopenia • Hepatotoxicity • Interstitial nephritis • Nephrotoxicity	• FDA pregnancy classification C • Human data extremely limited	• Use in pregnancy supported by international recommendations in all pregnant patients with active TB after the first trimester; particularly essential for multidrug-resistant TB and HIV-positive patients.
Streptomycin • Dose varies	• Ototoxicity	• FDA pregnancy classification D • Reports of fetal ototoxicity preclude use.	• Avoid use in pregnancy.

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

vestibular and auditory eighth nerve damage,[99] leading to deafness in the newborn. Although detailed human pregnancy safety data are not available for pyrazinamide, most official recommendations now support its use in pregnancy. If pyrazinamide is not included in the initial treatment regimen, the minimum duration of therapy is 9 months.

Isoniazid should always be given in conjunction with pyridoxine 25 to 50 mg daily to minimize the risk of neuropathy.[100,101] The amount of pyridoxine in multivitamins is variable but generally less than the needed amount. Vitamin K should probably also be given to the mother from 36 weeks' gestation onward in a dose of 10 mg daily to decrease the risk of hemorrhagic disease of the newborn.[102] Drug-induced hepatitis is the most serious common adverse effect of isoniazid. Symptoms of hepatotoxicity (e.g., nausea, abdominal pain, hepatic tenderness) in association with hepatic transaminase elevations greater than three times the normal range or asymptomatic elevations in transaminases greater than five times the normal range should lead to discontinuation of therapy and consideration of the use of an alternative regimen. There is some evidence to suggest that pregnant women are at a higher risk of developing isoniazid-related hepatotoxicity; therefore, testing of hepatic transaminases at initiation of treatment and at monthly intervals thereafter is advisable.[103–105] During treatment of patients with pulmonary TB, a sputum specimen for microscopic examination and culture should be obtained at a minimum of monthly intervals until two consecutive specimens are negative on culture.

Management of HIV-related tuberculosis is complex and requires expertise in the management of both HIV disease and TB. Because HIV-infected patients are often taking numerous medications, some of which interact with antituberculous medications, it is strongly encouraged that experts in the treatment of HIV-related TB be consulted.

TB PROPHYLAXIS

The role of prophylaxis for positive tuberculin skin testing varies with the size of the patient's TST response, HIV status, and immune status and whether or not the patient has had recent contact with an active case of TB. The standard TST is a Mantoux test of 5 tuberculin units (TU) injected into the skin and reviewed at 48 to 72 hours by measuring the maximum area of induration. All HIV-infected women exposed to an active case of TB and all HIV-infected patients with a TST result >5 mm should receive prophylactic therapy even during pregnancy. Although some controversy around this issue exists, the pregnant woman with a normal immune status and a positive TST who has not been previously treated should probably only receive prophylaxis during pregnancy if there has been a recent contact with an active TB case and the patient has a TST that is >5 mm. Otherwise prophylaxis for TB in the asymptomatic immunocompetent pregnant woman can generally be delayed until the postpartum period.[106,107]

The preferred tuberculosis prophylaxis regimen is isoniazid 5 mg/kg (up to a maximum of 300 mg) daily for 9 months. A 6-month course may also be used but is less preferred than the 9-month regimen. Twice-weekly doses of 15 mg/kg (up to a maximum of 900 mg) for 9 months may also be used as an alternative but only if therapy is directly observed. Administration of pyridoxine 25 to 50 mg daily should occur, similar to what is done when treating active TB. Again, monthly clinical reassessment and monitoring of liver function tests should occur in pregnancy. Symptoms of hepatotoxicity (e.g., nausea, abdominal pain, hepatic tenderness) in association with hepatic transaminase elevations greater than three times the normal range or asymptomatic elevations in transaminases greater than five times the normal range should lead to discontinuation of therapy and consideration of the use of rifampin as an alternative regimen.

Labor and Delivery

No specific recommendations are needed for labor and delivery except as they relate to infection control issues. Transmission of infection from the mother to the infant can occur after delivery; thus the mother should be carefully evaluated for potential infectiousness at the time of delivery.[108]

Postnatal

After delivery, patients with sputum-positive tuberculosis (i.e., tubercular bacilli in their sputum) should be separated from their babies until they are no longer overtly infective. Because pyrazinamide renders the sputum sterile in 10 days, this situation should occur infrequently. In addition, the neonate should be given isoniazid to prevent it acquiring infection from its mother and should be given isoniazid-resistant BCG to boost its immunity.[109]

Breastfeeding should not be discouraged for women being treated with isoniazid, pyrazinamide, ethambutol, and/or rifampin. These agents are found in only small concentrations in breast milk and are not known to produce toxicity in the nursing newborn. These concentrations are also not significant enough to provide any protection to the nursing infant from infection with TB.[110]

CONCLUSIONS

TUBERCULOSIS

- All women from inner city minority populations and women from high risk areas of the world should be screened for TB in the setting of pregnancy with tuberculin skin testing.

CONCLUSIONS (Continued)

- Women with active TB should have cultures sent for antibiotic sensitivity testing and be started on a four-drug regimen of isoniazid, rifampin, ethambutol, and pyrazinamide.
- Hepatic transaminases should be measured monthly in pregnant women on isoniazid because of an increased risk of hepatotoxicity. All patients on isoniazid should receive daily pyridoxine.
- Infants should be separated from mothers with active TB as demonstrated by mycobacterium seen in their sputum. Ten days of treatment with a typical regimen will sterilize most patients' sputum.
- HIV testing in all women who have a positive TST or who have TB is strongly recommended.
- Women with a positive TST who have a known recent exposure or who are HIV infected should receive isoniazid prophylaxis in pregnancy. Other patients may have prophylaxis delayed until after delivery.

SUMMARY OF MANAGEMENT OPTIONS
Tuberculosis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Establish the diagnosis and treat the condition prior to pregnancy.	IV	C	111,112
Screening of at-risk populations is advised.			
Counsel regarding the potential teratogenesis of streptomycin if being used (it is not standard therapy).	III	B	99
Prenatal			
Perform tuberculin skin testing on all women from inner city minority populations and women from high risk areas of the world.	IV	C	111,112
Recommend HIV testing to all women with a positive TST.	IV	C	111,112
Administer isoniazid prophylaxis during pregnancy to TST-positive mothers without active TB if they have a known recent exposure or are HIV infected.	IV	C	111,112
Send sputum cultures with antibiotic sensitivity testing on women with active TB and start a four-drug regimen of isoniazid, rifampin, ethambutol, and pyrazinamide.	IV	C	95,96,97
Give pyridoxine when using isoniazid.	III	B	100,101
Measure hepatic transaminases monthly in pregnant women on isoniazid.	IV	C	103
Labor and Delivery			
No specific recommendations except institute infection precautions with active disease.	IV	C	111,112
Postnatal			
Only separate mother from baby if open TB present and until no longer infective (approximately 10 days into therapy).	IV	C	108,111,112
Administer BCG and BCG-resistant isoniagid to neonate.	III	B	109
Advise mother that she can breastfeed.	IV	C	110
Be aware that oral contraceptive efficacy is impaired by antituberculous drugs.	IV	C	111,112

KYPHOSCOLIOSIS

General

The term *kyphosis* refers to spinal deformity with anteroposterior angulation; *scoliosis* refers to lateral displacement or curvature of the spine. Most commonly the disorder is idiopathic (80%) and begins in childhood. The degree of spinal deformity correlates well with the degree of lung function impairment. A restrictive pattern is seen on pulmonary function testing, with decreased total lung capacity (TLC) and vital capacity (VC) and preserved residual volume (RV). Chest wall compliance decreases with age and increases the work of breathing. Pulmonary hypertension develops in some patients as a result of persistent hypoxemia.

Mild disease has a good prognosis and requires supportive care only. Patients with cor pulmonale have a life expectancy of less than 1 year. Surgical treatment has little role in adults with kyphoscoliosis. Medical therapy is the mainstay of management and can include pulmonary rehabilitation, supplemental oxygen, and use of negative- or positive-pressure ventilators.[111]

The prevalence of kyphoscoliosis in pregnancy depends on the criteria used for the definition. However, kyphoscoliosis will not affect pregnancy unless there is some degree of respiratory impairment; such circumstances prevail in less than 0.1% of pregnancies. It is remarkable that patients can achieve successful pregnancy despite so much deformity; the abdominal cavity often appears so contracted that there should be insufficient room for a fetus to develop normally. Nevertheless, babies can and do grow normally in these adverse surroundings.

Maternal and Fetal Risks

The risks to the mother are those of cardiac failure and cor pulmonale in the very few patients with pulmonary hypertension. To develop pulmonary hypertension, the condition has to be severe enough to produce hypoxemia at rest. If the VC is <1.5 L, the patient is at risk of respiratory failure, especially so if it is <1 L.[112,113] The risks to the fetus are intrauterine growth restriction (IUGR) caused by maternal hypoxemia and preterm delivery,[114] which is often elective because of concern about maternal well-being. Very severe hypoxia in a single patient with kyphoscoliosis (maternal PaO_2 <59 mmHg) has been associated with brain damage in the fetus.[115]

Management Options

Prepregnancy

Prepregnancy counseling should be given, incorporating the previously stated information. Pulmonary function testing should be obtained. If VC is >2 L, patients will generally tolerate pregnancy and delivery. If it is <2 L, patients will be at increased risk for pulmonary complications with pregnancy. An ABG analysis should also be obtained in all patients with a VC of <2 L. If the resting PaO_2 is decreased, the fetus is at risk of growth deficiency. If the $PaCO_2$ is increased, the risk of pulmonary complications is very high.

In the setting of significant compromise in pulmonary function testing—hypoxia or hypercapnia—the patient should be evaluated for pulmonary hypertension. Because of the distortion of the chest, the electrocardiogram is particularly poor at estimating right ventricular hypertrophy in kyphoscoliosis. Therefore, an estimate of the pulmonary circulation should be made by echocardiography, preferably with Doppler ultrasonography. Moderate to severe pulmonary hypertension is a relative contraindication to pregnancy (see Chapter 37). However, before such a drastic recommendation is made, the physician may want to perform a direct assessment of pulmonary vascular resistance by measurement of pulmonary artery pressure and cardiac output either by formal right-sided cardiac catheterization.

Prenatal

Patients who have significantly increased pulmonary vascular resistance should be offered termination because of the maternal risk. All other patients require optimal medical care directed toward diagnosing and treating respiratory infection and bronchospasm and any cardiac failure. In addition, supplementary domiciliary oxygen therapy to prevent growth deficiency should be considered in those who are hypoxemic. This form of therapy has not been evaluated for this indication; however, it is successful in preventing the development of pulmonary hypertension in nonpregnant patients, and granted the association between growth deficiency and maternal hypoxia, it seems worth pursuing.

Patients may require hospital admission from about 30 weeks' gestation either because of concern about impending respiratory failure or simply because they get so tired. Nasal positive-pressure ventilation has been used to help in some patients who have deteriorated in the third trimester.[116,117] Obstetric prenatal care relates to detecting IUGR. Elective preterm delivery may be necessary for maternal reasons, increasing hypoxemia or frank respiratory failure, or because of the signs of fetal hypoxia either with or without IUGR.

Labor and Delivery

Many patients with severe kyphoscoliosis are delivered by cesarean section because of associated pelvic

deformity.[118] This is better performed with epidural block rather than with general anesthesia. Surprisingly, epidural puncture and catheterization is often possible in these patients. This is because the defect in kyphoscoliosis is often in the upper part of the spine.

Postnatal

No special measures are necessary after delivery apart from a continuation of optimal medical and obstetric care, including early mobilization and physiotherapy.

CONCLUSIONS

KYPHOSCOLIOSIS

- Kyphoscoliosis will usually only represent a significant risk in pregnancy if the mother has hypoxia and/or pulmonary hypertension.
- Obtaining an ABG and pulmonary function testing will help assess the degree of pulmonary compromise from the skeletal abnormality.

SUMMARY OF MANAGEMENT OPTIONS
Kyphoscoliosis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Counsel regarding risk for increase in pulmonary compromise as pregnancy advances, and risks for IUGR and preterm delivery.	III	B	118
Assess pulmonary vital capacity and obtain ABGs to assess O_2 and CO_2 levels.	III	B	118
Assess for evidence of pulmonary hypertension (unlikely); if present, advise against pregnancy.	IV	C	119
Prenatal			
Monitor respiratory function clinically and with Sao_2.	III	B	118
Discuss pregnancy termination if pulmonary hypertension present.	III	B	118
If severe cardiorespiratory compromise, begin prenatal surveillance for IUGR and fetal well-being in early third trimester.	III	B	118
Administer supplementary oxygen when hypoxemia present. Consider use of nasal intermittent nasal positive-pressure ventilation if respiratory status deteriorating.	IV	C	116,117
May need early delivery for frank respiratory failure.	III	B	118
Labor and Delivery			
Provide supplementary oxygen if Sao_2 low.	III	B	118
Perform cesarean section if associated pelvic deformities; vaginal delivery possible with most cases; regional anesthesia possible in many cases.	III	B	118
Postnatal			
Provide physiotherapy, especially if general anesthesia used.	–	GPP	–

CYSTIC FIBROSIS

General

Cystic fibrosis (CF) is an autosomal recessive multisystem disorder. The incidence of CF is between 1 in 2000 to 1 in 3000 live births. One in 20 whites are heterozygous for the CF gene. Although CF remains a fatal disease associated with a significant decrease in life expectancy, treatment of CF has undergone a rapid evolution in the past two decades that has lead to a substantial improvement in patient survival. Increasing numbers of women with CF are now surviving to an age at which pregnancy is possible.[119]

Cystic fibrosis is caused by mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene located on chromosome 7.[120] This gene codes for a complex chloride channel found in all exocrine tissues. Mutations in this gene cause deranged chloride transport that leads to thick, viscous secretions in the lungs, pancreas, liver, intestine, and reproductive tract. It also leads to increased salt content in sweat gland secretions.[121]

The usual presenting symptoms and signs of CF include persistent pulmonary infection, pancreatic insufficiency, and elevated sweat chloride levels. Pulmonary disease is the leading cause of morbidity and mortality in patients with CF. Pulmonary involvement is characterized by recurrent pneumonias, chronic bronchitis with or without bronchiectasis, and an obstructive pattern on pulmonary function testing. Digital clubbing is common among adults with this disease.

Abnormal lung secretions permit colonization of the airway and sinuses with pathogenic bacteria. *Staphylococcus aureus* and *Haemophilus influenzae* are common pathogens during early childhood, but *Pseudomonas aeruginosa* is ultimately isolated from the respiratory secretions of most patients. Greater than 70% of adults with CF are chronically infected with these bacteria. Persistent infection with *Burkholderia cepacia* is associated with an accelerated decline in pulmonary function and shortened survival. This organism induces airway injury and often demonstrates a high level of antibiotic resistance.[122]

Antibiotics are routinely prescribed when patients with CF develop acute or subacute increases in cough, sputum production, fever, and/or shortness of breath. Spirometry usually demonstrates worsened airflow obstruction during these episodes, although chest radiographs may not show significant changes over baseline. Low-grade fevers may or may not be present. Oral antibiotics are appropriate if the exacerbation is relatively mild, providing all pathogens identified are sensitive. Treatment is usually continued for 2 to 3 weeks. Intravenous antibiotics are used if the exacerbation is severe or a previous course of oral antibiotics has failed. Nebulized antibiotics are often used as well. Dosing of antibiotics often requires alteration, as medication pharmacokinetics are greatly altered in patients with CF.

Most physicians prescribe aerosolized beta-adrenergic agents to CF patients, particularly those who have manifestations of asthma. Ipratropium bromide is also occasionally prescribed, but theophylline use has declined in parallel with its less frequent use in asthma. The nebulized endonuclease DNase I is often used in CF patients with persistent productive cough. It can decrease the viscosity of expectorated sputum by cleaving long strands of DNA into smaller segments and can be given on an alternate-day dosing schedule.

All patients who produce sputum should be instructed in some form of chest physiotherapy for secretion clearance. Because patients vary in their responses to different modes of therapy, several techniques should be introduced to each patient. Inhaled corticosteroids and/or daily azithromycin therapy are also sometimes used in the long-term management of this disease.

Pancreatic insufficiency is common in CF, leading to malabsorption of fat and protein. These problems can often be reversed with oral supplementation of pancreatic enzyme extracts. Many patients may remain significantly underweight. Diabetes mellitus can also be seen, particularly in adults. Less commonly cholelithiasis and biliary cirrhosis can be seen in patients with CF.

Advancements in the treatment of CF lung disease have delayed disease progression but have not stopped it. Premature death from respiratory failure still occurs in the majority of patients. As in other progressive lung diseases, lung transplantation provides an additional, albeit imperfect, management option for CF. Thirty-three percent of all double lung transplants in adults are performed for CF.[123]

Because of the complex nature of this disease, care for patients with cystic fibrosis is best accomplished in a multidisciplinary clinic with chest therapists, nutritionists, and social workers lead by a physician experienced in the care of CF.

Maternal and Fetal Risks

Maternal Risks

Fertility may be decreased among women with CF. This is likely due both to malnutrition-related amenorrhea and to the production of an abnormally tenacious cervical mucus.[124] Data from the United States[125] and the United Kingdom[126] suggest a pregnancy rate for women with CF over age 16 of 40/1000 per year (compared with 80/1000 for healthy women in the United Kingdom). Up to 70% to 80% of pregnancies in patients with CF will result in a delivery. In those pregnancies that continue beyond the first trimester, the likelihood of delivering a live infant is high.

Early reports of poor outcome in mothers with CF have been discounted by studies demonstrating the safety of pregnancies in women with CF with good lung function.[127–130] When patients with CF become pregnant, it

is now known that maternal and fetal outcomes are generally favorable if the prepregnancy forced expiratory volume in 1 second (FEV_1) on pulmonary function testing exceeds 50% to 60% of the predicted value. However, if the mother has any evidence of pulmonary hypertension, her prognosis is much more guarded. Pulmonary hypertension in pregnancy from any cause carries with it a significant risk of right ventricular decompensation and maternal mortality.

In a retrospective study of 92 pregnancies in 54 women with CF, 49 women gave birth to 74 children and were followed for a mean of 11 years. Maternal deaths usually occurred in those with the most severe lung disease, with a cumulative mortality rate of 7.9% at 6 months after delivery and 13.6% at 2 years. Absence of *Burkholderia cepacia*, pancreatic sufficiency, and prepregnancy FEV_1 greater than 50% of predicted value were all associated with better survival rates. Pregnancy did not appear to affect the decline in FEV_1 survival as compared to the entire adult female CF population.[131]

Pregnancy puts an additional nutritional demand on the mother with CF, and women who enter a pregnancy underweight may become emaciated if unable to keep up with the nutritional demands of the fetoplacental unit.

Diabetes is also associated with an increased risk of adverse pregnancy outcome in women with CF. In those patients with CF who do not have diabetes, glucose tolerance is often already impaired and the risk of gestational diabetes may be high.

Fetal Risks

For the most part well-nourished mothers with reasonably preserved lung function can expect a good pregnancy outcome. However, IUGR and premature labor can result from chronic hypoxia. Acute severe hypoxia during delivery may also result in fetal loss. Pneumonia is associated with an increased risk of preterm delivery and pregnancy loss. Malnutrition can also lead to growth restriction. Although most medications used for treatment of CF are safe for use in pregnancy, infection with some multidrug-resistant organisms may require use of agents with less extensive pregnancy data.

Careful genetic counseling is necessary to explain the risk of having an affected child, as determined by the partner's carrier status, and to clarify the intentions of the couple with regard to testing the partner, antenatal diagnosis, and whether to terminate if a high risk pregnancy or affected fetus is identified. Any child of a mother with CF will be at least heterozygous and has a considerable risk of being a homozygote in view of the high prevalence of the CF gene in the community. Identification of the specific gene mutation in the mother will help in screening her partner and fetus if this is desired. At the time of writing, 90% of CF mutations can be identified by the screening typically employed for the 20 to 30 most prevalent mutations.[132] Screening for the

remaining 10% is impractical because there are now over 900 identified mutations of the CFTR gene. If a mutation is identified in both mother and father, prenatal diagnosis with chorionic villus sampling or amniocentesis can be used to exclude CF in the fetus.[133] Prenatal diagnosis does carry a small risk of pregnancy loss. Parents should be aware that because there is no cure for CF, prenatal diagnosis should be performed either to help the couple emotionally prepare for an affected child or to guide them toward termination if the fetus is found to be affected.[134]

Management Options

Prepregnancy

Counseling, including detailed genetic counseling, should be given, acting on the preceding information. The patient's nutritional status should be assessed and optimized. The presence of pulmonary vascular disease should be accurately determined if this is to be a reason for precluding or terminating the pregnancy. Examination for evidence of pulmonary hypertension (elevated jugular venous pulse, right ventricular heave, and/or a loud or palpable second heart sound), obtaining current pulmonary function tests, ABGs, and an echocardiographic estimation of pulmonary artery pressures would all be advisable to help assess a women's pregnancy risk. Pulmonary hypertension and cor pulmonale should lead the clinician to strongly discourage pregnancy because of the high maternal risk.[135,136] Pregnancy should also be strongly discouraged when FEV_1 is <50% of predicted; completed pregnancies have been reported, but outcomes have been poor, with prematurity, infant complications, and maternal death.[137] A BMI <18 kg/m^2 should also be considered a relative contraindication to pregnancy.[108]

Medical care and drug treatment should be optimized before conception. In addition, the fact that a future child is at risk of being left without a mother at a relatively young age needs to be tactfully raised and future child care issues considered. The 10-year mortality rate among pregnant women with CF is 20%. Although heart and lung transplantation may be possible for some patients with CF, it will not be possible for the majority, if only because of the shortage of donors. Patients who are already significantly malnourished should be warned of the further weakness and emaciation that pregnancy may cause.

Prenatal

The principles of management of patients with CF in pregnancy are optimization of pulmonary and nutritional status. Patients with severe lung impairment and/or pulmonary hypertension should be informed of the substantial personal risk of a pregnancy to their own health and should be offered a termination of pregnancy.

Patients who are continuing with pregnancy require optimal medical care for their respiratory condition. Most patients who survive to become pregnant are giving

themselves chest physiotherapy on a daily basis, and they or their partners should be encouraged to continue and increase this treatment. Pulmonary exacerbations should be treated as they would be outside of pregnancy. Pulmonary exacerbations can lead to hypoxia and increase the risk of preterm delivery. There should be no hesitation in arranging hospital admission either because of exacerbation of respiratory infection or because of malnutrition. Antibiotic dosing may need adjustments because of the altered pharmacokinetics of both CF and pregnancy. Use of penicillins, cephalosporins, and aminoglycosides for episodes of deterioration in pulmonary status is safe and readily justifiable in pregnancy for this indication.[138,139] Limited data have not shown quinolones to increase teratogenic risk in humans, and these agents should be used when indicated in pregnancy for the management of CF.[140,141] Use of trimethoprim/sulfamethoxazole may be necessary in pregnancy to treat *Burkholderia cepacia*. Nearly all bronchodilator drugs can be used safely in pregnancy. For patients with hypoxia, use of supplemental oxygen is routine. However, large-scale studies of supplemental oxygen have not been performed on CF patients.

Malnutrition may be the cause of IUGR. The healthy 10- to 12-kg weight gain usually associated with pregnancy can be a challenge for the pregnant woman with CF. Most patients with CF need to eat 120% to 150% of their recommended daily requirements to maintain their body weight even when not pregnant. Normal pregnancy weight gain requires them to eat a further 300 kcal/day.[142] Significantly underweight women may become emaciated in pregnancy because of the additional nutritional demands of the fetoplacental unit. However, even in those patients with normal weight, several factors may complicate weight gain. Pregnancy-related dyspepsia, reflux, nausea and vomiting, and constipation may lead to a decrease in caloric intake. The additional calorie requirements needed for pregnancy may then be difficult to match without resorting to enteral feeding. In some cases complicated by hyperemesis gravidarum, enteral feeding may be required.

Patients with diabetes will require the usual tight control of blood glucose to optimize pregnancy outcome. Because many women with CF will have impaired glucose tolerance, screening for gestational diabetes should occur early. Most CF patients identified to have gestational diabetes will require insulin therapy.

Intrauterine growth restriction, decreasing maternal weight, and deteriorating respiratory function despite optimal medical treatment in hospital are all indications that should prompt consideration of preterm delivery late in gestation.

Labor and Delivery

At delivery, the aim should be for a vaginal delivery to decrease the risk of postoperative pneumonia associated with surgery. The patient should be encouraged to receive an epidural to decrease maternal oxygen requirements associated with pain and avoid the need for general anesthesia should an urgent cesarean delivery be needed. Forceps or vacuum delivery should be considered early in the second stage of labor to avoid or relieve maternal exhaustion.

Postnatal

Most patients with cystic fibrosis should be encouraged to breast-feed. Most medications needed for the treatment of CF are safe to take during breastfeeding. Breastfeeding is not advisable, however, where maternal nutrition is a problem. Furthermore, if the mother's general health is very poor, bottle feeding has the advantage that somebody else can do it at night and thus allow the mother to rest. The breast milk of mothers with CF has normal electrolyte content but a slightly lower fat content than normal, specifically for essential fatty acids, although it has enough to nourish the child.[143-145]

Infants of mothers with CF will often be screened for CF by their pediatrician.

CONCLUSIONS

CYSTIC FIBROSIS

- Prepregnancy counseling of women with CF should include tactful discussions about her shortened life expectancy and the risk of CF in the patient's offspring.
- Obtaining pulmonary function testing, ABGs, and an echocardiographic estimation of pulmonary artery pressures is important in helping the woman with CF prepare for pregnancy.
- Women with CF who have a good nutritional status, an FEV_1 that exceeds 50% of the predicted value, no evidence of pulmonary hypertension, and have not been colonized by *Burkholderia cepacia* are most likely to have good pregnancy outcomes.
- A BMI <19, an FEV_1 <50% of predicted, and infection with *Burkholderia cepacia* all are predictors of poor outcome in pregnant women with CF. The presence of pulmonary hypertension is associated with a significant risk of maternal mortality.

PNEUMONIA

General

Pneumonia remains the leading cause of infectious death in the United States[146] but is relatively infrequent in pregnancy. At the Sloan Hospital in New York, Berkowitz[147] found that the incidence of pneumonia in 1988–1989 was 1:3670 deliveries and in 1992 was 1:2288 deliveries. The mothers who developed pneumonia usually had coexisting medical problems, including drug abuse, anemia, and HIV infection.

In managing cases of pneumonia in pregnancy, perhaps the most important role for physicians is to carefully review the differential diagnosis. Pulmonary embolism is the leading cause of maternal mortality in the United States and the United Kingdom and can present identically to an acute pneumonia with dyspnea, cough, chest pain, fever, and chest x-ray infiltrates. Aspiration chemical pneumonitis, amniotic fluid embolism, and pulmonary edema related to sepsis, tocolysis, or preeclampsia can also present in a similar fashion.

Rigorous investigation into the specific etiology and treatment of pneumonia in pregnancy has not occurred.

However, the pathogens responsible for severe community-acquired pneumonia are likely similar in pregnant and nonpregnant patients. Importantly, the reduction in cell-mediated immunity associated with pregnancy does place women at an increased risk of severe pneumonia and disseminated disease from some atypical pathogens such as herpes virus, influenza,[148] varicella,[149] and coccidioidomycosis.[150] Pathogens known to cause pneumonia in pregnancy are reviewed in Table 38–6.

Maternal and Fetal Risks

The risks to the fetus are those of miscarriage and preterm labor; these are nonspecific risks associated with any febrile illness in pregnancy. In addition, the organism causing pneumonia may present specific risks to the fetus, particularly if it is a virus (e.g. varicella).[155] However, most cases of pneumonia in pregnancy are caused by organisms that do not affect the fetus. The fetus may also be at risk from maternal conditions that predispose to pneumonia (e.g., HIV infection), and all women who present with pneumonia in pregnancy should be offered HIV testing.

Effective antibiotic therapy has removed the excess maternal risk that pregnancy might have added to bacterial pneumonia. Even though the patients in Berkowitz's series from New York were seriously ill and required aggressive treatment, it is likely that this was because of their other underlying conditions rather than because of pregnancy.

TABLE 38–6

Causes of Community-Acquired Pneumonia[41]

ORGANISM	PERCENTAGE OF CAUSES OF COMMUNITY-ACQUIRED PNEUMONIA	COMMENTS
Streptococcus pneumoniae	20–60%	Currently believed that many culture-negative cases of pneumonia are caused by pneumococcus
Haemophilus influenzae	3–10%	More common in smokers or patients with underlying lung disease such as asthma
Staphylococcus aureus	3–5%	Rare in healthy young people, except in the setting of postinfluenza pneumonia
Gram-negative bacilli	3–10%	Unusual as a cause of pneumonia in the absence of underlying disease; therefore, rare in a young healthy pregnant population
Aspiration	6–10%	In the past aspiration pneumonia often associated with cesarean deliveries and general anesthesia. Typical case of aspiration pneumonia in obstetric populations is abrupt-onset chemical pneumonitis in which infection plays a limited, if any, role. Modern anesthetic management appears to have greatly decreased its occurrence. Treatment generally supportive. Bacterial aspiration pneumonia usually has a more insidious onset. Mouth anaerobes are the typical pathogens.
Legionella	2–8%	Not frequently seen in young patients without underlying disease
Mycoplasma pneumoniae	1–6%	Common cause of pneumonia in young adults but usually presents indolently
Chlamydia pneumoniae	4–6%	Similar indolent presentation as *Mycoplasma*
Viruses	2–15%	Among the many causes of viral pneumonia, pregnant women appear to be particularly susceptible to herpes, varicella, and influenza pneumonia. Altogether, 10% of cases of maternal varicella infection may be complicated by pneumonia, which can be very severe. In one series, two patients required ventilation and one died. In influenza epidemics, half the cases of maternal mortality have been due to pneumonia,[151] though this has not been a problem recently.
Miscellaneous	3–5%	Includes *Neisseria meningitidis*, *Moraxella catarrhalis*, *Streptococcus pyogenes* (group A streptococcus), psittacosis (from exposure to birds), tularemia (from exposure to rabbits), and *Coxiella burnetti* (from exposure to parturient animals or cats) *Mycobacterium tuberculosis* is an important and increasing cause of pneumonitis that should be particularly considered among inner city and new immigrant populations. *Pneumocystis carinii* always warrants consideration in patients with HIV infection. Coccidioidomycosis ("desert fever") is usually a mild pneumonia associated with arthralgias and erythema nodosum but can lead to disseminated disease, including meningitis, in pregnant women. It should be suspected in patients with a history of travel to the American Southwest.[150,152] In a series of 50 cases of coccidioidomycosis from North America, 22 became disseminated during pregnancy, with a maternal mortality of 100% in patients not treated with amphotericin B.[153,154]

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

Management Options

Prepregnancy

Prepregnancy counseling is usually not relevant, since pneumonia presents as an acute event without warning. However, in HIV-infected individuals with low CD4 cell counts requiring pneumocystis prophylaxis, patients should be counseled to continue this therapy into pregnancy. Additionally, based on recently revised recommendations from the Centers for Disease Control and Prevention (CDC) and the American College of Obstetricians and Gynecologists, women anticipating pregnancy should be advised that they should routinely receive influenza vaccination during the influenza season.[156] Pneumococcal vaccine is recommended before or during pregnancy for women with high risk conditions such as diabetes mellitus, asthma, chronic cardiac or pulmonary disease, or immune compromise disease. It is mandatory postsplenectomy and in women with functional hyposplenism (e.g., sickle cell disease). It is also recommended for women living in long-term care facilities or prisons.[157]

Prenatal

The patient with community-acquired pneumonia typically presents with the sudden onset of rigors followed by fever, pleuritic chest pain, and cough productive of purulent sputum. Physical examination shows tachycardia, tachypnea, fever, and crackles on lung auscultation, but any of these features may be absent at the time of presentation. Pneumonias caused by agents such as *Mycoplasma*, *Legionella*, *Chlamydia*, and viruses are likely to have a more indolent presentation, but the clinical utility of this observation when making treatment decisions is questionable as evidence suggests that all etiologies may present either acutely or subacutely.[158]

The presence of an infiltrate on chest x-ray is considered the "gold standard" for diagnosing pneumonia and should be obtained in most patients.[159] There should be no hesitation about performing chest radiology in pregnancy for patients who are suspected of having pulmonary disease. The radiation to the fetus is minimal (about equal to one day's background radiation), and the likelihood of harm to the fetus from missing a diagnosis such as pneumonia is far greater than the likelihood of harm from radiation. Despite traditional teaching to the contrary, studies have shown that radiologists cannot reliably differentiate bacterial from nonbacterial pneumonia on the basis of the x-ray appearance.[160] The role of routine cultures of sputum and blood and/or serologic studies in all individuals with pneumonia before initiation of therapy is controversial because an etiologic agent is found in only about half of cases investigated.[161-163]

In patients who present with high fever, purulent sputum, chest pain, and clinical and radiologic signs of consolidation, the diagnosis is not a problem. But patients who have only modest pyrexia, no sputum, and indeterminate physical and radiologic signs may well have pulmonary infarction rather than infection. They should be treated for both conditions simultaneously (if there is no contraindication to anticoagulation; see Chapter 43) until the diagnosis is best established, usually by radioisotope ventilation-perfusion scans or CT angiography.

TREATMENT

A synthesis for the pregnant patient based on present empiric therapy recommendations of the Infectious Disease Society of America (IDSA),[164] British Thoracic Society (BTS),[165] and the American Thoracic Society (ATS) is reviewed in Table 38-7. Treatment differs with the severity of illness (as reflected by whether the patient is being treated as an inpatient or an outpatient) and reflects the prevalence of drug-resistant pneumococcus. Patients initially treated with intravenous antibiotics can be switched to oral agents once the patient is afebrile. With appropriate antibiotic therapy, some improvement in the clinical course should be seen within 72 hours. Continuation of therapy for a total of 10 to 14 days is recommended for all agents except azithromycin, which can be given for only a 5-day course because of its extended half-life.

These recommendations need a few additional words of caution. First, although reasonable data exists that erythromycin is not a human teratogen, the use of the estolate ester of erythromycin has been associated with a relatively high incidence of subclinical, reversible hepatotoxicity when used during pregnancy[166] and should be avoided in favor of other formulations of this agent. Second, published human data regarding azithromycin safety in pregnancy is surprisingly small despite the widespread use of this agent. It is also considerably more expensive than erythromycin. For these two reasons, this author believes azithromycin

---

TABLE 38-7

Empiric Antibiotic Regimens for the Treatment of Community-Acquired Pneumonia in Pregnancy[41]

- For uncomplicated pneumonia in patients who do not require hospitalization:

Standard: erythromycin 250 mg qid PO for 10–14 days
Alternate: azithromycin 500 mg PO on day 1 followed by 250 mg daily for 4 days

- For uncomplicated pneumonia in patients requiring hospitalization:

Ceftriaxone 2 g IV once daily with erythromycin 500 mg IV q6h (azithromycin 500 mg IV daily may be used as an alternative to erythromycin if erythromycin is poorly tolerated). Once patient is afebrile and stable, switch to erythromycin 250–500 mg PO qid with cefuroxime axetil 500 mg PO bid for a total antibiotic course of 14 days
If patient has been treated with azithromycin instead of erythromycin, this antibiotic can be administered for a 5-day course only (500 mg the first day and then 250 mg daily for days 2 through 5) because of its long half-life.

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15(6):913–936.

should remain a second-line choice for women unable to tolerate or comply with erythromycin therapy.

Although clarithromycin and levofloxacin are often recommended for the treatment of possible resistant pneumococci in the nonpregnant population, these drugs should be avoided in pregnancy. Clarithromycin appears to be a teratogen in some animals and should only be used in humans in situations where it is the drug of choice. Although fluoroquinolones do not appear to be fetotoxic or teratogenic in animals, their use in pregnancy and pediatrics has been discouraged because of the ability of ciprofloxacin and ofloxacin to cause an irreversible arthropathy in immature experimental animals. Although recently published human data has been reassuring, these agents should still be considered relatively contraindicated in pregnancy at this point.[140,141] Tetracyclines should not be used in pregnancy because of their effects on fetal bones and teeth.

Dosage of antibiotics should be toward the upper range of therapeutic doses in pregnancy[51] because of increased renal clearance. Patients should receive aceta-minophen as an antipyretic. Those that are very sick may require assisted ventilation as judged by deteriorating ABG status. Respiratory failure is one of the leading reasons for ICU admission of pregnant patients; pneumonia is responsible for some portion of these cases.[167,168]

The CDC recommends that all nonpregnant women of childbearing age who are not immune to varicella be vaccinated for it. If exposure to varicella occurs in pregnancy in a woman without immunity, varicella zoster immune globulin should be administered within 96 hours in an attempt to prevent maternal infection. Varicella embryopathy may occur as a result of maternal infection, particularly in the first half of pregnancy, with an incidence of 1% to 2%. Varicella of the newborn is a life-threatening illness that may occur when a newborn is delivered within 5 days of the onset of maternal illness or after postdelivery exposure to varicella. Because of the high prevalence and morbidity of pneumonia associated with varicella infection in pregnancy, parenteral acyclovir should be given to all varicella nonimmune patients who develop respiratory symptoms within 10 days of exposure to varicella.[169–173]

CONCLUSIONS

PNEUMONIA

- Pneumonia in the absence of fever, crackles on lung auscultation, and tachypnea is rare.
- Diagnosis is based on clinical presentation and chest x-ray. Chest x-rays are safe and readily justifiable in pregnancy.
- Pneumonia in pregnancy should only be diagnosed after careful consideration of the differential diagnosis of pulmonary embolism, pulmonary edema, and asthma.
- Treatment of community-acquired pneumonia can be done as an outpatient with erythromycin and with ceftriaxone and erythromycin in an inpatient.
- All women who are pregnant or anticipating a pregnancy should be offered influenza vaccine if they will be pregnant during influenza season.
- Varicella exposures in pregnancy in nonimmune individuals require prophylaxis with varicella zoster immune globulin and initiation of acyclovir treatment with the onset of any symptoms.

PULMONARY EDEMA, ACUTE LUNG INJURY, AND ACUTE RESPIRATORY DISTRESS SYNDROME

General

Pregnant women are known to develop pulmonary edema more frequently than nonpregnant women. The incidence of pulmonary edema in pregnancy is estimated to be 80 per 100,000.[174]

Pulmonary edema is due to the movement of excess fluid into the alveoli as a result of alteration in one or more of Starling's forces. Pulmonary edema can be cardiogenic or noncardiogenic. In cardiogenic pulmonary edema, a high pulmonary capillary wedge pressure (PCWP) is responsible for the movement of fluid into the alveoli. This phenomenon is commonly known as *congestive heart failure*. The causes and treatment of cardiogenic pulmonary edema are discussed in Chapter 37. Noncardiogenic pulmonary edema can be caused by a variety of disorders in which factors other than elevated PCWP are responsible for protein and fluid accumulation in the alveoli. For the diagnosis of noncardiogenic pulmonary edema to be made, the PCWP should be <18 mmHg and there should be no evidence of a cardiac cause.[176]

It is not always possible to make the distinction between cardiogenic and noncardiogenic causes, because the clinical syndrome may represent a combination of several different disorders. Determining which is the most important contributor is important, however, because treatment varies considerably depending on the underlying pathophysiologic mechanisms.

The major causes of noncardiogenic pulmonary edema are acute lung injury and the acute respiratory distress syndrome (ARDS). These two entities are defined in Table 38-8. ARDS has an incidence in the general population of 13.5 per 100,000 per year.[177] These entities generally represent diffuse damage to the alveoli, require mechanical ventilation, and run a protracted course associated with a significant mortality. Precipitants of acute lung injury/ARDS include sepsis, aspiration, pneumonia, severe trauma and burns, massive blood transfusion, sudden relief of upper airway obstruction, lung and bone marrow transplants, medications (especially aspirin, cocaine, narcotics, and nitrofurantoin), leukoagglutination reactions in the lungs after a blood transfusion, venous

TABLE 38-8

Diagnostic Criteria for Acute Lung Injury and Acute Respiratory Distress Syndrome[181]

1) Acute onset
2) Bilateral chest radiographic infiltrates
3) A pulmonary artery occlusion pressure of <18 mmHg or no evidence of left atrial hypertension
4) Impaired oxygenation manifested by a PaO_2/FiO_2 of <300 mmHg (<40 kPa) for acute lung injury and <200 mmHg (<27 kPa) for ARDS

Adapted and updated from material used with permission from Powrie RO: Acute lung injury. In Lee RV. Rosene-Montella K, Barbour LA, et al. (eds): Medical Care of the Pregnant Patient. Philadelphia, American College of Physicians, 2000, pp. 397–411.

air embolism with central venous catheter insertion, and neurocardiogenic (associated with a intracerebral bleed or seizure).[176,178]

Although many of the cases of noncardiogenic pulmonary edema seen in pregnancy will meet the strict diagnostic criteria set for acute lung injury/ARDS, the majority of the pregnancy-related cases will not run the protracted course typically seen with true ARDS. In fact, the majority of pregnancy related cases will improve rapidly with treatment and/or removal of the inciting factor and will not require mechanical ventilation. Experts suggest that such cases might better be termed *permeability pulmonary edema* rather than acute lung injury/ARDS. However, although the course of pregnancy-associated permeability pulmonary edema and ARDS may be different, the initial clinical presentations are often indistinguishable and the causes remain the same.[168,175,180–184]

Physiologic Changes in Pregnancy That Predispose Pregnant Women to Pulmonary Edema

The unique predisposition that pregnant women have to permeability pulmonary edema is attributable to a number of normal physiologic changes that occur in pregnancy. These changes can be viewed as "contributing" factors that increase the likelihood that a pregnant woman with a particular insult or condition will go into pulmonary edema, but do not, in and of themselves, cause pulmonary edema. These changes are summarized in Table 38–9 and discussed in the following.

Pregnancy-Associated Drop in Plasma Colloid Osmotic Pressure

Pregnancy is associated with a significant expansion of blood volume that occurs predominantly through an increase in plasma free water. This increase in plasma free water leads to a progressive decrease in the concentration of plasma proteins manifested by the dropping serum albumin seen with advancing gestation. Plasma protein concentration is the main determinant of plasma colloid osmotic pressure (PCOP), one of the forces that in Starling's law limits net filtration across the capillary wall,

so its decrease may partly explain the increased propensity in pregnant women for fluid to move out of the intravascular spaces and into the interstitium.

The pregnancy-associated decrease in PCOP seen throughout gestation has been shown to drop further in the puerperium. The mechanism for this further decrease is multifactorial but normal peripartum blood loss, "autotransfusion" of blood into the circulation with each uterine contraction, and the sudden increase in preload that occurs when the gravid uterus' compression of the inferior vena cava is released all contribute to it. Preeclampsia is also associated with an additional drop in PCOP, which partially explains the increased risk of pulmonary edema seen with this entity.[185–192]

Pregnancy-Associated Increase in Blood Volume and Cardiac Output

The normal pregnancy is characterized by a progressive increase in blood volume and cardiac output (CO), which reaches a maximum at 26 to 32 weeks' gestation. Fever, pain, preeclampsia, and multiple gestations can further increase cardiac work and lead to a rise in pulmonary artery occlusion pressure (PCOP) that, although within the "normal" (<18 mmHg) range, can, in the setting of low PCOP and/or endothelial damage, lead to pulmonary edema.

Pregnancy-Associated Decrease in Functional Residual Capacity

Third, increased minute ventilation and elevation of the diaphragm by the gravid uterus decreases the FRC in pregnant women by around 18% as compared with nonpregnant individuals. Therefore, at end-expiration the pregnant woman is closer to her *critical closing volume* (the volume at which alveoli collapse upon themselves) than the nonpregnant woman. Some investigators believe that this decreased FRC increases the ease with which small airways and alveoli collapse when small amounts of pulmonary edema are present and may thereby contribute to a progressive worsening of oxygenation when intra-alveolar fluid is present.

Precipitating Causes of Pulmonary Edema

Despite the predisposition of the pregnant women to develop pulmonary edema due to low colloid osmotic pressure and increased cardiac work, the occurrence of pulmonary edema still requires an inciting agent or event to "tip the balance" and allow fluid to move into the interstitial spaces of the lung. All of the conditions described as causes of ARDS can cause pulmonary edema in pregnant women. Table 38–10 lists those causes of pulmonary edema most likely to be seen in pregnancy. The most common precipitants seen in pregnancy are reviewed in more detail in the text that follows. Some of these inciting agents or events have clear, causative relationships, but for others the link is not

---

TABLE 38-9

Normal Physiologic Changes of Pregnancy That Predispose to and May Exacerbate Pulmonary Edema

20% decrease in colloid osmotic pressure
50% increase in blood volume and cardiac output
Decreased FRC in pregnancy means end-expiratory volumes
   closer to critical closing volumes

Adapted and updated from material used with permission from Powrie RO: Acute lung injury. In Lee RV, Rosene-Montella K, Barbour LA, et al. (eds): Medical Care of the Pregnant Patient. Philadelphia, American College of Physicians, 2000, pp. 397–411.

readily apparent. Some are unique to pregnancy; others are common to both the pregnant and nonpregnant populations. In all cases, it would appear that the presence of anemia and/or multifetal gestations further increases the risk that a particular inciting event will lead to pulmonary edema. In addition, the routine administration of generous amounts of crystalloid fluids to provide hydration during labor may have ill effect, because those patients with some other predisposition toward pulmonary edema may not be able to compensate for this excess volume.

Tocolysis

A relatively common cause of permeability pulmonary edema is the use of β-adrenergic agonists (such as terbutaline) and magnesium for tocolysis. Although β-adrenergic agonists have been used extensively in the treatment of asthma in nonpregnant patients without this complication, there is a clear association in the obstetric literature between these agents and pulmonary edema, the etiology of which remains unclear. Possible contributing factors include a primary cardiogenic component related to barometric-induced myocardial fatigue or altered capillary permeability. Fluids routinely given in association with tocolysis may be responsible for some cases; the β-adrenergic agonists themselves can cause further decreases in PCWP beyond the normal physiologic drop seen in pregnancy. The altered physiology of normal pregnancy must contribute to the effects of β-adrenergic agonists because this complication is not seen in nonpregnant individuals who receive β-adrenergic agonists for other indications.[193–200]

Preeclampsia

Preeclampsia is an important cause of pulmonary edema in pregnancy. Three percent of patients with preeclamp-

sia will develop pulmonary edema during the course of their illness. Thirty percent of pulmonary edema associated with preeclampsia will occur antepartum and 70% will occur postpartum, usually within the first 72 hours after delivery. Maternal mortality from pulmonary edema may be as high as 10%; perinatal mortality may be as high as 50% in the presence of pulmonary edema associated with preeclampsia. This alarmingly high fetal mortality rate may be related to placental abruptions and therefore may be more reflective of the severity of the preeclampsia than the presence of the pulmonary edema itself.

Preeclampsia is believed to cause pulmonary edema by a variety of mechanisms. In some cases, the pulmonary edema is attributable to the additional drop in PCOP that occurs in pregnancy-induced hypertension (PIH) and is in excess of the normal PCOP drop in pregnancy. This additional decrease in PCOP may be enough in some cases to allow fluid to move into the interstitial spaces of the lungs. In other cases, there is evidence that the endothelial damage characteristic of severe PIH may disrupt the normal endothelial barrier in the lungs, as occurs with early sepsis or leaky capillary syndromes, thereby allowing the escape of fluid into the alveoli and interstitium. In some cases, a stiff left ventricle from chronic hypertension with significant diastolic dysfunction may be an important factor contributing to pulmonary edema in women with preeclampsia who have a sudden and dramatic increase in afterload due to the intense vasospasm and increased systemic vascular resistance. Last, a significant number of cases of pulmonary edema occurring in the setting of preeclampsia can be attributable to left ventricular systolic dysfunction. The occurrence of left ventricular dysfunction in preeclampsia has been well described but is poorly understood. Presumably the intense vasospasm and endothelial damage that characterizes preeclampsia have a significant impact on myocardial oxygen supply and thereby myocardial contractility.[201–206]

Sepsis

Sepsis is also a very important cause of pulmonary edema in pregnancy. Pneumonia can progress to acute lung injury and ARDS and is an important cause of prolonged mechanical ventilation in pregnant women (see Pneumonia). However, it would appear that any systemic bacterial infection can lead to pulmonary edema in pregnant women. This increased incidence of sepsis-related pulmonary edema in pregnancy seems to be related to a combination of decreased PCOP, altered capillary permeability, and increased sensitivity of pregnant women to endotoxins. The most well-described example of this is the occurrence of pulmonary edema in as many as 10% of cases of pyelonephritis during pregnancy. The greatly increased incidence of pyelonephritis in pregnancy makes this infection a particularly important cause of pulmonary edema and argues against

routine outpatient management of pyelonephritis in pregnancy.[207-211]

Aspiration Syndromes: Mendelson's Syndrome and Bacterial Aspiration Pneumonia

Aspiration syndromes are seen in pregnancy because of the delayed gastric emptying and decreased lower esophageal sphincter pressure seen in all pregnant women. In the setting of altered mental status from drugs, anesthesia, or seizures, stomach contents can be aspirated and lead to Mendelson's syndrome and/or bacterial aspiration pneumonia.

Mendelson's syndrome usually occurs in association with a difficult intubation or during the postanesthesia period when the gag reflex may be depressed, but it may also occur de novo in pregnant women. Gastric juice is aspirated into the lungs and leads to intense pulmonary inflammation that can proceed with rapidity to a full acute lung injury/ARDS picture over 8 to 24 hours. The patient becomes tachypneic, hypoxic, and febrile. Chest x-ray changes classically show a complete "white out." Despite this rapid and marked deterioration, this syndrome generally resolves without antibiotics within 48 to 72 hours unless bacterial superinfection intervenes.[212] Modern anesthetic management has thankfully made this a far less common event than it was in the past.

Bacterial aspiration pneumonia usually has a more insidious onset than Mendelson's syndrome, with clinical manifestations presenting 48 to 72 hours after aspiration with persistent fever, sputum, and leukocytosis. Classically chest x-ray findings are localized to the basilar segments if the patient aspirated while upright and to the posterior segment of the upper lobe or the superior segment of the lower lobe if the patient aspirated while supine. The bacterial infection is generally polymicrobial, with mouth anaerobes predominating, so treatment with penicillin or clindamycin is advisable.

Massive Hemorrhage

Massive red cell transfusion for antepartum or postpartum hemorrhages can result in pulmonary edema. The mechanism for this is often multifactorial and can include volume overload, decrease in PCOP from replacement of whole blood loss with packed red cells and crystalloids, endothelial damage from a systemic inflammatory response to the massive hemorrhage, and, rarely, leukoagglutination in the lung.

Amniotic Fluid Embolism (Anaphylactoid Lung of Pregnancy)

Amniotic fluid embolism is a rare but catastrophic complication of pregnancy that may present as pulmonary edema but often proceeds to full ARDS. Its incidence is variably quoted as being between 1 in 8000 and 1 in 80,000 pregnancies. Prolonged labor, multiparity, increased maternal age, meconium staining of the amniotic fluid, and use of forceps are risk factors for this catastrophic complication. It almost always occurs at the time of delivery but has been reported to occur antepartum. It has a mortality rate that has been recently estimated to be between 26% and 60%[213] and is responsible for 10% of maternal deaths in the United States.[214–217] Amniotic fluid embolism usually presents with a sudden onset of agitation and dyspnea that is followed by symptomatic hypotension, hypoxia, and disseminated intravascular coagulation (DIC) resulting in massive obstetric hemorrhage. Seizures can also be seen with acute amniotic fluid embolism. The diagnosis is difficult to establish with certainty but should be considered in any woman near term (and especially in labor) who presents with sudden cardiorespiratory failure. Although the entry of amniotic fluid into the maternal circulation through the endocervical veins or uterine tears is an important prerequisite of the amniotic fluid embolism syndrome, it would appear from animal studies that it is not enough in itself to cause the catastrophic reaction seen in patients with this diagnosis. For this reason, some researchers would prefer that the diagnosis *anaphylactoid lung of pregnancy* be used to describe the syndrome of amniotic fluid embolism, thereby emphasizing the importance of the maternal immunologic response in this syndrome.

Presentation of Pulmonary Edema in Pregnancy

Clinical Features

The symptoms and signs of pulmonary edema in pregnancy are very similar to those seen in the general medical population. Early signs and symptoms of pulmonary edema may be few and mild; therefore, it can be difficult to distinguish pulmonary edema from other causes of cardiopulmonary complaints seen in pregnancy. One of the most common mistakes is a delay in diagnosis when the mild symptoms of pulmonary edema in pregnancy are attributed to less serious and more common causes of dyspnea such as respiratory tract infections, asthma, or dyspnea of pregnancy. This may be because the absence of comorbid conditions in the majority of pregnant women makes patients "look" better and maintain respiratory and cardiovascular stability longer than the typical medical patient with pulmonary edema.

Tachypnea is an important clinical sign that a woman's complaints are more than just the normal increased shortness of breath on exertion seen in pregnancy. The chest may initially be clear to auscultation early in the course of evolving pulmonary edema, especially in the otherwise well pregnant woman. The patient will often display some degree of anxiety related to mild dyspnea or hypoxia. Eventually, as the condition progresses and alveoli fill with fluid, diffuse crackles, wheezing, and cough will be present. Tachycardia is common, but heart rate should be interpreted with the knowledge that a resting pulse of 100 beats/minute is not unusual in normal pregnancies.

Arterial Blood Gas, Chest X-Ray, and Electrocardiogram Findings

Arterial blood gases in patients with pulmonary edema typically initially show a decrease in both PaO_2 and $PaCO_2$. As the condition worsens, PaO_2 will decrease further, but $PaCO_2$ will increase as the patient is no longer able to maintain adequate ventilation and respiratory failure ensues. (It is worth emphasizing again that a PaO_2 of 70 mmHg or a $PaCO_2$ of 40 mmHg in a pregnant woman is very abnormal and highly suggestive of ventilatory failure.)

The chest x-ray in pulmonary edema may initially be normal. Subsequently, pulmonic infiltrates, and in some cases pleural effusions, will become manifest. Although classically pulmonary edema is associated with diffuse chest x-ray changes, in some cases of pulmonary edema the damage may be patchy or unilateral, particularly if a patient has spent prolonged periods in the left lateral decubitus position. The radiation exposure necessary to obtain a proper chest film is well below the recommended maximal levels of radiation for pregnancy; therefore, an indicated chest x-ray should never be withheld due to concerns about fetal effects.

Additional tests that should be routinely obtained in the setting of suspected pulmonary edema are CBC, creatinine, and BUN, because anemia and renal failure may be contributing factors. "Preeclampsia labs" (aspartate aminotransferase, uric acid, and urinalysis in addition to CBC and creatinine) should also be obtained.

Treatment of Pulmonary Edema in Pregnancy

Pulmonary edema in pregnancy is a medical emergency. Irrespective of the etiology, the immediate goal is to maintain adequate maternal oxygenation ($PaO_2 \geq 70$ mm Hg) to avoid hypoxia in the fetus.[218–220] Therefore, it is recommended that maternal SaO_2 be kept >95%. The second goal is to treat the underlying causes of the edema. Third, relief of symptoms leading to improved patient comfort must be instituted.

Careful monitoring of fluid balance should be initiated. Intravenous morphine sulfate is safe when used cautiously to reduce maternal anxiety and decrease pulmonary congestion. Clear, reassuring communication with both the patient and her support person is also important in decreasing maternal distress. Lastly, although the majority of patients with pulmonary edema in pregnancy will not be volume overloaded, diuresis to try to achieve the lowest possible PCWP that will still support normal blood pressure is advisable. Data from the treatment of ARDS in nonpregnant patients tell us that decreasing the PAWP by 25% with diuretics and fluid restriction can improve pulmonary function and perhaps outcome.[221–223] It is our experience that many of the patients with pulmonary edema in pregnancy who do not have cardiac or renal disease will still respond dramatically to intravenous doses of furosemide as low as 10 mg. Using the lowest possible dose of diuretics has an addi-

tional importance in the setting of preeclampsia in which patients are relatively volume contracted despite having massive amounts of peripheral edema and pulmonary edema. Overdiuresis in these patients can lead to intravascular hypovolemia that can impair placental perfusion and lead to fetal distress.

Differential Diagnosis of Pulmonary Edema in Pregnancy

Other causes of respiratory failure in pregnancy that should be routinely considered as part of the differential diagnosis of pulmonary edema are listed in Table 38–11. Differentiating the diagnosis of noncardiogenic pulmonary edema from cases of peripartum cardiomyopathy, ischemic heart disease, or occult valvular heart disease should begin with a careful history, cardiac examination, and electrocardiogram. When any doubt exists however, an echocardiogram is indicated to discern whether the pulmonary edema is actually congestive heart failure. A prospective study of 45 pregnant pulmonary edema patients found that echocardiography identified an unsuspected cardiac abnormality in 47% of cases and should probably be considered routine for these patients.[203] If pulmonary edema is persistent and severe without a clear precipitant and there appears to be no cardiac cause, a bronchoscopic alveolar lavage or lung biopsy can be necessary in cases of full ARDS.

A drug screen should be done for cocaine and heroin in most patients, although the vast majority of patients with cocaine-associated pulmonary edema will be notable for their severe hypertension.

Likewise, consideration of the possibility of acute infectious pneumonia should also occur. Features suggestive of pneumonia include the presence of a prodrome, fever, purulent sputum, chills, rigors, and pulmonary edema; consideration of use of empiric antibiotics pending cultures is often advisable in the initial 48 hours.

A careful drug history should be obtained because drug-induced pneumonitis is a rare but reversible cause of

---

TABLE 38–11

Causes of Respiratory Failure in Pregnancy to Be Considered in the Differential Diagnoses of Pulmonary Edema[41]

Cardiac disease	Peripartum cardiomyopathy Ischemic heart disease Valvular heart disease
Pneumonia	*Streptococcus, Haemophilus, Klebsiella, Staphylococcus,* bacterial aspiration pneumonia, *Mycoplasma, Legionella,* influenza A, varicella, measles
Drug-related pneumonitis	Nitrofurantoin, commonly used as urinary tract infection prophylaxis in pregnancy, can cause an acute pulmonary reaction

Adapted and updated from material used with permission from Powrie RO: Acute lung injury. In Lee RV, Rosene-Montella K, Barbour LA, et al. (eds): Medical Care of the Pregnant Patient. Philadelphia, American College of Physicians, 2000, pp. 397–411.

respiratory failure and has been reported to occur with the antibiotic nitrofurantoin, commonly used as a prophylactic agent for urinary tract infections during pregnancy.

Remove or Treat the Underlying Cause

TOCOLYTIC-RELATED PULMONARY EDEMA

Most important to the management of pulmonary edema in pregnancy is to treat the underlying cause. If the underlying cause is tocolytic agents, the tocolytic agents should be removed. This can be a difficult decision to make if the patient is in labor at a very early gestation. However, this decision can be made more comfortably when one recognizes that (1) fetal well-being is dependent on maternal well-being; and (2) tocolytics are of limited proven efficacy for prolongation of gestation beyond 48 hours.

PREECLAMPSIA-RELATED PULMONARY EDEMA

If the etiology is related to preeclampsia, delivery is the treatment of choice. Even in the absence of typical feature of preeclampsia, consideration of preeclampsia as a possible etiology of pulmonary edema is required. Blood pressure should be brought down below 160/100 in the setting of preeclampsia-associated pulmonary edema because a decrease in afterload may help decrease pulmonary edema. The intravenous infusion of magnesium sulfate (used for seizure prophylaxis in the setting of preeclampsia) requires high doses of fluids; this medication should be administered in the smallest volume considered safe with close following of total fluid balance.

INFECTION-RELATED PULMONARY EDEMA

Sepsis-related pulmonary edema is indicated by the presence of fever and should be treated with broad-spectrum antibiotics. As is the case for suspected pneumonia, it is generally advisable to initiate empiric antibiotic coverage pending cultures. Any abdominal pain and tenderness should prompt consideration of the possible diagnoses of appendicitis and chorioamnionitis/endometritis. Pyelonephritis should be considered in any cases of pulmonary edema associated with fever and a urinalysis and urine culture obtained.

AMNIOTIC FLUID EMBOLISM/ANAPHYLACTOID SYNDROME

Amniotic fluid embolism has no specific treatment other than supportive management. There is no pathognomonic finding or diagnostic test to prove this diagnosis, but there are few conditions present so suddenly with such severe manifestations aside from acute pulmonary embolism. Tests for DIC must be carried out when this diagnosis is considered. Treatment is supportive and should begin with aggressive volume administration to maintain blood pressure but will almost always require intubation, mechanical ventilation, and vasopressor support. Hemorrhage should be treated with fresh frozen plasma and cryoprecipitate as needed.

Endotracheal Intubation

If oxygenation cannot be maintained above a PaO_2 of 70 mmHg or the patient shows evidence of "tiring out" (either by subjective evidence based on the findings of accessory muscle use, intercostal indrawing, and abdominal breathing or on the basis of a rising $PaCO_2$), a trial of spontaneous breathing with supplemental oxygen and positive end-expiratory pressure (PEEP) administered through a tight-fitting mask should be attempted. Noninvasive nasal intermittent positive-pressure ventilation (NIPPV) may also be used, but concerns about its use in the setting of pregnancy-associated upper airway edema and the propensity of pregnant women to aspiration pneumonia may limit its use in critical care obstetrics.

Intubation is generally required if the patient is unresponsive to therapy and has signs of respiratory failure (PaO_2 <70 mmHg or $PaCO_2$ >45 mmHg on 100% oxygen administered through a tight-fitting mask and a nonrebreathing mask). In borderline cases it is worth remembering that it is always preferable to intubate a patient electively rather than delay intubation until it is required emergently. This is particularly true of pregnant women for several reasons. First, the upper airway in pregnant women is often difficult to visualize because of soft tissue swelling related to physiologic hyperemia of mucosal tissues during gestation. Second, pregnant women are at high risk for aspiration because of lower gastroesophageal sphincter tone and delayed gastric emptying, also a normal physiologic occurrence in pregnancy. Third, because pregnant women have decreased FRC, there is less available oxygen in their lungs to maintain PaO_2 between periods of "bagging." Preoxygenation with 100% oxygen should therefore always be done prior to and between any attempts to intubate a pregnant woman. Last, there is reason to believe that the fetus tolerates maternal hypoxia poorly and that a prolonged period off the manual inflation bag and supplemental oxygen necessary for intubation may harm the fetus. It is therefore paramount that intubation of the pregnant woman always be performed by the most experienced individual available and that every effort is made to ensure that all equipment is readily available and functioning properly before beginning an attempt at intubation (see Table 38–12). The rate of failed elective intubation attempts in pregnant patients is eight times greater than that seen in general surgical patients.

Mechanical Ventilation

Mechanical ventilation for the pregnant woman with pulmonary edema should be done in the same manner as for the nonpregnant patient. A reasonable method to start with would be volume-cycled ventilation in the assist control mode with PEEP added in increments of 3 to 5 cm H_2O to improve arterial oxygenation. Tidal volumes should be set at 10 to 12 mL/kg. Patients with decreased lung compliance may need lower volumes (6 to 8 mL/kg) to minimize peak airway pressures. The fraction of

TABLE 38–12

Equipment and Medications Necessary for the Intubation of a Pregnant Woman[41]

Continuous ECG monitoring

Blood pressure monitor on patient's arm

Pulse oximeter

High-flow oxygen source

Large-bore intravenous access secured in place

Intubation to be performed by most experienced individual available, with assistant at his/her side; the incidence of failed intubation in pregnancy is 1 in 200 to 1 in 300 cases, almost 10 times as high as for nonpregnant patients[226,227]

Mask (that fits patient securely) and manual bag-valve inflation device

Oropharyngeal suction equipment

Endotracheal tubes (with tested inflatable cuff) for oral intubation (rather than nasal intubation) with smaller endotracheal tube (6–6.5) than would be used with similar nonpregnant patient preferable due to upper airway narrowing in pregnancy[228]

Laryngoscope with light

Stylet

Medications for sedation and (if necessary) paralysis of patient, usually thiopental 3–5 mg/kg IV for sedation, and succinylcholine 1–1.5 mg/kg, up to 150 mg IV, for paralysis

Etomidate 0.3 mg/kg IV over 60 seconds may be needed in certain circumstances for muscle relaxation

Method readily available to assess that endotracheal placement is not esophageal (listener with stethoscope or CO_2 detector)

Self-inflating bulbs or syringes have been found to be unreliable in pregnant women

Chest x-ray to be done shortly after intubation to ensure endotracheal tube is properly placed 4–7 cm above the carina

Gloves, mask, goggles, and gown available to intubater

Plan in place for next step if intubation attempt fails. Use of the laryngeal mask has been described in pregnancy and should be available in this circumstance.[229]

Adapted and updated from material used with permission from Powrie RO: Acute lung injury. In Lee RV, Rosene-Montella K, Barbour LA, et al. (eds): Medical Care of the Pregnant Patient. Philadelphia, American College of Physicians, 2000, pp. 397–411.

inspired oxygen (FIO_2) should be kept less than 60% if possible. There is little reason to use PEEP at greater than 15 to 20 cm H_2O. $PaCO_2$ should ideally be kept at 28 to 32 mmHg to mimic the physiologic changes in respiratory function seen in the normal pregnancy. Respiratory alkalosis from overventilation should be avoided, however, because alkalemia can have adverse effect on uterine blood flow. Some advocates in critical care suggest use of smaller tidal volumes (<6 mL/kg), pressure-limited ventilation (rather than volume cycled), PEEP at levels of 17 cm H_2O, and "permissive hypercapnia" for patients with ARDS, but the experience with such an approach among pregnant women is limited and there are theoretical reasons to believe that the fetus may not tolerate the acidosis necessary to this approach. Inverse-ratio ventilation has also been used in pregnant women. Clinicians should be aware that the degree of sedation or paralysis necessary for this mode of ventilation will make fetal testing uninterpretable.

Positive-pressure ventilation in pregnancy-associated pulmonary edema often results in a marked and rapid improvement in these patients, because the positive pressure helps to move fluid out of the interstitium. If a patient requires intubation it is important to correct the underlying cause before extubation because patients prematurely extubated may simply slip back into pulmonary edema once they are no longer under the therapeutic effects of positive-pressure ventilation.

Role of Pulmonary Artery Occlusion Pressure Monitoring in Pulmonary Edema/ARDS in Pregnancy

In the majority of cases of pulmonary edema in pregnancy, central hemodynamic monitoring will not be necessary for diagnostic purposes. In the absence of preeclampsia, and in the absence of history, physical examination, or ECG findings suggestive of cardiac disease, it can generally be assumed that the PCWP is unlikely to be >18 mmHg in a young pregnant woman. Preeclampsia is an exception because severe preeclampsia may be associated with either diastolic or systolic dysfunction. In cases where cardiac dysfunction is suspected, a bedside echocardiogram can be extremely useful in deciding if PCWP monitoring may be helpful.

In the absence of prompt clinical response to oxygen, diuresis, and morphine, invasive hemodynamic monitoring may be indicated to aid management. The goal of invasive monitoring in pulmonary edema in pregnancy is to reduce the PCWP and improve and optimize left ventricular performance. In general, however, it must be remembered that a PCWP that is normal for a nonpregnant patient may represent too high a level in the setting of preeclampsia or during the postpartum period. Since the most important factor is not the absolute number of the PCWP but the relationship of PCWP to the colloid osmotic pressure, therapeutic decisions may be difficult in some circumstances. If colloid osmotic pressure is very low, as it is in PIH and in the postpartum period, then a "normal" PCWP can still be associated with significant pulmonary edema. In general, trends in the PCWP may be more useful to follow than absolute numbers. However, it has been the experience of our group that in the absence of cardiac disease or sepsis, hemodynamic monitoring in the setting of pulmonary edema in pregnancy is not generally necessary.[228–242]

Use of Vasoactive and Inotropic Medications

Use of vasoactive substances to help maintain cardiac output at a lower PCWP may be helpful in some cases of pulmonary edema in pregnancy where cardiac dysfunction is present. In the setting of critical illness it is important not to withhold any potentially beneficial treatment from a pregnant woman because of concerns about possible fetal effects. However, the paucity of human data on the effects of most of these medications on placental blood flow should caution against their use to fine-tune maternal hemodynamic parameters.[242]

CONCLUSIONS

PULMONARY EDEMA, ACUTE LUNG INJURY, AND ACUTE RESPIRATORY DISTRESS SYNDROME

- Pregnancy predisposes women to pulmonary edema, particularly in the setting of tocolysis, sepsis, and preeclampsia.
- Pulmonary edema in pregnancy often responds to treatment or removal of the inciting agent, fluid restriction, and a small dose of intravenous diuretic.
- Endotracheal intubation in pregnancy is more difficult and should be done by an experienced anesthesiologist with the proper equipment readily available whenever possible.

SUMMARY OF MANAGEMENT OPTIONS

Pulmonary Edema, Acute Lung Injury, and Acute Respiratory Distress Syndrome

Management Options	Quality of Evidence	Strength of Recommendation	References
General care: communicate with patient and family, relieve anxiety, administer analgesia if appropriate.	–	GPP	–
High or intensive care setting; place patient at 45-degree angle if possible.	–	GPP	–
Provide supplemental oxygen to maintain PaO_2 >65 mmHg and SaO_2 >95%.	III	B	218, 219, 220
If patient is maintaining blood pressure and placental perfusion is not in question, consider administration of intravenous furosemide (at a dose of 10 mg if patient has not received furosemide in past).	IV	C	221, 222, 223
Consider possibility of primary pneumonia by questioning patient regarding presence of a prodromal illness, fever, chills, rigors, sputum, and by reviewing chest x-ray for focal pulmonary findings more suggestive of pneumonia. Treat empirically if significant suspicion of pneumonia entertained.	IV	C	207
Consider possibility of cardiogenic causes (ischemic heart disease, peripartum cardiomyopathy, and valvular heart disease) by careful review of history, cardiac exam, and ECG. Obtain echocardiogram in most cases to rule out cardiogenic causes.	III	B	175
Monitor fluid balance and avoid fluid overload; minimize intravenous fluids.	III	B	223
Remove or treat underlying causes of pulmonary edema in pregnancy: • Discontinue tocolytics. • Evaluate for presence of preeclampsia and begin active efforts toward delivery of fetus if patient has preeclampsia. • Evaluate for presence of infection (especially pyelonephritis) and treat if present. • Protect airway if aspiration is suspected. • Check INR, aPTT, and CBC if amniotic fluid embolism suspected.	–	GPP	–
If oxygenation cannot be maintained, consider use of nasal intermittent positive-pressure ventilation or semielective intubation.	IV	C	241, 242
Consider placement of central hemodynamic monitoring line if: • cardiac cause suspected and patient unresponsive to diuretics • poor urine output despite diuretic administration • hypotension present.	IV	C	228–233
Consider use of inotropic and vasoactive agents to maximize cardiac output in the minority of cases. Therapy should be guided in this setting by central hemodynamic monitoring.	IV	C	241, 242

Anemia and White Blood Cell Disorders

Jane Strong

ANEMIA: OVERVIEW

Anemia is defined as a hemoglobin value that is lower than the threshold of two standard deviations below the median value for a healthy matched population. The World Health Organization defines anemia in pregnancy as a hemoglobin concentration of less than 11g/dL.[1] The cutoff point suggested by the United States Centers for Disease Control is 10.5g/dL in the second trimester.[2]

Marked physiologic changes in the composition of the blood occur in healthy pregnancy. Increased total blood volume[3] and hemostatic changes[4] help to combat the hazard of hemorrhage at delivery. Plasma volume increases dramatically (50%), and red cell mass increases as well (18%–25%, depending on iron status). These changes cause a physiologic dilution in hemoglobin concentration that is greatest at 32 weeks' gestation. In iron-replete women, hemoglobin returns to normal by 1 week postpartum.

Worldwide, pathologic anemia is the most common medical disorder of pregnancy. Deficiency of essential hematinics usually arises from increased requirements and inadequate intake. Iron deficiency is the most common hematinic deficiency in pregnancy, followed by folate deficiency. Vitamin B_{12} deficiency rarely causes anemia in pregnancy. Addisonian pernicious anemia does not usually occur in the reproductive years, and when it does, it is usually associated with infertility. Pregnancy occurs only when vitamin B_{12} deficiency is corrected. Only vegans and those from very poor communities are likely to have a diet that is deficient in vitamin B_{12} (i.e., containing no animal protein). In nonindustrialized countries, anemia is responsible for 40% to 60% of maternal deaths.[5] In industrialized countries, approximately 18% of women are anemic during pregnancy. The average prevalence is 56% in nonindustrialized countries.[6]

ANEMIA: IRON DEFICIENCY

Maternal Risks

To replenish losses, an adult man must absorb approximately 1 mg/day iron. Women of reproductive age require larger quantities of iron to compensate for menstrual losses. During an average menstrual cycle, a woman loses 10 to 15 mg iron. To maintain iron balance, women of reproductive age require 2 mg iron daily. Pregnancy further stresses iron balance. The iron requirements in pregnancy are approximately 900 mg.[7] The main demands for iron arise from expansion of the red cell mass (approximately 500–600 mg), and the fetus and placenta require approximately 300 mg. The daily iron requirement in pregnancy is approximately 4 mg (2.5 mg/day in early pregnancy, increasing to 6 to 8 mg/day from week 32 onward).[8] These requirements can be achieved only by maximizing dietary iron absorption and mobilizing iron stores.[9,10] If a woman enters pregnancy with depleted iron stores, the effects of iron deficiency develop. Vegetarians are at an additional disadvantage because heme iron (derived from meat) is more readily absorbed than non-heme iron, and heme iron also facilitates the absorption of non-heme iron in a mixed diet. Absorption of iron is less than 10%, so an average of 40 mg dietary iron is required daily. For many women, especially in nonindustrialized countries, where diets are low in iron bioavailability, sufficient iron is not supplied by diet alone.

As iron deficiency develops, the ferritin level decreases first and then the serum iron level. A decrease in hemoglobin concentration is a late development.[11] Iron-dependent enzymes in every cell are affected, and there is a profound effect on body functions (e.g., impaired muscle function, neurotransmitter activity, exercise tolerance, epithelial changes, alteration in gastrointestinal function).[12]

Tissue enzyme malfunction occurs, even in the early stages of iron deficiency. The various effects of iron deficiency on cellular function may be responsible for the reported association between anemia during pregnancy and preterm birth and the anecdotal evidence that blood loss at delivery is greater in women with anemia.[13,14]

In normal pregnancy, hypervolemia modifies the response to blood loss.[4] Blood volume decreases after the acute loss at delivery but remains relatively stable as long as the loss does not exceed 25% of predelivery volume. No compensatory increase in blood volume occurs, and plasma volume decreases gradually, primarily because of diuresis. The overall result is that hematocrit gradually increases and blood volume returns to nonpregnant values.

The average blood loss that can be tolerated without causing a significant decrease in hemoglobin concentration is 1000 mL, but this depends on a healthy increase in blood volume before delivery and on iron status.

Fetal Risks

The fetus obtains iron from maternal transferrin, regardless of maternal iron stores. The placenta traps maternal transferrin, removes the iron, and actively transports it to the fetus, mainly in the last 4 weeks of pregnancy.[7] If maternal iron stores are depleted, the fetus obtains iron from erythrocyte breakdown or maternal intestinal absorption. Most fetal iron is found in fetal hemoglobin, but one third is stored in the fetal liver as ferritin.

When maternal iron stores are depleted, the fetus cannot accumulate as much iron and there is a decrease in fetal iron stores.[15] This may have an important bearing on iron stores and the development of anemia during the first year of life, when oral iron intake is very poor.[16–18]

Studies suggest that behavioral abnormalities occur in children with iron deficiency. These abnormalities are related to changes in the concentration of chemical mediators in the brain.[18] Iron deficiency in the absence of anemia is associated with poor performance on the Bayley Mental Development Index.[19] Development delays in iron-deficient infants can be reversed by treatment with iron.[20] Cognitive function can also be improved with iron supplementation, as was shown in a randomized study in nonanemic, iron-deficient adolescent girls.[21]

Recent studies suggest that prophylaxis of iron deficiency during pregnancy may have an important role in the prevention of adult hypertension.[22,23] High blood pressure in adults appears to originate in fetal life and is associated with lower birth weight and high ratios of placenta to birth weight. Placental size at term was shown to be inversely proportional to serum ferritin concentrations at initial evaluation.

Diagnosis

Hemoglobin Concentration

A reduction in the concentration of circulating hemoglobin is a relatively late development in iron deficiency and is preceded by depletion of iron stores, reduction in serum iron levels, and detectable decrements in hemoglobin. However, measuring hemoglobin concentration is the simplest noninvasive practical test available. Hemoglobin values of less than 10.5 g/dL in the second and third trimesters are probably abnormal and require further investigation.

Red Cell Indices

The increased drive to erythropoiesis, resulting in a higher proportion of young large red cells, appears to mask the effect of iron deficiency on mean corpuscular volume (MCV) in pregnancy, even when anemia is established. Healthy, iron-replete pregnancy is associated with a small physiologic increase in red cell size, on average 4 fl*, but in some women, the increase may be as high as 20 fl.[24] MCV is a poor indicator of iron deficiency that develops during pregnancy.[25] Some women enter pregnancy with established anemia as a result of iron deficiency or with grossly depleted iron stores, and florid anemia quickly develops, with reduced MCV, mean corpuscular hemoglobin (MCH), and MCH concentration. These do not present diagnostic problems. Those who enter pregnancy with a precarious iron balance and a normal hemoglobin value present the most difficult diagnostic problems. Recognition of iron deficiency before a decrease in hemoglobin or an effect on red cell indices depends on several noninvasive laboratory tests.

Serum Iron and Total Iron-Binding Capacity

Serum iron level and total iron-binding capacity (TIBC) provide an estimate of transferrin saturation. Reduced transferrin saturation indicates a deficient iron supply to the tissues and the development of iron deficiency. At this early stage, erythropoiesis is impaired and iron-dependent tissue enzymes are adversely affected.

In health, the serum iron of adult nonpregnant women shows considerable diurnal variation and can fluctuate from hour to hour. TIBC rises in association with iron deficiency and decreases in chronic inflammatory states. It is increased in pregnancy because of the increase in plasma volume. In nonanemic patients, TIBC is approximately one third saturated with iron.

In pregnancy, most reports describe a decrease in both serum iron and percentage saturation of TIBC, which can be largely prevented by iron supplements. Serum iron,

---

* fl = femtoliters (10^{-15}L)

even in combination with TIBC, is not a reliable indicator of iron stores, because it fluctuates widely and is affected by recent ingestion of iron and other factors that are not directly involved in iron metabolism, such as infection.

Zinc Protoporphyrin

Zinc protoporphyrin increases when there is a defective iron supply to the developing red cell. Although zinc protoporphyrin may increase in patients with chronic inflammatory disease, malignancy, or infection, the increase usually is not as marked as the increase in ferritin.

Ferritin

Ferritin is a high-molecular-weight glycoprotein that is stable and is not affected by recent ingestion of iron. It appears to reflect iron stores accurately and quantitatively in the absence of inflammation, particularly in the lower range associated with iron deficiency, which is so important in pregnancy. In the development of iron deficiency, a low serum ferritin level is the first abnormal laboratory test result.

Transferrin Receptor

Serum transferrin receptor (TfR) is a relatively new method for assessing cellular iron status.[26] It is present in all cells as a transmembrane protein that binds transferrin-bound iron and transports it to the cell interior. A reduction in the iron supply increases TfR synthesis. Sensitive immunologic techniques show that TfR, like ferritin, circulates in small amounts in the plasma of all individuals, and the concentration is proportional to the total body mass of TfR. In patients with iron deficiency anemia, the plasma receptor is elevated threefold. This elevation is accompanied by an increase in the density of surface TfR in iron-deficient cells. Little or no change in the serum TfR concentration occurs during the early stages of storage iron depletion, but as soon as tissue iron deficiency is established, the serum TfR concentration increases in direct proportion to the degree of iron deficiency. This change, which precedes the reduction in MCV and the increase in zinc protoporphyrin, is a valuable measurement of early tissue iron deficiency. This measurement is particularly helpful in identifying iron deficiency in pregnancy.[27] It differentiates truly iron-deficient women from those who have a low serum ferritin level as a result of storage iron mobilization or those who have a low hemoglobin concentration as a result of hemodilution. It also helps to distinguish those with a normal or high serum ferritin level as a result of chronic inflammatory disease from those who have low stores that lead to genuine cellular iron deficiency. TfR accurately reflects tissue iron deficiency, both in pregnancy and in anemia of chronic disease, in which serum ferritin may be inappropriately elevated because of release from cells. In combination with serum ferritin, TfR gives a complete picture of iron status. Serum ferritin reflects iron stores (in the absence of chronic inflammatory disease), and TfR reflects tissue iron status.[26]

Marrow Iron

The most rapid and reliable method of assessing iron stores in pregnancy is by examination of an appropriately stained preparation of a bone marrow sample. Without iron supplementation, there is no detectable, stainable iron in more than 80% of women at term.[28] No stainable iron (hemosiderin) may be visible once serum ferritin has decreased to less than 40 mg/L,[29,30] but other signs of iron deficiency in developing erythroblasts, particularly late normoblasts, confirm that anemia is caused by iron deficiency in the absence of stainable iron. The effects of folate deficiency, which often accompanies iron deficiency, are also apparent (discussed later). Iron incorporation into hemoglobin *is blocked* if there is acute or chronic inflammation, particularly if it is caused by urinary tract infection, even if iron stores are replete. This problem is shown by examination of the marrow aspirate stained for iron and can be predicted by simultaneous assessment of serum ferritin and TfR and an indicator of chronic inflammatory disease, such as C-reactive protein.

With the development of noninvasive tests of iron status (described earlier), bone marrow examination is reserved for the differential diagnosis of severe anemia during pregnancy when the cause cannot be determined by any other means and for the investigation of other hematologic abnormalities that arise de novo during the index pregnancy.

Management Options

Prenatal

PROPHYLACTIC IRON SUPPLEMENTATION

Iron supplementation is used to prophylactically treat women with low iron stores or those at risk for low iron levels in pregnancy. Women with iron deficiency anemia are a different group and they require treatment doses of iron (discussed later).

Iron supplementation in pregnancy is controversial. Despite increased iron absorption from the gastrointestinal tract,[31] physiologic iron requirements in pregnancy often are not met by diet alone. In addition, many women enter pregnancy with depleted iron stores. The goal of prophylactic iron administration is to maintain maternal iron stores during the time of increased physiologic iron demand; it may also prevent anemia in infancy.[15] Studies found no improvement in maternal hemoglobin levels with iron prophylaxis, and it does not appear to benefit fetal growth or pregnancy outcome.[32] According to the

Cochrane library database, routine supplementation with iron or iron and folate had no detectable effect on substantive measures of fetal or maternal outcome.[33,34]

Other studies suggested that iron supplementation improves maternal iron status and increases neonatal iron reserves, preventing iron deficiency in the first year of life.[35] In pregnant women who did not receive supplementation, iron deficiency persisted many months after delivery.[36,37] Iron supplementation may prevent reduced or absent iron stores after pregnancy and reduce the risk of iron deficiency in subsequent pregnancies.[38]

Iron supplementation has few adverse effects. The dosage is generally low enough to avoid the gastrointestinal side effects seen with treatment doses. Iron supplements may interfere with the absorption of other trace elements, such as zinc.[39] Zinc depletion may be associated with fetal growth restriction.[40] A study of the effects of oral iron supplementation on zinc and magnesium levels during pregnancy concluded that decreases in the concentration of these elements were physiologic and unaffected by iron supplementation.[41]

High maternal hemoglobin concentrations are associated with poor pregnancy outcome.[42,43] This has led to concerns about iron prophylaxis. However, iron supplementation in iron-replete women does not increase hemoglobin level.[44] In iron-replete pregnancies, the hemoglobin concentration is largely dependent on the increase in plasma volume. Ineffective plasma volume expansion increases the rate of poor pregnancy outcome.

The other concern about iron prophylaxis is that excess iron can result in the production of free radicals and oxidative damage and may be implicated in cardiovascular disease and cancer.[45,46] Concerns about iron overloading in women with hemochromatosis have been raised. Approximately 12% of western white women are heterozygous for the common mutation of the hemochromatosis gene, and 0.5% are homozygous. A recent study of hemochromatosis and iron stores in pregnancy suggested that heterozygosity for the hemochromatosis mutation did not affect iron storage levels in reproductive-age women. One woman in the study who had markedly reduced iron stores was homozygous for the gene.[47]

Iron supplementation can be given on a selective or routine basis. Selective administration is appropriate for women with low or depleted iron stores, usually based on ferritin levels in early pregnancy. Ferritin cutoff levels for action vary between publications. A serum ferritin level less than 50 μg/L in early pregnancy is an indication for iron supplements. Some groups further stratify the starting time of these supplements, depending on ferritin levels.[48]

This approach avoids unnecessary supplementation in women with adequate iron stores. It identifies those who are at risk for iron depletion and anemia and targets these women with prophylactic or treatment doses of iron. The need for routine iron supplementation is debatable in western countries, but supplementation is recommended

in nonindustrialized countries.[49,50] Various official bodies made recommendations for routine iron supplementation. The World Health Organization recommends universal oral iron supplementation with 60 mg elemental iron daily for 6 months in pregnancy in areas where the prevalence of iron deficiency is less than 40%. In areas where the prevalence is greater than 40%, the recommendation is to continue supplementation for 3 months postpartum.[51] The Centers for Disease Control and Prevention recommends supplementation with 30 mg elemental iron daily, as does the American College of Obstetricians and Gynecologists.[52,53] Some consider universal supplementation a practical and cost-effective approach.[32,54] The debate is ongoing, and the decision to choose universal or selective prophylaxis depends on the prevalence of iron deficiency in the obstetric population served, along with nutritional, economic, and social factors.

Prevention of iron deficiency also requires education about diet. Dietary iron has two forms, heme and non-heme iron. Heme iron is the most bioavailable form of iron in the diet and comes from food containing heme molecules, essentially animal meat, viscera, and blood. Non-heme iron is obtained from cereals, vegetables, milk, and eggs. Absorption of non-heme iron is enhanced by ascorbic acid, proteins, and heme, and inhibited by phytates, tea, coffee, and calcium. Many countries now fortify food products with iron compounds.[55] In nonindustrialized countries, other actions to prevent iron deficiency include iron prophylaxis in nonpregnant women[51] and treatment of hookworm infestation.[56]

Prophylaxis of iron deficiency is generally provided with oral iron. Various iron salts are available in tablet or syrup form (ferrous fumarate, gluconate, sulfate, and succinate). The elemental iron content of the different salts varies slightly. Compound preparations with folic acid are available, as are modified-release preparations, which release iron into the gastrointestinal tract slowly. However, these preparations may carry iron past the first part of the duodenum, where absorption is optimal, to areas of the gut where iron absorption is poor.

The frequency of oral dosing with iron supplementation has been questioned. Intermittent weekly or twice-weekly dosing schedules are as effective as daily dosing schedules.[57–59] In nonindustrialized countries, intermittent intramuscular iron dextran injections are used to ensure compliance and maintenance of adequate iron stores.[60] Compliance is a major problem with iron supplementation and may be as low as 36%.[61] In oral intermittent iron supplementation, compliance may be an even larger issue than with daily dosing schedules.[62] Iron-rich natural mineral water may be an acceptable alternative to oral iron prophylaxis. For example, Spatone Iron-Plus contains ferrous sulfate 0.20 mg/mL, which is highly bioavailable and maintains ferritin levels more effectively than placebo.[63]

MANAGEMENT OF IRON DEFICIENCY

Iron deficiency anemia is usually treated with oral iron preparations. The oral dose of elemental iron required to treat iron deficiency is 100 to 200 mg daily. Ferrous sulfate 200 mg three times daily is equivalent to 195 mg elemental iron daily. Many iron preparations are available, and no scientific evidence suggests that one brand is superior. Treatment doses of iron should continue until hemoglobin normalizes and should be followed with prophylactic or maintenance doses until 3 months postpartum to ensure that iron stores are replenished. Side effects with oral iron are common. Iron salts cause gastrointestinal irritation, with dose-related nausea and epigastric discomfort. Altered bowel habits (constipation or diarrhea) and abdominal cramping are common and have a less clear dose relationship. If side effects occur, reducing the dose or taking the tablets before meals (absorption can be reduced up to 50% if the dose is taken with meals) may help. Alternative iron salts can be tried, but tolerance is often related to reducing the dose of elemental iron. The addition of laxatives should overcome problems with constipation. The response to treatment doses of elemental iron is rapid. Reticulocyte counts increase within 5 to 10 days of initiation, and hemoglobin should rise 0.8 g/dL/wk (1.0 g/dL/wk in nonpregnant women). If no clinical or hematologic response is seen after 3 to 4 weeks of oral iron therapy, diagnostic reevaluation is required. Patients who do not respond to oral iron should be evaluated for ongoing blood loss, concomitant infection, additional hematinic deficiency, noncompliance, and other causes of anemia.

Parenteral iron therapy can be administered intravenously as an infusion or injection and also intramuscularly. It has no advantage over oral therapy if oral iron is well tolerated and absorbed. The response rate to parenteral iron is similar to that with oral preparations.[64] The advantage of parenteral therapy over oral therapy is the certainty of its administration.[65] Parenteral iron is given when oral iron therapy is unsuccessful because of patient intolerance, noncompliance, or malabsorption. Parenteral forms of iron include iron dextran and iron sucrose. Iron dextran is a complex of ferric hydroxide that contains 50 mg/mL iron and can be given intravenously. Dosage is calculated according to body weight and iron deficit. A small test dose is given, and the patient is observed for 1 hour for evidence of anaphylaxis. If the test dose is tolerated, the total dose can be administered in a 0.9% sodium chloride infusion over several hours. The product is licensed in the United Kingdom in the second and third trimesters but contraindicated in patients with a history of allergy. Anaphylactic reactions have been reported, and facilities for cardiopulmonary resuscitation must be available when these drugs are administered. Patients require close monitoring during and after administration, and treatment should be given in a hospital setting.

Iron dextran is now also available by deep intramuscular injections. Total dosage is calculated according to body weight and iron deficit. It is administered as a series of undiluted injections of up to 100 mg iron each. As with the intravenous preparation, anaphylactic emergency treatment should be available.

Preparations of iron sucrose complex contain 20 mg/mL iron and used in pregnancy as 5- to 10-mL aliquots up to three times per week in the second and third trimesters.[67]

Blood transfusions are rarely indicated in pregnant women with iron deficiency anemia. With vigilant antenatal care and appropriate iron prophylaxis and treatment, severe anemia should not be detected late in pregnancy. If a woman has severe anemia beyond 36 weeks' gestation and there is not time to achieve a reasonable hemoglobin concentration before delivery, blood transfusion is considered.

Recombinant human erythropoietin has also been used in difficult cases. Most experience has been with Jehovah's Witnesses.

Treatment of iron deficiency anemia in pregnancy was the subject of a recent Cochrane review.[68] Of 54 identified studies, only 5 met the inclusion criteria. Most studies evaluated laboratory outcome data rather than clinical outcome and did not address the question of whether treatment of iron deficiency anemia alters maternal or neonatal outcome. The review concluded that it was not possible to give evidence-based guidelines for the treatment of iron deficiency anemia in pregnancy.

Labor and Delivery

There are no specific recommendations for the management of iron-deficient patients during labor. Cross-matching should be carried out for women who are anemic on admission for labor. Blood transfusion may be necessary if significant blood loss occurs because these women have little reserve to tolerate bleeding.

Postnatal

As the physiologic effects of pregnancy diminish, hemoglobin levels rise during the puerperium. Patients who have clear evidence of iron deficiency anemia should continue oral supplementation for at least 3 months.

ANEMIA: FOLATE DEFICIENCY

Folic acid, together with iron, has assumed a central role in the nutrition of pregnancy. At a cellular level, folic acid is reduced first to dihydrofolate and then to tetrahydrofolate, which is fundamental to cell growth and division, through linkage with L-carbon fragments. The more active a tissue is in reproduction and growth, the more dependent it is on the efficient turnover and supply of folate coenzymes.

Maternal Risks

Megaloblastic anemia in pregnancy is nearly always secondary to folate deficiency. Plasma folate levels decrease as pregnancy advances, reaching approximately half of nonpregnant values at term.[24] Explanations for the reduction in folate levels include reduced dietary folate intake because of loss of appetite,[69] increased plasma clearance of folate by the kidneys (believed to play a minor role),[70, 71] transfer of folate from the mother to the fetus (approximately 800 µg at term), and uterine hypertrophy and expanded red cell mass. As pregnancy proceeds, increased folate catabolites are excreted in maternal urine.[72]

Worldwide, folic acid deficiency may complicate one third of pregnancies. The incidence is higher in multiple pregnancies and closely spaced successive gestations.[73] Folate is readily available in most diets. Good sources include broccoli, Brussel sprouts, and spinach. Folate is often lost in the cooking process. It is heat-labile and rapidly destroyed by boiling or steaming.

Body stores of folate are found predominantly in the liver and total approximately 10 mg. When body reserves of folate are low, stores last approximately 4 to 5 months before symptomatic anemia develops. A survey of reports from the United Kingdom suggests that the incidence of folate deficiency is 0.2% to 5.0%, but more women have megaloblastic changes in their bone marrow that are not suspected based on examination of peripheral blood alone.[74] The incidence of megaloblastic anemia in other parts of the world is considerably greater and is believed to reflect the nutritional standards of the population. There is controversy about the requirement for folate, particularly during pregnancy. In the past, the World Health Organization recommended daily folate intake of up to 800 µg in the prenatal period and 600 µg during lactation.[75] Current recommendations advise folic acid intake of 400 µg daily with 60 mg iron for 6 months during pregnancy and continuing for 3 months postpartum in areas of the world with poor nutrition.[51]

The maternal risk of folate deficiency appears to be megaloblastic anemia. This condition usually has an insidious onset, with gradually progressive symptoms and signs of anemia. It can be abolished with routine use of folic acid supplements during pregnancy.[76]

Fetal Risks

The risk of megaloblastic anemia is increased in the neonate of a folate-deficient mother, especially if delivery is preterm. Data also suggest an association between periconceptional folic acid deficiency and harelip, cleft palate, and most important, neural tube defects.[77,78] This subject was well reviewed in the past,[79] and the association between periconceptional folate deficiency and the recurrence of neural tube defects was confirmed in a multicenter controlled trial of prepregnancy folate supplementation.[80] Periconceptional folic acid reduces the recurrence of neural tube defects.[81]

A large randomized controlled trial in Hungary showed that periconceptional supplementation with 800 µg folic acid in a combined vitamin preparation prevented the first occurrence of neural tube defects.[82]

It is not known how folate supplements reduce the incidence of neural tube defects. Women who have children with this disorder do not appear to differ hematologically from those who have children who are unaffected. Terathanasia (selective spontaneous abortion of fetuses with birth defects) may explain the protective effect of folic acid supplements,[83] but many authorities dispute this.

Diagnosis

Outside of pregnancy, the hallmark of megaloblastic hemopoiesis is macrocytosis. This can be more difficult to interpret in pregnancy when there is a physiologic increase in red cell size and the possibility of a masking iron deficiency anemia. Examination of the blood film with oval macrocytes and hypersegmented neutrophil nuclei can provide useful diagnostic clues. The reticulocyte count is also low in relation to the hemoglobin. To diagnose folate deficiency, red cell folate assay is performed. Plasma folate levels fluctuate substantially from day to day, and postprandial increases are noted, limiting the use of serum folate as a diagnostic test. Red cell folate is believed to give a better indication of overall body tissue levels. However, the turnover of red blood cells is slow, and there is a delay before significant reductions in the folate concentration of red cells is evident. Patients who have a low red cell folate concentration at the beginning of pregnancy have megaloblastic anemia in the third trimester.[24] Folate deficiency in pregnancy is not always accompanied by significant hematologic changes. In the absence of changes, megaloblastic hemopoiesis is suspected when the expected response to adequate iron therapy is not achieved. Ultimately, the diagnosis of folate deficiency may depend on bone marrow examination and the finding of large erythroblasts and giant, abnormally shaped metamyelocytes. This test is usually reserved for patients with pancytopenia rather than isolated anemia.

Management Options

Prepregnancy

As with other anemias, a careful diagnostic evaluation should be undertaken, followed by prompt therapy before conception. The risks (described in earlier and later sections) should be discussed before pregnancy, and dietary advice about folate-rich foods should be given. Women who are contemplating pregnancy should be advised to take folate supplements 400 µg

daily.[84,85] Targeted fortification of food is under consideration in the United Kingdom and United States. The plan includes adding folate to basic foods in an effort to ensure that women of reproductive age have adequate dietary folate to prevent neural tube defects.[86]

Prenatal

PROPHYLAXIS

The case for giving prophylactic folate supplementation throughout pregnancy is strong,[87,88] particularly in countries where nutritional and megaloblastic anemia is common. Folate should be given in combination with iron supplements. The folic acid content must be approximately 200 to 300 µg daily. The concern about routine folate supplementation is the risk to a woman with undiagnosed vitamin B_{12} deficiency. Folate treatment can worsen neuropathy in patients with vitamin B_{12} deficiency. The risk is low in pregnancy, and patients with severe vitamin B_{12} deficiency are usually infertile. Pernicious anemia is generally a disease of older people. Not one case of subacute combined degeneration of the spinal cord was reported among the thousands of women receiving folate supplements during pregnancy.[24]

MANAGEMENT OF ESTABLISHED FOLATE DEFICIENCY

Severe megaloblastic anemia is uncommon in the United Kingdom and the United States, largely as a result of prophylaxis and prompt treatment. Once megaloblastic hematopoiesis is established, treatment of folic acid deficiency is more difficult, presumably as a result of megaloblastic changes in the gastrointestinal tract that impair absorption. If the diagnosis is made prenatally, initial treatment is with folic acid 5 mg once daily continued for several weeks postpartum.

ANTICONVULSANTS AND FOLIC ACID

Outside of pregnancy, folate deficiency can develop in patients who take anticonvulsants. Folate status is further compromised in pregnancy.[87] Interference with epilepsy control by folate supplementation may be overestimated.[89] Anticonvulsant therapy is associated with an increased incidence of congenital abnormalities,[90] prematurity, and low birth weight.[91] Hence, folate supplements should be given to all pregnant epileptic women who take anticonvulsants.

DISORDERS THAT MAY AFFECT FOLATE REQUIREMENTS

Women with hemolytic anemia, particularly hereditary hemolytic conditions, such as hemoglobinopathy and red cell membrane and enzyme disorders, require extra folate supplements from early pregnancy onward, if megaloblastic anemia is to be avoided. The recommended supplementation is 5 to 10 mg orally daily. Anemia as a result of thalassemia trait is not strictly caused by hemolysis, but by ineffective erythropoiesis. However, the increased abortive marrow turnover results in folate depletion, and these women would probably benefit from routine administration of folic acid, 5.0 mg orally daily, from early pregnancy onward.

Labor and Delivery

There are no specific management recommendations for folate-associated anemia during labor and delivery, as long as the patient is hemodynamically stable and blood replacement therapy is available, if needed.

Postnatal

In the 6 weeks after delivery, indices of folate metabolism return to nonpregnant values. However, if folate deficiency develops and remains untreated in pregnancy, it may be seen clinically for the first time in the puerperium. Lactation provides an added folate stress. A folate content of 5 µg/100 mL human milk and a yield of 500 mL daily implies a loss of 25 µg folate daily in breast milk. Red cell folate levels in lactating women are significantly lower than those in infants during the first year of life.

SUMMARY OF MANAGEMENT OPTIONS
Iron and Folate Deficiency Anemia

ANEMIA: VITAMIN B$_{12}$ DEFICIENCY

Muscle, red cell, and serum vitamin B$_{12}$ concentrations decrease during pregnancy.[92,93] Women who smoke tend to have lower serum vitamin B$_{12}$ levels, which may account for the positive correlation between birth weight and serum levels in women without deficiency.

Maternal and Fetal Risks

Vitamin B$_{12}$ absorption is unaltered in pregnancy,[94] but tissue uptake is increased under the influence of estrogens. Oral contraceptives also cause a decrease in serum vitamin B$_{12}$ levels. This decrease in pregnancy is related to preferential transfer of absorbed vitamin B$_{12}$ to the fetus at the expense of maintaining maternal serum concentration. The vitamin B$_{12}$-binding capacity of plasma increases in pregnancy because of the increased levels of transcobalamin II, which is derived from the liver and affects vitamin B$_{12}$ transport. Cord blood serum vitamin B$_{12}$ levels are higher than maternal vitamin B$_{12}$ levels. Pregnancy does not greatly affect maternal vitamin B$_{12}$ stores. Adult stores are 3000 μg or more, and stores in newborns are approximately 50 μg. Minimal amounts of vitamin B$_{12}$ are required for fetal development, which may account for the few fetal problems seen in pregnancies complicated by vitamin B$_{12}$ deficiency. A deficiency syndrome is described in breast-fed neonates of mothers with significant vitamin B$_{12}$ deficiency. It is usually apparent by 6 months of age and is characterized by failure to thrive, developmental regression, and

anemia.[95] Addisonian pernicious anemia is unusual during the reproductive years and is usually associated with infertility. Pregnancy is likely only if the deficiency is corrected.

Dietary deficiency of vitamin B_{12} is possible in strict vegans who consume no animal products. Other disorders associated with vitamin B_{12} deficiency include tropical and nontropical sprue, Crohn's disease, and surgical resection of the distal ileum.

Management Options

Prepregnancy

Women with vitamin B_{12} deficiency should have their therapy optimized and their anemia corrected before they become pregnant. This approach may be needed to restore fertility.

Prenatal

The recommended intake of vitamin B_{12} is 2.0 μg daily in the nonpregnant patient and 3.0 μg daily during pregnancy.[96] This intake is met by almost any diet that contains animal products. Strict vegans, who do not eat any animal-derived substances, may have a deficient intake of vitamin B_{12}, and this type of diet should be supplemented in pregnancy.

Difficulties can arise when interpreting vitamin B_{12} levels measured in pregnancy because many women have lower values than those quoted as the normal range outside of pregnancy.[97] This decline in vitamin B_{12} levels is not believed to represent a true deficiency. There is a minimal increase in vitamin B_{12} requirements in pregnancy, and this is unlikely to cause a significant decrease in vitamin B_{12} levels. Interestingly, supplementation in pregnancy does not prevent the progressive decrease in vitamin B_{12} levels.[98] These levels return to normal in the puerperium. Care must be taken in the interpretation of vitamin B_{12} levels in pregnancy. If deficiency is suspected, the etiology should be considered. A Schilling test is contraindicated because of the risks of radiation exposure. Intrinsic factor antibodies may be useful if the results are positive. Therapy is instituted empirically if there is clinical concern, especially if neurologic findings are consistent with vitamin B_{12} deficiency. The earliest symptoms are numbness and paraesthesia of the fingers and toes, followed by weakness, ataxia, and poor concentration. Patients may have changes in mental status that range from forgetfulness to dementia and possible psychosis.

Treatment of vitamin B_{12} deficiency is generally parenteral because patients usually have absorptive problems. Cyanocobalamin or hydroxycobalamin 1 mg is given three times a week for 2 weeks, and then every 3 months. In patients who have neurologic involvement, the dosage is higher. These patients are given 1 mg on alternate days until no further improvement is noted, and then 1 mg every 2 months. Oral vitamin B_{12} can be used in patients with dietary deficiency.

Labor, Delivery, and Postnatal

There are no specific measures for patients with genuine vitamin B_{12} deficiency, apart from continuing maintenance therapy.

Labor and Delivery			
Continue treatment if already instituted	–	GPP	–
Postnatal			
Continue treatment if already instituted; if the patient is not receiving treatment, check vitamin B_{12} levels postpartum	–	GPP	–

HEMOGLOBINOPATHIES

Hemoglobinopathies are inherited disorders of hemoglobin. Hemoglobin is composed of heme (a combination of iron and porphyrin) and four globin chains. The type of globin chain determines many of the characteristics of the hemoglobin. Several types of globin chains are present at different times in embryonic development, in fetal life, and through to adulthood (Fig. 39–1 and Table 39–1). Abnormalities of the quantity or quality of the globin chains produced result in conditions known as hemoglobinopathies.

Hemoglobinopathies can be divided into two subgroups:

- Sickling disorders, which are qualitative abnormalities. An amino acid substitution in an α-globin or a β-globin chain results in the synthesis of an abnormal hemoglobin. Many types of hemoglobin can sickle.
- Thalassemia syndromes are usually quantitative problems of globin chain synthesis. They result in impaired production and imbalance of globin chains. α-Thalassemia is caused by reduced α-chain production, and β-thalassemia is caused by reduced or abnormal β-chain production.

Women with major sickling and thalassemic conditions require specialized multidisciplinary team management preconception and throughout pregnancy. Timely screening programs must be in place to identify women and their partners who are carriers of these conditions and couples who are at risk for having an infant affected with a major hemoglobinopathy. The chance of being a carrier is dependent on ancestry. Tables are available that show the prevalence of traits in different countries and ethnic groups.[99]

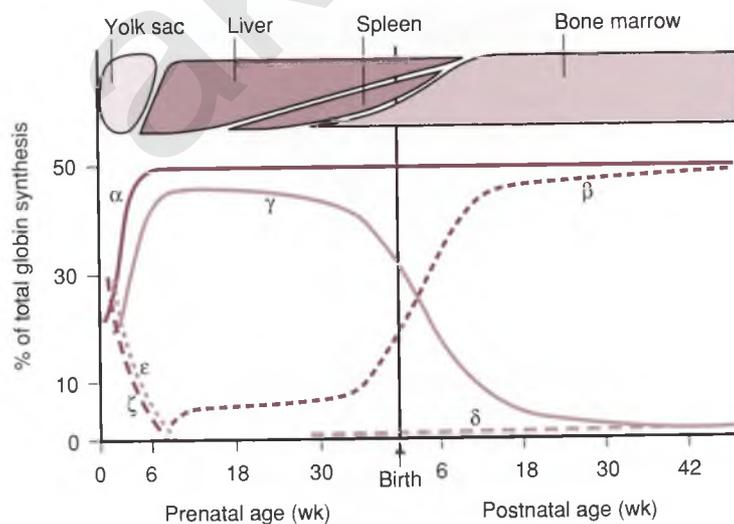
It is useful to be aware of the changes in complete blood count that are caused by these traits and the effects of superimposed conditions, including the physiologic changes of pregnancy.


TABLE 39–1			
Composition of Adult Hemoglobin			
FEATURE	**HEMOGLOBIN A**	**HEMOGLOBIN F**	**HEMOGLOBIN A$_2$**

Sickle Cell Syndromes

More than 300 abnormal (variant) hemoglobins are recognized. These qualitative defects are often caused by a single amino acid substitution in the globin chain. Sickle cell disease caused by homozygosity of hemoglobin S (i.e., HbSS) is the most common sickling disorder. It is caused by a point mutation in the β-globin gene on chromosome 11 that produces an amino acid change at position 6, changing valine to glutamic acid. This enhances the polymerization of hemoglobin S in the deoxygenated state and causes increased red cell rigidity and sickling. Increased blood viscosity and tissue hypoxia occur as sickled cells occlude the microcirculation. Clinical consequences of sickling include the following:

- Vaso-occlusive crises (micro- and macro-infarcts, leading to a painful crisis and organ damage)
- Anemic crises as a result of severe hemolysis, red cell aplasia, or splenic sequestration
- Chest and girdle syndrome
- Neurologic events

Maternal and Fetal Risks

Sickling occurs in the homozygous condition (HbSS) or in compound heterozygous states (e.g., HbSC or HbS β-thalassemia, HbSD-Punjab, HbSE, HbSLepore,

FIGURE 39–1
Production of different globin chains (From Hoffbrand AV, Pettit J: Essential Haematology, 3rd ed. Oxford, 1993, Blackwell, p 95.)

HbSO-Arab). Hemoglobin C, D-Punjab, E, and O-Arab are variant hemoglobins with mutations in the B globin gene. Hemoglobin Lepore is a variant hemoglobin that behaves like β-thalassemia.

The heterozygous state, or sickle cell trait (HbAS), is essentially a benign condition that is believed to have no particular antenatal sequelae. However, women with sickle cell trait are slightly more prone to renal papillary necrosis and urinary tract infection.[100] Their hemoglobin levels are similar to those of other pregnant women and should be managed similarly. Their sickle cell trait should be noted on their records, and the anesthesiologist should be informed of this condition if a general anesthetic is required. A recent study showed an increased incidence of preeclampsia in women with sickle cell trait.[101] Women with sickle cell trait should be identified by antenatal hemoglobinopathy screening. The goal of screening is to detect pregnancies in which there is a risk of a major hemoglobinopathy. Partners must be tested as well. If the partner of a woman with sickle cell trait also carries the trait, there is a 1 in 4 chance that the offspring will be affected by homozygous sickle cell disease. These couples require counseling and the opportunity for antenatal diagnosis. Termination is an option if a fetus is diagnosed as having a major hemoglobinopathy. This should be fully discussed with parents prior to prenatal diagnosis.

Pediatricians must be alerted to the possibility of sickle cell disease in neonates because antipneumococcal vaccines can now be given from 2 months of age and infants with sickle cell disease require long-term prophylactic penicillin treatment and regular evaluation.

People with major sickling disorders start life relatively protected from crises for 3 to 6 months because of the ongoing production of fetal hemoglobin. When hemoglobin A production becomes predominant, chronic hemolytic anemia develops. The severity and complications of the disease vary widely between patients. Many have debilitating chronic disease and frequent crises that require hospital admission. Others appear to be free of complications but have progressive organ damage. The life expectancy of these patients is still 25 to 30 years less than that of the general population, even in the developed world, with access to medical care.[102]

There are increased risks involved in pregnancy for the mother with sickle cell disease and her fetus.[103] These risks are not so great as to prohibit pregnancy. The importance of good prenatal care, with a multidisciplinary team, must be emphasized.

Maternal risks include exacerbated sickle cell disease phenomena,[104] such as anemia, vaso-occlusion, ischemic injury, and organ damage as a result of the physiologic stress of pregnancy. These patients have greater susceptibility to infection (chest and urinary tract), hypertensive disorders of pregnancy, and thromboembolic complications.

Risks to the fetus include increased frequency of miscarriage, intrauterine growth retardation, preterm labor, and premature delivery.[105,106] Perinatal morbidity and mortality rates vary widely in different regions of the world[107–109] but are higher than in the general poulation.

Diagnosis and Management Options

PREPREGNANCY

Before an affected woman becomes pregnant, a number of issues should be addressed.

Sickle Cell Disease. The frequency and management of crises outside of pregnancy is a useful starting point and may indicate the likelihood of crises throughout pregnancy. The patient's transfusion history and red cell antibody values should be documented. Discussion of hydroxyurea is important. Hydroxyurea is a disease-modifying drug that increases hemoglobin F, improves red cell hydration, and decreases the rate of polymerization of hemoglobin S. Its use decreases the frequency of crises.[110] However, it should be discontinued in women who are planning to conceive because it is teratogenic in animal models. Although there is little information about its effect on the human fetus, there are case reports in which hydroxyurea was taken throughout pregnancy with no reported adverse fetal effects.[111,112]

Contraception. Discussion of contraception and pregnancy planning is useful in women who have a chronic debilitating disease. They should be reassured about contraceptive choices. None are excluded on the grounds of sickle cell disease. The risks of pregnancy outweigh those of contraception.

Maternal and Fetal Complications. The patient's obstetric history is important, including a discussion of maternal and fetal risks associated with sickle cell disease. Strategies to reduce these risks require discussion, as does the part the women plays in reducing risk. Patients should be told that active prenatal management significantly affects pregnancy outcome, and the importance of attending visits should be emphasized.

Multidisciplinary Team Approach. The community sickle cell service and midwifery team, along with hospital obstetric, hematology, anesthetic, and pediatric teams, play an important role in the care of the pregnant woman and fetus.

Partner's Hemoglobinopathy Status. It is important to establish the partner's hemoglobinopathy status, ideally, before pregnancy. This information facilitates appropriate, timely, and nondirective counseling about antenatal diagnosis.

PRENATAL

These women should be seen early in pregnancy. Ideally, they should be seen by an obstetrician with experience in this area and also by the hematology team. Partner screening should be carried out if it has not been done. A discussion about prenatal diagnosis should take place, if appropriate, and time should be taken to review the

patient's obstetric history and history of sickle cell disease, including a drug history and the typical management of crises.

Laboratory evaluation should include a complete blood count, hemoglobin electrophoresis (if not previously done or available), reticulocyte count, ferritin level, folate level, urea and electrolyte levels, liver function tests, blood typing, and red cell antibody screen. The red cell antibody screen serves two purposes: to identify women whose fetuses and newborns may be at risk for hemolysis because of red cell antibodies and to ensure screening for the most common minor red cell antigens so that phenotypically matched blood will be available for transfusion. This is especially important because the donor population differs in ethnic origin, carries different minor cell antigens, and may sensitize this group of patients. As a result, it may be difficult to obtain suitable blood for transfusion. Blood tests should be performed to determine hepatitis A, B, and C, HIV, and rubella antibody status. Urine dipstick and culture allow identification and treatment of women with asymptomatic bacteruria. This group is more susceptible to urinary tract infections.

People with homozygous sickle cell disease may have a hemoglobin concentration of 5 to 12 g/dL, but concentrations are typically 6 to 10 g/dL. Hemoglobin S has a lower affinity for oxygen, and symptoms of anemia are decreased by the increased delivery of oxygen to the tissues. The reticulocyte count is elevated in patients with sickle cell disease, reflecting increased red cell turnover. The bilirubin level also indicates the rate of hemolysis. Other abnormal liver function test results may indicate chololithiasis or acute cholecystitis as a result of chronic hemolysis or chronic hepatitis.

Pregnancy outcome appears to be similar in women who undergo prophylactic transfusion compared with those who undergo selective transfusion for clinical reasons.[113] No improvement in obstetric outcome was seen in a retrospective multicenter study in the United Kingdom.[114]

There is debate about the use of blood transfusions throughout pregnancy. Prophylactic versus selective blood transfusions was the subject of a recent Cochrane review.[115] This review found that there was not enough evidence to reach conclusions about the use of prophylactic blood transfusions. The development of atypical red cell antibodies is a real concern.[116] Transfusion is generally given before anesthesia or as an exchange procedure in severe crises, but no data suggest that transfusions should be given prophylactically.

Red cell indices in patients with sickle cell disease alone should be normal, but low MCV and MCH may indicate iron deficiency or an associated thalassemia trait. The blood film shows variable numbers of sickle cells and features of hyposplenism (Howell-Jolly bodies, target cells, and increased platelet and white cell counts). Hemoglobin electrophoresis and high-performance liquid chromatography can separate out the various hemoglobins and allow detection and characterization of variant hemoglobins. In homozygous sickle cell disease, hemoglobins S, F, and A_2 are seen. Hemoglobin S is usually the predominant hemoglobin, making up 90% to 95% of total hemoglobin. Hemoglobin A is absent. In compound heterozygous states, other hemoglobins are found, except in hemoglobin S β-thalassemia, in which hemoglobin S level is lower than that in homozygotes.

A sickle solubility test is a quick screening test for sickling hemoglobin, but it does not elucidate the type or quantity of sickling hemoglobin. In other words, it does not distinguish between a person with homozygous sickle cell disease and a person with sickle cell trait.

The antenatal care plan should be outlined, with a discussion of the risks for both mother and fetus and strategies to reduce these risks. The patient should be advised to avoid precipitating factors that may cause sickle crises, including education about the signs and symptoms of infection and appropriate analgesics.

Return visits are recommended every 2 to 3 weeks to allow early detection of maternal or fetal complications. The purpose of these visits is to monitor the course of the pregnancy, with regular monitoring of blood pressure and urine and assessment of fetal growth and development at appropriate intervals. Patients with sickle cell disease also should be asked about pain and crises and should undergo laboratory assessment, including complete blood counts, reticulocyte counts, and bilirubin measurements.

COMPLICATIONS OF SICKLE CELL DISEASE

Vaso-occlusive or Painful Crisis.[117,118] Crises occur when rigid sickle cells obstruct blood vessels in the microvasculature. This obstruction leads to tissue hypoxia, infarction, and pain. It is the most common type of crisis and the reason for most hospital admissions. Factors that may precipitate or exacerbate a crisis include cold, infection, dehydration, exercise, and stress. The pain is usually bony, although it may occur in the chest or abdomen. Systemic markers include low-grade fever, tachycardia, and mild leukocytosis.

As a result of sickling in the splenic circulation, most patients become hyposplenic at a young age, increasing their susceptibility to encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. This increased susceptibility is the rationale for pneumococcal, *H. influenzae* B, and meningococcal vaccination and prophylactic penicillin administration.

Treatment and evaluation are as for nonpregnant women. Most pain occurs in the third trimester and the postpartum period. Underlying precipitants of pain, such as infection and toxemia, should be sought. The management hinges on good rehydration, with careful fluid balance and adequate analgesia. The pain normally requires opioid analgesia as an infusion or patient-controlled analgesia. Nonsteroidal anti-inflammatory drugs are a useful adjunct but should be avoided in the second half of pregnancy because of the risk of patent ductus arteriosus.

Oxygen supplementation and intravenous antibiotics covering encapsulated organisms may be required. If intravenous antibiotics are not required, penicillin prophylaxis should be ongoing. Folic acid supplementation (5 mg daily) also should be ongoing. The patient should be kept warm. All of the relevant teams must be involved, including obstetricians, hematologists, and obstetric anesthesiologists. In women who have frequent sickling crises and heavy narcotic use, fetal growth must be monitored carefully because of the risk of intrauterine growth retardation. Pediatricians must be made aware of the risk of opiate dependence in the newborn and the need for opiate tapering. Blood testing must be performed frequently. On admission, the patient should have a complete blood count, reticulocyte count, biochemistry testing, blood typing, blood cultures, arterial gases and/or pulse oximetry. Potential sites of infection require culturing (e.g., throat swab, midstream urine, sputum, blood). Hemoglobin requires regular monitoring. Transfusion is generally given if hemoglobin is less than 5 g/dL. Review is required at regular intervals to assess the response to pain relief and look for evidence of infection, girdle or chest syndrome, splenic or hepatic sequestration, and complications of pregnancy, such as preeclampsia.

Acute Anemia. When a precipitate decrease in hemoglobin occurs, the differential diagnosis includes blood loss, bone marrow suppression secondary to infection, hyperhemolysis, and sequestration. Careful examination and basic blood tests are useful in determining the cause. A reticulocyte count will determine whether the bone marrow is responding appropriately to the anemia. If the count is low or absent, parvovirus B19 infection should be considered. This infection causes red cell aplasia, and transfusion is required. It can also cause miscarriage or hydrops, so careful fetal monitoring is required.

Prompt transfusion in splenic sequestration can be lifesaving when the decrease in hemoglobin is precipitous and hazardous for the mother and fetus. Patients have acute abdominal pain, with rapid enlargement of the spleen. This situation is rare because most patients with homozygous sickle cell disease are hyposplenic. Approximately 5% have splenomegaly, but it is more common in compound heterozygote sickling states, such as HbSC and HbS β+ thalassemia.

Acute Chest Syndrome.[119] Acute chest syndrome is a form of acute lung injury that is distinct from pneumonia. It is believed to be caused by fat emboli from the bone marrow along with red cell sequestration. It does not resolve with antibiotics but may become secondarily infected. It usually causes clinical or radiologic evidence of consolidation, with elevated temperature, cough, and pleuritic chest pain. Hypoxemia, which may be severe, and leukocytosis are also features. Treatment is the same as for a crisis, as discussed earlier, with early recourse to top up or exchange transfusion, depending on the baseline hemoglobin. Oxygen saturation and blood gas values must be monitored carefully, and antibiotics and bron-

chodilators are useful. An intensive care setting is often the best place to monitor these patients.

Neurologic Events. Neurologic events are common in patients with sickle cell disease. Thrombotic cerebrovascular accidents and seizures are the main concern. The differential diagnosis (including metabolic disturbances, toxemia, subarachnoid or intracerebral hemorrhage, ischemic stroke, cerebral veneus thrombosis, meningitis, cerebral abscess, epilepsy, or tumor) must be considered, and studies may include neuroimaging, examination of the cerebrospinal fluid if fever is present, and assessment for toxemia. Sickle-related central nervous system events should be treated with exchange transfusion to reduce the sickle hemoglobin percentage to less than 30%. This value should be maintained by transfusions to keep hemoglobin levels between 10 and 11 g/dL.

LABOR AND DELIVERY

Close supervision is required during labor. The risk of sickle cell crisis in labor increases if the woman is dehydrated or has hypoxia, acidosis, or infection. Care should be taken to prevent these complications.

Labor is also a time of increased cardiac output, exacerbated by the pain of uterine contractions. Cardiac function may be reduced by chronic hypoxemia and long-standing anemia. Pain relief is important in reducing cardiac work, and epidural is particularly effective.[120] Prolonged labor should be avoided. The woman should be kept warm, well-hydrated, and oxygenated. Continuous intrapartum monitoring should take place. The timing and mode of delivery must be determined by obstetric factors.

Transfusion is considered if the hemoglobin is less than 8g/dL.[121]

Thromboprophylaxis is given to women who are immobilized or experiencing a sickle crisis at the time of delivery. Routine thromboprophylaxis for women with sickle cell disease is controversial. There are no randomized controlled trials, and efficacy has not been conclusively shown.

Patients who have cesarean delivery should have chest physiotherapy, and early mobilization is encouraged.

Cord blood can be sent to the laboratory for hemoglobinopathy screening. Those who interpret the results must be aware of the possibility of maternal contamination. Universal neonatal screening for sickle cell disorders has recently been introduced in England as part of the newborn blood spot test.

POSTPARTUM

The heightened risks of sickle crisis persist after delivery, and vigilance must be maintained. Adequate oxygenation and hydration must be ensured, and findings must be monitored closely for the first 24 hours. Patients must be monitored for infection and crises, and thromboprophylaxis may be considered, depending on

the degree of mobility and individual risk assessment. Contraception can be discussed at this time (discussed earlier).

The results of neonatal screening and follow-up arrangements with the pediatrician should be confirmed before discharge.

SUMMARY OF MANAGEMENT OPTIONS
Sickle Cell Syndromes

Management Option	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Counsel against conception until disease status is optimized; assess renal and liver function	–	GPP	–
Counsel about the risks of pregnancy	–	GPP	–
Screen partner; if the result is positive, counsel about prenatal diagnosis	–	GPP	–
Prenatal			
Hemoglobin electrophoresis screening of the entire population or high-risk groups	–	GPP	–
Screen partner; if the result is positive consider counseling and prenatal diagnosis			
Prompt treatment of crises (adequate hydration, oxygen, screening for infection) may include exchange transfusion	–	GPP	–
Prenatal fetal surveillance and tests for fetal well-being	–	GPP	–
Screen for:	–	GPP	–
• Urinary infection			
• Hypertension or preeclampsia			
• Renal and liver function			
• Pathologic fetal growth and umbilical artery blood flow			
Labor and Delivery			
Ensure adequate hydration	–	GPP	–
Avoid hypoxia	–	GPP	–
Continuous cardiotocography	–	GPP	–
Postnatal			
Use of prophylactic antibiotics is controversial	–	GPP	–
Maintain good hydration and oxygenation, especially for the first 24 hours	–	GPP	–
Contraceptive counseling	–	GPP	–
Testing of the neonate for hemoglobinopathies	–	GPP	–

Thalassemia Syndromes

Thalassemia syndromes are usually quantitative disorders of globin chain production that affect either the α- or the β-globin chain.

α-THALASSEMIA

There are normally two pairs (i.e., four) functional α-globin genes. If one or two of these genes are missing, the result is an α-thalassemia trait. The type of thalassemia trait is an important factor to consider when offering antenatal counseling and diagnosis. These traits are not detected on hemoglobin electrophoresis because no abnormal hemoglobin is made. In addition, there is neither excess nor lack of any normal hemoglobins.

Deletion of three α-globin genes results in hemoglobin H disease, a chronic hemolytic anemia, with normal life expectancy. This condition can be detected by hemoglobin electrophoresis.

In α-thalassemia major, there is no α-chain production and no synthesis of hemoglobin F, A, or A_2. Tetramers of fetal gamma chains (γ_4) form because no α chains are present. This condition is known as hemoglobin Barts. Patients have severe anemia, failure of

oxygen delivery to tissues, cardiac failure, and abnormal organogenesis. The condition is incompatible with life and causes intrauterine hydrops. Serious obstetric complications often occur, including preeclampsia and delivery difficulties because of the large fetus and placenta. Experimental fetal treatment may be available if the condition is detected early in pregnancy. Antenatal screening for α-thalassemia is directed at preventing hemoglobin Barts hydrops. To prevent this condition, women and their partners who have a cis-(2) α-gene deletion (i.e., genotype- -/αα, or α_0-thalassemia trait) must be identified. These couples have a one in four chance of having a fetus with hydrops. In practice, these couples are identified on the basis of otherwise unexplained hypochromic, microcytic red cell indices. An MCH of less than 25 pg suggests the genotype - -/αα or - α/-α. Hemoglobin electrophoresis does not detect α-thalassemia traits, and definitive diagnosis requires DNA analysis. This diagnostic procedure is undertaken only if both the woman and her partner have indices and test results that suggest α_0-thalassemia trait. Persons particularly at risk for α_0-thalassemia trait are those of Chinese, Southeast Asian, and Mediterranean descent.

DIAGNOSIS AND MANAGEMENT OPTIONS

Prepregnancy. Women who have α_0-thalassemia trait should be identified before pregnancy so that they can be alerted to the one in four chance of having a hydropic fetus if their partner carries the same trait. Early screening of partners is strongly encouraged. If the woman and her partner are at risk, the possibility and techniques of antenatal diagnosis can be discussed. Women with hemoglobin H disease should be encouraged to take regular folate supplementation outside of pregnancy to meet the demands of increased bone marrow turnover. They may require transfusion to meet the demands of pregnancy. Partner screening specifically for α_0-thalassemia trait is an important aspect of management.

Prenatal. Prenatally, the main issues are antenatal diagnosis (if required) and maintenance of adequate hemoglobin. In women with indices that suggest α_0-thalassemia trait or hemoglobin H disease, partner carrier status should be sought early in pregnancy to determine risk, especially in affected racial groups. At-risk couples should be counseled about the risks and offered antenatal diagnosis.

In hemoglobin H disease, folate supplementation (5 mg daily) is recommended, and transfusion may be needed.

Labor, Delivery, and Postpartum. There are no specific management recommendations.

β-THALASSEMIA

MATERNAL AND FETAL RISKS

β-thalassemia has three phenotypic presentations: the trait, intermedia, and major.

β-thalassemia trait, or heterozygote state, is important to detect for antenatal screening purposes. It does not affect the mother's health, but causes hypochromic, microcytic red cell indices. Iron therapy must be based on hematinic measurements rather than the complete blood count.

Partner screening should be performed to determine the risk of having a child affected with a major hemoglobinopathy. If the partner carries a sickle cell trait, a β-thalassemia trait, or hemoglobin E, and the mother carries a β-thalassemia trait, there is a one in four risk of having a child with a major hemoglobinopathy. Sickle cell/β-thalassemia is a major sickling disorder, whereas hemoglobin E/β-thalassemia and homozygous β-thalassemia are transfusion-dependent states, with the associated problems of iron overload and iron chelation therapy.

Couples at risk for having a child with a major hemoglobinopathy need timely, nondirective counseling, with education about the possibility and techniques available for antenatal diagnosis.

Partners of women with β-thalassemia or hemoglobin E/β-thalassemia need antenatal screening to determine the risk of major hemoglobinopathy. If the partner has a relevant heterozygous condition, the risk of having an affected fetus increases to one in two. Although fertility is reduced in women with transfusion-dependent thalassemia, pregnancy has been reported.[122-124]

There are important considerations during pregnancy for both the mother and the fetus. The physiologic stress of pregnancy may exacerbate symptoms of thalassemia. The transfusion regimen must be monitored carefully because blood requirements tend to increase in pregnancy. Iron chelation therapy also needs to be reviewed. Outside of pregnancy, iron chelation is usually performed with deferoxamine mesylate (Desferal), which is given as a subcutaneous infusion over 12 hours 5 to 7 days per week. Continuing this treatment periconceptually and during pregnancy may put the fetus at risk for skeletal anomalies. This finding was noted in animal studies at doses equivalent to human dosages. The small number of reported cases in pregnant women is not sufficient to establish the safety of deferoxamine mesylate in this setting. There are case reports of desferrioxamine mesylate use in early pregnancy,[125] but ideally, iron status is optimized prepregnancy and chelation is discontinued periconceptually, at least for the first trimester, but ideally, throughout pregnancy. A risk–benefit assessment of continuing iron chelation in pregnancy is required, and the results will depend on the degree of iron overload at the start of pregnancy. At conception, various organs may already be affected by iron overload, particularly the heart, liver, and endocrine system. These patients require careful evaluation prepregnancy and monitoring throughout gestation.

Patients with β–thalassemia major are often small in stature, and affected women have small pelvic bones. This finding may be the reason for the increased rate of cesarean delivery reported in these women.[124]

The fetus is primarily at risk if the transfusion regimen is inadequate and the mother is anemic. Fetal hypoxia

may occur and has been associated with intrauterine growth retardation, pregnancy loss, and preterm labor. These complications do not occur when maternal anemia is managed well. Women with iron overload are at increased risk for maternal diabetes, which can lead to an increased risk of birth defects and prenatal and maternal complications.

DIAGNOSIS AND MANAGEMENT OPTIONS

Prepregnancy and Prenatal. β-Thalassemia trait is indicated by hypochromic, microcytic red cell indices and usually is seen with a finding of increased hemoglobin A_2 on hemoglobin electrophoresis. Complications in diagnosis can arise in patients with iron deficiency anemia because it can falsely decrease hemoglobin A_2.

Racial groups at greatest risk include those of Mediterranean origin and some Asian populations, but it can occur in any racial group. The overall carrier rate in the United Kingdom is approximately 1 in 10,000 compared with 1 in 7 in Cyprus.

Women who are carriers of β-thalassemia trait need early education about the advisability of partner testing and the availability of antenatal diagnosis.[126,127]

In most cases, women with β-thalassemia intermedia or major are identified well before pregnancy and are receiving regular follow-up. Fertility is reduced in women with transfusion-dependent thalassemia major, but pregnancy is possible for some. Many require regular transfusion programs and iron chelation therapy. Unnecessary iron loading should be avoided. Oral and intravenous iron supplements are contraindicated. If possible, iron chelation therapy is discontinued during pregnancy. Assessment of the function of organs affected by iron overload (heart, liver, and endocrine system) should be carried out regularly throughout medical follow-up. Assessment includes evaluation of cardiac status, liver function tests, thyroid and parathyroid function tests, and glucose testing. If pregnancy was achieved spontaneously, (i.e., without fertility treatment) the pituitary axis is likely to be functioning, but thyroid function should be evaluated.

Involvement of a hematologist is essential in monitoring the transfusion regimen, which tends to increase in pregnancy. The fetomaternal medicine team should monitor the health of the mother and the growth and well-being of the fetus. Partner screening should be performed.

Labor, Delivery, and Postpartum. There are no specific management recommendations. As discussed earlier, issues relating to pelvis size, diabetes, and cardiac function may require assessment on an individual basis.

SUMMARY OF MANAGEMENT OPTIONS
Thalassemia Syndromes

Management Option	Quality of Evidence	Strength of Recommendation	References
β-Thalassemia Major			
Prepregnancy and Prenatal			
Pregnancy is rare	–	GPP	–
Avoid iron	–	GPP	–
Give folate	–	GPP	–
Regular transfusions for anemia	–	GPP	–
Screen partner; if the result is positive, consider counseling and prenatal diagnosis	–	GPP	–

Provide iron and folate supplementation	–	GPP	–
Screen partner; if the result is positive, consider counseling and prenatal diagnosis	–	GPP	–

HEMOLYTIC ANEMIAS

Hemolytic anemias are characterized by accelerated red cell destruction, which typically results in an increased unconjugated bilirubin level, increased urobilinogen excretion, and an increased lactate dehydrogenase level. The reticulocyte count increases as the bone marrow responds. If intravascular hemolysis is present, free plasma hemoglobin and absent serum haptoglobins are characteristic findings.

Clinically, patients may have anemia, jaundice, splenomegaly, and pigment gallstones.

It is useful to think of hemolytic anemias as being caused by something intrinsic or extrinsic to the red blood cell. Intrinsic causes of hemolysis include abnor-

malities in hemoglobin structure or function (i.e., hemoglobinopathies), the red cell membrane (e.g., hereditary spherocytosis), or red cell metabolism (e.g., pyruvate kinase, glucose-6-phosphate dehydrogenase [G6PD] deficiency). Extrinsic causes may be the result of a red-cell-directed antibody (i.e., autoimmune hemolytic anemia), altered intravascular circulation (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura) [see Chapters 79 and 80], or infection.

Red Cell Membrane Disorders

Hereditary spherocytosis occurs in approximately 1 in 2000 individuals of Northern European descent.[128] The inheritance pattern is autosomal dominant. The red cells

are spherocytic and osmotically fragile. The condition is caused by defects in red cell membrane proteins and is clinically and genetically heterogeneous. Diagnosis is made by a combination of nonimmune hemolysis and typical blood film findings, with spherocytes and either osmotic fragility testing, or more recently, the use of an eosin-5-maleimide probe. This probe is a flow cytometric test that measures the fluorescence intensity of intact red cell membrane labeled with the dye eosin-5-maleimide. This fluorescent label binds to a component of the red cell membrane known as band 3. Binding is significantly reduced in hereditary spherocytosis.[129] A pregnant woman with this condition should be monitored for anemia and should receive folic acid supplementation (at least 5 mg daily). Patients must be aware of the symptoms and signs of the aplastic and hyperhemolytic crises that may occur. Aplastic crises are usually caused by parvovirus B19, which switches off erythropoiesis and causes a dramatic decrease in hemoglobin.[130] The virus may also affect fetal erythropoiesis and development. Hyperhemolysis is characterized by increased jaundice and splenic enlargement. Treatment with blood transfusion may be necessary.

Splenectomy ameliorates hemolytic anemia and reduces gallstone formation, but does not alter the underlying red cell defect. After splenectomy, women should ensure that their presplenectomy vaccinations (pneumococcal, *H. influenzae* B, and meningococcal) are current preconception and should take prophylactic penicillin V. Some small case series suggest that maternal morbidity and fetal outcome may be more favorable after splenectomy.[131] Pediatricians should be made aware of infants who are born to these women because there is a 50% chance that these children will be affected with hereditary spherocytosis, which may cause neonatal jaundice. Affected infants require long-term follow-up.

Red Cell Metabolism Disorders

The mature red cell has two principal pathways of glucose metabolism, the glycolytic pathway and the hexose monophosphate shunt. The glycolytic pathway provides the red cell with ATP as an energy source. Other products include the reduced form of nicotinamide adenine dinucleotide to reduce methemoglobin and 2,3-diphosphoglyceric acid to regulate the oxygen affinity of hemoglobin.

Pyruvate kinase deficiency is the most common defect of the glycolytic pathway. It is inherited in an autosomal recessive fashion and is clinically and genetically heterogeneous.[132] Varying degrees of anemia are seen. The need for transfusion of red cells must be assessed throughout pregnancy. Folic acid supplements are important for these patients, especially during pregnancy. Patients who have had splenectomy should be current with their vaccinations and are probably receiving prophylactic penicillin.

Metabolism of glucose through the hexose monophosphate shunt produces the reduced form of nicotinamide adenine dinucleotide phosphate to maintain the antiox-idative activity of the red cell. G6PD deficiency is the most common abnormality of red cell metabolism.[133] Worldwide, it affects more than 200 million people and offers a survival advantage in the face of *Plasmodium falciparum* malaria.[134]

G6PD deficiency is X-linked. More than 300 genetic variants occur, and they are categorized according to the variant enzyme activity. The severity of hemolytic anemia depends on the type of defect, the level of enzyme activity, and the oxidative challenge (typically, drugs and fava beans). The G6PD A variant is an unstable enzyme, and enzyme activity decreases as the red cells age. This variant is found in approximately 10% to 15% of African American men. Women with this condition usually are only mildly anemic. The G6PD B variant (also known as G6PD Mediterranean) is found in up to 5% of people with Mediterranean or Asian ancestry and is clinically more severe. Men and heterozygous women may have severe hemolysis. The responsible agent must be removed because even the reticulocytes have low enzyme levels and are prone to hemolysis. Some variants cause congenital hemolytic anemia with persistent splenomegaly.

In more severe variants, women must be monitored for anemia throughout pregnancy, should avoid oxidant stresses, should take folic acid, and may need transfusion. The pediatrician must be alerted to the risk of hemolysis and neonatal jaundice because affected patients need careful monitoring and early therapy. Hepatic G6PD deficiency is probably an important factor in neonatal jaundice.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia may be primary or secondary to drugs, infection, autoimmune disease (typically systemic lupus erythematosus), neoplasia, or other hematologic disorders.

Usually, the antibodies are of the immunoglobulin G class, and antibody-coated red cells are cleared by the spleen. Symptoms of autoimmune hemolytic anemia are indistinguishable from those of other causes of hemolysis. The positive direct antiglobulin test (Coombs' test) is the mainstay of diagnosis.

Treatment is usually with glucocorticoids, but some patients have undergone splenectomy or are taking other immunosuppressive agents, such as cyclophosphamide, azathioprine, and cyclosporine. Transfusion may be required in patients who do not respond to treatment, but the autoantibodies may cause difficulties with crossmatching and close liaison with the blood bank is advisable.

Women who have autoimmune hemolytic anemia should have prepregnancy counseling, and treatment should be optimized. Careful antenatal supervision to assess maternal hemoglobin and markers of hemolysis, with adjustment of steroid therapy, is required.[135] Transplacental antibody transfer may occur, and hemoglobin levels in the newborn should be evaluated. Some infants require exchange transfusion,[136] but usually, no treatment is necessary.[137]

Autoimmune hemolytic anemia has been reported specifically associated with pregnancy, with remission occurring after delivery. This condition tends to recur in subsequent pregnancies. The anemia responds to steroids, and most infants are not affected.[138]

ANEMIA: BONE MARROW APLASIA

Aplastic Anemia

Aplastic anemia is a syndrome of bone marrow failure that is defined by pancytopenia and bone marrow hypocellularity. Normal hematopoietic tissue in the marrow is replaced by fat. Causative agents include infection, medications, and toxins, but most cases are idiopathic. Patients have pallor and fatigue as a result of anemia and bruising and bleeding as a result of thrombocytopenia. Infection is a risk because of neutropenia. Musculoskeletal abnormalities may indicate an inherited syndrome of bone marrow failure. The patient should be examined carefully for organomegaly and lymphadenopathy. These findings suggest viral infection or another underlying disease.

In patients with pancytopenia, testing should be directed by a hematologist and will include bone marrow aspirate and trephine with cytogenetic analysis and chromosome fragility tests.

Treatment of aplastic anemia is initially supportive, with blood products and growth factors. For younger patients with matched sibling donors, bone marrow transplantation is the treatment of choice. Immunosuppressive therapy with antilymphocyte globulin in combination with cyclosporin is also effective.

There are sporadic case reports of aplastic anemia in pregnancy[139–142] and reports of pregnancy occurring in women with underlying aplastic anemia.[143–145]

Aplastic anemia in pregnancy is rare. The relationship between aplastic anemia and pregnancy is uncertain, but the literature suggests that there is not a strong association in most cases.[146] In a few women, however, pregnancy may play an etiologic role. There are case reports of aplastic anemia that are diagnosed for the first time in pregnancy, with spontaneous remission occurring after cessation of pregnancy.[147]

Pregnancy may exacerbate bone marrow depression and cause clinical deterioration.[148]

If severe aplastic anemia occurs in the first trimester, early termination should be considered. If spontaneous recovery does not occur after termination, bone marrow transplantation is performed as soon as possible in women who have a histocompatible sibling donor. In women with severe aplastic anemia later in pregnancy and those who refuse termination, intensive hematologic support with red cells and platelet transfusions is required until delivery. After delivery, bone marrow transplantation should be considered if spontaneous recovery does not occur. There are case reports of the use of antilymphocyte globulin in pregnancy,[147] but each case requires individual assessment and close liaison between obstetricians and hematologists.

NEUTROPHILS

Neutrophilia

The neutrophil count increases throughout pregnancy. The increase is more marked during labor and immediately postpartum. Occasional band forms and myelocytes in the peripheral blood may be a normal finding during pregnancy. Neutrophilia may be associated with the following:

- Bacterial infection
- Acute or chronic inflammatory disorders
- Tissue damage or infarction
- Preeclampsia
- Hemorrhage
- Malignant disease, either hematologic (e.g., chronic myeloid leukemia) or nonhematologic

Neutropenia

The finding of neutropenia on an automated complete blood count should be verified by examination of the peripheral blood film. Aged samples may show spurious neutropenia or neutrophil clumping. A repeat count should be obtained to ensure that the findings are reproducible. Ethnic origin affects the neutrophil count; persons of African and Caribbean descent tend to have a lower peripheral blood neutrophil count because of an increase in the marginating pool. Neutropenia may be acute or chronic and isolated or part of generalized pancytopenia. It may be caused by peripheral destruction or underlying bone marrow disease. A summary of the causes of nonmalignant neutropenia is shown in Table 39–2. The investigation of neutropenia in the pregnant woman is identical to that outside pregnancy. Drugs that may be implicated should be discontinued immediately, especially if neutropenia is severe. If clinical assessment and examination of the blood film do not show the cause of neutropenia, bone marrow examination is indicated.

Maternal and Fetal Risks

In severe neutropenia, the principal maternal risk is sepsis. A patient with moderate or severe neutropenia (neutrophil count $<1.0 \times 10^9/L$) and fever should have prompt cultures of blood, urine, and sputum, if available, followed immediately by empirical treatment with broad-spectrum intravenous antibiotics, according to local policy. Antifungal therapy is considered if the fever does not resolve after 48 to 72 hours, especially when neutropenia is prolonged.

TABLE 39-2

Nonmalignant Neutropenia

TYPE	CAUSES
Acute	Drug-induced bone marrow suppression
	Agranulocytosis
	Viral infection
	Vitamin B_{12} or folate deficiency
Chronic	Race
	Immune neutropenia
	Primary
	Associated with connective tissue disorder or
	autoimmune disease
	Felty's syndrome
	Congenital neutropenia
	Kostmann's neutropenia
	Associated with other congenital disorders
	Chronic idiopathic neutropenia
	Cyclical neutropenia
	Aplastic anemia

There are many case reports of pregnancy in patients with cyclic neutropenia.[149,150] This disorder is characterized by cyclic fluctuations of the neutrophil count, with a periodicity of approximately 21 days. At its nadir, neutropenia is usually severe and is often associated with clinical infection. The onset is usually in childhood, but adult-onset cyclic neutropenia is also described. Pregnancy in cyclic neutropenia is associated with premature labor and stillbirth, possibly because of chorioamnionitis associated with the neutropenia. There are also reports of improvements in symptoms and neutrophil counts during pregnancy in patients with cyclic neutropenia, possibly because of the production of neutrophil growth factors, such as granulocyte-macrophage colony-stimulating factor, by the placenta.[151] In approximately one third of cases, cyclic neutropenia appears to be inherited in an autosomal dominant fashion; therefore, the fetus may be affected.

Management Options

Recombinant granulocyte colony-stimulating factor is successfully used to treat patients with severe chronic neutropenia of differing etiologies, including cyclic and congenital types.[152] A few pregnancies have occurred in patients treated with granulocyte colony-stimulating factor for severe chronic or cyclic neutropenia.[153] Pregnancy outcome was normal in some, but fetal abnormality, including bilateral hydronephrosis, occurred in others. Data on the safety of the use of granulocyte colony-stimulating factor during pregnancy are inconclusive. Risks and benefits should be evaluated individually.

For a patient with severe neutropenia, prophylactic antibiotics should be considered to cover invasive procedures for labor and delivery.

Some viral infections that cause neutropenia have implications for fetal development and congenital infection (e.g., rubella, parvovirus, cytomegalovirus) or hepatitis. Maternal autoimmune neutropenia may lead to transfer of antineutrophil antibodies across the placenta, resulting in fetal neutropenia.[154,155]

SUMMARY OF MANAGEMENT OPTIONS
White Cell Disorders

Management Options	Quality of Evidence	Strength of Recommendation	References
Neutrophilia			
Prenatal			
Increase in values for pregnancy	—	GPP	—
Search for pathology and treat if the count is above normal	—	GPP	—
Neutropenia			
Prepregnancy and Prenatal			
Give antibiotics for fever (and antifungals if fever persists)	—	GPP	—
For severe cases, consider recombinant granulocyte colony-stimulating factor; experience in pregnancy limited to case reports	Ib	A	152
Labor and Delivery			
Consider prophylactic antibiotics	IV	C	149

CONCLUSIONS

IRON DEFICIENCY ANEMIA

- The condition is common.
- Prophylactic iron treatment should be considered before deficiency develops.
- Oral, intramuscular, and intravenous forms of iron are equally effective.
- Treatment should continue into the postpartum period and be monitored by the full blood count and ferritin levels.

FOLATE DEFICIENCY ANEMIA

- Folate prophylaxis should be considered in patients who are at risk. The condition is more common in patients who take anticonvulsants or have a high turnover state, such as hemolytic anemia. Folate prophylaxis is indicated in these groups.
- Periconceptual use of folic acid is advised to reduce the incidence of neural tube defects.

VITAMIN B$_{12}$ DEFICIENCY ANEMIA

- This condition is rare.
- Vitamin B$_{12}$ levels decrease in pregnancy, but a decrease does not usually indicate deficiency.
- Intrinsic factor antibodies may be helpful if positive.

HEMOGLOBINOPATHIES

- Women should be screened for the trait or disease. If the results are positive, their partners should be screened. Counseling about prenatal diagnosis is appropriate.
- Patients with major hemoglobinopathy should be treated by senior obstetric and hematology teams throughout pregnancy.

Malignancies of the Hematologic and Immunologic Systems

John Maelor Davies / Lucy Kean

INTRODUCTION

Fortunately, malignancy complicating pregnancy is uncommon. Hematologic disorders account for most malignancies in women of reproductive age. The incidence of acute leukemia complicating pregnancy is approximately 1 in 75,000, and lymphoma complicates 1 in 5000 pregnancies.[1,2] Hematologic malignancy is an important consideration in pregnancy because it threatens life and is potentially curable. This chapter discusses acute myeloblastic leukemia (AML), acute lymphoblastic leukemia (ALL), chronic myeloid leukemia (CML), lymphoma (both Hodgkin's disease and non-Hodgkin's lymphoma), chronic lymphocytic leukemia (CLL), and myeloma and the myeloproliferative disorders. The classification of tumors of the hemopoietic and lymphoid tissues is complex and subject to change. The World Health Organization classification[3] provides the major framework for categorizing these disorders. Much of the literature on these conditions in pregnancy predates the introduction of effective modern management. In some areas, data are limited, but as far as possible, the management principles discussed later are evidence-based.

ACUTE LEUKEMIA

Acute leukemia is caused by malignant changes in the hemopoietic precursor cells. Acute leukemia is traditionally subdivided into AML and ALL, depending on the cell lineage. Further subdivision of AML and ALL provides additional prognostic and therapeutic information. Both AML and ALL are usually acute and lead to progressive bone marrow failure, with symptoms and signs of anemia, neutropenia, and thrombocytopenia. More rarely, ALL, in particular, may cause extramedullary involvement.

Maternal Risks

Pregnancy does not appear to affect either the development or the course of acute leukemia. Patients who have symptoms or signs of abnormalities in the complete blood count suggesting bone marrow failure or infiltration should undergo appropriate testing. Studies in pregnant patients with acute leukemia do not differ from those in nonpregnant patients. They include bone marrow aspiration, trephine biopsy, and examination of the cerebrospinal fluid, as appropriate. Newer cytogenetic and molecular diagnostic techniques should be used because they provide additional prognostic information rapidly.[3] Renal and hepatic function should be monitored. Infection and bleeding are major risks in uncontrolled acute leukemia, particularly in some types, such as acute promyelocytic leukemia. Laboratory assessment of the degree of thrombocytopenia and evidence of coagulation factor depletion and disseminated intravascular coagulation should be undertaken.

Supportive care, with blood and platelet transfusions and antibiotic administration, should be instituted early. However, chemotherapy offers the only prospect for long-term maternal survival. If delivery is contemplated before complete remission is achieved, then infection and bleeding pose a major risk to maternal survival. These patients require antibiotic administration and appropriate coagulation factor and platelet replacement.

The outcome in both AML and ALL depends on a number of prognostic factors. The prognosis is determined by the response to treatment and the type of treatment offered. For example, when patients with acute promyelocytic leukemia are treated with modern protocols, the prognosis is relatively favorable,[3] whereas patients with Philadelphia-chromosome-positive ALL present significant management problems. This disease is essentially incurable with current chemotherapy

regimens alone.[4] Discussion of the prognosis should be highly individualized and undertaken only when all necessary information is available. Fertility is likely to be maintained in many patients with AML and ALL treated with conventional chemotherapy, and future pregnancy outcome in survivors of AML and ALL is also likely to be favorable. Counseling and contraceptive advice should include these considerations.

Increasing numbers of patients have been treated with both autologous and allogeneic hemopoietic stem cell transplantation for acute leukemia. Although successful pregnancy has been reported, in most patients, this procedure impairs fertility.[5,6]

Fetal Risks

The main risks to the fetus are growth restriction, which occurs in both treated and untreated pregnancies, and chemotherapy-induced effects, both reversible and irreversible. Historically, fetal growth restriction and spontaneous preterm delivery occurred in approximately 40% to 50% of cases and appeared to be multifactorial.[7] With modern chemotherapy and the attainment of remission in most patients within 4 to 6 weeks, the fetal survival rate has improved significantly.[8] Congenital leukemia is rare and can essentially be discounted. The fetal risks associated with chemotherapy depend, in part, on the timing of the treatment in terms of gestational age and also on the agents used. Although data are limited, general conclusions can be drawn about the fetal risks of chemotherapy.

First, adverse fetal events may occur at any point in gestation, although congenital malformation is more likely to occur with first-trimester exposure to chemotherapy. The literature suggests that the risk of major fetal abnormality is 10% to 30%, depending on the degree of exposure and the agents used.[9,10] When a patient has known first-trimester exposure to cytotoxic agents, a careful fetal ultrasound should be performed at 18 to 22 weeks. However, not all teratogenic effects are detectable by ultrasound examination, and parents should be carefully counseled.

Second, some chemotherapeutic agents are more likely than others to produce adverse fetal effects. For example, first-trimester use of high-dose methotrexate produces adverse fetal effects.[11] Data on newer agents used to treat acute leukemia are limited. For example, when administered early in gestation, fludarabine, now widely used to treat AML, produces skeletal malformation in both rats and rabbits. The agent is not recommended for use at any stage in human pregnancy, and there are no adequate, well-controlled studies in pregnant women. Similarly, all-trans-retinoic acid, which is used to treat acute promyelocytic leukemia, is related to other retinoids that are potent human teratogens. These agents are contraindicated in women of childbearing age. There are single case reports of the use of all-trans-

retinoic acid in the later stages of pregnancy. Maternal versus fetal risk must be balanced at all stages in patient management.[12]

Finally, many chemotherapeutic agents are associated with markers of chromosomal damage. The significance of this observation is not clear, and data on long-term effects in surviving infants exposed to chemotherapeutic agents in utero are encouraging. However, this observation may reflect a lack of good information rather than a true lack of adverse events. Chemotherapy-induced malignancies are the major potential concern.[13]

Management Options

Prepregnancy

Women who undergo chemotherapy for acute leukemia should be counseled and advised against conception until remission is achieved and chemotherapy is discontinued. Oral contraceptives are not contraindicated.

A much more common scenario is a woman who is in complete remission. As a result of the 1994 European Registration of Congenital Anomalies (EUROCAT) study of policies for karyotyping in pregnancy, patients began to seek invasive prenatal testing because of maternal anxiety about exposure to chemotherapy or radiation therapy.[14] Prepregnancy counseling should include a discussion of the prognosis in terms of the disease and the effect of the disease and its treatment on pregnancy. Although chemotherapy may cause chromosome breaks, there does not appear to be an increase in the risk of chromosomal or genetic problems in offspring. Previous chemotherapy does not appear to increase the risk of miscarriage, growth restriction, or stillbirth.[15,16]

Large studies have not determined whether the incidence of childhood cancer is increased in the offspring of patients who have undergone chemotherapy. However, smaller studies suggest that there is no increased risk. Given the lack of evidence suggesting an increase in the risk of chromosomal abnormalities in the fetus, invasive prenatal diagnosis should be based on normal criteria in relation to age and screening test results. Women who have undergone pelvic radiation therapy have a significantly increased risk of growth restriction in the fetus and should be counseled that increased surveillance is needed in pregnancy.

Prenatal

A pregnant woman with acute leukemia should be treated aggressively, with full supportive care and combination chemotherapy. Untreated acute leukemia is fatal to both mother and fetus. When possible, standard treatment is given, with appropriate counseling about fetal risk. No good data are available on the need for dosage modifications of chemotherapeutic drugs in pregnancy. In some cases, agents that are less likely to cause fetal abnormalities can be used (e.g., intrathecal cytarabine rather than

intrathecal methotrexate for central nervous system prophylaxis in ALL). However, nonstandard regimens of unproven efficacy should not be substituted on the basis of fetal risk without full and informed discussion of maternal risks.

Counseling about the teratogenic risks of treatment should be provided, and fetal and maternal well-being should be monitored throughout pregnancy by a hemato-oncologist and an obstetrician.

Labor and Delivery

Delivery should be expedited for normal obstetric indications. The goal of management is to deliver a viable infant while the mother is in hematologic remission. This approach offers the best prospect for uncomplicated delivery and infant survival. There is no contraindication to the use of steroids before delivery to enhance fetal surfactant production. Early assessment of the infant should be undertaken to detect complications from in utero exposure to chemotherapy. This evaluation includes assessment of potential abnormalities and hematologic testing to exclude short-term effects (e.g., neutropenia as a result of recent in utero exposure to cytotoxic agents administered to the mother). If the mother recently received chemotherapy, a cord blood sample should be sent for a complete blood count.

Postnatal

If delivery is inevitable in a patient who is not in remission, vigorous supportive care should be continued. If the disease is in remission at the time of delivery, counseling and appropriate contraceptive advice should be given after delivery. Data on the excretion of cytotoxic drugs in breast milk are variable; however, patients who are receiving active treatment with cytotoxic drugs should not breastfeed.

CHRONIC LEUKEMIA

Chronic Myeloid Leukemia

CML is a triphasic disease (chronic phase, accelerated phase, and blast crisis) that is usually diagnosed in the chronic (early) phase. It accounts for 15% to 20% of cases of leukemia, and the median age at diagnosis is in the fifth and sixth decades. CML arises from a cytogenetic abnormality that results in production of the Philadelphia chromosome. As a result, the BCR/ABL fusion gene is produced and encodes for a protein with tyrosine kinase activity. CML causes systemic symptoms, such as weight loss, fatigue, and splenomegaly. Laboratory findings include marked leukocytosis, and as discussed earlier, a specific marker chromosome that is detectable in blood and bone marrow. Hyperleukocytosis with ocular and other central nervous system effects may occur.

Management Options Outside Pregnancy

The management of CML was revolutionized by the introduction of the specific tyrosine kinase inhibitor imatinib mesylate.[17] This agent is superior to α-interferon, either alone or in combination with cytarabine.[17] When imatinib is available, few patients are treated with the older treatment options of hydroxyurea and α-interferon. The role of related or unrelated allogeneic hemopoietic stem cell transplantation, which traditionally has been used to treat this condition, is under reevaluation. The practical management of patients with CML in the imatinib era has been reviewed.[18]

Maternal and Fetal Risks

There is no evidence that the behavior of CML is altered in pregnancy. Control of the maternal white count may be achieved in a number of ways. The risk to the fetus is probably secondary to exposure to maternal therapy, and control of the maternal white count with physical means, such as leukapheresis, should be considered. Successful pregnancies have been reported after the use of alkylating agents in pregnancy.[19] However, these agents should be avoided, at least in the first trimester. Successful pregnancy is also reported in patients treated with α-interferon, although data in pregnancy are limited.[20] Patients treated with imatinib should be counseled against becoming pregnant because there are no good data on its use in pregnancy.

Management Options

PREPREGNANCY

The implications and risks of pregnancy should be fully explained, and appropriate contraceptive advice should be given.

PRENATAL

Regular hematologic review is required to determine the need for active treatment. As discussed earlier, leukapheresis may be an effective method to control the white cell count, particularly in the first trimester. This approach may be continued throughout pregnancy. Successful pregnancies are described in patients treated with hydroxyurea and α-interferon, although cumulative data are insufficient to allow an estimate of the real risk of fetal abnormality. Patients who become pregnant while taking imatinib should be counseled about the risk of fetal abnormality, which is essentially unquantifiable. Careful ultrasonographic examination of the fetus should be performed in women who wish to continue the pregnancy. Patients in the early chronic phase who become pregnant while taking imatinib are advised to discontinue use of the agent; other methods to control the white cell count may be instituted.

Hematologic abnormalities that suggest disease progression, such as signs of the accelerated phase or blast crisis, should lead to management review. In the accelerated phase, delivery is expedited. Maternal options include reintroduction of imatinib and referral for hemopoietic stem cell transplantation, which is the only likely curative option. Blast crisis in pregnancy may be treated with imatinib, if the patient is not already receiving this agent, or with combination chemotherapy, as for other forms of acute leukemia. However, the maternal outlook is poor, and particularly if a second chronic phase occurs, urgent consideration should be given to early delivery and referral of the mother, if appropriate, for hemopoietic stem cell transplantation.[21]

Chronic Lymphocytic Leukemia

CLL is a disease of older populations[5] and rarely occurs in pregnancy. A "wait and watch" approach is often appropriate, and the patient may need treatment only if symptoms occur. When treatment is required, standard therapies include corticosteroids, alkylating agents, and fludarabine. Given the usual indolent course of CLL, most pregnancies can be managed without fetal exposure to potentially teratogenic agents and with no detriment to maternal outcome.

Myeloma

Myeloma is also a disease of older age groups and is rare in pregnancy. It presents a unique set of management problems and may cause significant skeletal damage, bone marrow failure, extended risk of infection, and renal failure. When treatment is required, standard therapies, as for nonpregnant patients, should be used.

LYMPHOMA

Lymphomas are a heterogeneous group of disorders that arise in lymphoid tissue. The major histologic subdivision of lymphoma is into the following categories:

- Hodgkin's disease
- Non-Hodgkin's lymphoma[3]

Hodgkin's Disease

Hodgkin's disease is an uncommon lymphoid malignancy.[22] However, because of the age distribution of patients with Hodgkin's disease, it is the most common type of lymphoma seen in pregnancy. Hodgkin's disease causes nodal enlargement, classically in the neck, and diagnosis requires biopsy of the affected tissue. Further management depends on the stage of disease. Early-stage or localized Hodgkin's disease is amenable to treatment and may be cured with either radiation therapy alone or a combination of chemotherapy and radiation therapy in modified dosage. Intermediate- or late-stage disease requires combination chemotherapy for cure. The Ann Arbor system is still the most commonly used staging system, but staging may be refined anatomically with the Cotswolds revision.[23] Additionally, information available from laboratory tests (e.g., lymphocyte count, erythrocyte sedimentation rate, serum albumin level) may be used to produce a prognostic index that may affect management. However, in pregnancy, laboratory findings are of less value.

Maternal Risks

Hodgkin's disease in pregnancy does not appear to differ from that in nonpregnant patients, although interestingly, Hodgkin's disease is less common in multiparous women. Diagnosis is made by biopsy. Further studies in the pregnant patient are associated with specific problems, particularly with regard to computed tomography; however, magnetic resonance imaging, which is generally safe in pregnancy, may be used.[24] Staging laparotomy has largely been abandoned.[25] The outlook for cure in patients with early-stage disease treated with radiation therapy, with or without a short course of chemotherapy, is excellent.[26] The long-term disease-free survival rate in patients with advanced disease treated with combination chemotherapy is 70% to 80%.[26] After relapse, high-dose therapy may produce additional long-term survivors.[27]

Most patients who are successfully treated for Hodgkin's disease return to a normal or very near normal quality of life on cessation of treatment. Many women who receive combination chemotherapy for Hodgkin's disease remain fertile, although there is a risk of premature menopause.[28] No apparent increase in the complications of pregnancy or fetal abnormality in subsequent

pregnancy is seen after combination chemotherapy for Hodgkin's disease.[29]

Fetal Risks

The risks to the fetus stem chiefly from the effects of either radiation therapy or chemotherapy. The risks to the fetus of diagnostic radiation have been reviewed.[30,31] Exposure of pregnant women to the radiation doses used in abdominal and pelvic computed tomography appears to have no substantial effect on the risk of fetal death or malformation. The risk of childhood cancer is more than doubled after fetal irradiation. When possible, irradiation of the fetus in utero should be avoided, but staging should be sufficient to determine the correct modality of treatment. Magnetic resonance imaging is the preferred tool for staging evaluation and avoids exposure to ionizing radiation.[24]

The use of therapeutic irradiation depends on whether early-stage Hodgkin's disease involves the abdomen or pelvis. Supradiaphragmatic irradiation with heavy lead shielding of the uterus resulted in no congenital abnormalities in one series.[32] When high-dose irradiation cannot be avoided by field manipulation, infradiaphragmatic radiation therapy with appropriate shielding carries a substantial risk of spontaneous miscarriage and fetal abnormality. Under these circumstances, chemotherapy rather than radiation therapy should be considered, with delivery before therapeutic irradiation. The fetal effects of combination chemotherapy used to treat Hodgkin's disease are unlikely to be substantially different from those seen in acute leukemia. The teratogenic risk is greatest with first-trimester exposure. However, some series found no apparent adverse effects with first-trimester exposure to the current "gold standard" treatment of doxorubicin (Adriamycin), bleomycin, vincristine, and dacarbazine (ABVD).[33]

Management Options

PREPREGNANCY

Women with active Hodgkin's disease should be counseled about the risks of pregnancy and should take appropriate contraceptive measures. Pregnancy outcome is good in patients who have been successfully treated for Hodgkin's disease, and routine amniocentesis is not recommended, as it is for leukemia (discussed earlier).

PRENATAL

The outlook for patients treated for Hodgkin's disease is good to excellent. Diagnosis and testing (discussed earlier) are as for the nonpregnant patient. Patients diagnosed in the first trimester should be counseled about the risks of continuing with the pregnancy. Early-stage supradiaphragmatic disease can be successfully treated with radiation therapy alone, with little fetal risk. Historically, early-stage intra-abdominal disease presented a management problem. The options were therapeutic abortion and early delivery, followed by local radiation therapy. Both supradiaphragmatic and infradiaphragmatic disease may be treated with a short course of combination chemotherapy until delivery, with radiation therapy given after delivery. Management decisions are complex, and discussion should include the patient, hemato-oncologist, obstetrician, and radiation oncologist.

Patients with more extensive disease should be counseled about the risks of proceeding with pregnancy. Some women continue with the pregnancy and opt for combination chemotherapy on evidence of disease progression. The optimum management in this context is not clear, but early in pregnancy, patients should receive standard chemotherapy, currently ABVD or an equivalent. Late in pregnancy, the mother can be treated with steroids alone or with single-agent vinblastine, which is not associated with a teratogenic risk at this point in gestation.[34] After delivery, patients may be treated with more aggressive combination chemotherapy, such as ABVD, as appropriate.

POSTNATAL

Careful counseling about the prognosis for both long-term disease-free survival and preservation of fertility should be given. Patients who are undergoing active treatment for Hodgkin's disease with combination chemotherapy should not breastfeed.[35]

Non-Hodgkin's Lymphomas

Non-Hodgkin's lymphomas comprise a heterogeneous group of malignancies. Unlike in Hodgkin's disease, extranodal presentation of non-Hodgkin's lymphoma is not uncommon. The increase in the incidence of non-Hodgkin's lymphomas is partly attributable to an aging population, but an unexplained real increase in incidence has been noted. As reflected in the literature, non-Hodgkin's lymphomas are uncommon in the reproductive years. The subclassification of non-Hodgkin's lymphomas is complex and changing. However, in general, three types of biologic behavior are seen.[3]

Low-grade, or indolent, lymphomas that are slow-growing do not threaten life and may be treated either on a wait and watch basis or with single-agent chemotherapy or local radiation therapy.[36] More aggressive lymphomas, such as diffuse large B cell lymphoma, have a much shorter clinical history and may cause early life-threatening complications. These are treated with combination chemotherapy in concert with a monoclonal antibody directed against CD20 (rituximab).[37] Some lymphomas, such as lymphoblastic lymphoma, behave biologically in a similar fashion to ALL. These must be treated with aggressive combination chemotherapy, the nature of which depends on the histologic subtype.

Maternal Risks

Diagnosis is made on biopsy, and testing and staging are as for Hodgkin's disease, although advanced disease is more common in non-Hodgkin's lymphomas. Treatment must be highly individualized and may, as discussed earlier, vary from a wait and watch policy to administration of intermediate- or high-dose combination chemotherapy. In these patients, the management and outlook are similar to those in nonpregnant patients.

Fetal Risks

The disease does not appear to affect the outcome of pregnancy, and the risks to the fetus are those of treatment. In terms of exposure to cytotoxic agents, fetal risk should not be substantially different from that seen in acute leukemia and Hodgkin's disease. The recent introduction of rituximab into the management of diffuse large B cell lymphoma poses an additional complication.[37] Insufficient data are available on the effects of rituximab on pregnancy to allow formal risk stratification. Rituximab is contraindicated in pregnancy. The introduction of an agent such as rituximab, which clearly improves outcome but has limited data in pregnancy, illustrates the dilemma that many physicians face.

Management Options

PREPREGNANCY

Women who have active non-Hodgkin's lymphoma should be counseled about the outlook for the particular subtype of disease and receive appropriate contraceptive advice. Patients who are receiving active treatment for non-Hodgkin's lymphoma should be advised against becoming pregnant.

PRENATAL

Management depends on the histologic subtype and extent of disease (discussed earlier).

POSTNATAL

Although data are limited, patients undergoing active treatment for non-Hodgkin's lymphoma should be advised against breastfeeding.

MYELOPROLIFERATIVE DISORDERS

Essential Thrombocythemia

Diagnosis, Assessment, and Risks

Essential thrombocythemia is a myeloproliferative disorder that usually occurs in the elderly. Occasional cases complicating pregnancy are reported in the literature. Causes of reactive thrombocytosis are much more common and should be carefully excluded. Common causes of reactive thrombocytosis include iron deficiency, hemorrhage, infection, and inflammatory conditions. In essential thrombocythemia, the platelet count is consistently elevated in the absence of an apparent underlying cause. Samples obtained on bone marrow biopsy usually have a characteristic appearance. Cytogenetic studies should be carried out on bone marrow aspirate material to exclude CML. Essential thrombocythemia may be complicated by abnormal bleeding as a result of defective platelet function or small vessel thrombosis. The incidence of these complications in younger patients is unknown, and thrombosis may be less common. The literature on pregnancy includes small series and case reports. Spontaneous abortion, intrauterine death, and intrauterine growth restriction are possible risks, because placental infarction may occur.[38,39] However, others reported good pregnancy outcomes in small series of asymptomatic women.[40,41]

Management Options

If the patient is asymptomatic and the platelet count is only moderately increased, an expectant approach is reasonable.[38] If thrombosis or hemorrhage occurs, however,

treatment is necessary. Because of a reluctance to use cytotoxic agents in pregnancy, plateletpheresis has been used.[38] However, this treatment is a very short-term measure, and it is virtually impossible to achieve good platelet control over longer periods. Aspirin may be used to treat thrombotic complications,[39] but routine use should be avoided because it may aggravate an underlying platelet function defect. Aspirin may have a role in patients with essential thrombocythemia and a history of previous pregnancy failure or growth restriction, but few data are available.[40] There are anecdotal reports of the use of hydroxyurea in essential thrombocythemia in pregnancy.[39] Most experience with this agent in pregnancy is with CML, when hydroxyurea has been used for prolonged periods. Because teratogenicity is reported in animals, however, first-trimester use of hydroxyurea and other cytotoxic agents should be avoided. The safety profile is good in the second and third trimesters. More recently, α-interferon has been used successfully throughout pregnancy in patients with essential thrombocythemia, without adverse effects.[42,43] More data are needed on the safety of α-interferon in pregnancy, but early reports are encouraging. It may emerge as the agent of choice if treatment of essential thrombocythemia is necessary in a pregnant woman.

Similarly, data on the safety of anagrelide, a new agent used to treat essential thrombocythemia, are limited. This agent should be avoided in pregnancy, and alternative methods should be used to control the platelet count, when necessary.

Because data are inconsistent, increased surveillance is appropriate when assessment of growth and umbilical artery Doppler recordings show intrauterine growth restriction and placental infarction.

Platelet dysfunction may lead to an increased risk of primary and secondary postpartum hemorrhage. Secondary hemorrhage is exacerbated by the risk of retained placental fragments from an infarcted placenta.

Polycythemia

Polycythemia occurs when hemoglobin, hematocrit, and the red cell mass are increased above the upper limit of normal for the patient's age and sex. Polycythemia may be relative or true. Relative, or stress, polycythemia occurs when plasma volume is reduced with no increase in the red cell mass. In true polycythemia, the red cell mass is greater than 32 mL/kg for women and 36 mL/kg for men. True polycythemia may be primary or secondary. Secondary polycythemia occurs in conditions associated with either chronic hypoxia or inappropriate erythropoietin production (e.g., renal cysts or tumors). Primary proliferative polycythemia, or polycythemia rubra vera, is caused by unchecked proliferation of erythroid precursors in the bone marrow. Primary polycythemia is believed to arise as a result of a clonal defect in a pluripotent stem cell. Polycythemia rubra vera is usually a disease of the elderly, but rare cases are described in women of childbearing age.[44]

The diagnosis of polycythemia is difficult during pregnancy because physiologic changes in plasma volume may decrease hemoglobin and hematocrit. Further, isotopic techniques used to determine the red cell mass and plasma volume are contraindicated in pregnancy. Definitive testing and diagnosis usually must be postponed until after delivery. In women who have a high hematocrit in pregnancy, secondary causes should be excluded. Preeclampsia and intrauterine growth restriction are associated with failure of normal plasma volume expansion. In these conditions, hematocrit may be relatively increased compared with levels in normal pregnancy, but an increase above the normal range in nonpregnant women usually does not occur. Features such as splenomegaly, increased white cell and platelet counts, and high serum vitamin B_{12} levels suggest primary polycythemia. If erythropoietin levels are available, a low level suggests primary proliferative polycythemia. However, erythropoietin levels increase physiologically during pregnancy,[45] and a normal or high level is difficult to interpret.

Maternal and Fetal Risks

In a series of patients with polycythemia rubra vera, 13 pregnancies were identified in 8 women.[44] Maternal outcome was good, but fetal outcome was adversely affected. Abortion, preterm delivery, and stillbirth were more common than expected. The risk of pregnancy-induced hypertension may also be increased. A relationship between pregnancy outcome and maternal red cell count was suggested, but the numbers in this study were too small to allow firm conclusions to be drawn. In some patients, hematocrit decreased significantly during pregnancy.

Management Options

Venesection may be performed to maintain the hematocrit below 0.45. Myelosuppressive therapy should be avoided but may be necessary in patients with associated marked thrombocytosis. Management principles are similar to those outlined for essential thrombocythemia. Thrombosis prophylaxis in the puerperium should be considered and should include compression stockings and early mobilization. Peripartum treatment with subcutaneous low-molecular-weight heparin is also an option, although there are no data in this patient group. Short-term treatment with low-molecular-weight heparin has a good safety profile for other indications, and the balance of risks is probably in favor of peripartum low-molecular-weight heparin prophylaxis in women with primary polycythemia.

SUMMARY OF MANAGEMENT OPTIONS
Myeloproliferative Disorders

Management Options	Quality of Evidence	Strength of Recommendation	References
Essential Thrombocythemia			
Prenatal			
Expectant approach in asymptomatic patients with moderate elevation of platelets	III	B	38
If the patient is symptomatic (thrombosis or bleeding), consider plasmapheresis	III	B	38
Give low-dose aspirin if the patient has thrombosis; no evidence supports use in all cases	III	B	39,40
Hydroxyurea has been used, but most experience is with chronic myeloid leukemia	III	B	39
Limited experience with alpha interferon	III	B	42,43
No experience with anagrelide; avoid	–	GPP	–
Serial fetal growth and umbilical artery Doppler recordings	–	GPP	–
Labor and Delivery			
Vigilance for PPH	–	GPP	–
Polycythemia			
Prenatal			
Vigilance for hypertensive disease	III	B	44
Serial fetal growth and umbilical artery Doppler recordings	III	B	44
Some advocate regular venisection to keep hematocrit <0.45; no evidence supports this practice	III	B	44
Postnatal			
Prophylactic low-molecular-weight heparin	–	GPP	–

PPH, postpartum hemorrhage

CONCLUSIONS

- Pregnancy should be deferred until the patient is in remission.
- When malignancy is diagnosed in pregnancy, the available options should be discussed with the patient.

Options include:
- Initiating treatment and continuing with the pregnancy
- Terminating pregnancy and initiating treatment
- First-trimester chemotherapy carries the risk of teratogenicity to the fetus.
- After the first trimester, the main fetal risk associated with chemotherapy is growth restriction.
- Radiation therapy is contraindicated in pregnancy.
