Many of the studies performed to assess the mortality and morbidity rates for fetuses undergoing vaginal breech delivery have been poor. They were mostly retrospective reviews of practice and often simply compared babies delivered vaginally by the breech and by the head. This approach does not compare like with like and is therefore invalid for our purposes. However, because of the rise in the popularity of elective cesarean section for breech presentation, increasingly vaginal breech delivery was being performed only when the woman presented in advanced labor with an unexpected breech presentation. This situation increased the risk of a breech birth being attended by inadequately trained or experienced personnel. Moreover, there was no opportunity for prior assessment for suitability for vaginal breech delivery. These women were a high risk group. Many of the long-term and short-term follow-up studies of vaginally delivered breech babies were performed on populations born in the 1950s and 1960s and reflected the standards of care being offered at that time. More recent studies have reported careful selection criteria for vaginal breech delivery and a cesarean section rate of 20% to 60%. Most of these have shown no difference in short-term outcomes for the fetus.[14,58,79–82] However, this was not accompanied by any reported overall decrease in the rate of birth asphyxia. Moreover, the evidence based on these retrospective reviews of practice remained contradictory. Mecke and associates[80] demonstrated a higher 1-minute Apgar score in breech neonates delivered by cesarean section compared to those delivered vaginally. Babies delivered by cesarean section also had higher pH values at delivery. Similar differences were observed when babies in cephalic presentation were compared by mode of delivery. That the breech delivered vaginally has a lower pH than the cephalic infant or the breech infant delivered vaginally is not in doubt; it is what this difference means clinically that is difficult to ascertain. Despite this continuing uncertainty, the cesarean section rate for breech presentation increased steadily, in some centers during the 1970s from 22% to 94%.

Some specific conditions associated with breech presentation probably increase the chances of trauma during delivery. Fetal neck hyperextension, which can cause damage to the cervical spine, is a contraindication to vaginal birth. Flexed legs appears to increase the risk of cord prolapse to as much as 15% compared with 1.4% to 6% if the legs are extended (the risk of cord prolapse with a cephalic presentation is only 0.24%–0.5%). If the arms are caught across the back of the neck at delivery (nuchal arm), the risk of brachial plexus injury is about 8.5% at term, although 70% of these injuries have resolved fully by 3 months of age.

Until the Hannah trial, there had been only two small randomized controlled trials of the mode of delivery of the term breech. Collea and associates[14] randomized 208 women at term in labor to receive a cesarean section or a vaginal delivery. Despite this intention, 45% of the latter group were delivered by cesarean section. Although there are some caveats about their methodology, they showed no statistically significant differences in short-term neonatal outcome between babies delivered vaginally and babies delivered by cesarean section, either by intention to treat or actual mode of delivery. By contrast, they showed "striking and concerning differences in maternal outcome," with higher maternal morbidity rates associated with cesarean section. Gimovsky and associates[15] recruited 105 women with non-frank breech presentation into another randomized controlled trial. They also showed no statistically significant differences in short-term neonatal outcome. The two meta-analyses of the mode of delivery of the term breech did not significantly challenge these findings.[12,13]

Eventually, the uncertainty about the best management, and the need for reliable information became so great that pressure built up for someone to organize a properly planned randomized trial. Hannah and coworkers accepted the challenge, and in 2000 they published the results of a multicenter randomized controlled trial of the optimum mode of delivery of the term breech.[76] From 121 centers in 26 countries, 2088 women with a frank or complete breech were recruited. By the time the trial ended, 1041 women had been assigned to planned cesarean section, of whom 941 (90.4%) were actually delivered by cesarean section, and 1041 women had been assigned to planned vaginal delivery of whom 591 (56.7%) were actually delivered vaginally. The trial was halted before the planned total had been recruited, on the advice of the data monitoring group because a highly significant difference had already emerged. Perinatal mortality, neonatal morbidity, and serious neonatal morbidity rates were significantly lower for the planned cesarean section group (1.6%) than for the planned vaginal birth group (5.0%) (relative risk 0.33), and there were no significant differences between groups in terms of maternal mortality or serious maternal morbidity rates (3.9% versus 3.2%).[75] These relative differences in outcome between planned cesarean section and vaginal breech delivery persist even when a variety of clinical differences between groups are taken into account: parity, type of breech, whether the fetus was larger or smaller than 3000 g, whether the pelvis had been assessed clinically or radiologically, whether labor was induced or augmented, the use of epidural anesthesia, presentation, the degree of experience of the clinician, and a variety of other clinical parameters that are usually held to be important predictors of the success and safety of attempted vaginal delivery. The only significant interaction was between the treatment group and the countries' reported perinatal mortality/morbidity rate (PNMMR) for the combined outcome of perinatal mortality, neonatal mortality, or serious neonatal morbidity rates. In countries with a low PNMMR (≤ 20 in 1000 births) the

risk from planned cesarean section compared with planned vaginal birth was 0.4% versus 5.7%, whereas the rates in countries with a high PNMMR (>20 in 1000 births) were 2.9% versus 4.4%. This difference in the developed countries disappeared when just the outcome of perinatal or neonatal death was considered. Neonatal morbidity showed the greatest differences according to geography, with reductions in morbidity being much greater for countries with low PNMMRs than for those with high PNMMRs. It is not clear why this might be the case. Possible explanations include incomplete ascertainment of poor neonatal condition in the first week of life or death before morbidity can be recognized. The observation might even be real, possibly because of high levels of experience with vaginal breech birth in countries with low cesarean section rates and high perinatal mortality rates—certainly fewer women allocated to vaginal breech delivery in those countries ended up with a cesarean birth.[83] Overall, this study indicated that, with a policy of planned cesarean section, for every additional 14 cesarean sections done, one baby will avoid death or serious morbidity. In countries with high PNMMR as many as 39 additional cesarean sections would need to be done to avoid one dead or compromised baby, whereas in countries with low PNMMR the number of additional cesarean sections required may be as low as seven.

Vaginal delivery still carries the risk of cord prolapse and extended arms at delivery as well as difficult delivery of the head. This risk may be approximately 1% to 2%.[14] Therefore, obstetric expertise should be maintained for dealing with unexpected breech presentations and for the late presenting (usually previously undiagnosed) breech in labor in whom cesarean section is logistically impossible; this may amount to 11% or more of all breech deliveries.[58] How to achieve this maintenance of competence in an era of few vaginal breech deliveries and many trainees with restricted hours for teaching has not yet been fully established; training on sophisticated mannequins is probably the best approach.

LONG-TERM INFANT FOLLOW-UP

Long-term follow-up studies fall into two main groups: those that review infants born prior to 1970 and those born after 1970. The standards of obstetric and neonatal care have changed so dramatically since 1970 that studies prior to this time demonstrate more about factors other than mode of delivery.

Those studies reviewing later born (1970–1980) children reflect the impact of rising cesarean section rates and more modern obstetric care. They are still mostly retrospective reviews of practice.

In one case-controlled study, breech-delivered infants were compared with cephalic-delivered infants (matched for sex, birth weight, gestational age, maternal age, parity, and year of delivery) at 4 to 10 years of age. A slight excess of minor neurologic dysfunction was found in the breech group but was not statistically significant.[84]

In a population-based study, Danielian and associates[82] compared the long-term outcome of infants delivered in breech presentation at term by intended mode of delivery. They identified 1645 infants from the Grampian region in Scotland during the years 1981 to 1990 who had been delivered alive at term after breech presentation. Elective cesarean section was performed in 35.9% of cases, and 64.1% were intended vaginal deliveries. There were no significant differences in terms of severe handicap, developmental delay, or neurologic deficit up to school age.

A variety of other prospective evaluations of long-term outcome have shown no difference in neurologic outcome, psychomotor problems, or cerebral palsy.[6,85]

Another long-term follow-up of infants born by the breech either spontaneously or using the Bracht maneuver for delivery of the head showed that psychometric and intellectual development were superior in those infants delivered spontaneously.[86]

Despite the fact that many of the studies are of dubious quality, they are remarkably consistent in reporting minimal risk of long-term neurologic damage after careful selection for vaginal delivery: Handicap rates are not demonstrably higher than for babies delivered by cesarean section (after correction for congenital anomalies).

Risk of Breech Delivery for the Mother

The risks of breech delivery to the mother are shown in Table 64–4.

Assessment for Vaginal Breech Delivery (Table 64–5)

All the available literature stresses the importance of adhering to an appropriate protocol when assessing women for vaginal breech delivery. These protocols have produced elective cesarean section rates from 25% to 65%.

Close consultation with the mother and partner and counseling about the implications of the choice of vaginal breech delivery versus elective cesarean section is important. It is the responsibility of the obstetrician to explain the options and the evidence to the woman and her family in the clearest possible terms. Although

TABLE 64-4

Comparison of Risks to the Mother of Vaginal Breech Delivery and Cesarean Section

Risks of vaginal breech delivery for the mother
  Perineal discomfort and morbidity
  Difficult birth experience
Risks of cesarean section for the mother
  Short-term morbidity: increased postpartum pyrexia, increased need for blood transfusion
  Increased maternal mortality rate
  Reduction in future fertility[20]
  Difficult birth experience
  Entering a subsequent pregnancy with a scar on the uterus

TABLE 64-5

Assessment for Vaginal Breech Delivery

Assessment of the cause of breech presentation
Exclude:
Placenta previa
Multiple pregnancy
Fibroids/pelvic tumors
Oligohydramnios/polyhydramnios
Hydrocephalus/anencephaly
Other congenital abnormality
Assessment of fetal condition
Exclude:
Intrauterine growth restriction
Rhesus disease
Fetal abnormality
Other
Assessment of fetal weight and attitude
Assessment of the maternal pelvis
Clinical pelvimetry (important for medicolegal reasons) (x-ray erect lateral pelvimetry no longer advocated)
Computed tomography scanning pelvimetry and magnetic resonance imaging may be unnecessary and unreliable
Assessment of maternal condition
Exclude significant maternal disease: diabetes, proteinuric hypertension, cardiac or renal disease
Assessment of maternal and parental wishes

cesarean section will be the recommended option for the vast majority of women, especially in the developed world, some women when informed of the options will still wish to attempt a vaginal delivery, and their wishes should be respected.

ASSESSMENT OF PELVIC CAPACITY – CLINICAL

Clinical pelvimetry is a low technology screening investigation that is probably of benefit only if there is gross contraction of the pelvis. A subjective assessment of the bony features of the pelvic cavity is made, including the sacral promontory, the curvature of the sacrum, whether the side walls are convergent or the ischial spines prominent, whether the sacrospinous ligaments will accommodate two fingers, whether the intertuberous diameter will accommodate the clenched fist, and whether the pubic arch is greater than 90 degrees. The success or otherwise of clinical pelvimetry is hard to assess, and most discussions about the assessment of pelvic capacity center on x-ray pelvimetry. With regard to a clinical assessment of the size of the pelvis, a consideration of the woman's height alone is probably useful.[87]

ASSESSMENT OF PELVIC CAPACITY

No prospective randomized trials have ever been performed to assess the value of x-ray pelvimetry. There is no absolute level of pelvic contraction as assessed by x-ray below which vaginal delivery is impossible, and antenatal assessment of fetal weight is probably a more important determinant of the success of attempted vaginal delivery.[87,88] One report, comparing three different protocols for the assessment for vaginal breech delivery, concluded that the one that did not include x-ray

pelvimetry produced a lower elective cesarean section rate and similar emergency cesarean section rates to protocols that included x-ray measurements. The authors concluded that progress in labor is the best indicator of pelvic adequacy.[89]

There is one reported study of the comparison of ultrasound with x-ray for determining the obstetric conjugate.[73] They found a highly significant correlation between the two measurements, but ultrasound measurements were consistently found to be 1 cm smaller than the x-ray values.

The advantage of computed tomography (CT) scanning for pelvimetry is clear: it will reduce the radiation dosage and is more accurate.[77] However, there is no evidence that it will predict the outcome of a trial of vaginal breech delivery any better than standard pelvimetry. Normal measurements do not guarantee vaginal delivery, and the Royal College of Obstetricians and Gynaecologists has concluded that no data support the routine use of radiologic pelvimetry before term breech delivery.[72]

One randomized controlled trial of magnetic resonance (MR) pelvimetry has been performed. Two hundred thirty-five women had MR pelvimetry and were then randomly assigned to two groups. In the study group, the results of the pelvimetry were disclosed to the clinicians who used them to decide on the optimal route of delivery. In the control group the clinicians assigned the route of delivery after consideration of other clinical factors alone. The authors found that the overall cesarean section rate was the same, although the emergency cesarean section rates were lower in the MR group. There were no significant differences in the baby's condition at birth or in the early neonatal period between the two groups.[90]

CRITERIA FOR SELECTION FOR VAGINAL BREECH DELIVERY

Various criteria have been proposed. In summary, the fetus should be neither too small nor too big and should have a well-flexed head; the mother should have at least an average capacity pelvis, judged clinically; and the mother and the baby should be in "good" condition.

An estimated fetal weight of 1500 to 3900 g is probably appropriate (for discussion of the delivery of the preterm breech, see previous section); however, the limits of fetal weight and gestation are contentious, with many different limits being suggested. In addition, clinical estimation of fetal weight is unreliable, and even when ultrasound is used, there is a margin of error of ± 15%. The error of the estimation of weight is greater in the breech than the vertex fetus.

It is probably wise to perform a clinical pelvimetry to exclude the obviously contracted pelvis, but x-ray pelvimetry should not be done because there is no clear evidence of its value and there is inevitably some very small risk from the radiation involved in its use. It is good practice and probably wise from the medicolegal point of view to explain this to the mother before labor.

Some authors would exclude the nulliparous woman with a breech from consideration of vaginal delivery, yet others consider the grand multiparous patient also at high risk.[10] The evidence for either proposition is not compelling. The fetus should ideally be in frank or complete breech presentation (not a footling), and absence of detectable congenital abnormality should be confirmed using ultrasound.

It is commonly assumed that the undiagnosed breech in labor is at higher risk of complications than those that have been diagnosed prelabor and adequately assessed for suitability for trial of vaginal delivery. However, the experience of some authors[91,92] is that these women do well and are more likely to deliver vaginally with no greater mortality or morbidity rates than those diagnosed and assessed prior to labor. They suggest that there are no grounds for delivering all undiagnosed breeches in labor by cesarean section.

<div style="text-align:center">PROCEDURE – VAGINAL BREECH DELIVERY</div>

PRACTICAL CONSIDERATIONS IN THE CONDUCT OF ASSISTED VAGINAL BREECH DELIVERY

The essence of the assisted vaginal breech delivery is allowing as much spontaneous delivery by uterine action and maternal effort as possible. Operator intervention should be limited to the maneuvers described here, which are designed to correct any deviation from the normal mechanism of spontaneous delivery. The operator may make the delivery more complicated by injudicious traction that encourages displacement of the fetal limbs from their normal flexed position across the fetal body or by promoting hyperextension of the fetal head. Traction can also cause injury of itself. The fetal body should, at all times, be treated with the utmost care and grasped, if at all, by the bony parts. Some authors recommend using a towel to cover the baby to prevent friction injury, to improve grip without the need for too much squeezing, and to keep the baby warm. Within these limits, there are many described procedures for the vaginal delivery of the breech.

First Stage

Many authors suggest that spontaneous labor increases the chance of successful vaginal delivery, and that if delivery is required before the onset of spontaneous labor, elective cesarean section is preferable to induction of labor.

Labor should be conducted in a labor ward with all the facilities needed to perform a cesarean section, with a full anesthetic service and senior obstetric staff available. The woman should be instructed to arrive early in labor so that her progress and the condition of the fetus may be monitored. Similarly, if the membranes rupture, she should attend the hospital because of the risks of cord prolapse. Rupture of the membranes at any point during the labor should prompt immediate vaginal examination.

On presentation in labor an intravenous line should be sited and blood taken for typing and to save serum. Because of the relatively high risk of cesarean section, oral intake should be avoided for the duration of the labor. After the usual assessment of the woman in labor she should be told that continuous electronic fetal monitoring is advisable and that an epidural anesthetic may be preferable. The latter will make any manipulation in the second stage more comfortable and make any urge to push prior to full dilation easier to resist. Bearing down prior to full dilation may push the relatively smaller breech through the incompletely dilated cervix and entrap the after-coming head behind the cervix. Epidural anesthesia is not essential, and some obstetricians suggest that there is a higher chance of spontaneous vaginal delivery without one. Chadha and associates[93] reported that epidural analgesia was associated with a longer duration of the second stage, an increased need for augmentation of labor with oxytocin infusion, and a significantly higher cesarean section rate in the second stage of labor. There is little doubt that epidural anesthesia obtunds the urge to bear down. However, the counter argument is that if a baby does not deliver easily with an epidural in situ, then it is better delivered by cesarean as there is likely to be mild relative disproportion. Because there is no clear scientific evidence to resolve this issue, it seems appropriate at the present time to allow the woman a major degree of personal choice in this respect. Whatever she chooses, however, an anesthetist should be in attendance during the second stage of labor in case rapid anesthesia should be required for an unexpectedly difficult delivery. Although on first principles the use of oxytocics should be avoided because of the risk of uterine hyperstimulation and consequent fetal hypoxia, in practice if the labor progress is slow, there is no evidence that the careful use of oxytocin is dangerous. Oxytocin is particularly appropriate if there is a primary dysfunctional labor (slow progress in the active phase, less than 1 cm cervical dilation every 2 hours). The use of an intrauterine pressure transducer may reassure the obstetrician that excessive uterine activity is not being generated. The other fear with oxytocin is that its use will produce descent of the breech in the presence of fetal-pelvic disproportion; hence, the disproportion will be detected only when the head is entrapped above the pelvic brim and the body is already delivered. The bitrochanteric diameter is usually smaller than the biparietal, and if the former does not easily traverse the pelvis, neither will the latter. However, Collea and associates[14] demonstrated that the use of oxytocin in selected patients does not produce an excess rate of maternal or neonatal complications.

Failure to make expected progress in cervical dilation or for the breech to descend appropriately in the first 4 hours of labor, or the appearance of cardiotocographic abnormalities, should prompt careful consideration of whether cesarean section is advisable. Total labor duration should be similar to that in cephalic presentation, although descent of the breech may be slow. The progress of the labor should therefore be plotted on a partogram in the usual way. There

is evidence that the use of the World Health Organization partogram in breech labor reduces the incidence of prolonged labor, reduces the incidence of cesarean section (at least in multigravidae), and improves the condition of the neonate at birth.[94] This probably reflects the importance of good progress in labor as a favorable prognostic variable for successful vaginal breech delivery.

Meconium staining of the liquor is common in breech labor, and its predictive value for asphyxia is poor. In early labor it is often found on the glove at the end of a vaginal examination. Its passage when the breech is still high in the birth canal in first stage may indicate "fetal distress," and careful evaluation of the fetal heart rate pattern at this stage will be necessary. However, the passage of meconium in the second stage is almost universal and is of no prognostic value. Cardiotocographic fetal heart rate abnormalities should be investigated using fetal blood sampling, preferably obtaining the blood from the region around the ischial tuberosity and avoiding the genitalia. The blade may have to be pressed firmly onto the buttock in order to ensure a good flow of capillary blood. There is no evidence that an adequate sample of blood obtained in this way has a different pH than blood obtained from the fetal scalp, and so the usual criteria of acidosis can be applied.

Second Stage (See Fig.64–1)

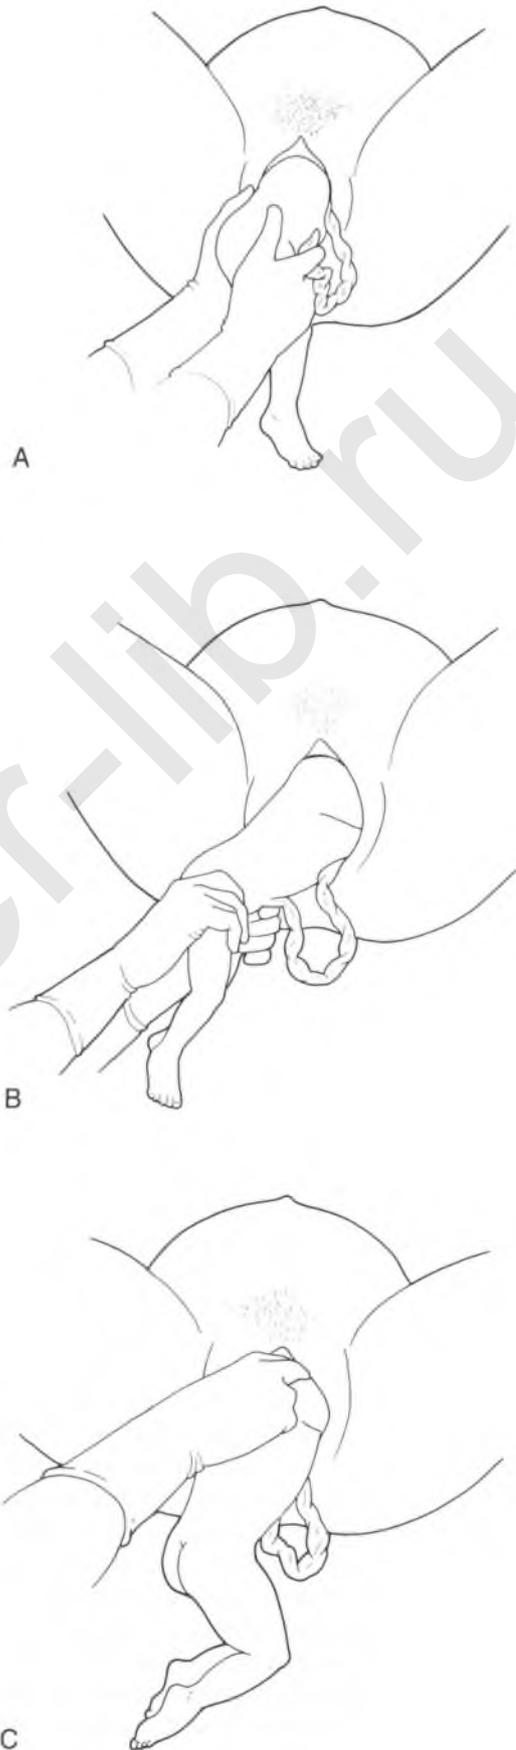
The second stage should be supervised by an experienced obstetrician (Fig. 64–1). The active second stage with vaginal breech delivery does not start until the cervix is fully dilated and the fetal anus is seen on the perineum without having to part the mother's labia. The woman should then be placed in the lithotomy position with her buttocks just over the end of the delivery couch. She should be cleaned and draped as for ventouse or forceps delivery. Care should be taken to avoid the completely supine position in case this causes hypotension secondary to caval compression, and lateral tilt using a wedge is probably advisable. It is best if the bladder and lower bowel are empty, and elective bladder catheterization is probably advisable, with an "in and out" catheter. Routine enemas are not, however, usually recommended. If effective regional anesthesia is not in place, a pudendal block with perineal infiltration should be used. An episiotomy is generally advised and should be performed at this point. An episiotomy will always be required if forceps are to be used to achieve delivery of the after-coming head, if extensive manipulation of the fetus is anticipated, and in all nulliparas. The breech, legs and abdomen should be allowed to deliver spontaneously to the level of the umbilicus; the only intervention recommended up to this stage is to correct the position to sacroanterior if it is not this already. At this point the obstetrician should deliver the legs, if they are extended, by abduction of the thigh and flexion of the fetal knee (using finger pressure in the popliteal fossa), allowing the fetal thigh to pass lateral to the fetal body. A loop of umbilical cord should then be brought down to minimize traction and possible tearing with consequent loss of fetal blood. The prognostic significance of the absence of cord


FIGURE 64–1
The second stage of vaginal breech delivery. Delivering the shoulder by Løvsett's maneuver.

pulsation is controversial. Fetal condition is probably better assessed by noting fetal tone and color.

Delivery to this point should ideally have been achieved with one contraction and one maternal expulsive effort. Delivery of the rest of the body, to delivery of the mouth, should be achieved over the next one or two contractions. The duration of time that should be allowed to elapse between delivery just below the umbilicus to delivery of the mouth is 5 to 10 minutes. Arulkumaran and associates[95] examined two different ways of delivering the breech. They allowed spontaneous delivery to the hip with one contraction, and maternal effort followed by an assisted delivery of the rest of the body and head in the next contraction in one group of women, and in another group they assisted delivery to the shoulders with one contraction and then an assisted delivery of the head was performed with the next contraction. The former method produced babies with a smaller fall in fetal blood pH and in better condition at delivery, judged by the Apgar score and need for ventilation. They hypothesized that this was due to exposure, stretching, and compression of the umbilical cord over a longer period of time during the delivery of the latter group, or possibly due to premature separation of the placenta. It should be noted, however, that the pH and the Apgar scores are anyway usually lower in vaginally delivered breeches than in babies delivered head first.[84]

Once the legs and abdomen have emerged, the fetus should be allowed to hang from the vulva until the wing of the scapula is seen. The arms are often found folded over the fetal chest, flexed at the shoulder and elbow, and in this case no particular maneuver is required to effect their delivery. If injudicious traction is exerted in order to deliver the breech, the arms may become extended over the fetal head. In this case the Lovsett's maneuver may be used to free the arm. This involves wrapping the fetus in a warm dry towel and grasping the body over the bony pelvis with the thumbs along the sacrum. The fetal back should then be turned through 180 degrees until the posterior arm comes to lie anteriorly. The elbow will appear below the symphysis pubis, and that arm and hand can be delivered by sweeping it across the fetal body. This maneuver is repeated in reverse to deliver the other arm. If these maneuvers fail, the traditional last resort is to induce deep anesthesia and push the body of the fetus well up, pass the hand along its ventral aspect and bring down the most accessible arm. This may then allow completion of vaginal birth. However, having pushed the fetus up successfully, it may well be safer to proceed with cesarean section.[95] The nuchal arm, where the arm is flexed at the elbow and extended at the shoulder coming to lie behind the fetal head, may be dealt with by a modified Lovsett's maneuver: rotating the fetal back through 180 degrees in the direction of the trapped arm may draw the elbow forward toward the face and over the fetal head by friction on the birth canal and render it amenable to a traditional Lovsett's maneuver to deliver the arm. If this technique does not suffice to release the nuchal arm, it may be forcibly extracted by hooking the finger over it, in which case it is almost always fractured.

The fetus should be allowed to hang from the vulva for a few seconds again until the nape of the neck is visible at the anterior vulva. This allows descent of the head into the pelvis and at this point the head may be delivered. Downward traction before spontaneous descent may result in hyperextension of the fetal head rather than flexion and descent, so again, operator interference can cause complications in the delivery. If the head negotiates the inlet of the pelvis easily, there is little danger that the progress of the head will be arrested in midcavity. If there is difficulty with the head in the midcavity, or the outlet, a properly performed Mauriceau-Smellie-Veit maneuver will overcome this (see later full description). Should the head fail to descend into the pelvis after the shoulders have delivered, the body of the fetus should be turned sideways and suprapubic pressure used to flex the head and push it into the pelvis in the occipitotransverse position. A vaginal finger in the mouth of the fetus may also tend to flex the head and help it to descend into the pelvis prior to delivery. A McRoberts maneuver can be used to facilitate delivery of the head if it is arrested at the inlet and suprapubic pressure and the Mauriceau-Smellie-Veit maneuver have failed. This involves a sharp flexion of the maternal thighs toward the maternal abdomen, and abduction of the legs, in a way directly analogous to the management of shoulder dystocia in the vertex delivery.[96] Continued failure of the head to descend into the pelvis may be due to hydrocephalus, in which case the head can be perforated through the foramen magnum (an epidural needle is a suitable instrument) and the cerebrospinal fluid drained. Such a maneuver should be performed only if the diagnosis has been confirmed by ultrasound and the fetus is already dead. Alternatively, the cervix may not be fully dilated, in which case the cervix must be incised. This is done with round-ended scissors, and the incisions made at 4 and 8 o'clock to avoid the bladder and rectum and the main blood vessels (which supply the cervix at 3 and 9 o'clock). If there are locked twins, there is no choice but to do a cesarean section; the traditional technique of decapitating the first twin is no longer acceptable. If none of these causes is present, then the operator must assume that cephalopelvic disproportion is present and there is then a strong case for the performance of a symphysiotomy.[97] With proper predelivery assessment and conduct of labor this situation should only arise very rarely.

PERFORMING A SYMPHYSIOTOMY (Fig. 64–2)

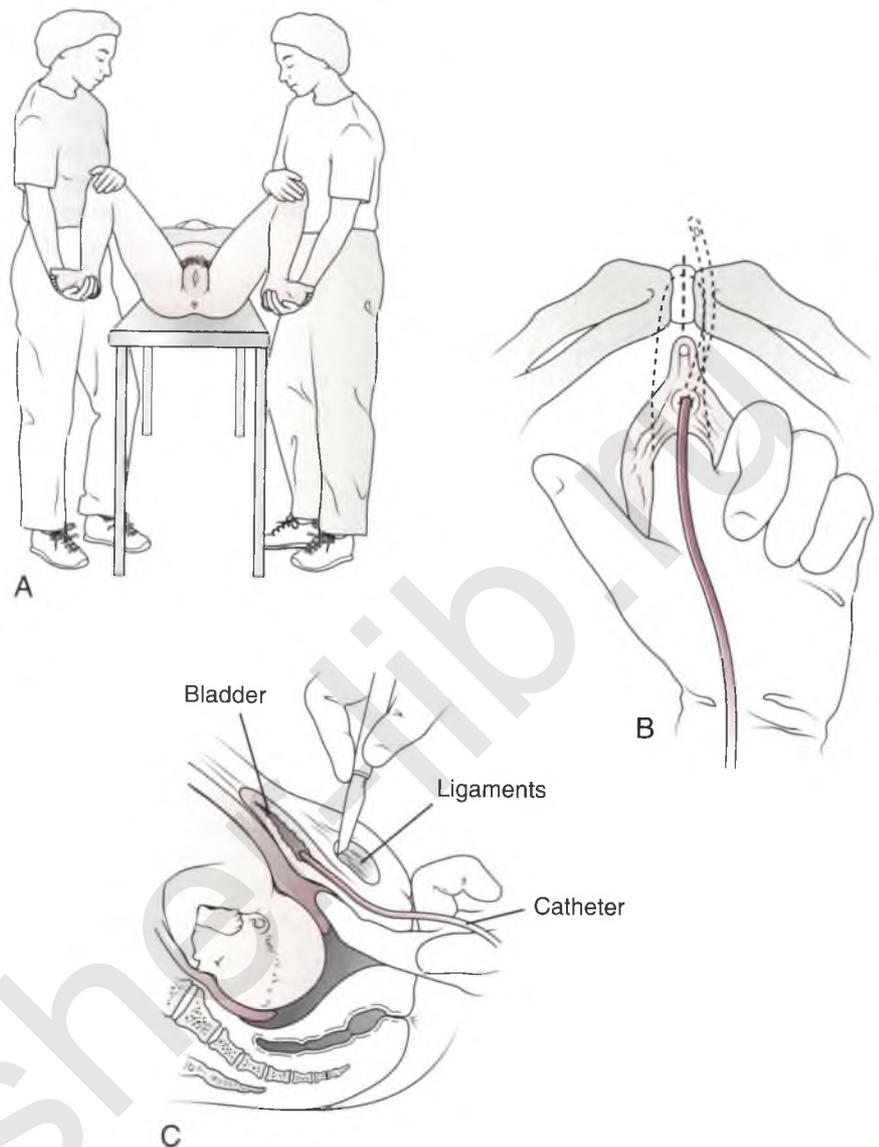
The episiotomy should be enlarged. If the mother does not have epidural analgesia, the anterior, superior, and inferior aspects of the symphysis should be infiltrated with lidocaine 0.5%. The usual precautions to prevent intravenous injection should be taken. While waiting for the analgesia to take effect, an indwelling urinary catheter should be inserted. The suprapubic skin should then be cleaned with antiseptic solution. Following this, the index finger should be placed in the vagina and lateral pressure applied to the catheter to move the urethra away from the midline. A thick, firm-bladed


FIGURE 64–2
Performance of a symphysiotomy. *A*, Position of the woman for symphysiotomy. *B*, Pushing the urethra to one side using a finger to press on the urinary catheter. *C*, Incising the symphysis, with the finger pushing the urethra to one side, to avoid damaging it with the knife. (From WHO: Managing complications in pregnancy and childbirth: A guide for midwives and doctors. Accessed at www.who.int/reproductive-health/impac/procedures/symphysiotomy_P53_P56.html)

scalpel should then be used to make a vertical stab incision over the symphysis. Keeping to the midline, the knife should be pressed down through the cartilage joining the two pubic bones until the pressure of the scalpel blade can be felt on the finger in the vagina. If the cartilage is not fully divided, the blade can be rotated and the cutting movement can be made back toward the top of the symphysis to finish the process. Following the delivery, there is no need to close the incision unless there is bleeding. It is, however, wise to give prophylactic antibiotics, e.g. ampicillin, gentamicin, and metronidazole. Elastic strapping from one iliac crest to the other will reduce postoperative pain, but analgesia will be necessary. The urinary catheter should be left in situ for a minimum of 5 days.

Techniques for Delivering the Head (See Fig.64–3)

It should be remembered that entrapment of the after-coming head can also occur with cesarean section, especially if an inadequate-size abdominal incision has been made.

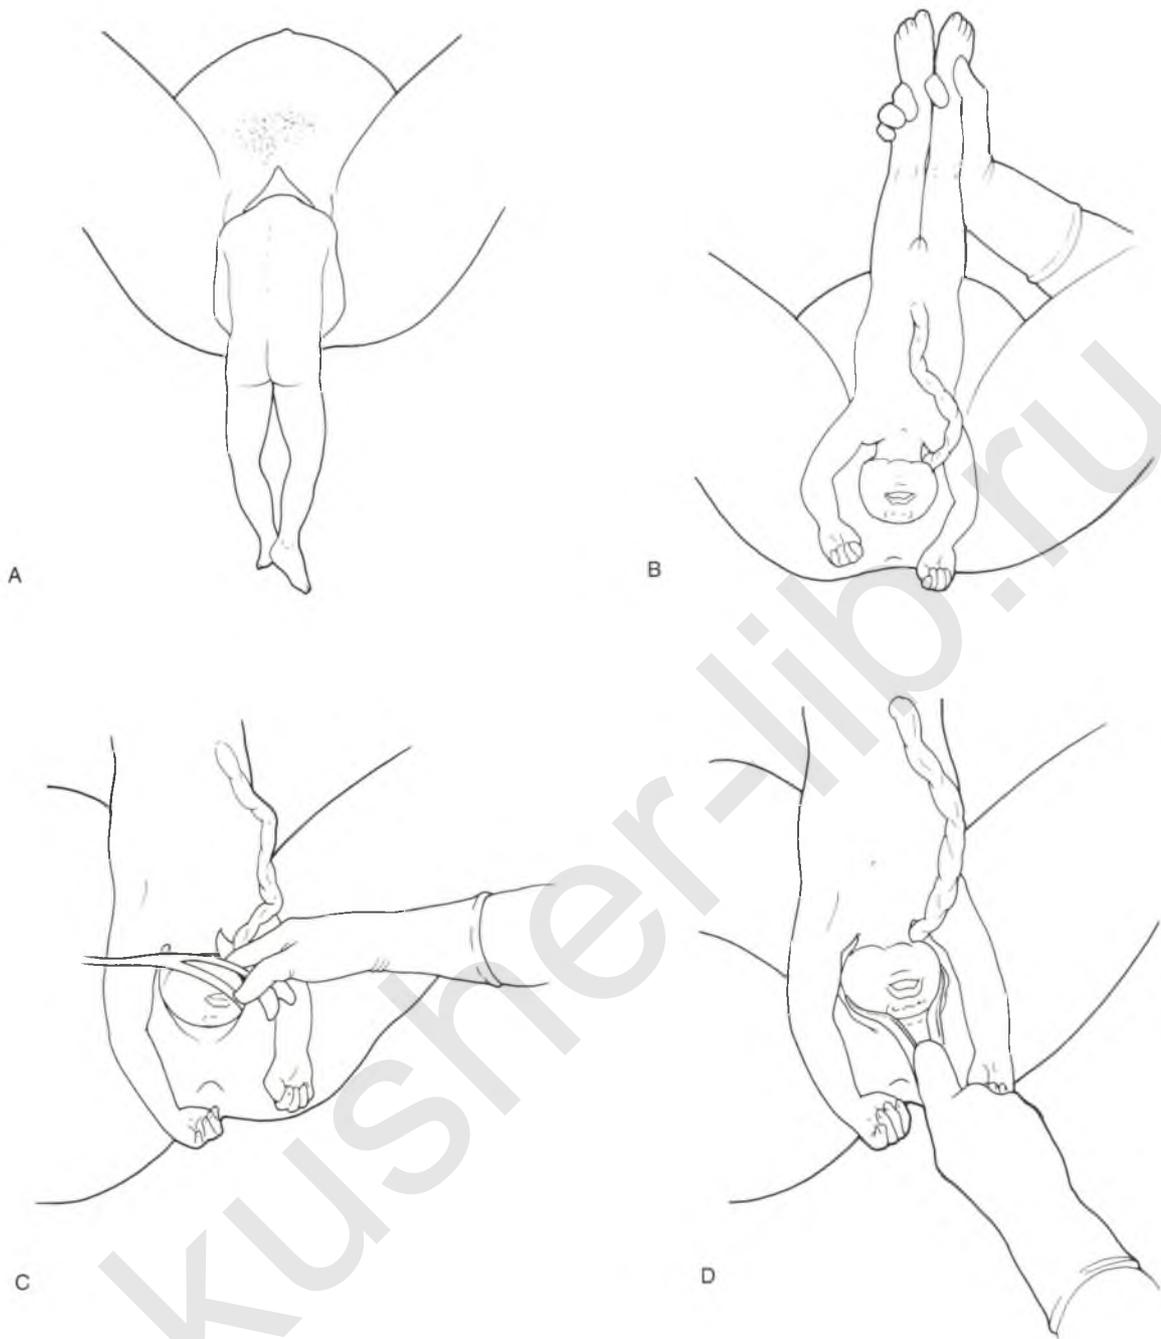
Robertson and associates[26] found no significant difference in the incidence of head entrapment by mode of delivery from 28 to 36 weeks' gestation, nor any association with adverse outcome following head entrapment. The techniques for delivery of the after-coming head are various (Fig. 64–3). Some authorities advise that the body should be supported on the right forearm of the operator and not be raised above the horizontal in order to minimize the chance of hyperextension of the fetal head. Others advise that the operator's assistant should grasp the ankles of the fetus and raise the body vertically above the mother's abdomen prior to any attempt to deliver the fetal head, as this will promote rotation of the fetal head and place it in the anteroposterior diameter of the pelvis. This is called the Burns-Marshall technique and may rotate the head and deliver it over the perineum without further intervention. It is therefore advisable to cover the perineum with the hand to prevent precipitate delivery of the head as the body is swung upward. The operator's hand can then be opened slowly in order to


FIGURE 64–3
Forceps delivery of the aftercoming head. *A*, Allowing the trunk to hang flexes the head and encourages descent. *B*, Once the head is in the pelvis, rotating the trunk over the mother's abdomen delivers the face. *C*, Applying forceps to the aftercoming head. *D*, Forceps used to control the rate of delivery of the head.

allow the rest of the head to deliver. Often, however, further assistance is required to deliver the head. The head may be delivered from this position using forceps applied below the fetal body. The operator should remember that the smallest part of the head is lowest in the vagina and that the tip of the forceps blade must accommodate the occiput; therefore, premature straightening of the forceps blade during application will cause undue pressure on the side of the fetal head. Forceps should be of a type with a long enough shank to permit the operator to visualize the maneuver, as often the

fetal arms obstruct the view, and if the fetal body is in the horizontal position, access is further reduced. The head should be delivered slowly (over about 1 minute) to reduce the compression-decompression forces on the fetal skull that may cause tentorial tears and intracranial bleeding.

The other frequently described technique of delivering the fetal head is the so-called "Mauriceau-Smellie-Veit" maneuver. This is actually a variety of techniques. The principle is that of traction down the axis of the birth canal while encouraging flexion of the fetal head to present the

most favorable diameters to the pelvis. With the fetus supported on the right forearm, the middle finger of the right hand is passed into the fetal throat and the forefinger and the ring finger are placed either on the fetal shoulders or the malar eminences. Pressure is applied on the tongue to flex and deliver the head. The middle finger should not be just inside the fetal mouth, as traction can produce dislocation or fracture of the mandible. If the finger is inserted too far down the throat, creation of a pseudodiverticulum of the pharynx has been described. The left hand is used to exert pressure upward and posteriorly on the fetal occiput to encourage flexion. Alternatively, suprapubic pressure can be applied to encourage head flexion and descent. All these maneuvers can be performed with the operator's assistant elevating the fetal body above the horizontal. Downward traction on the fetal shoulders tends to stretch the cervical spine and in combination with flexion of the fetal head will draw the base of the skull away from the vault, thus causing a tentorial tear. Therefore, traction on the trunk should not be used. All these permutations have been described by various authors as the Mauriceau-Smellie-Veit maneuver.

A pediatrician should always be present at the delivery, and ideally the mouth and pharynx should be sucked out on the perineum prior to complete delivery of the head, although often the head delivers too quickly for this to be done.

The Zavanelli maneuver has also been described for the delivery of the breech with an entrapped after-coming head. Tocolysis is used to facilitate replacement of the fetal body into the uterus, and cesarean section completes the delivery.[98] As experience with this maneuver is very limited, its use in this desperate situation remains controversial.

Considerations in the Performance of Breech Extraction (Fig. 64–4)

Currently, breech extraction is rarely performed because of the risks of fetal and maternal trauma and because of the effects of excessive traction on the fetal body. Its main current indication is for the delivery of a second twin after internal podalic version, or if cord prolapse complicates the late second stage. It may also be appropriate if the fetus is dead. Groin traction is performed to draw the breech over the perineum, Lovsett's maneuver is employed routinely, and downward traction is exerted to bring the head into the pelvis. In effect, all the stages of assisted breech delivery are achieved actively by the obstetrician.

Choice of Mode of Delivery

CESAREAN SECTION

Practical considerations in the performance of cesarean section for the delivery of the term breech. The orthodox obstetric practice of considering any woman with a breech presentation and any other medical or obstetric complication for delivery by elective cesarean

A

B

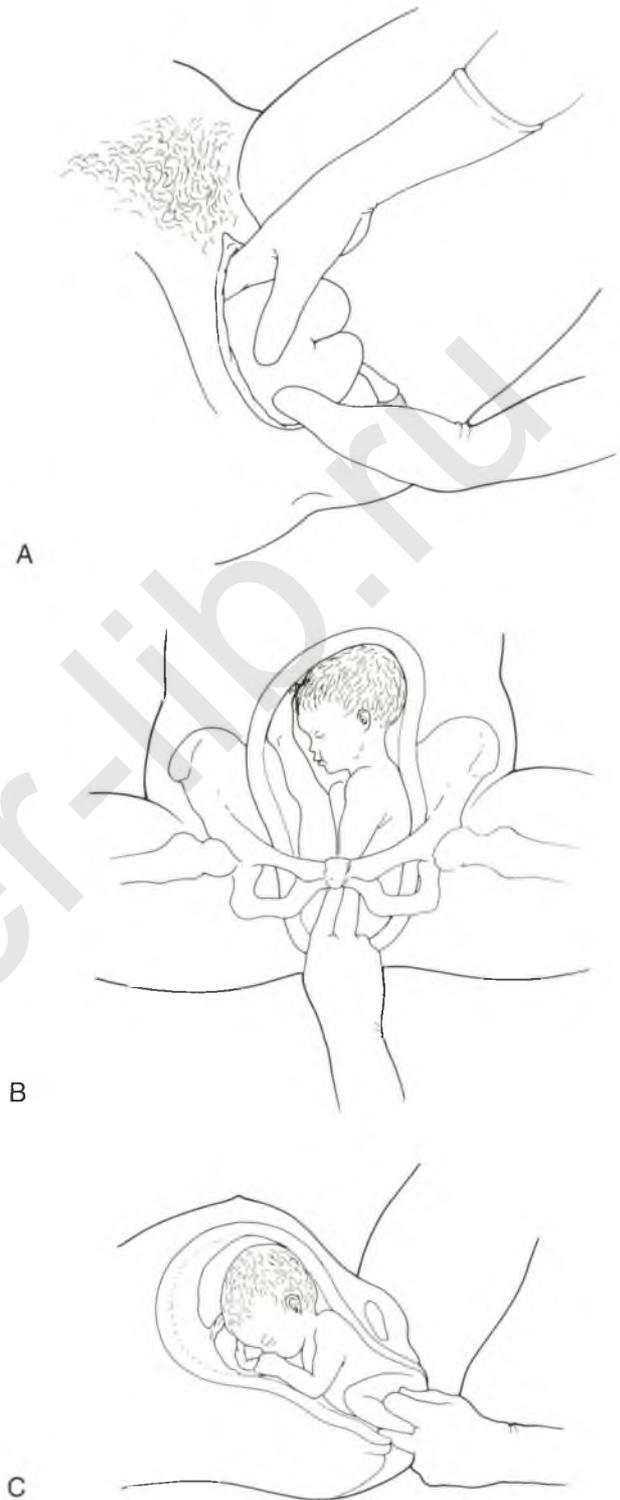
C


FIGURE 64–4
Active breech delivery (Breech extraction).

section has much to recommend it. Elective and even emergency cesarean section for the term breech should present few technical problems. It should be remembered that the performance of a cesarean section does not prevent the possibility of birth injury and many of the foregoing considerations about the careful delivery of the after-coming head and the dangers of traction on the

fetal spine still apply. The lower segment will be the site of choice for the incision with a term breech presentation. Schutterman and Grimes[99] reviewed 416 breeches of all gestations allocated randomly to transverse or low vertical incisions in the uterus and found no advantages for low vertical incisions. An elective cesarean section when adequate liquor is still present and the uterus is less likely to contract rapidly before completion of delivery of the breech will present few problems to the experienced operator. Forceps may be employed for delivery of the after-coming head. Cesarean delivery at full dilation in the absence of liquor may be difficult because an arm may prolapse through the uterine incision; it should immediately be pushed back. Instead, a leg should be grasped and brought through the incision. Traction will then effect the rest of the delivery. The head can be trapped by a well-contracted lower segment, and the incision will then need to be enlarged in a J-shaped fashion to increase access. In general the mode of effecting delivery through the uterine incision is the same as for vaginal breech delivery, and many of the same complications may arise.

The fetal head may become entrapped in the uterine incision at the point of delivery, as the lower uterine segment contracts rapidly down. For this reason, even at an elective cesarean section it is prudent to have a pediatrician present for delivery. Because of this complication, uterine tocolysis has been evaluated to see if its use improved the ease of delivery or the condition of the fetus at birth. Ritodrine was compared with nitroglycerin and no therapy. No effect was found for the fetus or the mother, and the incision-delivery interval was not significantly different. Tocolytics cannot be recommended for routine deliveries but might be useful when delivery is expected to be difficult or traumatic.[100]

Deficiencies in the conduct of vaginal breech deliveries, resulting in perinatal death, have been systematically evaluated in a blinded case-controlled audit. The authors concluded that infant death at term was to a large extent potentially avoidable but that in control breech infants who survived, suboptimal care was not uncommon.[84]

ACTIVE BREECH DELIVERY

With increasing consumer pressure over the last few years toward less interventionist obstetrics, a demand for an active method of delivering the breech has appeared. This demand has been satisfied in the United Kingdom by a group of mainly midwife practitioners who perform the so-called "active breech delivery." This encourages women to be active during labor, and although encouraging the woman to adopt the most comfortable position during labor, they favor a standing position for the delivery itself. They emphasize nonpharmacologic analgesia, and encourage maternal participation in the birth. The breech is usually allowed to deliver spontaneously without any interference from the birth attendants. The author's experience of 21 of such deliveries being conducted in her own maternity unit is that one baby died during the final stages of birth, one definitely has persisting neurologic damage, and another may have. In the light of these poor outcomes, the technique cannot be recommended.

CONCLUSIONS

For the Preterm Breech in Labor:

- Exclude, as far as possible, congenital abnormality and placenta previa.
- Accurately determine and confirm presentation (preferably with ultrasound).
- Accurately diagnose and confirm preterm labor by careful vaginal examination, cervical ultrasound, and biochemical markers (see Chapter 61).
- Carefully observe fetal and maternal condition.
- Use epidural anesthesia (with maternal agreement).
- Involve an experienced obstetrician.
- Clear-cut recommendations about the optimal mode of delivery will have to await the performance of a properly conducted trial, which in the light of previous experience, seems unlikely ever to be performed. In the absence of such evidence, the decision about the mode of delivery should be reached after close consultation with the laboring woman and her partner.

For the Term Breech (37 weeks and over):

- The presence of breech presentation in both the term and the preterm pregnancy confers an increased risk on the fetus regardless of the mode of delivery. This increased risk is only partly due to an increased rate of congenital malformations.
- The use of external cephalic version in the appropriately assessed woman after 37 weeks' gestation shows a clear benefit in the reduced numbers of cesarean sections and an increased rate of vaginal delivery in the cephalic position and has a good safety record.

CONCLUSIONS *(Continued)*

For the Term Breech (37 weeks and over): (Continued)

- There is now convincing evidence that women with a term breech should be advised that planned elective cesarean section reduces the risk of death or serious morbidity for the fetus with no evidence of increased morbidity in the mother.
- Despite this, some women (particularly in less developed countries) may still choose to try to deliver vaginally.
- Consideration for vaginal delivery:
  - Fetal morphology
  - Estimated fetal weight
  - Fetal attitude
  - Fetal well-being
  - Placental location
  - An assessment of the maternal pelvis
  - Assessment of any maternal conditions that would preclude vaginal delivery
- Approximately 50% of women who go into labor with a breech fetus at term will require an emergency cesarean section.
- Approximately 10% of breech presentations at term will be undetected until presentation in labor; because of this, vaginal breech deliveries will continue to occur, and thus, the skills to accomplish vaginal breech delivery as safely as possible should not be forgotten.

SUMMARY OF MANAGEMENT OPTIONS
Breech Presentation

Management Options	Quality of Evidence	Strength of Recommendation	References
Term Breech Presentation			
Fetal Assessment			
Confirm diagnosis and determine placental site.	–	GPP	–
Confirm normality as association of breech presentation with congenital anomalies.	III	B	10
Version in Prenatal Period			
There is insufficient evidence to advocate postural methods to promote spontaneous version.	Ia	A	46
External cephalic version (ECV) at 36+ weeks' gestation should be recommended.	Ia	A	48
Tocolysis increases the success of ECV.	Ib	A	54,55,56
There is insufficient evidence that epidural anesthesia increases the effectiveness of ECV.	Ib	A	57
Need for fetal heart rate monitoring before and after ECV.	III	B	45
If the Woman Chooses to Attempt a Vaginal Delivery			
The health of the mother and baby should be assessed.	IV	C	72
Ultrasound should be performed to confirm the diagnosis, check for fetal abnormalities, and assess placental site, fetal attitude, and estimated fetal weight.	IV	C	72,75
A written protocol is advisable, and a skilled birth attendant for labor and delivery is mandatory.	IIb	B	76
Pelvimetry need not be used routinely.	III	B	72,87,89

SUMMARY OF MANAGEMENT OPTIONS
Breech Presentation (*Continued*)

Management Options	Quality of Evidence	Strength of Recommendation	References
Labor and Delivery			
Evidence is that planned cesarean section for breech at term is the preferred method of delivery because it significantly reduces perinatal mortality and morbidity rates.	Ia Ib	A	12, 13 76
Preterm Breech Presentation			
Prenatal			
There is insufficient evidence that ECV before term offers any benefit.	Ia	A	42, 53
Labor and Delivery			
There is insufficient evidence to recommend cesarean section for the preterm breech.	Ib	B	41
For the preterm breech in labor an ultrasound scan should be performed to confirm the presentation and normality; the mode of delivery should be determined in close consultation with the woman and her family.	IV	C	72

Unstable Lie, Malpresentations, and Malpositions

I. Z. MacKenzie

INTRODUCTION

Near term and during labor, the fetus normally assumes a longitudinal lie and presents with the cephalic pole to the maternal pelvis with the neck flexed and the vertex in the lowermost part of the uterus. In approximately 5% of labors, the lie is not longitudinal. This is usually associated with dangers to both mother and fetus and demands intervention. As with much of medicine, the prior identification of the pregnancy at particular risk of an unstable lie, malpresentation, or malposition can allow intervention in advance of a complication developing and improve the outcome for mother and baby. This chapter will not consider issues relating to fetal breech presentation as these are dealt with elsewhere (see Chapter 64).

DEFINITIONS

Unstable Lie

This is a description generally used beyond 37 weeks' gestation when the fetal lie and presentation repeatedly change, the lie varying from longitudinal, to transverse, and oblique, and the presentation from cephalic, to back, limbs, breech, or a combination. By 37 weeks the fetus usually adopts a "stable" lie and a presentation that will be unchanging until labor and delivery; the fetal position, describing the relationship of the fetal back to the maternal side may, however, change.

Malpresentation Including Compound Presentation

This refers to the fetus that does not present to the maternal pelvis by the vertex alone. The presenting part is defined as that part of the fetus that is lowermost in the uterus. Alternatives include face, brow, breech, and shoulder, as well as compound presentations that involve more than one fetal part, including a combination of the head or breech with a limb or limbs or umbilical cord or a combination of limbs with or without the umbilical cord.

Malposition

A fetal malposition refers to when the fetal vertex presents to the maternal pelvis in a position other than flexed in an occipitoanterior position. Malpositions include occipitotransverse and occipitoposterior positions and may involve some degree of asynclitism (sideways tilt of the head).

Figure 65–1 is an illustration of the various positions that the vertex and brow or face may adopt during labor.

ETIOLOGY

Unstable Lie

Unstable lie is much more common in parous than nulliparous women, but may be caused by or associated with a number of factors. Any situation that discourages or prevents the fetal head or breech from entering the maternal pelvis will predispose to an abnormal and unstable fetal lie. Figure 65–2 illustrates some of the factors associated with an unstable fetal lie.

Maternal Factors

HIGH PARITY

Increasing muscle laxity in the maternal anterior abdominal wall so that it fails to act as a brace and encourage

Vertex presentations

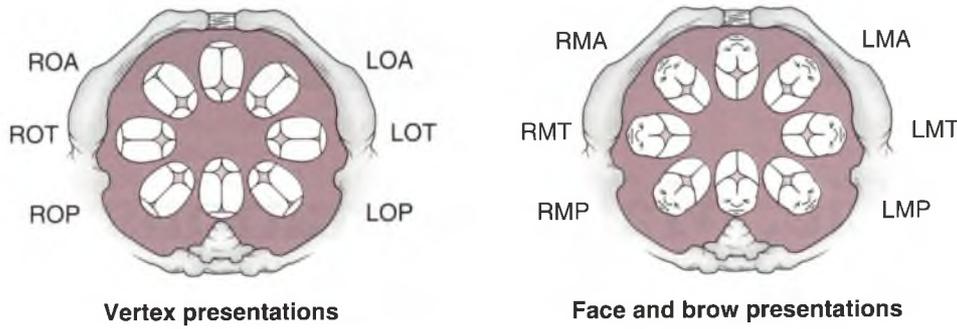
Face and brow presentations


FIGURE 65–1
Diagrammatic representation of the positions for vertex and face presentations. A, anterior; L, left; m, mento; O, occipito; R, right; T, transverse.

and maintain a longitudinal fetal lie is probably the most frequent associated factor. In addition, there is a commonly held view that the highly parous uterus has reduced myometrial tone, thereby encouraging an unstable lie; this has not been proven and is of doubtful relevance.

PLACENTA PREVIA

A persistently changing fetal lie may be the only clinical feature leading to the diagnosis of placenta previa. In addition, a placenta situated in the fundus may also predispose to an unstable lie.[1]

PELVIC TUMORS

Ovarian cysts and low-lying fibroids can obstruct the fetal head or breech entering the pelvis and may result in a high head or breech and transverse or oblique lie.

UTERINE MALFORMATION

Uterus cordiformis, subseptus, or septus may be causative. More severe forms of uterine anomaly, including uterus bicornis and uterus didelphys, are less likely to lead to an unstable lie due to the restricted uterine capacity; a predisposition to fetal breech presentation, however, results.

High parity
Uterine anomaly
Pelvic cyst or fibroid
Distended bladder
Pelvic contracture

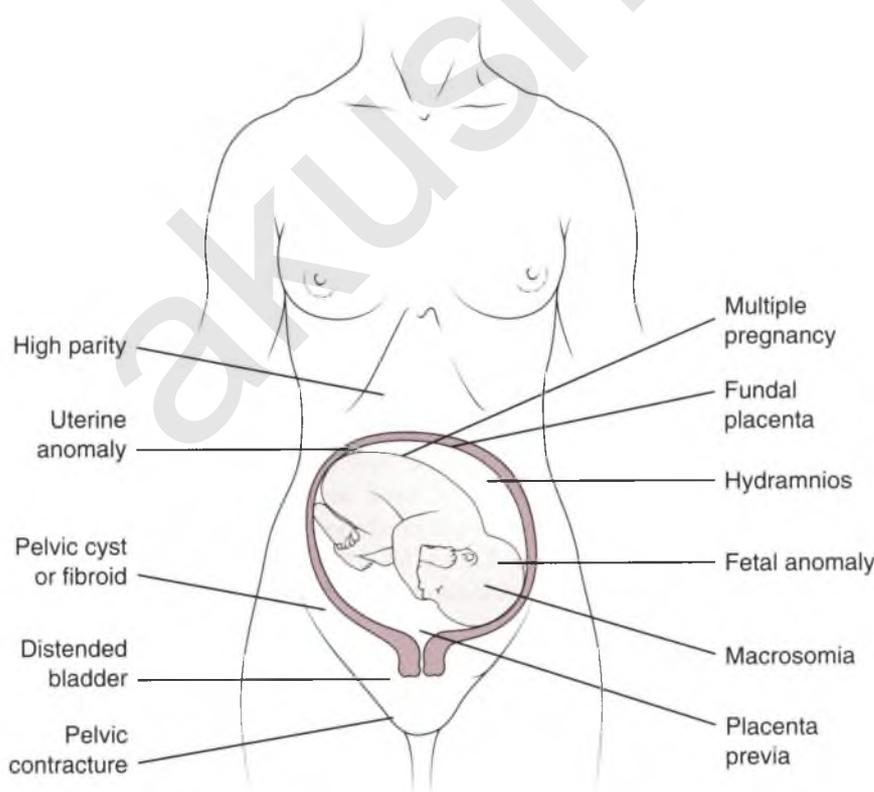
Multiple pregnancy
Fundal placenta
Hydramnios
Fetal anomaly
Macrosomia
Placenta previa


FIGURE 65–2
Etiologic factors and conditions associated with unstable fetal lie.

DISTENDED MATERNAL URINARY BLADDER

Maternal urinary retention with a distended bladder can cause a changing fetal lie, usually only temporarily, with resolution occurring with urinary voiding or bladder catheterization.

Fetal Factors

POLYHYDRAMNIOS

Polyhydramnios, excessive volumes of amniotic fluid, may produce marked uterine distension, enabling the fetus to move around more freely. This probably represents the most common "pathologic" cause for an unstable lie and is also potentially the most hazardous for mother and fetus (see Chapter 13).

OLIGOHYDRAMNIOS

By restricting fetal movement, oligohydramnios can prevent the breech fetus from undergoing spontaneous version to cephalic.

MULTIPLE PREGNANCY

The discovery of an abnormal lie during the last three weeks of pregnancy may arouse suspicion of a multiple pregnancy and lead to investigations that result in the diagnosis being reached; nowadays such a diagnosis is unlikely to have been missed until this stage of pregnancy because of the widespread use of routine ultrasonography during the early weeks of gestation. When the lie of one or both fetuses repeatedly changes, there is usually polyhydramnios.

FETAL MACROSOMIA

Fetal macrosomia produces the same effect as pelvic contracture and must also be considered in such cases.

FETAL ABNORMALITIES

Significant hydrocephaly, tumors of the fetal neck or sacrum, fetal abdominal distension as occurs with hydrops fetalis, and fetal neuromuscular dysfunction (including extended legs) may impede or discourage engagement of a fetal pole in the maternal pelvis. In cases of intrauterine death, the fetus is more likely to present abnormally due to loss of tone, sometimes even requiring delivery by cesarean section because vaginal delivery is impossible.

Compound Presentation

Compound presentations are most usually associated with polyhydramnios and high parity and are more common during the early weeks of the third trimester. Multiple pregnancies, especially those that are monoamniotic, represent a particular risk. Pelvic tumors, including uterine fibroids low in the uterine body or an ovarian cyst situated in the pouch of Douglas, also predispose to compound presentations.

Presentations that involve the umbilical cord are similarly associated with the features previously mentioned. Fetal breech presentation, notably the nonextended breech presentation, is the most common malpresentation associated with cord presentation and prolapse.[2–5]

Brow and Face Presentations

The majority of cases of brow and face presentation are thought to arise when there is a minor degree of deflexion of the presenting vertex that then undergoes further extension; with a more exaggerated extension, a brow presentation will become a face presentation. This may occur during the antepartum period, resulting in a primary face presentation, or develop during the course of labor, resulting in a secondary face presentation.

Primary face presentations are generally associated with fetal malformations, such as anencephaly, meningocele, dolichocephaly, congenital branchiocele, goiter or other anterior neck tumors, and tense extensor neck muscles. Polyhydramnios with the increased space within the uterus and a tight nuchal cord have also been implicated as predisposing factors.

Secondary face presentations are thought to be associated with a contracted or abnormally shaped pelvis. This was considered responsible for 40% of face presentations in a series reported from the Johns Hopkins Hospital early in the last century.[6] It is also much commoner in preterm labor, probably due to the more capacious pelvis accommodating the relatively small fetus.[7]

Malpositions

Recent data derived from ultrasound examinations at the start of labor have suggested that the majority (68%) of posterior positions confirmed toward the end of labor were in an occipitoanterior position at the beginning of labor. The other 32% began labor as an occipitoposterior position, and these labors are more likely to result in an assisted delivery.[8]

Maternal pelvic shape is thought probably to be the major determinant of fetal position prior to labor. When the anteroposterior pelvic dimension of the brim equals or exceeds that of the transverse dimension, occipitoposterior positions are favored. Thus women with an android pelvis are more likely to have an occipitoposterior position in late pregnancy and at the start of labor since the larger dimensions toward the back of the pelvis encourage the broader occiput to be accommodated there rather than in the anterior compartment. In addition, when there is a high assimilation pelvis, with an extra vertebra included in the formation of the sacrum, the inclination of the brim increases, which favors an occipitoposterior position. The much less common anthropoid-shaped pelvis, with the lessening of the posterosagittal diameter (the distance between the midpoint

of the widest transverse diameter and the sacrum), affects not only the brim but commonly extends to the lower levels of the pelvis and to the outlet. In particular, the concavity of the sacrum from promontory to tip is often reduced or abolished (flat sacrum), leaving a reduced space in which the sinciput can turn should internal rotation commence. This leads to the head impacting in the pelvic cavity, resulting in a "deep transverse arrest." It has been suggested that increased muscle tone in the extensor muscles of the fetus might also predispose to an occipitoposterior position, but there is little evidence to support this theory.

Most important is the observation that a high proportion of patients with a malposition making poor progress through labor respond to augmentation of uterine contractions with oxytocin and deliver spontaneously vaginally.[9] This suggests that the quality of uterine contractions plays a significant part in determining the position and attitude of the fetal head. As well as uterine contraction strength being important, there is now good evidence that the tone of the pelvic floor is also relevant. Use of regional anesthesia for the management of pain relief during labor has been implicated as a mechanism for the increased rates of malposition in late labor[10,11] although this is disputed. Regional anesthesia provides an extremely effective method of reducing the distress of labor, distress that is more common with a preexisting occipitoposterior position. The issue of cause and effect thus comes into play. The experience reported from Dublin provides some evidence to suggest that regional blockade is not causal in the evolution of fetal malposition. It was noted that despite a 30-fold increase in intrapartum epidural usage between 1975 and 1998, occipitoposterior position at the end of a first labor decreased from 3.8% to 2.4%.[12]

INCIDENCE

Unstable Lie

Figures are not generally available for the incidence with which unstable lie is encountered in a population. The incidence will be influenced mainly by the proportion of multiparae and particularly the numbers of grand-multiparae. Similarly, in societies where malnutrition is prominent and maternal or fetal skeletal deformities are relatively common, the incidence will be higher. In a well-nourished and developed population where high parity (greater than four) is uncommon, the incidence will be in the range of 0.1% to 1.0%, and the occurrence rate of transverse lie in labor is in the region of 0.4%.[13]

Compound Presentations

There is a relatively sparse literature on the incidence of compound presentations that involve one or more limbs and the fetal head or breech. Overall the incidence has been quoted to be between 1:377 and 1:1213 deliveries;[14–16] personal experience suggests that the lower incidence is more usual in the developed world. Combinations involving the upper limbs and head are the most common. Diagnosis in late labor is the usual situation, with as many as 50% of compound presentations being diagnosed during the second stage of labor.

The incidence of cord presentation has not been widely reported although cord prolapse occurs in around 1:300 to 1:700 total births[3,5,17,18]; 1:900 cephalic presentation labors, 1:56 breech labors, 1:23 twin labors,[5] and 1:5 to 1:10 compound presentations that involve a limb.[14,15,19] Thus cord prolapse in a singleton pregnancy with a cephalic presentation at term has an incidence of around 1:1400 labors. These rates are almost certainly lower than the incidence of cord presentation, since recognized cord presentation is likely to be managed by cesarean section before a prolapse can occur.

Brow and Face Presentation

Brow presentation in labor has an incidence of between 1:200 and 1:500 labors.[20–22] Face presentations are generally quoted to occur in around 1:1000 to 1:1500 deliveries.[23] The incidences during pregnancy are less well documented, especially for brow presentation, since it is probable that this presentation is usually only transient, with reversion to vertex with flexion of the neck or face presentation with further deflexion.

Malpositions

During the antepartum period, prior to the onset of labor, the occipitoposterior position exists in around 11% of singleton pregnancies.[24,25] Once labor starts, the incidence is in the region of 20% to 25%; if the fetal back is on the maternal left, the occipitoposterior position is much less common than when the back is on the maternal right.[20] It is said to be more common in cases of membrane rupture before the onset of labor with an incidence of 27%.[26] Between 20% and 35% of those that start labor in an occipitoposterior position remain in that position to the end of labor, indicating that 65% to 80% undergo spontaneous rotation during labor. As few as 1% to 5% are delivered in an occipitoposterior position.[27,28]

DIAGNOSIS

Unstable Lie

This diagnosis is usually suspected when repeated clinical examinations show a variable fetal lie during the last month of gestation. Occasionally, in those women in whom clinical examination is not easy (including those

with a raised body mass index), the diagnosis may fortuitously be made by an ultrasound examination performed for other reasons. An unstable lie would appear to be more common than is presently thought, from the evidence of the frequency with which fetal breech presentation is missed prior to the onset of labor, despite frequent and recent antenatal clinical examinations. Further, the observation of spontaneous and unexpected version of the fetus from a cephalic to breech presentation during the last weeks before delivery adds weight to this observation.[29,30]

Compound Presentations

A compound presentation involving a fetal arm with the head, or an arm with a leg is only likely to be diagnosed during the antepartum period as a coincidental finding at an ultrasound examination or in rare circumstances on radiographic or magnetic resonance imaging examination. The high nonengaged head that cannot be encouraged into the maternal pelvis might prompt an ultrasound examination, leading to the diagnosis.

Diagnosis during labor may be suspected because of a delay in the presenting part entering the pelvis and is confirmed on vaginal examination by identifying an errant limb or limbs. Occasionally, the diagnosis is made unexpectedly at a vaginal examination when the maternal pelvis is large and the interloping limb with the head or breech does not delay engagement of the presenting part.

Compound presentations involving the umbilical cord are usually classified according to Naegele, who distinguished between "presentation" before membrane rupture and "prolapse" after membrane rupture. A diagnosis of cord presentation will not usually be made prior to the onset of labor except in those cases of an unstable lie when a vaginal examination is performed as part of the assessment of the strategy for continued management. Although some have documented reaching the diagnosis with ultrasound, this is not a widely reported observation.[31]

Face Presentation

Older texts report that abdominal palpation allows the diagnosis of a fetal face presentation to be made by the recognition of a much broader lower pole presenting to the pelvis than usual and the palpation of a marked depression between the fetal back and the occiput (Fig. 65–3). This is more easily demonstrated if the fetus is lying in a dorsoanterior, or mentoposterior presentation; this is less common than a mentoanterior presentation.[20] It is also said that the fetal heart sounds are very easily heard when listened to over the fetal chest, especially with a mentoanterior position; this potentially valuable clinical sign is lost if hand-held Doppler machines are routinely used to detect fetal heart pulsations in preference to a Pinnard stethoscope. Despite this, it is the author's experience that these clinical signs are difficult to elicit, even in those cases of face presentation already confirmed by radiology or ultrasonography.

Confirmation of the presentation should be made by vaginal examination during the intrapartum period. The obstetrician, however, should be wary of confusion between a face and a breech presentation, due to the inevitable facial edema that readily forms during labor, and the added difficulty associated with a high presenting part and a poorly dilated cervix. Identification of the supraorbital ridges, the ridge of the nose, and the alveolar processes within the mouth should lead to the diagnosis. If the technology is available, an ultrasound examination can be used to confirm the clinical suspicion.[32]

Brow Presentation

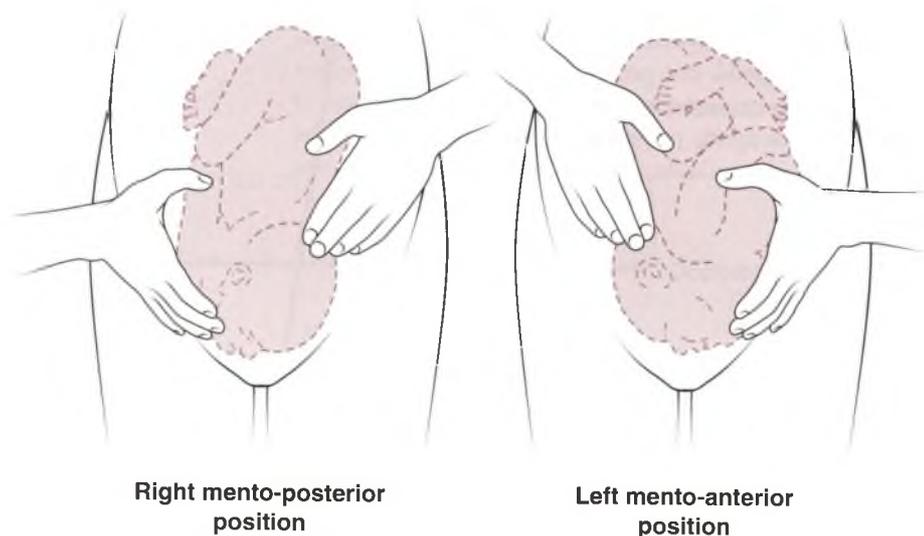
Although occasionally a brow presentation may be recognized during the antenatal period, usually coinciden-


FIGURE 65–3
Palpation of the fetus and the landmarks associated with a face presentation.

Right mento-posterior position   **Left mento-anterior position**

tally at an ultrasound examination, in most instances this is not a permanent position. The suspicion of a broader head than expected for the overall size of the fetal body resting above the pelvic brim may (rarely) lead the astute clinician to suspect this possible diagnosis. Diagnosis during the intrapartum period is only likely to be made during advanced labor when the cervix is moderately well dilated and the brow palpable to the examining fingers. Identification of the anterior fontanelle and the supraorbital ridges confirms the diagnosis, but any significant caput succedaneum can mask these landmarks. As with face presentations, ultrasound examination is the most practical way to confirm or refute the diagnosis.

Malpositions

It is often written that the outline of the distended uterus occasionally suggests an occipitoposterior position; a flatness with a dip between the head and the trunk may be evident. Certainly fetal movements may be readily observed over much of the anterior surface of the abdomen if the baby is active at the time of the examination. However, the fetal back may be difficult to identify on palpation although the shoulder is felt toward the flank with the limbs often obvious to palpation over the abdomen. With Pawlik's grip, the sinciput is said to be prominent, but personal experience would not suggest this to be a reliable feature. Importantly, the fetal heart is heard maximally in the flank to which the back is directed; the Pinard stethoscope allows this clinical sign to be elicited while the small Doppler fetal heart detectors generally do not. An ultrasound examination should confirm or refute the clinical findings.

During labor, the anterior fontanelle is easier to reach when the position is occipitoposterior than occipitoanterior, although caput succedaneum may make this more difficult, especially late in labor. Palpation of the more anterior of the two ears can be helpful, but this may be misleading if the pinna has been turned forward. At this examination, not only should the degree of flexion be noted but also any asynclitism. Diagnosis of a deep transverse arrest should not present difficulties unless caput succedaneum or anterior or posterior asynclitism is marked. Once again, palpation of the fetal ear could be helpful, or if available, ultrasound will confirm the position.[33,34]

RISKS

Unstable Lie and Compound Presentation

There are no hazards to mother or fetus during the antenatal period from an unstable lie per se. It is possible that cord entanglement is a greater risk, although this has not been positively shown. During the latter weeks of pregnancy, spontaneous resolution to a longitudinal lie before labor starts occurs in the region of 85%.[35–37]

There are, however, very serious risks to mother and fetus with the onset of labor if the lie is not longitudinal. Once the membranes rupture, with or without accompanying uterine contractions, there is a risk of cord prolapse if the fetal lie is oblique or transverse, or the presenting part is high above the pelvic inlet. Cord prolapse may result in damaging hypoxia or even stillbirth. Perinatal death has variously been reported to occur as frequently as 5% to 10% of cases[5,38,39] or even as often as 43%.[40] The risk of hypoxic damage is less well documented and it may be as little as 1% in survivors.[5] Keeping the interval between cord prolapse and delivery as brief as possible is likely to be important.[39,41]

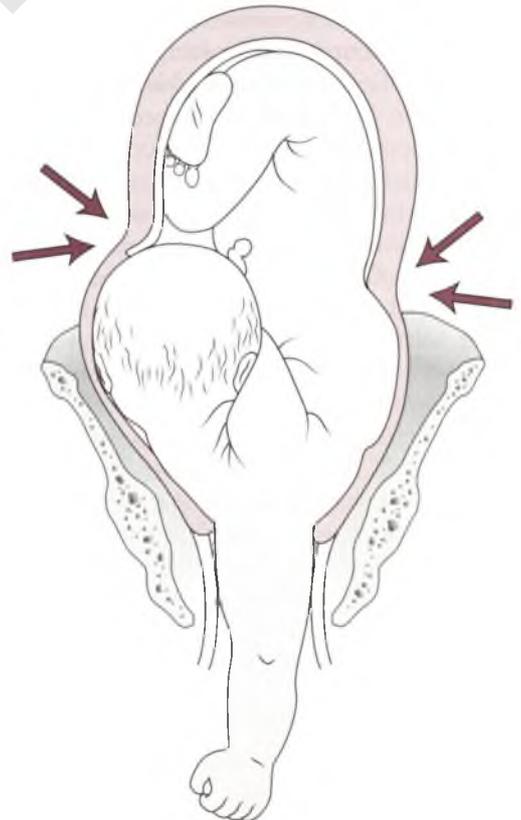
If labor starts when the lie is not longitudinal, a compound presentation may result, or the pelvis may remain empty. If left unattended, fetal distress will eventually supervene, ultimately resulting in fetal death. A Bandl's ring or retraction ring (Fig. 65–4) may form, making delivery even by cesarean section potentially hazardous.[42] In addition uterine rupture is a real possibility, especially in multiparae, with potentially serious consequences for mother and fetus (see Chapter 77).


FIGURE 65–4
Fetal shoulder presentation, illustrating the site of Bandl's, or retraction, ring forming at the junction of the upper and lower uterine segments with an obstructed labor.

Malpresentation

Face

Cord prolapse may be marginally increased over a vertex presentation, but once established in labor with the head engaged in the pelvis, this is unlikely. Progress should be as for a vertex presentation without any additional risk to the fetus since the presenting head diameters are similar (Fig. 65–5). However, with the largest presenting diameter (biparietal) displaced toward the back of the pelvis, a generous episiotomy should be performed, to reduce the risk of a third-degree tear. Providing the face is mentoanterior, vaginal delivery is likely. If there is any delay in delivery, forceps rather than a ventouse should be used, as the ventouse cannot be applied effectively or safely with the face presenting. The parents should be advised in advance of the delivery that their baby will appear very unattractive initially due to the inevitable bruising and marked edema, both of which disappear within a few hours of birth.

Brow

There are no added risks to the mother with a fetal brow presentation during the antenatal period. As with a face presentation, the risk of cord presentation and prolapse is increased.

Except with very preterm labor, the fetus cannot be delivered as a persistent brow unless there is a very capacious pelvis, because of the large mentovertical diameter that presents to the pelvis (see Fig. 65–5). If continued extension of the neck to a face presentation does not occur and the brow presentation persists, the chance of fetal distress and even uterine rupture is high if labor in a parous woman is not progressing and is left to continue for too long.

Malpositions

Few risks are associated with a fetal malposition prior to labor. As already stated, there is a belief that prelabor rupture of the membranes is more common with an occipitoposterior position. Since the head is usually not engaged and may not be well settled into the pelvis, the risk of cord prolapse is increased.

Once in labor, progress may be slower than with an anterior position, and maternal distress is often increased, with discomfort felt particularly in the back. As well as a protracted first stage of labor, there is often a delay during the second stage with the need for augmentation of contractions with oxytocin, or assistance with manual rotation, forceps delivery with or without rotation, or assistance with the ventouse. With a current reluctance to engage in rotational procedures, especially if fetal distress is suspected, there is an increased risk of cesarean section.

It has recently been shown by one group that the occipitoposterior position that persists to the time of vaginal delivery presents a significant risk of anal sphincter damage for both nulliparae and multiparae.[12]

MANAGEMENT

Unstable Lie and Compound Presentation

Antenatal

During the antenatal period management can be expectant or active, while delivery can either await spontaneous onset of labor or be arranged as a planned event. An algorithm of the various options is illustrated in Figure 65–6.

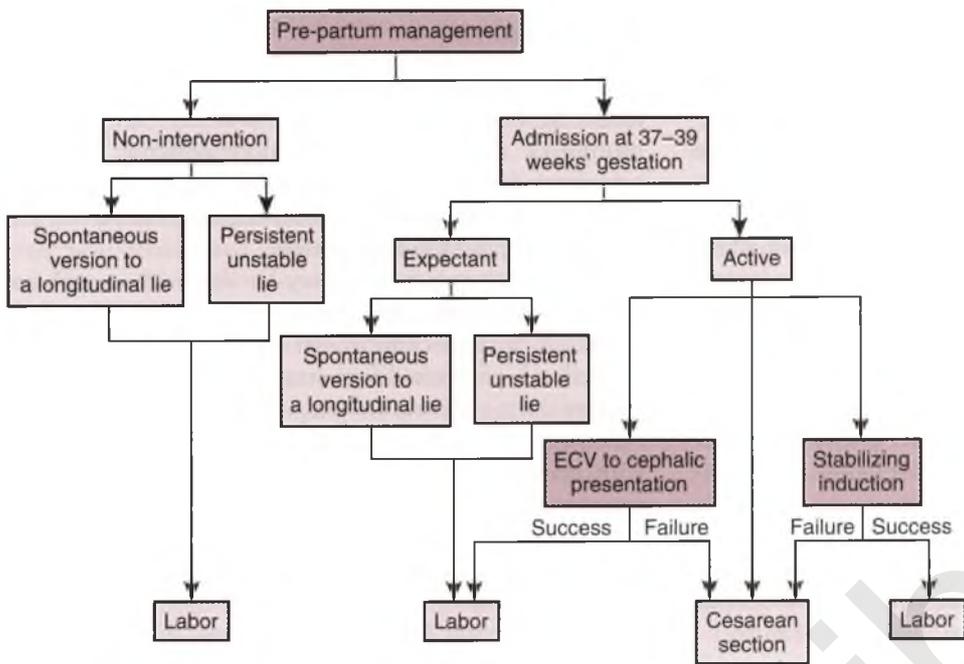

FIGURE 65–6
Algorithm for the prenatal management of unstable lie in late pregnancy. ECV, external cephalic version.

NONINTERVENTION

Once an unstable lie is identified, no specific action is taken in anticipation that the lie will become longitudinal before the membranes rupture or labor starts: this is likely to occur in more than 80% of cases.[35–37] Manipulation to a longitudinal lie at an antenatal examination can sometimes be performed. Every attempt should be made to identify any obvious mechanical cause for the unstable lie, especially if it is likely to result in obstructed labor, thus requiring elective cesarean section. The patient should be advised of the risks associated with an unstable lie and the need for urgent attention should labor start or the membranes rupture. If the woman lives very far from the delivery unit, it may be necessary to admit her from about 37 weeks to await the onset of labor to ensure prompt attention at the onset of labor.

A number of physical exercises, such as the woman adopting the knee-elbow position for short periods on a number of occasions each day, have been advocated to promote spontaneous version, generally from a breech to cephalic presentation.[43–46] Such maneuvers possibly improve the chances of a longitudinal lie by 5% to 10%, but there is no established evidence base for this proposition.

INTERVENTION

Admission may be advised from 37 to 39 weeks' gestation onward. This enables daily observations of fetal lie and presentation to be made; provides the opportunity for active treatment to correct the lie if necessary; allows for immediate clinical assistance upon membrane rupture or the onset of labor; and facilitates urgent management if the lie is not longitudinal, fetal distress occurs, or the cord is presenting or prolapsed.

If spontaneous resolution to a longitudinal lie occurs and is established as cephalic or breech presentation and maintained for 48 hours, the patient may be discharged home to await labor; some currently discourage labor with a breech presentation and reference should be made to the relevant chapter on this topic.

If spontaneous resolution of an abnormal lie does not occur, an active approach to management may be adopted. External cephalic version can be attempted if facilities permit immediate delivery in the event of placental abruption, membrane rupture, cord prolapse, or acute fetal distress for any reason[41,47] (see also Chapter 64 on breech presentation). If a longitudinal lie is established and maintained, the patient may be released home to await spontaneous onset of labor; rhesus immunoprophylaxis should be given to at-risk women either before or soon after the version attempt, and a Kleihauer-Betke test is ideally checked about 20 minutes after the attempt to determine whether additional prophylaxis is necessary. If a longitudinal lie is not maintained, the version can be repeated as often as necessary, and if not successful the patient can be kept in the hospital until labor supervenes. The success of version antenatally for unstable lie is unclear, but in cases of breech presentation it is around 40% to 65%.[39,40,48] Tocolysis can be used, such as intravenous infusions of ritodrine 50 μg/minute for 15 minutes[39] or terbutaline sulfate 250 μg intravenously over 1 to 2 minutes,[24] but is often unnecessary with a transverse or oblique lie (see Chapter 64).

In the event of a continuing unstable lie, a stabilizing induction may be performed, either immediately following admission or when an appropriate gestation (usually 38–39 weeks) has been reached during the following days or weeks. Following transfer to the labor suite an exter-

nal cephalic version is performed converting the fetal lie to longitudinal. Once in position, regular abdominal palpations are performed to confirm the longitudinal lie is maintained and a titrated intravenous infusion of oxytocin is commenced to stimulate uterine contractility.[38] As soon as contractions are occurring at 10-minute intervals or more frequently, a low amniotomy is performed, having ensured the lie is still longitudinal and the presentation is not compound and in particular that the cord is not presenting. If the cord presents, an emergency cesarean section is necessary. Once low amniotomy is performed, a reasonable volume of amniotic fluid should be released, followed by confirmation that the cord is not presenting and the presenting part is fixed in the pelvic brim. Thereafter, once labor is established, management continues as for an uncomplicated labor. A hindwater amniotomy using a Drew-Smythe catheter[49] can be performed. This catheter is passed through the cervix, behind the presenting part between the uterine wall and the fetal membranes, taking every possible care to avoid trauma to the fetus and the placenta, especially if it is posterior. The stylet within the catheter is advanced to puncture the membranes and allow a controlled release of amniotic fluid. This procedure aims to reduce the chances of cord prolapse occurring, but is rarely done in modern practice because of a fear that the rigid catheter will damage the fetus or placenta or perforate the uterus. A more modern approach to hindwater rupture is to use an intrauterine catheter (preferably a solid-state blunt-ended transducer) passed up alongside the fetal head. This has the advantage that the catheter can then be used to measure uterine activity as an aid to appropriately controlling it. Uterine contractility can also be stimulated with local (vaginal) or oral prostaglandins, but this is probably less advisable since the response to prostaglandins is unpredictable and occasionally hyperstimulation can occur, requiring either acute tocolysis or emergency cesarean section, especially if the lie reverts to oblique or transverse.

Finally, a decision to deliver by elective antepartum cesarean section can be made at a convenient time, often at 38 to 40 weeks' gestation,[37] ideally converting the lie to longitudinal at laparotomy and using a lower segment incision rather than a classical (vertical midline). This approach is particularly appropriate if there is a contraindication to external version, external version fails, or there is a mechanical obstruction to vaginal delivery.

Intrapartum

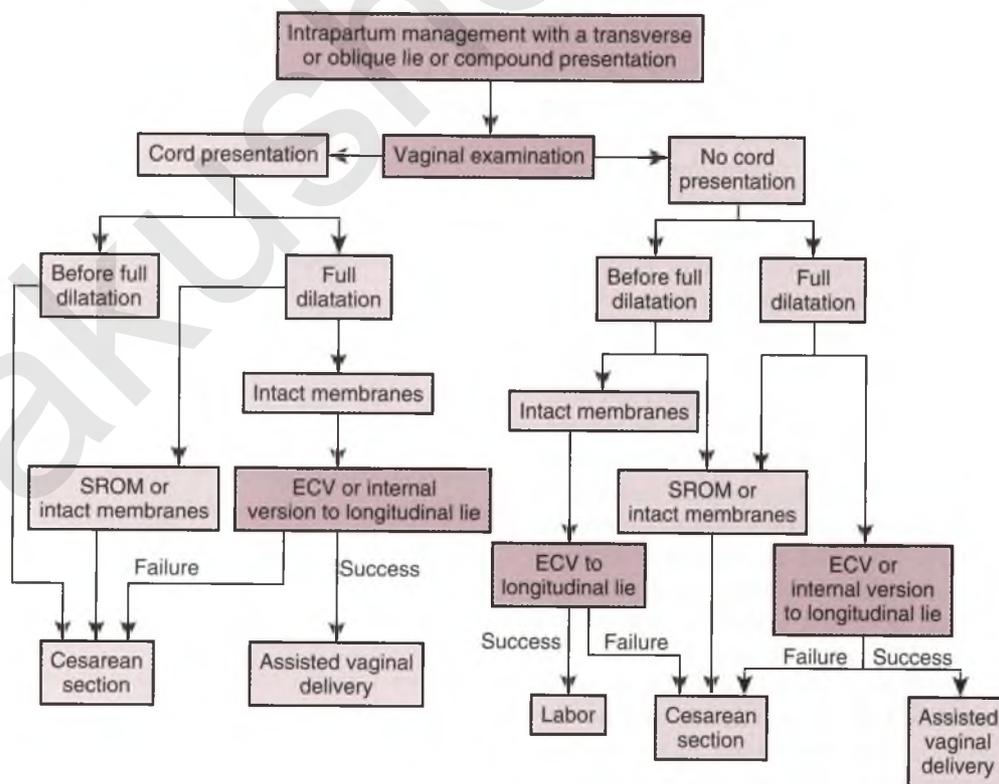
When the fetal lie is transverse or oblique and the membranes rupture or labor starts, the options for management illustrated in the algorithm in Figure 65–7 indicate that a cord presentation or prolapse will prompt different immediate decisions on management depending on the stage of labor and whether the membranes are intact or ruptured.


FIGURE 65–7
Algorithm for the intrapartum management of unstable lie. ECV, external cephalic version; SROM, spontaneous rupture of membranes.

CORD PRESENTATION BEFORE FULL CERVICAL DILATATION

Delivery by cesarean section should be organized in this case; an ultrasound examination at this stage has been used to demonstrate the umbilical cord in the lower pole of the uterus.[31] If there is evidence suggesting fetal distress, the arrangements should be made with urgency. If there is a cord prolapse before full dilatation of the cervix, a "crash" procedure to deliver by cesarean section is required. An attempt is made to reduce pressure on the umbilical cord with digital counterpressure within the vagina or use of the Trendelenberg or knee-chest positions; an attempt to replace the cord may be successful[18] (see Chapter 71 on fetal distress). Cord presentation at full dilatation may be managed by external cephalic or internal cephalic version; delivery by cesarean section should be arranged urgently if the expertise for version is not immediately available or the attempt is unsuccessful. If a cord prolapse is present and the lie is not longitudinal, urgent crash cesarean section is required. Immediate vaginal delivery with forceps for a cephalic presentation, or a breech extraction, should be considered if the necessary skills are available and the presenting part is low enough in the pelvis; the ventouse is a slower option in the hands of many clinicians compared with forceps.[50]

NO CORD PRESENTATION AND THE CERVIX NOT FULLY DILATED

Management of this circumstance will depend on whether the fetal membranes are intact or ruptured. With intact fetal membranes an external version can be performed, and, if successful, labor can continue, with close observation to ensure the lie remains longitudinal until the presenting part engages in the maternal pelvis. Either the attempt at external version is made between contractions, or a tocolytic agent can be infused to relax the uterus. Tocolytic agents that can be used in this situation include β-agonists such as terbutaline infused at 5 to 20 μg/minute, salbutamol (albuterol) 2.5 to 4.5 μg/minute, ritodrine 100 to 350 μg/minute,[51] or the oxytocin antagonist, atosiban, given as a single IV bolus dose of 6.75 mg.[42] If the version is successful, a repeat vaginal examination should be performed to exclude cord presentation or prolapse. Once this has been done, labor can be allowed to establish and progress augmented with oxytocin if necessary. If the version has been unsuccessful, delivery by cesarean section should be performed (see later discussion). With ruptured membranes, delivery by cesarean section is generally the only option unless the patient is in very early labor and an attempt at external cephalic version is successful. If the compound presentation involves the fetal head and a hand or arm is also present, attempts should be made to push the arm up or nip one of the fetal fingers to try to encourage its withdrawal out of the pelvis. It is also reasonable to allow the labor to continue with close supervision in anticipation that spontaneous withdrawal will occur with continuing uterine contractions, causing discomfort to the arm and hand. If it is still present at full dilatation with the head engaged in the pelvis, a decision will need to be reached to determine whether vaginal manipulation can encourage the hand out of the pelvis so that vaginal delivery can continue or whether cesarean section should be performed. A shoulder presentation, sometimes with a prolapsed arm into the vagina, is a serious situation (see Fig. 65–5). Clamping of the uterine wall around the fetus by a retraction or Bandl's ring may have contributed. Delivery must be by cesarean section. Administration of a uterine relaxant such as halothane administered by the anesthetist can facilitate the delivery, which is most safely achieved through a classical uterine incision. This incision allows the fetus to be withdrawn through the fundus of the uterus, whereas a lower segment incision makes it nearly impossible to manipulate the fetus into a position that will allow delivery without damage to the fetus. This management is indicated even if the fetus has already died, to avoid uterine rupture and other serious uterine trauma at the time of the delivery.

A TRANSVERSE LIE AT FULL DILATATION WITH INTACT MEMBRANES

This condition can be managed by external cephalic version with an assisted vaginal cephalic or breech delivery following. If an internal podalic version is attempted, a conclusion should have been reached that there is no anticipated fetopelvic disproportion. With adequate anesthesia (either a general or fully effective regional block) using an appropriate aseptic technique, the obstetrician introduces a hand into the uterus, identifies the foot of the anteriorly positioned leg and applies traction on the leg, withdrawing the foot and leg and subsequently the breech through the vagina (Fig. 65–8). It is even better if both feet can be grasped and pulled down, as this avoids the "splits," with one leg down and one leg

FIGURE 65–8
Principle of securing the foot of the anterior leg at internal podalic version.

up, which can splint the baby and make it difficult to deliver. The delivery is as described for a breech extraction (see Chapter 64). Great care must be taken to avoid both fetal bony injury and laceration of the uterus. Tocolysis may be helpful for this procedure. If version is not successful, delivery should be achieved by cesarean section; attempts at version should only be performed when immediate resort to section is available.

ALREADY RUPTURED MEMBRANES AT FULL DILATATION

If the fetus is in a transverse or oblique lie or there is a compound presentation, delivery should be performed as urgently as possible, using the classical cesarean section incision unless an attempt at external version can be successfully made on opening the abdominal wall and immediately before the uterine is incised. A transverse incision in the lower uterine segment is likely to be inadequate for fetal extraction because the loss of amniotic fluid reduces the surgeon's ability to manipulate the fetus within the uterus. Struggling to deliver the fetus through a lower segment incision can cause serious trauma to the fetus, uterus, or both; or the uterine incision will need to be extended as an inverted T or as a U-shape incision. Such incision extensions may result in compromised healing and a vulnerable area of scar integrity, which may predispose to uterine rupture in future labors.

SUMMARY OF MANAGEMENT OPTIONS
Unstable, Transverse, and Oblique Lie

ECV, external cephalic version.
*The use of internal podalic version should be limited to the obstetrician with experience of the technique and when fetopelvic disproportion is not suspected.

Malpresentation

Antenatal

Once an identifiable specific cause for the malpresentation has been diagnosed, treatment of the precipitating condition may be indicated (see relevant chapters). For those cases without identifiable cause, there are no recognized and universally accepted managements to adopt for correcting a fetal brow or face presentation. In view of the increased risk of cord presentation and thus cord prolapse, the patient should be advised of early admission when labor starts or membrane rupture occurs.

As with an unstable lie, admission from 39 weeks' gestation should be considered for this reason. If delivery is indicated for other reasons, planned cesarean section without recourse to labor may be a safer option than inducing labor if there is a high presenting fetal part. The alternative is labor induction with either local prostaglandins or intravenous oxytocin and low amniotomy once contractions are established and the fetal head fixed or engaged in the pelvic brim. Preparation should have been made to allow for rapid cesarean section should cord presentation or prolapse be diagnosed, with the patient forewarned of this possibility.

Intrapartum

Labor management should be the same as for a vertex presentation, assuming routine maternal and fetal observations are satisfactory and good progress is maintained; many brow presentations convert to a face or vertex and the majority of face presentations present as mentoanterior. Oxytocin augmentation is acceptable if uterine contractions are inadequate, but caution should always be shown since labor may become obstructed with dire consequences if left unattended. If progress in labor is slow, resort to cesarean section may be a wiser option. Figure 65–9 illustrates the management options.

Once full dilatation is reached with a brow presentation, spontaneous delivery will not follow unless the fetus is very small or the pelvis is unusually capacious. Providing the assessment of the pelvis indicates that there is no evidence of absolute disproportion, the presentation can be converted with rotational forceps to face or vertex, whichever proves to be the easier, and then delivered. Some have advised the use of the ventouse in this situation but this requires the cup to be applied behind the bregma and this is unlikely to be possible in the majority of cases (see Chapter 74). The current majority view is that unless the head is engaged in the pelvis at the start of vaginal manipulations, delivery by cesarean section is recommended.

With a face presentation, vaginal delivery should be anticipated if the head is engaged, with the delivery occurring spontaneously or assisted with forceps. The head should be a mentoanterior position at the delivery, achieved by forceps rotation if necessary (see Chapter 74). The ventouse has no place in the management of a face presentation. Thus cesarean section to complete the delivery may be necessary if the obstetrician does not have the necessary skills to conduct a rotational forceps procedure.

Spontaneous delivery as mentoanterior with adequate episiotomy.			
Rotate to mentoanterior and deliver.			
Recommend cesarean section if pelvic disproportion suspected.			

Malposition

Antenatal

There is probably little benefit from trying to alter an occipitoposterior position diagnosed during the antenatal period because the majority of cases correct themselves once labor starts. There may be some virtue in advising the patient that her membranes may rupture prior to the onset of contractions, that labor may be more uncomfortable and possibly more prolonged, and that there is a greater chance of requiring assistance with a vaginal delivery and need for delivery by cesarean section, when compared with a more optimal position. Some women say that they find difficult labor easier to cope with if forewarned, and they may be more inclined to choose an epidural early in labor. On the other hand, many occipitoposterior positions will correct sponta- neously to occipitoanterior during labor, in which case anxiety will have been generated to no purpose, and it may increase the likelihood of maternal request for delivery by elective cesarean section. Some have sug- gested the patient adopts a variety of positions to encourage rotation of the fetus. An analysis of the liter- ature, concentrating on the use of the maternal hands/knees position during the antenatal and intra- partum periods, concluded that this position compared with others resulted in a short-term reversion to an ante- rior position. There was no indication that this maneu- ver enhanced labor outcome, however.[52]

Intrapartum

When the diagnosis of malposition is made early in labor, as much information as possible should be gathered at

this time about the fetal position, including the amount of head palpable per abdomen, the degree of deflexion and asynclitism, the amount of molding and caput formation, the level of the presenting part in relation to the ischial spines, and maternal pelvis size and shape. Issues relating to fetal well-being including fetal heart rate pattern and the color of the liquor should also be taken into account as with any labor.

Options at this point are as illustrated in the algorithm (see Fig. 65–9) and include

- no specific action if acceptable progress is being made.
- provide oxytocin augmentation if uterine contractions are incoordinate, infrequent, or of poor quality.
- abandoning labor in favor of cesarean section.

- encouraging the patient to lie on the same side as the fetal back.[53]

Once the second stage of labor has been reached, spontaneous delivery in the occipitoposterior position may occur, or spontaneous rotation may still occur with spontaneous delivery as occipitoanterior. Alternatively, delivery may be delayed by a persistence of the occipitoposterior position or the evolution of a deep transverse arrest. It has been suggested that vaginal manipulation to rotate the fetus to an occipitoanterior position should be avoided if fetal distress is suspected at that time, with resort instead to delivery by cesarean section. The decision on management at this stage should be determined by assessing which method of delivery is most likely to result in earlier delivery.

CONCLUSIONS

UNSTABLE LIE AND COMPOUND PRESENTATIONS

- A fetal or uterine abnormality can be responsible for the changing lie and compound presentation.
- The risk of complications such as cord prolapse and uterine rupture exists when the membranes rupture or once contractions begin.
- Some of the risks can be reduced by antenatal admission with action to correct the lie or deliver by cesarean section before labor.
- The most significant risk when the membranes rupture or labor starts is umbilical cord prolapse. This usually mandates delivery by cesarean section, but replacement of the cord is sometimes possible and should be considered.
- External or internal version at full dilatation should be considered if the lie is transverse or oblique and the membranes are intact.
- If there is a compound presentation with ruptured membranes, cesarean section is usually necessary, and a classical incision may be needed.

MALPRESENTATION AND MALPOSITION

- A primary face presentation may indicate a fetal abnormality and warrants appropriate investigation.
- During labor with a malpresentation, there is an increased risk of cord prolapse.
- In general, a fetus with a persistent brow presentation cannot be delivered vaginally, but conversion to vertex or face at full dilatation should be considered unless pelvic disproportion is anticipated.
- Fetuses with a face presentation can deliver vaginally in a mentoanterior position.
- Fetuses in an occipitoposterior position at full dilatation may deliver spontaneously occipitoanterior or posterior, require an assisted delivery occipitoposterior, or be rotated and delivered occipitoanterior, or may need to be delivered by cesarean section.
- A deep transverse arrest can usually be delivered vaginally by rotation and assisted delivery.

Prolonged Pregnancy

John M. Grant

INTRODUCTION

Induction of labor for prolonged pregnancy is one of the commonest interventions in pregnancy, with up to one quarter of pregnant women undergoing this procedure. Obstetricians may fear prolonged pregnancy, for if the infant is stillborn at 43 weeks' gestation, they will be criticized by the parents and by their peers, and can be subject to litigation. Pregnant women may ask for induction of labor to relieve themselves of the discomforts of pregnancy in the later weeks. Midwives may comfortably undertake induction of labor, bearing in mind the ease of administration of vaginal prostaglandin. It is not surprising, therefore, that induction of labor for prolonged pregnancy is so common. So secure seems the practice of induction of labor for prolonged pregnancy that authoritative organizations recommend that "women should be offered induction of labor after 41 weeks gestation."[1,2] Yet this recommendation is founded on uncertain clinical science.

DEFINITION

This is the first uncertainty. Even the name of the condition is uncertain, and may be called "prolonged pregnancy," "postmaturity," "post-dates pregnancy," and "post-term pregnancy." The International Federation of Gynecologists and Obstetricians defines prolonged pregnancy as one that is longer than 294 days after the last menstrual period.[3] The Cochrane Collaboration has identified 13 randomized trials of induction of labor after 41 weeks' gestation.[4–17] In 10 of the trials, prolonged pregnancy was defined: prolonged pregnancy was considered to be 287 days after the last menstrual period in two trials,[9,15] 290 to 297 days in one,[10] 292 to 294 days in one,[8] 293 days in one,[5] 294 days in four,[6,9,11,14] and 287 to 301 days in one.[16] The largest trial, which contributed 59% of women to the systematic review, used 287 days as the definition of prolonged pregnancy.[15] This variation in the definition of prolonged pregnancy is important, for a pregnancy at 287 days' gestation is biologically different from a pregnancy at 301 days, both from the risk of uteroplacental insufficiency and from the ease of induction of labor. This variation in definition contributes much to the confusion surrounding prolonged pregnancy.

INCIDENCE

Why are we so exercised by the concept of prolonged pregnancy? It is because of the risk of intrauterine death of the infant, birth asphyxia in labor, and shoulder dystocia at delivery. Induction of labor for prolonged pregnancy is intended to be a prophylactic measure to prevent these serious complications. These risks increase with increasing gestational age after term, but are still small. After 42 weeks' gestation the risk of stillbirth is about 1 in 1000 pregnancies, and after 43 weeks' gestation it is about 1 in 500 pregnancies.[18] There are similar risks of neonatal death at these gestational ages. Thus, even after 43 weeks' gestation the risk of perinatal death is small, about 1 in 250 pregnancies. Observational studies show that the frequency of birth asphyxia is also small, the estimate being 1 in 350 pregnancies at 42 weeks' gestation in one study[19] and 1 in 490 pregnancies in another.[20] Shoulder dystocia in prolonged pregnancy is due to increasing birth weight in the infant beyond term. It may be more frequent than fetal death in pregnancy and birth asphyxia in labor. The estimates for shoulder dystocia are 1 in 75 pregnancies at 42 weeks' gestation in one study,[21] 1 in 28 pregnancies in a second,[22] and 1 in 77 pregnancies in a third.[23] Shoulder dystocia also has a variable definition, according to the perception of the obstetrician. Probably, shoulder dystocia that matters requires

procedures beyond the McRobert's maneuver for its resolution. These procedures are not commonly stated in the literature, and so the frequency of important shoulder dystocia in prolonged pregnancy is unknown.

Many more women are considered to have prolonged pregnancy than are at risk of these serious complications. After the due date, spontaneous labor will occur every day in 10% of women who have not yet delivered. This means that the proportions of women who have not yet delivered will be about 24% at 41 weeks', 11% at 42 weeks', and 5% at 43 weeks' gestation. Many women are delivered before the due date by elective cesarean section, many women undergo induction of labor before the due date for preeclampsia and other medical indications, and many women undergo induction of labor before the due date for social reasons or because of the discomforts of late pregnancy. The variation in the definition of prolonged pregnancy, and the variation in the frequency of elective delivery before the due date partly account for the variation in the incidence of prolonged pregnancy in different populations.[18–23] Measurement of gestational age by ultrasound in early pregnancy reduces the incidence of mistaken prolonged pregnancy.[24–27] Another consideration is the definition of the due date. This may be defined as 280 days or 40 weeks after the date of the first day of the last menstrual period, which is the mean value if gestational age is assumed to adopt a statistical normal distribution. However, the distribution is not normal, for it is skewed toward lower gestational ages on account of prematurity, and also toward higher gestational ages, perhaps on account of some pregnancies that are genuinely pathologically prolonged. It is statistically more correct to consider the due date as the median or the mode. The median is 282 days, and the mode is 283 days.[28] If the due date is counted as 283 days after the last menstrual period, then a definition of prolonged pregnancy of an arbitrarily chosen number of days after this date would reduce the number of women who would be considered eligible for induction of labor by about 27%.

RISKS

Maternal Risks

The main risk to the pregnant woman is not from prolonged pregnancy itself, but from the consequences of induction of labor to prevent prolonged pregnancy.

The Cochrane Collaboration has carried out a meta-analysis of the effect of induction of labor at 41+ weeks' gestation on the likelihood of cesarean section. The meta-analysis suggests that the risk of cesarean section is reduced by 13% (typical odds ratio 0.87; 95% confidence interval [CI] 0.76–0.99; $P = 0.02$).[5,6,8–17] This information has been used by authoritative organizations to support their recommendation for the routine offer of induction of labor after 41 weeks' gestation.

However, analysis of these trials shows that clinically they were quite different. We have already noted the variation in the definition of prolonged pregnancy. There were also variations in the physical characteristics of the cervix at induction of labor. In five randomized trials, women with both favorable and unfavorable cervices were included[5,8,10,11,13]; in four trials women with unfavorable cervices only were included[6,9,16,17]; and in the trial by Hannah and colleagues the cervix had to be less than 3 cm dilated.[12] In the other three trials the state of the cervix was not mentioned. There was variation in the methods of induction of labor. In five randomized trials, labor was induced by low amniotomy and simultaneous oxytocin infusion[5,6,10,11,13]; in one trial by 3 mg of vaginal prostaglandin[8]; in one trial initially by 3 mg of vaginal prostaglandin followed by 0.5 mg intracervical prostaglandin[9]; in one trial by 3 mg intracervical prostaglandin[15]; and in two trials by 0.5 mg intracervical prostaglandin.[16,17] But the greatest variation was in the methods of fetal monitoring in the control subjects: amnioscopy[5]; urinary estriols[11,13]; nonstressed cardiotocography[8–10,15–17]; fetal movement charts[6,8,15,16]; oxytocin challenge test[6,11]; fetal biometry[8]; amniotic fluid volume[6,8,9,16,17]; and the "atropine test."[13]

These randomized trials show such clinical variation that they should never have been combined in a meta-analysis. Variations in the definitions of prolonged pregnancy, the state of the cervix at induction of labor, the methods of induction of labor, and the methods of fetal monitoring in the control group have a much greater influence on cesarean section than induction of labor overall. We cannot be confident that randomization would have smoothed out all the variation in prognostic factors between the experimental and the control groups, for many of the trials were small, and differences in prognostic factors in each trial may have occurred by chance. Many of the trials are old and used methods of induction of labor and fetal monitoring that are not used today. We cannot be confident even of the largest, most recent randomized trial.[16] This trial used a method of induction of labor that is not common in the United Kingdom, intracervical prostaglandins; women in the control group did not have intracervical prostaglandins if uteroplacental insufficiency was suspected; and obstetricians may have been more likely to perform a cesarean section in the control group if they suspected fetal hypoxia in labor.

This misleading meta-analysis shows the dangers of a systematic review performed by statisticians, and not by obstetricians. In this systematic review far too much attention was paid to the mathematics of meta-analysis than to the clinical characteristics of the trials contributing to the systematic review. Obstetricians should not accept the results of a systematic review unless they themselves have analyzed the content of the randomized trials contributing to the review. If there is clinical variation in the trials, the statistical results of any meta-analysis arising from the systematic review should be rejected.

Almost certainly, in primigravidas at least, in most maternity units induction of labor increases the risk of cesarean section. I carried a systematic review in MEDLINE of observational studies carried out from 1995 to 2001, of induction of labor in primiparas, using the keywords *primipara, induction of labor* and *cesarean section*. In each study women who underwent induction of labor were compared with women who did not undergo induction of labor. The overwhelming indication for induction of labor was "post dates," genuine medical indications such as preeclampsia being very much in the minority. Fourteen such studies were found.[29–42] Because the frequency of uteroplacental insufficiency in prolonged pregnancy is rare, it is likely that uteroplacental function in the women who underwent induction of labor was no different from uteroplacental function in the women who did not undergo induction of labor. If induction of labor did not increase the likelihood of cesarean section, we would expect, by chance, that in these 14 studies induction of labor would be associated with a decrease in the rate of cesarean section just as often as an increase in the rate of cesarean section. Two of the 14 studies showed a decrease, and 12 showed an increase in the rate of cesarean section with induction of labor. By the sign test this difference is statistically significant, the probability that this difference is due to chance being 0.008. Thus, in general, induction of labor in primiparas results in an increase in the risk of cesarean section.

Why should the results of the randomized trials be so different from the observational studies? Almost certainly the interpretation of the randomized trials has been too naïve, for induction of labor, and labor itself, are very complex processes. We know that in spontaneous labor the risk of cesarean section strongly depends upon organizational factors governing the management of labor in maternity hospitals. These factors include policies concerning active management of labor; a dedicated midwife; a member of the family or other companion during labor; the timing of routine vaginal examinations; the training of obstetricians and midwives in electronic fetal monitoring; and the number and seniority of the midwives and obstetricians attending the labor ward. In most maternity units it is likely that induction of labor will act adversely, in conjunction with one or more of these factors, to increase the likelihood of cesarean section. Induction of labor is a complex procedure that involves much work and supervision by midwives and obstetricians—administration of vaginal prostaglandins, amniotomy, electronic fetal monitoring, and intravenous oxytocin infusion. There is an increased chance of slow labor, epidural analgesia, and abnormalities of the fetal heart rate. Thus, in an understaffed maternity unit induction of labor is an unwelcome burden and will result an increased likelihood of cesarean section in order to clear the decks for women who actually have an important medical complication of pregnancy, such as preeclampsia.

Less commonly, induction of labor will act beneficially, in conjunction with one or more of these factors, to decrease the likelihood of cesarean section. Thus, in a well-staffed maternity unit with a midwife dedicated to the care of each woman in labor and who is well trained in the interpretation of fetal heart rate traces, induction of labor may increase the chance of a vaginal delivery.

The important lesson is that maternity units should not turn to meta-analyses of randomized trials to guide their policies concerning induction of labor, but that each maternity unit should make its own comparison of primiparas who have their labor induced and primiparas who do not have their labor induced. If the rate of cesarean section in women who undergo induction of labor is significantly higher than in women who do not undergo induction of labor, as in 12 of the maternity hospitals in this survey, then induction of labor for "postdates" pregnancy should be restricted. If the rate of cesarean section in women who undergo induction of labor is lower than in women who do not undergo induction of labor, as in two of the maternity hospitals in this survey, then induction of labor for "post-dates" pregnancy should be liberal.

Fetal and Neonatal Risks

The risk of stillbirth from 37 weeks onward is 1 in 3000 pregnancies, from 42 weeks onward it is 1 in 1000 pregnancies, and from 43 weeks onward it is 1 in 500 pregnancies.[18] The risk of neonatal death from birth asphyxia and from trauma in prolonged pregnancy is not certain. The systematic review in the Cochrane Collaboration involved 6073 women, 3071 allocated to induction of labor and 3002 allocated to fetal surveillance.[4–12] There was one perinatal death in the women who underwent induction of labor and seven perinatal deaths in the control group (odds ratio 0.22; 95% CI 0.05–0.87; $P = 0.03$). The odds ratio is impressive, suggesting that the risk of perinatal death is reduced by a factor of 4 with a policy of induction of labor. The 95% CI does not cross unity, suggesting that even allowing for statistical sampling error, the risk of perinatal death is reduced by a policy of induction of labor.

This information has been used to justify a policy of induction of labor at 41 weeks' gestation and beyond, but is this policy justifiable? The 13 randomized trials in the Cochrane Collaboration resulted in only eight perinatal deaths in more than 6000 women. This is surely a tiny number of perinatal deaths with which to justify such an invasive intervention in so many women in pregnancy. By 41 weeks' gestation, one quarter of all pregnant women would be considered eligible for induction of labor. According to the results of this systematic review 498 women would have to undergo induction of labor at 41 weeks' gestation and beyond in order to prevent one perinatal death. This would not matter if induction of labor were a trivial procedure, but as we have seen, it is a

very complex procedure. If in this systematic review there had been two perinatal deaths in the women who were allocated to induction of labor, the difference in perinatal mortality between induction of labor and fetal surveillance would no longer be statistically significant (odds ratio 0.32; 95% CI 0.09–1.19; $P = 0.09$). Thus, we would be less secure in advocating a policy of induction of labor from 41 weeks onward. This illustrates the marginal nature of the evidence underlying current recommendations.

Almost certainly, the combined size of the 13 randomized trials in the Cochrane Collaboration is too small to be able to show reliably a reduction in perinatal mortality rate with induction of labor. The results of the systematic review in the Cochrane Collaboration show that perinatal death occurred in about 1 of 500 pregnancies in the women allocated to fetal surveillance. In order to test the hypothesis that induction of labor will reduce this rate of perinatal mortality by one half, 47,000 women at 41 weeks' gestation would be required to participate in the trial ($\alpha = 0.05$; $1 - \beta = 0.80$). The power of the 13 trials in this systematic review is 0.17. In this systematic review, therefore, with 6073 participants, there was only a 17% chance of being able to show a reduction in perinatal mortality rate with induction of labor. The apparent significant reduction in perinatal mortality rate found in this systematic review could easily be a type I statistical error. The justification for supposing that a policy of induction of labor from 41 weeks onward will reduce perinatal mortality rate is therefore very shaky.

MANAGEMENT OPTIONS

Prepregnancy

Nothing can be done before pregnancy to influence the problems of post-term pregnancy.

Prenatal

Estimation of gestational age by ultrasound examination in early pregnancy will reduce the number of women who are subjected to induction of labor.[24–27] In the Western world estimation of gestational age by ultrasound has become routine, for reasons that are not connected with prolonged pregnancy, such as the timing of prenatal diagnosis. In maternity units with a high rate of induction of labor for prolonged pregnancy, assessment of gestational age in early pregnancy should be performed.

Fetal Surveillance

The focus of randomized trials in prolonged pregnancy has been the comparison of a surgical intervention, induction of labor, and "fetal surveillance," in its broadest sense. Little attention has been paid to a comparison of various forms of fetal surveillance and no surveillance,

or various forms of fetal surveillance with one another. Observational studies suggest that cardiotocography, measurement of the volume of amniotic fluid by ultrasound, and Doppler assessment of fetal and uteroplacental arteries are unlikely to predict fetal outcome reliably. A randomized trial of cardiotocography and measurement of the amniotic fluid index compared with induction of labor suggested that the rates of cesarean section and meconium below the vocal cords were increased in pregnancies beyond 42 weeks' gestation.[43] Another trial compared amniotic fluid index with maximum depth of the amniotic fluid in prolonged pregnancy, and found that use of the amniotic fluid index increased the likelihood of induction of labor with no apparent benefit to the infant.[44] A third randomized trial compared a modified biophysical profile score with cardiotocography combined with maximum depth of the amniotic fluid, and found that there were more abnormal results in the women randomized to measurement of the biophysical profile score with no apparent benefit to the infant.[45] Counting of fetal movements by the pregnant woman in prolonged pregnancy does not decrease the risk of stillbirth.[46]

Prolonged pregnancy is the commonest indication for induction of labor and involves an enormous expenditure of effort by obstetricians and midwives, yet its pathophysiology is poorly understood. In some respects the effect of prolonged pregnancy is similar to idiopathic intrauterine growth restriction, but whereas the pathophysiology of the latter condition is well understood, the pathophysiology of the former has been scarcely researched. In intrauterine growth restriction biopsies of the decidua at the site of attachment of the placenta show failure of trophoblastic invasion of the spiral arteries, resulting in reduced uteroplacental blood flow, reduction of growth of the infant, and progressive fetal hypoxia and metabolic acidosis.[47] Because uteroplacental insufficiency is a progressive phenomenon in pregnancy, some cases of fetal death in prolonged pregnancy may be due to the syndrome of idiopathic growth restriction continuing beyond term. Certainly we know that when fetal death occurs in prolonged pregnancy the birth weight is lower than when fetal death does not occur, yet other parameters of uteroplacental compromise, such as umbilical blood flow and amniotic fluid volume, are not abnormal in prolonged pregnancies (see earlier discussion). Could the problem with prolonged pregnancy lie with cellular function in the trophoblast? Does apoptosis occur to a greater degree when fetal death occurs in prolonged pregnancy?[48] The controversies surrounding prolonged pregnancy will not be resolved until these and similar questions are answered by research into the basic science of the problem.

Other Interventions

Certainly it defies common sense to subject so many women to such an invasive procedure as induction of

labor in the face of so little understanding of the scientific nature of prolonged pregnancy. Above all, there should be an embargo on randomized trials of induction of labor in prolonged pregnancy, and maternity units should seek ways of reducing the number of women subjected to induction of labor.

The very existence of "prolonged pregnancy" has even been questioned. It probably does exist, because perinatal mortality rate increases progressively from term onward, but even at 43 weeks' gestation this risk is still very small. Even at this gestational age fetal hypoxia and metabolic acidosis are rare.

The obstetrician is therefore faced with a dilemma when attempting to give advice to a woman about prolonged pregnancy. Induction of labor has entered the culture of obstetrics in the Western world, and women may wish to have labor induced, even long before 41 weeks' gestation. Refusal to induce labor risks losing the trust of the pregnant woman, especially given the current widespread practice of recommending induction at 41 weeks; and if the tragedy of a stillbirth occurs, the obstetrician may become involved in unpleasant litigation.[49] The obstetrician will find it difficult to defend the concept that prolonged pregnancy does not exist. It is probably wise to recommend induction of labor after 42 completed weeks' gestation, this being the definition of prolonged pregnancy by an authoritative body, the International Federation of Gynecologists and Obstetricians.[3] If before that time the woman is anxious about prolonged pregnancy, then sweeping of the membranes may be performed[50]; this simple procedure will result in natural labor occurring in three quarters of the women. If the woman prefers induction of labor before 42 weeks' gestation, she must be made to understand the risks of failed induction of labor, cesarean section, fetal distress due to hypertonic uterine action, greater need for epidural analgesia, and a greater chance of vacuum extraction or forceps delivery.

CONCLUSIONS

- Prolonged pregnancy has an uncertain definition and uncertain pathophysiology; more basic research into the pathophysiology of prolonged pregnancy is required.
- If a definition of 41 weeks is used, about one quarter of all women will be considered to have prolonged pregnancy; using 42 weeks as the definition will reduce this figure to 11%.
- Meta-analysis of randomized trials of induction of labor in prolonged pregnancy suggests a reduction in perinatal mortality rate and a reduction in the rate of cesarean section; but the randomized trials are so variable clinically that these conclusions are not justified.
- Observational data suggest that routine induction of labor for prolonged pregnancy increases the risks of cesarean section (especially in primigravidas), fetal distress, greater need for epidural analgesia, and a greater chance of an assisted vaginal delivery.

SUMMARY OF MANAGEMENT OPTIONS
Prolonged Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—General			
Establish accurate gestational age as early as possible.	Ia	A	4, 24–27
Menstrual dates overestimate gestation. Routine early scan of value in preventing induction for "post dates."	Ia	A	4, 24–27
Sweeping membranes at term reduces chances of pregnancy going beyond 41 weeks.	Ia	A	50
Prenatal—At 41 Weeks			
Re-evaluate for possible risk factors.	—	GPP	—
Active Management Option (induction of labor): Controversy continues over this issue			
a) RCT evidence supports this approach: Routine induction of labor for prolonged pregnancy reduces perinatal mortality.	Ia	A	4
Labor induction does not increase cesarean section rate or operative vaginal delivery rate if cervix made favorable first.			

Prolonged Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—At 41 Weeks			
The author believes that the interpretation of the RCT data is flawed because			
Randomization does not preclude an effect from the varied clinical practice between the trials.			
Although a difference in perinatal mortality was observed, this was on the basis of very small differences.			
b) Observational data do not support this approach	IIa–III	B	29–42
Routine induction of labor for prolonged pregnancy increases the risks of cesarean section (especially in primigravidae), fetal distress, greater need for epidural analgesia, and a greater chance of an assisted vaginal delivery.			
Expectant Management Option (fetal surveillance): *Overall very little evidence to suggest that monitoring identifies at-risk fetuses or improves outcome though most studies underpowered.*			
Routine fetal movement counts alone not shown to reducing perinatal deaths—no specific data in prolonged pregnancies.	Ib	A	46
NST and measurement of the amniotic fluid index in pregnancies beyond 42 weeks have higher rates of cesarean section and meconium below the vocal cords compared to induction of labor.	Ib	A	43
Modified biophysical profile score testing in prolonged pregnancy results in more abnormal results and interventions compared to NST combined with maximum depth of the amniotic fluid with no apparent benefit to the infant.	Ib	A	45
Assessment of amniotic fluid index versus vertical pockets of amniotic fluid increase obstetric intervention.	Ib	A	44
Labor and Delivery			
Vigilance for fetal hypoxia and shoulder dystocia	–	GPP	–

AFV, amniotic fluid volume; NST, non-stress test.

Labor—An Overview

Philip J. Steer

WHY HUMAN LABOR IS DIFFICULT

Recent years have seen an explosion of knowledge about early human origins (see, for example, www.modernhumanorigins.com and www.talkorigins.org); it is now thought that bipedal apes were living in Africa as long ago as 6.5 million years (MY) ago.[1,2] By about 3 MY ago, it is likely that at as many as six separate species of hominid coexisted in Africa.[3–5] These Australopithecines ("southern apes") had an almost human-shaped pelvis and walked erect efficiently, but still had a brain capacity equivalent to that of a chimpanzee—about 400 cm.[3] Among the many theories for the evolution of erect posture are that it provided an expanded visual horizon from standing upright on the savannah, which by then covered much of Africa, exposed less body area to the direct rays of the noonday sun, conferred the ability to go fishing in shallow water, and freed the hands for tool holding. Whatever the selectional advantages of the upright posture, the narrow pelvis that resulted (aiding the efficient transfer of forces from the legs to the spine while running) severely limits the cranial capacity of any infant that can be born successfully. However, the development of rotational birth enabled larger fetal heads to pass through the maternal pelvis,[6] and about 1.5 MY *Homo erectus* appeared with an adult cranial capacity of 900 cm[3].[7] It was probably the demands of socialization in troupes (or tribes) that selected for higher brain capacity, with the development of a language instinct being particularly advantageous.[8] The mechanism may well have been neoteny, the persistence of the fetal form into adult life, producing in this case a larger brain/body ratio. Species such as *Homo neanderthalensis* and *Homo sapiens* emerged, both with cranial capacities ranging from 1000 to 1800 cm[3].[3] It may have been *Homo sapiens'* superior language skills that allowed it to succeed by developing a culture, which could be passed down the generations, whereas *Homo neanderthalensis* showed no such progress and died out about 30,000 years ago.[8]

Although being able to run fast and think quickly are both advantageous, they produce an obvious conflict at the time of birth. Babies with large heads can (and do) wreak havoc on their mother's pelvis, causing urinary[9] and fecal[10] incontinence, and even vesicovaginal fistulae.[11] Neglected, prolonged, obstructed labor can in addition lead to renal failure, pelvic inflammatory disease, osteitis pubis, foot drop, and secondary infertility. In rural Africa, the lifetime risk of maternal mortality from childbirth may be as high as 1 in 15.[11] One study has shown that even in Sweden, where birth injury is relatively uncommon, 1 in 40 women will experience some degree of anal sphincter rupture during childbirth.[12]

The growing appreciation of the risk of normal childbirth to pelvic function in women[13–15] as well as the increasing safety of cesarean section[16,17] have led more women (especially doctors!) to request elective cesarean section,[18] to which obstetricians are increasingly likely to accede.[19–21] Many women see the predictability and control of an elective procedure as important advantages.[22]

It may appear paradoxical that the increase in cesarean section rates seen in most developed countries[23–29] and the widespread uptake of epidural anesthesia[30] has occurred against the background of a rising tide of pressure by women's groups to be allowed "natural labor."[31] Such pressure may be due to "female machismo" the desire of some women to "do it by themselves" without assistance (especially from male obstetricians). It can be speculated that such a philosophy has resulted in part at least from the century-long tradition of female emancipation, and feminism, sometimes referred to as "women's lib(eration)." Whatever the root cause of the natural childbirth movement, it has given rise to increasing numbers of "alternative birth centers,"[32,33] and in some countries, even to increases in home birth.[34,35] Most studies show such "low tech" births to be safe, provided careful selection is practised.[34–38] Some women will persist in their aim to achieve a vaginal birth even when it is not safe, and this may lead to the death of her fetus, or even herself. The

obstetrician must accept even this extreme view, and, provided the woman is mentally competent, the law in the United Kingdom prevents compulsory cesarean section,[39] a stance that is supported in the United Kingdom by the Royal College of Obstetricians and Gynaecologists.[40] Women have autonomy in childbirth.[41]

FEAR OF CHILDBIRTH

An underappreciated reason why women request cesarean section is a natural fear of childbirth. Historically, childbirth has been dangerous, and in many parts of the world, it still is, with maternal mortality rates per pregnancy approaching 1%,[40,42–50] giving a lifetime risk of 5% or more. Each year, about half a million women die in childbirth.[42] Many of these deaths are a direct consequence of prolonged labor (associated with hemorrhage and sepsis, for example), which, as explained earlier, is a particularly human problem. Prolonged labor also produces a huge toll of maternal morbidity, as detailed previously. In African cities such as Kano and Lagos in Nigeria and Addis Ababa in Ethiopia some hospitals specialize entirely in the repair of vesicovaginal fistula. In the developing world, even where cesarean section is available, mortality is still significant. In a recent study of over 8000 cesarean sections in Malawi, two thirds were performed because of obstructed labor, and 1% of mothers died.[51] Two thirds of the surgeons were not medically qualified.

We often forget that it is less than 100 years since the maternal mortality rate in the developed world was similar to that in India today, about one maternal death in every 250 pregnancies. British history is littered with disastrous labors such as that of Princess Charlotte in 1817. Her labor lasted over 2 days, and resulted in a stillborn male infant; the mother herself died the following day, and the obstetrician committed suicide some time later. Even at the famous Queen Charlotte's Hospital (London, United Kingdom) in the 1940s, mothers were dying after being in labor for 5 or 6 days.[52] There were also high perinatal mortality rates; 1 baby in 15 did not survive birth in the 1930s.

In more modern practice, obstetricians and midwives can be lulled into believing that labor is no longer a painful experience. I became aware of the error of this view in the early 1990s, when I analyzed a national survey of pain relief in labor for the National Birthday Trust (set up in the 1930s to campaign for better pain relief for women in labor). Even with the ready availability of analgesics and epidural anesthesia, only 6.5% of women said that pain in labor was mild. Overall 37.5% said that they had experienced severe pain, and 56% said that pain had been "unbearable."[53] Even in the last few years, the media in the United Kingdom have carried articles from women reporting terrifying experiences. Jane Dewar, in *You* magazine, April 1999, wrote "it took me two years to recover from the

trauma of giving birth. I didn't feel joyful after the birth of my son—I felt violated, angry and betrayed." Cristina Odone, writing in the *Daily Telegraph* on the 15th of August 2003, wrote about the "pointless suffering inflicted by some dogmatic midwives" who encouraged her to persevere with a "natural" approach to labor against her wishes. She went on to describe how 48 hours of latent labor left her cervix "stubbornly undilated," and she castigated the "self-righteous mantras about bravery and perseverance." She was petrified and indignant about her experience. There is now a UK website devoted to fear of childbirth (www.tokophobia.com). In Finland, Sweden, and the United Kingdom, fear of childbirth is the reason that many women request cesarean section, accounting for up to a fifth of all cesarean births.[54] Previous complicated childbirth or inadequate pain relief are the most common reasons for requesting a cesarean section among women who have previously given birth..[55] Even counseling by specially trained midwives does not appear to be sufficient to dispel the fear of childbirth. In a prospective trial, women who had been treated for the fear of childbirth reported a rather more frightening experience of delivery, and more frequent symptoms of posttraumatic stress related to delivery than women in a comparison group.[56]

In contrast to the fear of natural childbirth, cesarean sections are often perceived as relatively straightforward and a guarantee that senior staff will be involved in the delivery. This perception has been enhanced by adverse publicity regarding the shortage of midwives in the United Kingdom;[57] mothers fear that they will not be adequately supported if they attempt a normal labor and vaginal birth. In Brazil, similar maternal concerns have resulted in cesarean section rates exceeding 80% in some areas.[27] It has also been shown in South America that as disposable income increases, there is a parallel rise in the demand for elective cesarean section.[29]

Perhaps a lesson to be drawn is the importance of women's choice, and the role of technology as a facilitator, allowing choice to be exercised safely. In this context, technology includes the diagnostic tests that enable the identification of those women who will be safest in hospital delivered by cesarean section (e.g., those with placenta previa) and those who can deliver at home with relative safety (e.g., the multipara with a previous normal birth). The availability and the cost of technologic interventions must also be taken into account. It should be with these considerations in mind that we consider the purpose of intrapartum care and even whether, given modern technology, it is necessary for women to labor at all.

SHOULD WOMEN BE ALLOWED AN ELECTIVE CESAREAN ON REQUEST?
(See also Chapters 75 and 76)

Although some have argued that to carry out a cesarean section without a medical indication is unethical,[58–60] in

most countries, obstetricians are willing to give women the choice.[61–63] Recently, the American College of Obstetricians and Gynecologists has reaffirmed the need to allow women the choice to elect an epidural anesthetic before 5 cm dilatation, even if this results in an increased cesarean section rate.[64] An ACOG bulletin in November 2003 advocated that elective cesarean section was an option that should be considered under the principle of patient autonomy.[65] The National Institute for Clinical Excellence in the United Kingdom recently (April 2004) published guidelines on cesarean section (www.nice.org.uk). Section 4.8 of the guidelines specifically addresses the issue of cesarean section for maternal request. The recommendations are:

- Maternal request is not on its own an indication for cesarean section and specific reasons for the request should be explored, discussed and recorded.
- When a woman requests a cesarean section in the absence of an identifiable reason, the overall benefits and risks of cesarean section compared with vaginal birth should be discussed and recorded.
- When a woman requests a cesarean section because she has a fear of childbirth, she should be offered counselling (such as cognitive behavioural therapy) to help her to address her fears in a supported manner, because this results in reduced fear of pain in labor and shorter labor. (Although it should be noted that in the single prospective randomized study on which this recommendation was based there was no significant difference in the proportion of women in the counseled or noncounseled groups who eventually went ahead with their planned cesarean section.[66])
- An individual clinician has the right to decline a request for cesarean section in the absence of an identifiable reason. However, the woman's decision should be respected and she should be offered referral for a second opinion.

It is quite clear from recommendation four that "the woman's decision (for cesarean section) should be respected," and thus maternal choice should be accommodated. Despite this clarity, however, the media in the United Kingdom widely portrayed this guideline as an attempt to restrict cesarean section for maternal choice. For example, a national newspaper, the *Daily Mail*, reported on the 28th of April 2004 that "a major clampdown on Caesarean births has been ordered by Health Chiefs. Doctors have been told that they must have a valid reason to perform (a cesarean section), not just because the mother is 'too posh to push.' Women will instead be encouraged to endure (sic) natural labor—and could face private medical bills of up to £5,000 if they insist on the surgical birth." I support John Queenan, deputy editor of *Obstetrics and Gynecology*, in his recent call to work toward a consensus on this issue.[67] As cesarean section becomes progressively safer year after year (e.g., with reductions in mortality and morbidity

rates secondary to the use of prophylactic antibiotics and anticoagulants, and the improvement in surgical techniques, especially those for controlling hemorrhage), the demand for elective cesarean section is likely to grow rather than diminish. We may arrive at a situation in which elective cesarean section is actually safer than spontaneous labor, particularly as successful vaginal delivery cannot be guaranteed, and spontaneous labor therefore always carries an unavoidable risk of a more dangerous emergency section. If this happens, then arguments in favor of universal elective cesarean section become stronger, and we will need to consider the question of whether all women should be offered this alternative.[68] Probably, such a question could only be answered by a prospective randomized controlled trial, which would need to include indicators of long-term outcome, both for the mother and baby.

INTRAPARTUM CARE

What Is its Purpose?

When asked to state the purpose of intrapartum care, contributors to the first edition of this book gave an interesting variety of answers. One considered that it was to ensure the delivery of the fetus in optimal condition for gestation while minimizing the potential hazards of childbirth and any underlying pathology to the mother; a very medical approach. Another also mentioned easing the physical and emotional burden on the parturient and her partner and the creation of a healthy family. A third said providing reassurance and guidance to the woman and her partner was its primary purpose and put identification of abnormalities in labor second. When considering the place of birth, the first contributor said the hospital was the predominant venue, the second said home intrapartum care and delivery was discouraged, while the third said that 40% of births in his area took place at home and that 60% of births were supervised by midwives and family doctors. These answers illustrate the current tension between the medical and midwifery models of care. The former declares that labor is only ever normal in retrospect (i.e., all labors should be considered a complication waiting to happen until proved otherwise), whereas the latter says that most labors are normal and should be treated as such, lest negative thoughts impair the natural process. Doctors tend to intervene surgically in labor because they are trained to do so, because they are afraid of litigation, because they have a heavy workload with conflicting demands, and because they have a perverse financial incentive to do so. Obstetricians are often paid more for surgical intervention than for normal delivery, and even if they are not, an operative delivery taking at the most an hour is much more cost-effective for the physician (although not for the patient or hospital) than the often protracted process

of natural birth taking up to a whole day. Midwives, on the other hand, sometimes overlook abnormalities in their ardent desire that things will be normal and are sometimes reluctant to recommend intervention because they will lose control of the case. Despite a wish to do so, they are often unable to provide continuity of care because of limited hours in shifts, and they commonly work in large teams (often because of their own family commitments). Perhaps the only sensible compromise in this situation is to expect a positive outcome to labor, while retaining an awareness that the negative can sometimes happen. A positive, reassuring but constantly vigilant attitude is surely even more important in maternity care than in any other branch of medicine.

Who Should Provide Care in Labor?

There is currently no evidence to suggest that any particular pattern of care is associated with a better perinatal outcome than any other. The first contributor quoted earlier works in a country that spends much more on maternity care than the third, but which has substantially higher perinatal mortality rates. In particular, there is no documented evidence that home birth in low risk cases (probably at least 70% of the population in most developed countries) is associated with higher perinatal mortality rates. Indeed, some have argued that morbidity is lower with home birth because of lower rates of surgical intervention and cross-infection. What therefore must take priority is delivering care that is appropriate to the individual mother. Even in the United States, probably home to the archetypal medical model, demand for birthing centers with all the comforts of home has grown over the last 20 years, and the practice of midwifery is gradually increasing. In Holland, the midwifery model is still preeminent, although there has been a shift to more hospital births over the last 30 years. In the United Kingdom, midwifery reached a low point in the mid-1970s, when medical intervention peaked (e.g., with a national induction rate of 45%), but with the widespread introduction of midwifery teams with improved continuity, and a named caseload with full responsibility for total care in normal cases, the practice has developed renewed confidence. Unfortunately, with a return to a successful national economy and almost full employment, many midwives have left practice for easier, and better remunerated, occupations with no antisocial hours. Moreover, the tendency for maternity services to rely on resident junior medical staff to provide out of hours cover is being challenged in Europe by the "European Working Time Directive," which already limits weekly working hours for junior staff to 56 and plans to reduce them to 48 by the end of the decade. The recent limitation of resident working hours to 80 per week in the United States may presage a similar trend.[69] Perhaps equally important has been the consumer revolution, with women wanting and demanding a greater participation in decisions affecting

their care. Increasing moves to patient-held records in the United Kingdom has facilitated this, and it is now the official government policy for maternity records. It is spreading to include a parent-held pediatric record and may become universal with the electronic patient record being developed by the National Health Service (with an investment currently planned of £6 billion). Another current issue is cost-effectiveness; the employment of expensively trained medical staff to perform normal deliveries is hard to defend and even harder to pay for. Although this may be a common pattern in a free-market system, such as that in the United States, there are increasing moves to "managed competition," in which audit and cost considerations play an important part. The widespread publication of birth statistics, including cesarean section rates, will result in a better informed and increasingly vocal public.

THE NEED FOR WOMEN TO HAVE CHOICE

The first aim in intrapartum care should therefore be to select women without obvious risk factors and offer them choice. They should be able to choose their birth attendant, the place of birth, and their mode of birth. There can be no justification for arbitrary rules, and if normal women wish to deliver on a bean bag on the floor surrounded by their family or in a birthing pool with their partner, they should be allowed to do so. There is no evidence that they are exposing themselves or their baby to undue risk, and there is good evidence that a supportive emotional atmosphere is beneficial to progress in labor. In the past, many women have been subjected to demeaning procedures such as pubic shaving and routine enemas, without a shred of evidence that they were beneficial; such practices have fortunately been discontinued in most institutions. On the other hand, many women wish to avail themselves of effective pain relief. The provision of safe epidural anesthesia requires a hospital setting with full staffing and equipment for maternal resuscitation, in case of a rare complication. For this reason alone, hospital maternity units are likely to remain popular. Even apparently normal nulliparas who choose to have their babies at home have a 25% chance of needing to be transferred to the hospital for specialized help, and therefore adequately trained paramedical staff need to be available for such emergencies (and for high risk women who have some sudden complication at home).

ELECTRONIC FETAL MONITORING: YES OR NO? (See Chapter 71)

Electronic fetal monitoring (EFM) remains a conundrum. Despite its many advocates, it has proved impossible to demonstrate its effectiveness conclusively. In

addition, the contribution of perinatal events to long-term disability is now believed to be much less than was at one time thought. There is some optimism that this realization might help to reduce the tide of litigation that is engulfing obstetric practice in many western countries, but it also reduces the apparent need for detailed and continuous monitoring in low risk cases. Again, it is important that the parents be involved in the decision about the way that their baby will be monitored in labor. Many obstetricians will have experienced the trauma of parents who decline EFM and who then have an unexpected stillbirth. On the other hand, there can be little doubt that EFM is responsible for many unnecessary cesarean sections, especially in those units where fetal blood sampling and pH estimation is not routinely practiced. The indications for EFM are clearly spelled out in Chapter 71, but the principle of autonomy means that the woman's choice must be paramount. In UK law, for example, the fetus is not a legal "person" until it is born and thus safeguarding the fetus cannot be used as an argument for over riding the mother's wishes. For the professionals' sake, however, clear records of her choice, and the reasons for it, should be kept. If the woman has risk factors but declines monitoring, explanation of the need for EFM should be clearly given and its use firmly advised. However, her choice must be respected, and there is no place for compromising other aspects of her care if she refuses advice on any particular issue. Choice should also be extended to women with complications. As explained in Chapter 64, there is little evidence that cesarean section for a preterm infant in breech presentation results in a better outcome for the child, although most obstetricians practice operative delivery in this situation. It may be difficult to share this uncertainty with a couple at a time of great stress; but not to do so removes from them the option of choosing a vaginal birth should they prefer it. This is particularly important at 24 to 26 weeks' gestation, when the prognosis for the child is very poor and the morbidity from a vertical incision in the uterus very considerable. The physician's first duty is to his or her patient, not to his or her self-esteem.

ACTIVE OR EXPECTANT MANAGEMENT OF LABOR (See Chapter 69)

The active management of labor, like EFM, has its passionate devotees. However, like EFM, the scientific evidence for its superiority is lacking. Although there is little doubt that use of oxytocin in labors progressing more slowly than average shortens labor, the evidence that the mode of delivery is affected is conflicting. Certainly, the risks of inadvertent uterine hyperstimulation are considerable, and inappropriate use of oxytocics is a common cause of litigation in obstetrics. A study from my own unit[70] showed that even if the cervix was dilating at less than 1 cm every 2 hours, 50% of women still achieved a vaginal delivery without the use of oxytocics. An editorial in the *Lancet* in 1988[71] commented: "since 50% of the untreated control group achieved a vaginal delivery, the conservative approach remains a valid clinical option. At present, low dose oxytocin infusion with careful assessment of uterine activity is the best policy in most cases." Almost 20 years later, we have hardly advanced at all in our understanding of slow labor (dystocia). Indeed, the guidelines on dystocia recently published by the American College of Obstetricians and Gynecologists emphasizes that there is a very wide range of acceptable practice.[72] No particular maternal position (or posture) in labor has been shown consistently to enhance the rate of cervical dilatation (although for a variety of reasons, the supine position should be avoided), amniotomy may enhance progress but also increases the incidence of fetal heart rate decelerations and (possibly) chorioamnionitis, high-dose oxytocin infusion speeds labor but increases the rate of uterine hyperstimulation, and there is no clear evidence that continuous EFM is necessary. Minimally effective uterine activity has been defined in the ACOG guidelines as three contractions every 10 minutes averaging more than 25 mm Hg active pressure above baseline. However, although active pressure has been shown to be more important than the frequency of contractions in determining the rate of cervical dilatation[73] and although several studies have shown that manual palpation is often highly inaccurate for the assessment of the pressure of uterine contractions,[74,75] there it is equally no evidence that measuring intrauterine pressure improves outcome. This may be because there have been very few trials of any size assessing the value of intrauterine pressure measurement. Clinical experience suggests that it may be useful in certain circumstances, such as when the mother is very obese or there is a uterine scar. Perhaps the only firm conclusion that one can draw is that women should not be sold active management on the basis that it has proven medical benefit for themselves if the real reason for using it is to speed labor and thus economize on staff time. On the other hand, many women in desultory labor, or with spontaneous prelabor rupture of the membranes, wish to "get on with it," and there is no reason why their views should not be the deciding factor.

INDUCTION OF LABOR (See Chapter 68)

The major factors influencing the outcome of induced labor are parity and the state of the cervix. Failed induction should be a rarity in parous women and is uncommon in nulliparas provided the cervix is favorable (a Bishop score ≥6). In such women, induction of labor can be undertaken with confidence if there are medical indications (which probably do not exist in more than about 5% of pregnancies). Induction of labor for social reasons remains controversial but widely practiced. Following an era in which in some institutions so-called medical

indications were said to exist in more than half of all pregnancies, it would seem perverse if the expertise in induction of labor thus gained should be denied to women who wish to take advantage of it for personal reasons that to them are compelling. In nulliparous women with an unfavorable cervix, two (small) doses of vaginal prostaglandin E_2 24 hours apart can be tried; if this does not precipitate labor or improve the ripeness of the cervix, the indications for induction should be critically reviewed.

THE MANAGEMENT OF PRETERM LABOR
(See Chapters 61 and 62)

In many ways, despite continuing improvements in neonatal care, the obstetric management of preterm labor has become more controversial over the last 10 years. Two particular issues are of concern.

Tocolysis

Firstly, following an era in which the use of tocolytics to suppress preterm contractions became de rigueur, the systematic reviews have cast steadily increasing doubt on their efficacy.[76] Early use of alcohol was rapidly supplanted by the use of β-sympathomimetics, and for many years ritodrine was widely used and presumably very profitable for the drug company producing it. However, although they have been shown to delay delivery, β-sympathomimetics have not been shown to improve perinatal outcome, and they have a high frequency of unpleasant and even fatal maternal side effects. In the United States, the use of magnesium sulfate to suppress preterm uterine activity persisted for many years despite the lack of any evidence for its efficacy. The latest *Cochrane Review* has stated that "Magnesium sulphate is ineffective at delaying birth or preventing preterm birth, and its use is associated with an increased mortality for the infant."[77] Therefore, there seems to be no justification for its continuing use for this indication. Nitric oxide donors such as glycerin trinitrate were fashionable briefly, but have been abandoned because they are no more effective than alternatives and give many women in whom they are used a severe headache.[78] In the *Cochrane Systematic Review*, when compared with any other tocolytic agent (mainly β-sympathomimetics), calcium channel blockers reduced the number of women giving birth within 7 days of receiving treatment (RR 0.76; 95% CI 0.60–0.97) and prior to 34 weeks' gestation (RR 0.83; 95% CI 0.69–0.99), "When tocolysis is indicated for women in preterm labour, calcium channel blockers are preferable to other tocolytic agents."[76] However, calcium channel blockers are currently unlicensed for this use. On the other hand, a licensed drug (atosiban) is available in Europe, and in multinational multicenter trials has been shown to be as effective as β-sympathomimetics in suppressing uterine

contractions, but with far fewer side effects.[79] Thus, it would probably be the treatment of choice, but unfortunately it is very expensive, and in a cash-limited National Health Service, this presents a problem. The cost of a day's treatment with atosiban is approximately £200 ($300), whereas nifedipine costs about 50p (£0.5, $0.75) per dose. The controversy regarding which drug to use was highlighted by the editor of the *British Journal of Obstetrics and Gynaecology* (BJOG) when he wrote "the economic arguments do not make much sense. Nifedipine is cheaper predominantly because it has not undergone the expensive pregnancy licensing process. There may also be unseen late costs. In the short run, hospital trusts [governing boards] risk being sued for using an unlicensed drug when the licensed one is available, and in the long run refusal to prescribe an effective licensed drug will discourage future drug development in pregnancy. If pharmaceutical companies make a good new drug, we should use it." His editorial raised concerns because the editor declared that he had been paid to advise the drug company that produces atosiban on their drug development program. In a subsequent letter to the BJOG it was noted that at a recent senior staff conference of the Royal College of Obstetricians and Gynaecologists, the majority of the obstetricians present indicated that their first-choice tocolytic agent was nifedipine.[80] The authors also pointed out that atosiban had been refused a license both in the United States and in Australia. Where does this leave us? Perhaps we should end with a comment from the current Royal College of Obstetricians and Gynaecologists guidelines* that "in the absence of clear evidence that tocolytic drugs improve outcome following preterm labor, it is reasonable not to use them."[81]

Antenatal Steroids for Fetal Lung Maturation

Since their introduction in the 1980s,[82] antenatal steroids have been used widely and have been shown to reduce both neonatal respiratory distress syndrome and mortality at or before 34 weeks' gestation.[83] Following a period during which major efforts were made to make sure that the mothers of all babies that could potentially benefit had received an appropriate course of steroids, the use of this powerful medication began to increase to include, for example, routine administration before elective cesarean section at 38 weeks' gestation and multiple courses in women considered to be at increased risk of preterm delivery. In the last 5 years, questions have been raised about the wisdom of such an approach. There is particular concern about potential long-term side effects. Animal studies have shown that maternal corticosteroid administration delays myelination in the fetal brain and reduces the growth of all fetal brain areas, particularly the hippocampus.[84] There may also be long-

---

*www.rcog.org.uk/guidelines.asp?pageID=106&guidelineID=44

term effects on the setting of the hypothalamopituitary axis and glucose homeostasis.[84–86] These latter changes are consistent with the Barker hypothesis of intrauterine fetal programming.[87,88] Some studies have already suggested that antenatal corticosteroid therapy is associated with higher systolic and diastolic blood pressures in adolescence and might lead to clinical hypertension in survivors well beyond birth.[89] Moreover, studies are now suggesting that repeated courses of antenatal steroids may result in a decreased neonatal head circumference[90] and decreased birth weight.[91] Multivariate analyses of the behavior of children in the Western Australian Preterm Infant Follow-up Study have shown that increasing the number of glucocorticoid exposures, for the purpose of enhancing lung maturation prior to preterm birth, is associated with both reduced birth weight and an increase in behavioral disorders at 3 years of age.[85] In 2000, the NIH (http://odp.od.nih.gov/consensus/cons/112/112_intro.htm) issued the following consensus statement: "The current benefit and risk data are insufficient to support routine use of repeat or rescue courses of antenatal corticosteroids in clinical practice. Clinical trials are in progress to assess potential benefits and risks of various regimens of repeat courses. Until data establish a favorable benefit-to-risk ratio, repeat courses of antenatal corticosteroids, including rescue therapy, should be reserved for patients enrolled in clinical trials." This conclusion has subsequently been supported by the American College of Obstetricians and Gynecologists[92] and a *Cochrane Review*.[93] A leading article in the *Journal of the American Medical Association* drew attention to the rapidly increasing number of papers reporting adverse long-term effects of antenatal steroids.[94] It should not be forgotten that before the adverse effects of the antenatal use of diethylstilbestrol were recognized, it had been given in over 4.5 million pregnancies, and more than 2 million men and women exposed in utero had their reproductive function adversely affected[95,96]; and that thalidomide resulted in the birth of over 10,000 babies with phocomelia before its dangers were appreciated.[97,98]

In summary, with systematic review and meta-analysis we are becoming better at understanding what we know, and defining what we know we do not know. However, it is those things that we do not know that we do not know which sometimes give us the most serious cause for concern when eventually the facts emerge. It is always best to remember "First do no harm."

CONCLUSIONS

- Human birth is difficult because of an evolutionary conflict between a small pelvis adapted for walking upright and an enlarged brain adapted to toolmaking and interpersonal communication.
- Fear of childbirth is therefore justified
- Caesarean section is increasingly requested by choice and most obstetricians will accede to this provided the woman is fully informed of the risks and benefits
- The most important component of intrapartum care is the presence of an experienced and competent birth attendant
- Electronic fetal monitoring makes labor safer for the fetus but increases the likelihood of operative intervention
- Active management does not affect the outcome of labor but may shorten it and this can have logistic advantages for both parturient and accoucheur
- Tocolytics are largely ineffective and not to use them is an acceptable option
- Steroids administered to the mother reduce neonatal mortality and morbidity if the baby delivers before 34 weeks, but have long term adverse consequences for babies that deliver at term because their mother was not really in labor.

Induction of Labor and Pregnancy Termination for Fetal Abnormality

Luis Sanchez-Ramos / Isaac Delke

INDUCTION OF LABOR

Definition

Labor induction is the stimulation of regular uterine contractions before the spontaneous onset of labor, using mechanical or pharmacologic methods in order to generate progressive cervical dilation and subsequent delivery. Although the term generally refers to patients who are at term, it is also employed for women who are at least 20 weeks' gestation. It is important to distinguish labor induction from augmentation, which refers to stimulation of uterine contractions when spontaneous contractions during labor have been considered inadequate.

Introduction

Induction of labor is an important and common clinical procedure in obstetrics. The rate of labor induction in the United States continues to rise significantly for all gestational ages. Preliminary data for the year 2002 from the National Center for Health Statistics indicate that the rate was 20.5% for the year 2001, more than twice the 1989 level of 9%.[1] The reason for this increase is unclear, although it may partly reflect a growing use of labor induction for post-date pregnancies and an increasing trend toward elective induction of labor for other indications (including maternal request).

Indications and Contraindications

Generally, labor induction is indicated when the benefits of delivery to the mother or fetus outweigh the potential risks of continuing the pregnancy. The most appropriate timing for labor induction is the point at which the maternal or perinatal benefits are greater if the pregnancy is interrupted than if the pregnancy is continued. Ideally, most pregnancies should be allowed to reach term, with the onset of spontaneous labor being the sign of physiologic termination of pregnancy. However, occasionally a woman is best delivered before the spontaneous onset of labor. Commonly accepted indications for labor induction are listed in Table 68–1. Of the standard indications for labor induction, pregnancy-induced hypertension and post-date pregnancies are among the most common, accounting for more than 80% of reported inductions. Given that there is an indication for induction, the risks to mother and fetus must then be considered, to make sure that the benefit outweighs these risks. The risks to the mother are mainly related to an increased chance that she will need operative delivery, compared with labor following the spontaneous onset of labor. The risks to the fetus are those of prematurity. Whenever there is evidence of fetal lung maturity, or the pregnancy has reached at least 39 weeks (confirmed by an early ultrasound) the decision to induce labor is not difficult. Maternal consent to any increased risk of operative delivery can be obtained, and the fetus is not likely to be at risk for complications that cannot be dealt with in a modern neonatal unit. However, the decision to induce labor prior to fetal maturity having been achieved is far more difficult. In such cases, premature delivery should offer the fetus clear benefits that outweigh the potential problems associated with preterm birth. Although elective induction of labor (without medical or obstetric indications) is generally not recommended, logistic factors such as distance from the hospital or a history of rapid labor and delivery may be reasonable indications for elective induction. The issue of induction of labor from 39 weeks at maternal request (usually due to intolerance of the discomforts of pregnancy, but sometimes for social reasons, e.g., the limited availability of the father to attend the birth) remains controversial.

Generally recognized relative and absolute contraindications to labor induction are listed in Table 68–2. There

TABLE 68–1

Commonly Accepted Indications for Labor Induction

Pregnancy-induced hypertension
Prelabor rupture of membranes
Chorioamnionitis
Severe intrauterine growth restriction
Isoimmunization
Maternal medical problems (diabetes mellitus, renal disease, lupus)
Fetal demise
Postdates pregnancy
Oligohydramnios
Logistic factors (risk of rapid labor, distance from hospital)

TABLE 68–3

Criteria for Fetal Maturity

Fetal heart tones have been documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler.
It has been 36 weeks since a positive serum or urine human chorionic gonadotropin pregnancy test was performed by a reliable method.
An ultrasound measurement of the crown-rump length, obtained at 6–11 weeks, supports a gestational age of 39 weeks or more.
An ultrasound scan, obtained at 12–20 weeks, confirms the gestational age of 39 weeks or more determined by clinical history and physical examination.

are few absolute contraindications to labor induction, and there can be certain clinical situations in which induction is usually contraindicated but exceptional circumstances make induction appropriate (i.e., prolapsed umbilical cord in the presence of fetal demise). A number of clinical situations that are not generally considered contraindications to labor induction but require caution include breech presentation, borderline clinical pelvimetry, grand multiparity, nonreassuring fetal testing not requiring emergency delivery, polyhydramnios, and multifetal gestation.

Requirements for Labor Induction

Prior to inducing labor, the obstetrician should carefully review the indication(s) for ending the pregnancy and obtain informed consent. In addition, the mother and fetus should be carefully examined and, if indicated, fetal pulmonary maturity should be documented. In order to avoid iatrogenic prematurity, an amniocentesis to assess fetal lung maturity may be required. Table 68–3 lists criteria, which if met, allow fetal maturity to be assumed, so that amniocentesis need not be performed.[2]

Preinduction Status of the Cervix

Successful labor induction is clearly related to the state of the cervix. Women with an unfavorable cervix, who have not experienced a cervical ripening phase prior to labor, present the greatest challenge with regard to labor induction. In addition, the duration of labor induction is affected by parity and to a minor degree by baseline uterine activity and sensitivity to oxytocic drugs. Many investigators have identified

the importance of assessing cervical status prior to induction of labor. Calkins and colleagues were the first to carry out systematic studies of the factors influencing the duration of the first stage of labor.[3] The authors concluded that the length, thickness, and particularly the consistency of the cervix were important parameters. In 1955, Bishop devised a cervical scoring system for multiparous patients with planned elective induction of labor in which 0 to 3 points are given for each of five factors.[4] He determined that when the total score was at least 9, the likelihood of vaginal delivery following labor induction was similar to that observed in patients with spontaneous onset of labor. Although several modifications have been suggested, the Bishop score has become a classical parameter in obstetrics and has since been applied to a much wider group of patients. Nulliparous women with a Bishop score no greater than 3 have a 23-fold increased risk of induction failure and a two- to four-fold increased risk of cesarean delivery compared with nulliparous women with a Bishop score of at least 4.[5] Similarly, multiparous women with a Bishop score of no greater than 3 have a sixfold increased risk of failed induction and twofold increased risk of cesarean birth compared with those women with higher Bishop scores.[5,6]

The Bishop score has become the most commonly employed preinduction scoring system. Several recent studies have assessed the predictive accuracy of ultrasound for successful labor induction.[7–9] However, there is a lack of convincing evidence that this technique provides significant additional information when compared to digital examination.

Preinduction Cervical Ripening

Cervical ripening is the process that culminates in the softening and distensibility of the cervix, thus facilitating labor and delivery. There is an inverse relationship between the Bishop score and the failure of labor induction, with low scores being associated with a high rate of failed induction. Moreover, not only is inducing uterine contractions in the presence of an unripe cervix more likely to lead to delivery by cesarean section, but even if vaginal delivery is eventually achieved, the labor will often have been prolonged. This is a particular problem

TABLE 68–2

Contraindications to Labor Induction

Placenta or vasa previa
Transverse fetal lie
Prolapsed umbilical cord
Prior classical uterine incision
Active genital herpes infection
Pelvic structural deformities

if the induction is for fetal indications, as then prolonged fetal monitoring is also required. In addition, an extended exposure to uterine contractions and the resulting reduction in intervillous blood flow can result in fetal hypoxia and acidosis. Thus, it is useful to employ cervical ripening agents to prepare the unripe cervix for labor induction. Ideally, a ripening agent would act upon the cervix to make it more favorable without inducing uterine activity; the length of the active phase of labor would thereby be minimized, limiting the stress on the fetus to the minimum. Unfortunately, it has proved difficult to separate methods of cervical ripening and labor induction. Patients with an unripe cervix may undergo cervical ripening without initiating labor contractions when a pharmacologic agent such as dinoprostone (PGE_2) is employed, but sometimes contractions ensue before the cervix has ripened. A considerable amount of research has been directed toward various methods to prepare or ripen the cervix prior to the induction of labor. Although many of these methods also initiate uterine activity, it should be appreciated that the principal role of these agents is to soften the unripe cervix independently of uterine activity. The various methods for cervical ripening can be divided into two categories (Table 68–4):

- Mechanical
- Pharmacologic

Mechanical Methods

FOLEY CATHETER

Mechanical methods have been employed for many years to ripen the cervix prior to labor induction.[10] Barnes, in the mid-19th century, was one of the first to describe the use of a balloon catheter to ripen the uterine cervix.[11] Since that time several variations of this method have been popularized. The balloon catheter currently most frequently used is a Foley catheter with a 25- to 50-mL balloon, which can be passed through an undilated cervix before inflation of the balloon above the internal os. It is thought that the mechanical separation of the fetal membranes from the cervix and lower segment stimulates local cytokine and prostaglandin release, and these act upon the ground substance of the cervix to break down the cross-links between the glycosaminoglycans. More recently, extra-amniotic saline infusion has been a successful modification to the use of balloon catheters for cervical ripening, presumably by enhancing this effect.[12–14] A recent review of 13 trials in which balloon catheters were used for cervical ripening concluded that with or without extra-amniotic saline infusion, the method resulted in improved Bishop scores and decreased induction-to-delivery intervals.[15] Simultaneous use of balloon-tipped catheters and pharmacologic agents has been shown to be even more effective for cervical ripening than for labor induction; however, the cost of such combination therapy is substantial.

LAMINARIA TENTS

Laminaria tents, natural and synthetic, have been used as a mechanical method for cervical ripening for many years. Although their safety and efficacy in the second trimester have been established, use of laminaria during the third trimester of pregnancy is associated with a high incidence of infection.[16] Synthetic hygroscopic cervical dilators have also been used for many years as agents to prepare the cervix for pregnancy termination. Several studies have shown that these osmotic dilators can also be successfully employed for cervical ripening in viable pregnancies with an unripe cervix.[17–19] Advantages to the use of osmotic dilators are their low cost and ease of placement and removal.

MEMBRANE STRIPPING

Membrane stripping (sometimes known as "membrane sweep") is a simple technique not infrequently used to ripen the cervix, in which a finger is inserted through the cervix and "swept" around the lower segment above the internal os in a circular motion. As with the Foley catheter, it appears to work by release of prostaglandin (especially prostaglandin $F_{2\alpha}$) from the decidua and the adjacent membranes. However, presumably because it is more vigorous, it often stimulates uterine contractions as well as causing ripening. A recent systematic review showed no evidence of an increase in the risk of maternal or perinatal infection when "sweeping" is used.[20] However, there are adverse effects such as discomfort during the necessarily vigorous vaginal examination and occasionally bleeding from the cervix or placental margins if the placenta is low lying. Moreover, if the induction is for fetal compromise, the ensuing contractions mandate fetal monitoring even if labor does not become established.

ACUPUNCTURE

Although much more common in Asia, acupuncture for cervical ripening and labor induction is also becoming more available in the Western world. A recent study concluded that acupuncture at points LI 4 (large intestine 4) and SP 6 (spleen 6) induces cervical ripening at term, and

in postdated pregnancies it shortens the time interval between the estimated date of confinement and the actual time of delivery.[21]

Pharmacologic Methods

PROSTAGLANDINS

The use of prostaglandins for cervical ripening has been reported extensively, involving a variety of prostaglandin classes, doses, and routes of administration.[22–24] The distinction between cervical ripening and labor induction is blurred in patients receiving prostaglandins because many women will go into labor even when prostaglandins are being used primarily for ripening. Dinoprostone, or PGE_2, is the prostaglandin most commonly employed. The local application of PGE_2 results in direct softening of the cervix by at least three mechanisms: (1) It softens the cervix by altering the extracellular ground substance of the cervix, (2) it increases the activity of the smooth muscle of the cervix and uterus, and (3) it leads to gap junction formation that is necessary for the coordinated uterine contractions of labor.[25,26]

Meta-analyses have shown that prostaglandins are superior to placebo and oxytocin alone in ripening the cervix.[27,28] A systematic review including at least 5000 pregnancies from more than 70 prospective trials suggests that PGE_2 is superior to placebo or no therapy in enhancing cervical effacement and dilation.[27]

Two forms of PGE_2 (dinoprostone) are available commercially in the United States, although even more forms are available in other Western countries. In randomized trials, the two forms are similar in efficacy.[29–31] The first is formulated as a gel and is placed endocervically, but not above the internal os. The application, 0.5 mg, can be repeated in 6 hours, not to exceed three doses in 24 hours. The second form is a 10-mg vaginal insert that is placed in the posterior fornix of the vagina. This formulation allows for controlled release of dinoprostone over 12 hours, after which it is removed.

Misoprostol (synthetic analogue of PGE_1) has been the subject of numerous recent articles describing its use as a cervical ripening agent.[32–50] Doses of 25 to 50 μg administered vaginally or orally have been shown in several studies to be effective in inducing cervical ripening and labor. However, because the majority of patients experience regular uterine contractions soon after the initial dose, misoprostol should be considered primarily a labor induction agent, which occasionally ripens the cervix without uterine activity.

The role of cytokines in cervical ripening has been the subject of several recent studies.[51] Interleukin 8 (IL-8) can lead to neutrophil chemotaxis, which is associated with collagenase activity and cervical ripening.[52] These inflammatory agents may be particularly important as mediators of cervical ripening associated with preterm labor. Nitric oxide synthase (NOS) and nitric oxide (NO) have been postulated to have a regulatory role in the myometrium and cervix during pregnancy and parturition.[53–55] In the human cervix, ripening is associated with an increase in inducible NOS (iNOS) and neural NOS expression in the cervix.

Resident and migrating inflammatory cells can cause an increase in iNOS activity. In the primate, cervical ripening has many aspects of an inflammatory process: tissue remodeling and breakage of chemical bridges between collagen fibers. Inflammatory agents such as IL-1, tumor necrosis factor-alpha, and IL-8 all seem to be involved in cervical ripening.[56–58] Currently, however, there is no commercial product available that exploits these properties directly.

Relaxin is a polypeptide hormone, similar to insulin, produced by the ovaries, decidua, and chorion. Because of its effect on connective tissue remodeling, it has been studied as a cervical ripening agent.[59,60] Based on data from animal studies, relaxin was predicted to have a cervical ripening effect in humans. The findings that porcine relaxin induces cervical ripening in humans supported this prediction. However, because studies showed that in fact administered human relaxin has no effect on the human cervix, the usual role played by relaxin in human pregnancy and parturition is unclear. At the present time, relaxin, either purified porcine or recombinant human, is not produced commercially as a cervical ripening agent, and its future potential in this context remains unclear.

Pharmacologic Methods for Labor Induction

Oxytocin

Oxytocin, a neurohormone originating in the hypothalamus and secreted by the posterior lobe of the pituitary gland, is the most commonly used drug for the purpose of labor induction in viable pregnancies. This octapeptide is secreted in a pulsatile manner, a fact that is reflected in the marked variability observed in minute-to-minute measurements of maternal plasma oxytocin concentration.[61] The half-life of oxytocin is 10 to 12 minutes.[62] The metabolic clearance rate is similar for men, pregnant women, and nonpregnant women: 20 to 27 mL/kg/minute.[63] The similarity of the metabolic clearance rate between men and pregnant women is striking in view of the large increase that occurs during pregnancy in the plasma concentration of leucine-aminopeptidase, an enzyme capable of hydrolyzing oxytocin. This suggests that factors other than this enzyme are responsible for the degradation of oxytocin.

There is considerable confusion regarding the pharmacokinetics of oxytocin; much of the original pharmacokinetic work was done prior to the availability of a reliable radioimmunoassay for oxytocin.[64] Indeed, the potency of oxytocin is still based on a bioassay of avian vasopressive activity with 1 United States Pharmacopeia (USP) unit being equivalent to 2 μg of oxytocin.

Traditionally, it has been held that oxytocin levels reached a steady-state level within 15 to 20 minutes of beginning an infusion or increasing the dosage. Recent work using a sensitive oxytocin radioimmunoassay has shown that approximately 40 minutes are required for any particular dose of oxytocin to reach a steady-state plasma concentration.[65]

It is well established that there is a marked variability in the response of the uterus to oxytocin, but in general, the sensitivity of the uterus to oxytocin increases dramatically as pregnancy progresses.[66] This increase in responsiveness is likely due to the increasing concentrations of oxytocin receptors in the myometrium and decidua with increasing gestational age.[67] It appears that oxytocin has direct stimulatory effects on the myometrium in addition to stimulating decidual prostaglandin production.[68] An increased level of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) metabolite was demonstrated in women undergoing successful oxytocin induction of labor, whereas this increase was not present in failed inductions.[69] The direct effect of oxytocin on the myometrium is believed to be mediated by polyphosphoinositide hydrolysis with production of inositol phosphates that act as a second messenger and lead to the mobilization of intracellular calcium ion.[70]

Other organs that show a response to oxytocin include breast, vascular smooth muscle, and kidney. Oxytocin stimulates contraction of the myoepithelium surrounding the alveoli of the mammary gland, leading to the milk ejection reflex. At dosages typically used for the induction of labor, there is no demonstrable effect on vascular smooth muscle tone. However, intravenous boluses of as little as 0.5 IU transiently decrease peripheral vascular tone, leading to hypotension.[71] Similarly, at low dosages, oxytocin exerts negligible effect on renal function; however, at high infusion rates, it exhibits a marked antidiuretic effect (which is not surprising, given its similarity in structure to antidiuretic hormone, also produced in the posterior pituitary). Excessively high infusion rates, coupled with infusion of crystalloid, have led to deaths from water intoxication.

Oxytocin can be administered by any parenteral route. It is also absorbed by the buccal and nasal mucosa. When administered orally and swallowed, oxytocin is rapidly inactivated by trypsin. The intravenous route is now used almost exclusively to stimulate the pregnant uterus because it allows precise measurement of the amount of medication being administered and a relatively rapid discontinuation of the effects of the drug when infusion is discontinued.

TECHNIQUES FOR THE ADMINISTRATION OF OXYTOCIN

Oxytocin is administered as a dilute solution with the flow rate into the intravenous line precisely regulated by an infusion pump. The health care professionals who attend the patient during an induced labor must be familiar with the use and potential complications of oxytocin. Likewise, a qualified physician who is able to manage any complications that may arise with the use of oxytocin should be readily available. Fetal monitoring is indicated prior to beginning the infusion to assess the baseline level of uterine activity and fetal status, and should then be continued during the infusion. Either external or internal monitoring is acceptable as long as uterine activity and fetal heart rate are adequately documented. Consideration should be given to the use of internal monitoring when high doses of oxytocin are required or when satisfactory progress in labor is not being made (see also Chapter 69 on the augmentation of labor). The tracing should be inspected frequently and carefully for any evidence of hyperstimulation as manifested by increased baseline tonus, tachysystole, or the onset of late decelerations; and the infusion of oxytocin must be stopped immediately should they occur.

Significant difference of opinion exists regarding the initial dose of oxytocin and the interval and frequency of dosage increase. A controlled intravenous oxytocin infusion remains the preferred method of induction of labor. Several trials have compared various regimens of oxytocin dosage increase and time intervals between dose increases.[72–76] Starting doses have ranged from 0.5 to 2.0 mU/minute, with some as high as 6 mU/minute. Increments of dose increase have ranged from a low of 1 to 2 mU/minute up to 6 mU/minute, with adjustments for increased uterine activity. Time intervals between increases have ranged from 15 to 40 minutes. Although low-dose regimens (initial dose 0.5–2.0 mU/minute, with incremental increases of 1–2 mU/minute every 15–40 minutes) are commonly utilized in the United States, high-dose regimens (initial dose 6–8 mU/minute, with incremental increases of 6 mU/minutes every 15–40 minutes) have been reported to be safe and effective for labor induction in patients with viable pregnancies, provided there was close fetal monitoring and early recourse to cesarean delivery in the event of fetal distress.[77] A meta-analysis of 11 trials comparing low-dose with high-dose oxytocin for labor induction found that larger dose increases and shorter intervals between increases were associated with shorter labors and lower rates of intra-amniotic infections and cesarean delivery for dystocia, but more hyperstimulation was noted.[78] Based on recent pharmacokinetic data,[79,80] many obstetricians have moved to a regimen whereby the dose of oxytocin is increased by 1 to 2 mU/minute every 40 minutes. Advantages of this regimen derive from not increasing the oxytocin dose before steady-state levels of oxytocin have been reached. This leads to a lower total dosage of oxytocin being used, in addition to a lower incidence of the hyperstimulation that can result from increasing the oxytocin dose before a steady state is reached. A potential disadvantage is that women who are relatively insensitive to oxytocin may have a very prolonged course before adequate labor is established. Nearly 90% of patients will respond to 16 mU/minute or less, and it is most unusual for a patient to require more than 20 to 40 mU/minute.[81]

The recognition that endogenous oxytocin is secreted in spurts during pregnancy and spontaneous labor has prompted exploration of a more physiologic manner of inducing labor with this agent. In 1978, Pavlou and associates were the first to describe a protocol of pulsatile infusion.[82] More recently, several randomized trials have compared the safety and efficacy of pulsatile oxytocin administration with continuous infusion.[83–85] Most authors conclude that although there does not appear to be a shortening of the induction-to-delivery interval, pulsatile administration of oxytocin reduces the amount of oxytocin required for successful labor induction.

SIDE EFFECTS AND COMPLICATIONS OF OXYTOCIN INFUSION

Although oxytocin is a safe medication with appropriate administration and monitoring, there is always the potential for adverse occurrences. The most common complication related to oxytocin induction of labor is uterine hyperstimulation. Uterine hyperstimulation may present as tachysystole with more than five contractions in 10 minutes, contractions of greater than 90 seconds' duration, or an increase in the baseline uterine tonus. The decreased intervillous blood flow associated with hyperstimulation ultimately leads to decreased oxygen transfer to the fetus, as indicated by the appearance of late decelerations. Oxytocin infusion should be discontinued immediately in the presence of hyperstimulation. If there is evidence of fetal distress, standard intrauterine resuscitation measures should be instituted, including oxygen administration and positioning the patient in the left lateral decubitus position.

Uterine rupture is a very uncommon complication when oxytocin is used appropriately. There are no prospective data in the literature describing the incidence of uterine rupture in oxytocin-induced labor. Retrospective series of uterine rupture have implicated oxytocin in 4.3%[86] to 12.5%[87] of occurrences. Factors that may reduce the risk of uterine rupture include avoidance of oxytocin in the grand multipara, use of internal uterine pressure monitoring for patients with previous cesarean delivery and when high doses of oxytocin are required, and avoidance of oxytocin in obstructed labors.

Water intoxication, an infrequent complication of oxytocin administration, may be avoided with appropriate management. The minimum effective dose of oxytocin should be used to avoid the antidiuretic effects of high-dose oxytocin. The risk of water intoxication increases in women who have received large volumes of free water; therefore, 5% dextrose solutions without electrolytes should generally not be used during labor induction. Symptoms occur as the plasma sodium concentration falls below 120 to 125 mEq/L and may include nausea and vomiting, mental status changes, and ultimately seizures and coma. Mild instances of water intoxication can be treated by discontinuing the hypotonic fluid and restricting fluid intake. With severe symptoms, correction of hyponatremia by saline infusion may be necessary.

Concern has been raised regarding a possible association between oxytocin-induced labor and an increased incidence of neonatal jaundice. Many of the older studies claiming that oxytocin leads to neonatal jaundice failed to control for confounding variables such as gestational age and the infusion of large volumes of free water. The more recent literature has not identified any correlation between oxytocin induction and neonatal hyperbilirubinemia.[88,89]

Prostaglandins

Exogenous prostaglandins, particularly dinoprostone (PGE_2), are frequently used as cervical ripening agents.[90–97] Because the prostaglandin-induced cervical ripening process often includes initiation of labor, approximately half of treated women with dinoprostone enter labor and deliver within 24 hours. Prostaglandins have the dual capability to ripen the cervix and initiate uterine contractility. As a consequence, induced labor with prostaglandins appears to be similar to that of spontaneous labor. The use of prostaglandins (PGs) as labor induction agents has been reported extensively in a variety of PG classes, doses, and routes of administration.[27] Prior to 1992 most trials assessing the impact of prostaglandins as cervical ripening and labor induction agents included various dosages of intracervical (0.3–0.5 mg) or intravaginal (3–5 mg) dinoprostone (PGE_2). In 1992, the Food and Drug Administration (FDA) approved PGE_2 (0.5 mg intracervically) for cervical ripening and labor induction. In 1995, a slow-release 10-mg dinoprostone vaginal insert also was approved for the same indications. Because most trials have compared these prostaglandin preparations with placebo, the relative efficacy of these two prostaglandin preparations has been difficult to assess. Additionally, once cervical ripening was completed and uterine activity initiated, most patients studied required further augmentation with oxytocin.

The optimal route for PGE_2 administration has not yet been determined. The intracervical route has been used in the majority of trials, especially those comparing the effectiveness of the FDA-approved formulations (Prepidil and Cervidil). Although intracervical administration of gel is more difficult than intravaginal administration, the former route appears to cause more significant cervical ripening. The intracervical method also appears to be associated with a lower risk of hyperstimulation. However, the easiest and most practical way to apply PGE_2 in routine clinical practice is via the vaginal route. The most commonly used doses are 3 to 5 mg. It has been suggested that the dose of PGE_2 should be varied according to the patient's cervical score, permitting a lower dose of PGE_2 to be used in many cases. Just as there is no consensus about the optimal dose and route of administration of PGE_2, the optimal frequency of administration is still a matter of debate. A commonly used approach to cervical ripening and labor induction

with PGE$_2$ is to administer approximately 3 mg at 4- to 6-hour intervals for two doses, followed by oxytocin induction or augmentation in 12 to 18 hours if necessary. Irrespective of the route and dose of PGE$_2$ employed, for the majority of patients, dinoprostone preparations should be regarded mainly as cervical ripening agents, and are not reliable as labor induction agents.

MISOPROSTOL FOR LABOR INDUCTION

Misoprostol is a synthetic prostaglandin E$_1$ (PGE$_1$) analogue that has been marketed in the United States since 1988 as a gastric protective agent for the prevention and treatment of peptic ulcers. It was licensed in a tablet form designed for oral absorption. Early studies performed in the late 1980s and early 1990s demonstrated that oral administration of misoprostol caused uterine contractions in early pregnancy.[98–100] Subsequent studies, performed abroad and in the United States, showed that intravaginal administration of misoprostol tablets can terminate first-trimester and second-trimester pregnancies.[101–105] A large number of published controlled trials have shown that misoprostol, administered either vaginally or via the oral route, is an effective agent for cervical ripening and labor induction in patients with viable pregnancies.[32–50,106–114] An initial meta-analysis suggested a significantly reduced cesarean delivery rate for patients induced with misoprostol.[115] Follow-up meta-analysis has shown that 84% of patients receiving misoprostol go into active labor, with only 29.4% requiring oxytocin augmentation. A significantly higher proportion of patients receiving misoprostol achieved a vaginal delivery within 12 hours (37.6% versus 23.9%). Similarly, 68.1% of patients receiving misoprostol achieved a vaginal delivery within 24 hours. Use of misoprostol for cervical ripening and labor induction is associated with an approximate 5-hour reduction of the interval from the first dose to delivery when compared with dinoprostone. The reduced induction-to-delivery interval seen with misoprostol compared with dinoprostone implies that either it produces higher levels of uterine activity, or that it is a more efficient cervical ripening agent. Consistent with the former hypothesis, compared with women receiving dinoprostone, Foley catheter, or placebo, women receiving misoprostol are twice as likely to experience tachysystole and uterine hyperstimulation, with the incidence of these conditions closely related to the dose of misoprostol administered.[115]

In relation to cervical ripening, most of the individual studies in meta-analyses assessing the efficacy and safety of misoprostol and dinoprostone have not shown a significant reduction in the overall cesarean delivery rate. However, the lack of a positive finding was probably because the sample sizes of the trials were small. The 44 trials included in the recent meta-analysis[115] provide data for 5735 subjects participating in trials assessing the impact of misoprostol treatment on the cesarean delivery rate. When all the trials were pooled, subjects receiving misoprostol had a significantly lower cesarean rate than subjects in the comparison groups (17.3% versus 22.9%). The most common indications for cesarean delivery were arrest of dilation or descent, failed induction, and abnormal fetal heart rate tracings. The rate of cesarean deliveries performed because of fetal heart rate abnormalities was similar for misoprostol-induced patients and those in the comparison group. Similarly, no difference was noted for the rate of cesarean deliveries because of dystocia. Patients receiving misoprostol had a significantly lower rate of cesarean deliveries because of failed induction. This suggests that it may be better at ripening the cervix than dinoprostone.

No evidence of adverse perinatal or maternal effects has been noted.[116] The statistical power resulting from the aggregation of 44 studies included in the meta-analysis increases confidence in our ability to assess safety. The number of subjects studied affords a power of at least 90% to detect a difference in neonatal intensive care unit admission rates of at least 4 percentage points (from 14% to 18%). Sufficient power was also noted for the detection of at least a doubling in the rate of abnormal 5-minute Apgar scores (from 1.4% to 2.8%).

Accordingly, these data provide strong support for the conclusion that misoprostol safely decreases the cesarean delivery rate among women undergoing labor induction compared with women receiving alternate induction agents.

ORAL VERSUS VAGINAL ADMINISTRATION

Initial pharmacokinetic studies compared the pharmacokinetics of vaginal and oral administration of misoprostol.[117–120] These studies showed that the peak plasma concentration of misoprostolic acid was higher and achieved earlier after oral administration, but the detectable plasma concentration lasted longer after vaginal administration. Systemic bioavailability of vaginally administered misoprostol was noted to be three times higher than that of orally administered misoprostol.[117] In all patients studied, independent of the dose or route of administration, the first effect of misoprostol treatment was an increase in uterine tonus. After oral administration, the effect was more rapid and the initial increase was more pronounced than after vaginal treatment. However, after vaginal treatment, tonus remained at a higher level for a longer time.

A significant proportion of the published randomized studies have evaluated the safety and efficacy of vaginally administered misoprostol for cervical ripening and labor induction. During the past few years, seven randomized trials have compared oral versus vaginal administration of misoprostol for labor induction.[109–114,121] In aggregate, 1191 patients were randomized to receive misoprostol orally ($n = 602$) or by the vaginal route ($n = 589$). The oral doses employed ranged from 50 μg to 200 μg every 4 to 6 hours. Vaginal misoprostol was administered in doses ranging from 25 μg to 100 μg every 3 to 4 hours. No

difference was noted in the proportion of patients who delivered vaginally within 12 and 24 hours in each group. Similarly, the intervals from start of induction to vaginal delivery were not different. The proportion of patients experiencing increased uterine activity (tachysystole or hyperstimulation) was similar for both groups. Additionally, no difference was noted for the incidence of abnormal 5-minute Apgar scores and rates of NICU (neonatal intensive care unit) admissions. Interestingly, the rate of cesarean delivery was significantly lower among those induced with oral misoprostol. Although both routes of misoprostol administration seem to be efficacious, the evidence documenting the safety of vaginally administered misoprostol is much more extensive.

DOSES OF MISOPROSTOL FOR LABOR INDUCTION

Owing to the small number of studies employing oral misoprostol, and the lack of uniformity in dosage, the most appropriate dose of misoprostol for labor induction has not been determined. At the present time, oral doses of 100 μg administered every 3 to 4 hours appear to be safe and effective. Further studies are needed to determine whether higher doses can improve efficacy without increasing the rate of adverse maternal and perinatal outcomes.

Since the majority of studies have assessed the safety and efficacy of vaginal administration, more data are available to determine the most appropriate dose. Although dosing regimens as high as 200 μg have been reported in the literature, most authors have used vaginal misoprostol doses of 25 or 50 μg. Because of the increased incidence of uteronic effects, some authors have advised against the use of doses greater than 25 μg. However, the data that form the basis for this recommendation are limited. Six randomized clinical trials have been specifically designed to compare the safety and effectiveness of 25 or 50 μg of misoprostol administered intravaginally.[122–127] These trials, although generally well designed, are hampered by small sample size and thus prone to type II errors. A systematic review with meta-analysis of five randomized trials concluded that intravaginal misoprostol at doses of 50 μg for cervical ripening and labor induction is more efficacious, but it is unclear whether it is as safe as the 25-μg dose.[128]

In addition to the six randomized trials and the systematic review, two separate studies have compared the two doses (25 versus 50 μg). These two studies compared intravaginal misoprostol with intracervical dinoprostone gel (Prepidil).[37,38] The misoprostol dosage for the first study was 50 μg every 3 hours for a maximum of six doses, whereas the second study used 25 μg every 3 hours for a maximum of eight doses. Taken together, these two studies indirectly compared two doses of misoprostol: 25 μg and 50 μg. Subjects allocated to receive 50 μg experienced shorter intervals to vaginal delivery and no differences in

overall cesarean or operative delivery rates, cesarean deliveries for fetal heart rate (FHR) abnormalities, or NICU admission rates. Although subjects receiving 50 μg of misoprostol experienced a greater incidence of tachysystole, no significant increases in adverse maternal or perinatal outcomes were noted. Meconium-stained fluid was noted more frequently for those receiving 50 μg of misoprostol. Given the reassuring perinatal findings noted previously, this latter finding, however, is of questionable importance. Because these two separate studies by Wing and associates[37,38] indirectly compare two doses of misoprostol, 25 μg and 50 μg, they were incorporated into the present analysis. Altogether, 906 patients were compared: 479 received doses of 25 μg and 427 received doses of 50 μg (Table 68–5). Patients who received the 25-μg dose had a lower incidence of tachysystole and hyperstimulation; however, they also had a longer interval to vaginal delivery, and a lower proportion of these patients delivered vaginally within 12 and 24 hours. No differences were noted in the cesarean delivery rate, cesareans performed for FHR abnormalities, operative delivery rates, or NICU admissions.

A recent ACOG (American College of Obstetricians and Gynecologists) Committee Opinion states that if misoprostol is used for cervical ripening and labor induction, 25 μg should be considered for the initial dose.[129] This opinion is based on the greater incidence of tachysystole noted with larger doses of misoprostol. Despite increased uterine activity with greater doses, however, greater rates of adverse maternal or perinatal outcomes have not been reported. Although existing evidence suggests that both the 25- and 50-μg doses of misoprostol are currently appropriate for intravaginal administration, we agree that further large prospective trials are required to define an optimal dosing regimen.

Cervical Ripening and Labor Induction in Special Circumstances

Previous Cesarean Delivery

Among patients with a previous cesarean section, the incidence of uterine disruption is greater with induced labor than with spontaneous labor (0.65% versus 0.40%).[130] Patients in this group undergoing cervical ripening and labor induction with PGE$_2$ (dinoprostone) experience a rupture rate of 0.9%.[131]

In women with unscarred uteri, vaginal or oral administration of misoprostol has been found safe and effective for patients with unfavorable cervices who require labor induction. There are indirect data, however, from which to assess the risks and benefits of using misoprostol to ripen the cervix and induce labor in women with a previous lower uterine segment scar. Recent publications have suggested that the use of misoprostol in patients with

previous cesarean delivery is associated with a high frequency of uterine disruption (dehiscence or frank rupture).[132–138] Most of these publications consist of a few case reports or are based on retrospective uncontrolled studies. A randomized trial designed to compare the safety and efficacy of vaginally administered misoprostol in women with previous cesarean deliveries was prematurely terminated.[133] At the time this study was halted, however, the study had not met specific criteria for early termination.[139]

We used several sources to identify all publications that have reported the use of misoprostol for cervical ripening and labor induction in women with previous cesarean delivery. Eleven studies have been published indicating the use of misoprostol for cervical ripening and labor induction in women with scarred uteri.[132–138,140–143] Uterine disruptions, dehiscence, or rupture were reported in six of the studies.[132–137] Of 355 patients included in these 11 studies, 16 (4.5%) experienced uterine disruption. Because several confounding factors were present, however, it is important to analyze these data in detail. Data are available for 10 of 16 patients reported to have experienced uterine disruptions. The mean age of the patients was 29.6 ± 4.7 years with a mean gestational age of 39.5 ± 2.1 weeks. Three patients had two previous cesarean deliveries and, in two other patients, the type of scar was unknown. Although the information is not precise, it appears that in at least in three cases, the patients had a dehiscence of the previous incision. Most patients were induced with single or multiple vaginal doses of 25 μg of misoprostol. Two patients received four doses, and two others received at least three doses of misoprostol. The median interval from the last dose of misoprostol until the diagnosis of uterine disruption was 10 hours (interquartile range 8.5–17.2 hours). Seven patients received oxytocin infusion after misoprostol was administered and before the diagnosis of uterine disruption. Only two experienced tachysystole, and all patients were delivered by cesarean. The mean birth weight was 3438 ± 572 g. Four cases of neonatal acidemia and one neonatal death were reported.

Because of the paucity of data, there is a lack of sufficient evidence from which to assess the risks and benefits of using misoprostol or other prostaglandins to induce labor in women with a scar from a previous lower segment cesarean delivery. Randomized controlled trials are needed to assess outcomes including vaginal delivery rates, interval to delivery, and number of failed inductions. We are currently completing a trial comparing intravaginal misoprostol with oxytocin infusion in patients with previous cesarean delivery. Because uterine disruption is such an uncommon event, however, only a large multicenter randomized controlled trial will yield adequate statistical power to assess safety in this population of patients. To detect a difference in uterine rupture from 1% to 3.7%, such a trial would have to include 565 patients in each group ($\alpha = 0.05$, $\beta = 0.80$). Until such a trial is performed, an alternative approach would be to perform a case-control study. In the meantime, the use of misoprostol for cervical ripening and labor induction in women with a previously scarred uterus should occur only in the setting of a research protocol.

Twin Pregnancies

Twin pregnancies frequently involve maternal and fetal complications, which require early delivery. Additionally, the optimal timing of birth for women with an otherwise uncomplicated twin pregnancy at term is uncertain, with clinical support for both elective delivery at 37 weeks as well as expectant management. Elective delivery at term may be performed via an elective cesarean or vaginally with the use of mechanical or pharmacologic agents for cervical ripening and labor induction. At present, there are insufficient data to support a practice of elective cesarean delivery for women with an otherwise uncomplicated twin pregnancy at term.

The safety and efficacy of uterotonic agents, particularly oxytocin, for labor induction in women with twins are not as clear as in those with singleton pregnancies. Some clinicians believe that the overdistended uterus encountered with twins is resistant to oxytocin and may require high doses to obtain adequate uterine contractions. Additionally, some clinicians suspect that a gravida with twins is prone to hyperstimulation or even uterine rupture with relatively low doses of oxytocin. Although there are no large randomized trials attesting to the safety and efficacy of cervical ripening and labor induction in patients with twin pregnancies, several retrospective studies have suggested that labor induction, with a variety of induction agents, is acceptably safe. A recent case-matched control study compared the safety and efficacy of labor induction with oxytocin versus spontaneous labor in 62 women with twin pregnancies.[144] Twin pregnancy had no adverse impact on the effectiveness or efficiency of oxytocin labor stimulation; indeed it appeared to be associated with fewer side effects. Additional case series of labor induction in twin pregnancies have included the use of intrauterine balloon catheters,[145] oral dinoprostone or PGE_2,[146] and oxytocin.[147]

Although misoprostol has been shown to be a safe and effective agent for labor induction in singleton pregnancies, there are no published studies in women with twin pregnancies. If misoprostol is chosen for labor induction in twins, continuous monitoring of the fetal heart rate and uterine contractions should be performed. Repeated doses should only be used if there is definitely no evidence of regular uterine activity.

According to the American College of Obstetricians and Gynecologists, twin pregnancies do not necessarily constitute a contraindication to labor induction.[148] However, as with misoprostol, patients with twin pregnancies who undergo labor induction with oxytocin, or with any other agent, need to be monitored very closely.

Fetal Death

The ideal method for termination of pregnancy in cases of intrauterine fetal demise should be effective and safe and should have minimal side effects. In the past, oxytocin infusion and PGE$_2$ vaginal suppositories (referred to as pessaries in the United Kingdom) were the most commonly used methods for labor induction in patients with fetal death.

INTRAVENOUS OXYTOCIN

Intravenous oxytocin is a time-honored, effective, and safe method for inducing labor in cases of intrauterine fetal demise. However, oxytocin infusion is less effective when used in patients with a very unripe cervix and in those remote from term. Large doses and prolonged administration may be required, circumstances that increase the risk of water intoxication and attendant central nervous system complications. For patients who are remote from term, some authors have reported the use of high-dose oxytocin.[149] One regimen describes the use of approximately 300 mU/minute (200 units of oxytocin in 500 mL of 5% dextrose lactated Ringer solution or 5% dextrose and half normal saline at 50 mL/hour). In this setting, 5% dextrose and water has been associated with hyponatremia. Electrolytes should be checked before beginning oxytocin and should be repeated every 24 hours or if signs and symptoms of water intoxication occur. Attention should be paid to fluid intake and urinary output. For patients at or near term, lower doses of oxytocin are usually required. Laminaria, or other mechanical means of cervical ripening, may be beneficial before the use of oxytocin for induction.

PROSTAGLANDINS

Many cases of fetal death can be managed simply and effective by PGE$_2$ vaginal suppositories. The customary dose is one 20-mg suppository inserted vaginally every 4 hours until contractions are sufficient to promote progressive cervical change. Generally, this dose is used only for patients who are at no more than 28 weeks' gestation. However, some authors have reported safe use in the third trimester.[150] Reported side effects with higher doses (20 mg) of PGE$_2$ vaginal suppositories include fever, nausea, vomiting, and diarrhea. These annoying side effects may be ameliorated with appropriate and specific pretreatment medications. Although PGE$_2$ vaginal suppositories have been used safely in the third trimester, the risk of uterine rupture is increased.

More recently, misoprostol (synthetic analogue of PGE$_1$) has been used safely and effectively for cervical ripening and labor induction in patients with fetal death. Mariani-Neto and associates first reported the use of oral misoprostol (400 µg every 4 hours) for induction of labor following fetal death.[151] The authors reported their experience with 20 patients with fetal demise at 19 to 41 weeks' gestation. All patients delivered successfully with a mean interval to delivery of 552 minutes. The mean dose of misoprostol required was 1000 µg (400 to 2800 µg). Additional studies have assessed the safety and efficacy of misoprostol in the management of fetal death.[152–153] The doses and routes of administration have varied significantly among the studies. Oral doses of 200 µg and vaginal doses ranging from 50 to 200 µg every 4 to 6 hours have been employed. Some authors have combined misoprostol with mifepristone; patients receive a single dose of 200 mg mifepristone orally, following which a 24- to 48-hour interval is recommended prior to administering 100 to 200 µg of misoprostol in the vagina every 3 hours.[152,153]

Wagaarachchi and associates first reported a combination of vaginal and oral misoprostol after priming with mifepristone.[154] Women received a single dose of 200 mg mifepristone followed by a 24- to 48-hour interval before administration of misoprostol. For gestations of 24 to 34 weeks, 200 µg of intravaginal misoprostol was administered, followed by four oral doses of 200 µg at three 1-hour intervals. Gestations over 34 weeks were given a similar regimen but a reduced dose of 100 µg misoprostol. The average induction-to-delivery interval was 8.5 hours, which was the shortest among the previous regimens. Improved patient acceptability and reduced risk of introducing intrauterine infection are potential advantages of oral over vaginal route.

High doses of misoprostol (vaginal or oral administration) may be associated with fever, chills, and diarrhea. Pretreatment with antidiarrheal and antiemetic agents may reduce adverse effects.

EXTRA-AMNIOTIC SALINE INFUSION

Extra-amniotic saline infusion has been shown to be successful in inducing labor in antepartum deaths after 20 weeks' gestation.[155] A size 18 Foley catheter is inserted through the cervix under direct vision. The balloon is inflated with 30 mL of sterile water, and the catheter is usually strapped to the thigh under slight traction. Normal saline (0.9%) infusion is started to run at 30 drops per minute, and a maximum volume of 2 L should be infused into the extra-amniotic space.

CONCLUSIONS

INDUCTION OF LABOR

- Labor induction is indicated when the benefits of delivery to the mother and/or fetus outweigh the risks of continuing the pregnancy.
- More than 80% of inductions are for post-dates and hypertension.
- Social inductions are controversial and should not be performed before 39 weeks because of the risks to the neonate of pulmonary immaturity.
- The success of induction is higher in parous than nulliparous women, and is also strongly dependent on the ripeness of the cervix.
- The most widely used index of cervical ripeness is the Bishop score.
- If the Bishop score is 6 or less, induction is best done with an agent that ripens the cervix as well as producing uterine activity; this is usually a form of prostaglandin.
- Mechanical methods, such as laminaria tents and balloons, are also effective at ripening the cervix.
- Dinoprostone (prostaglandin E_2) is widely used for ripening and induction but misoprostol has the advantages of easier storage (because it is stable at room temperature and does not need to be stored in a refrigerator) and cheapness. Appropriate doses (for parous/nulliparous women) are 1-2mg of dinoprostone and 25–50 μg of misoprostol.
- Parenteral administration of oxytocin is effective at inducing labor, especially when combined with artificial rupture of the membranes. It has no direct effect on ripening of the cervix.
- The safest and most widely used regimens for induction with intravenous oxytocin commence at 1-2 mU/min and increase the dose by 1–2 mU/min every 40 minutes until contractions are effective (with a contraction frequency of no more than five in ten minutes). Less than 10% of women will require more than 16 mU/min to establish satisfactory uterine activity.
- All oxytocics carry a small risk of causing uterine rupture; the risk is higher in parous women and even higher in women with a scarred uterus. The risk is higher with prostaglandins (including misoprostol) than with oxytocin because the oxytocic effect is less controllable.

SUMMARY OF MANAGEMENT OPTIONS
Induction of Labor

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—General			
Bishop score is still the most reliable indicator of success of induction.	III	B	4
Prenatal—Indications			
Women should have a valid indication for IOL and no contraindications (see Tables 68–1 and 68–2).	III	B	81
Indications should be such that mother or fetus will benefit from a higher probability of a healthy outcome than if birth is delayed.	III	B	81
For a consideration of the validity of specific indication for induction of labor, see specific chapters.	–	–	–

Prostaglandins are effective.	Ia	A	267
In women with intact membranes, vaginal prostaglandin E_2 is superior to oxytocin.	Ia	A	27,28
Although both routes are equally effective, intravaginal PGE_2 is preferable to intracervical as it is less invasive.	Ia	A	267
PG tablets (3 mg) are equally effective as PG gel (1–2 mg) every 6 hours, but tablets offer financial savings.	Ia	A	267
Oxytocin use in women with intact membranes should be combined with amniotomy.	III	B	81
Oxytocin should not be started for 6 hours following prostaglandin administration.	III	B	81
Oxytocin starting dose is 1–2 mU/minute, increased at intervals of 30–40 min.	III	B	81
Misoprostol appears to be a cheap, effective induction agent. Safety issues are probably related to dose or route and are being assessed.	Ia	A	115
Other methods such as mechanical methods, estrogens, relaxin, hyaluronidase, castor oil, bath, enema, and breast stimulation have varying efficacy.	III	B	81
Labor-Monitoring			
Fetal well-being should be established prior to induction of labor.	III	B	81
Following insertion of prostaglandin, fetal well-being should be established once contractions begin.	III	B	81
When oxytocin is being used for induction, continuous electronic monitoring should be used.	III	B	81
If there is uterine hypercontractility, tocolysis should be considered.	Ia	A	37,38,128

TERMINATION OF PREGNANCY FOR FETAL ANOMALY

Introduction

In 2001, 12% of all legal terminations of pregnancy (TOP) reported to the U.S. Centers for Disease Control and Prevention (CDC) occurred after 12 weeks' gestation. Only 5.6% were performed after 15 weeks' gestation: 4.2% at 16 to 20 weeks and 1.4% at 21 to 24 weeks. Dilation and evacuation (D&E) accounted for 96% of these procedures. From 1974 through 2001, the percentage of second-trimester TOP performed by D&E increased from 31% to 96%; and the percentage of second-trimester TOP performed by intrauterine instillation (intra-amniotic, extra-amniotic) using hypertonic saline, urea, or prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) decreased from 57% to 1.3%.[156] D&E, preceded by cervical preparation, is safe and effective when undertaken with appropriate instruments by practitioners who have a sufficient workload to maintain their skills.[157,158] Compared with intra-amniotic instillation methods, dilation and evacuation has lower complication rates.[158–161] However, almost all the comparative data relate to obsolete abortifacients (such as saline and urea solutions) that are rarely used today.

The introduction of PG analogues in the late 1970s changed the management of TOP in the second trimester; they were initially instilled into the amniotic cavity, and later used for cervical ripening. The subsequent introduction of the antiprogestin, mifepristone, shortened the induction-to-TOP interval still further, and the dosage of PG analogues required was reduced. Today, medical TOP is the method of choice in many centers that perform second-trimester TOP.[162–164]

Both D&E and medical induction are relatively safe, with low complication rates.[159,165] The method chosen is largely dependent on physician preference and level of technical expertise, coupled with the patient's informed decision.

Definition

Termination of pregnancy is the medical or surgical removal of a pregnancy before the time of fetal viability while preserving the life and health of the mother. Patients in need of TOP can be identified at any gestational age; however, the great majority are performed at 24 weeks' gestation or less.

Indications

The most commonly accepted indications for TOP are as follows:

- A pregnancy that would result in the birth of a child with anomalies incompatible with life or associated with significant physical or mental morbidity
- Fetal death
- To save the life of the mother or preserve the health of the mother

Fetal Conditions

Significant structural and chromosomal conditions affect at least 3% to 5% of all births, and an increasing number of women will be faced with the decision to end a pregnancy based on fetal health concerns.[166,167] Unfortunately, because fetal assessment (e.g., using biochemical screening, ultrasound, chorionic villus sampling, or amniocentesis) is not available until the second trimester, TOP for this indication is usually later in gestation than TOP for social indications. The number of fetal conditions that can be identified during pregnancy continues to expand because of the steady improvement of the technology available for prenatal diagnosis. Conditions that can be identified include the following:

1. Chromosomal disorders (e.g., trisomy 21, 18, 13)
2. X-linked disorders (e.g., hemophilia)
3. Metabolic disorders (e.g., Tay-Sachs)
4. Neural tube defects (e.g., anencephaly, spina bifida)
5. Structural anomalies associated with exposure to teratogens
6. Infections (e.g., rubella, cytomegalovirus, toxoplasmosis)
7. Structural anomalies of multifactorial or unknown etiology
8. Other fetal indications, including preterm prelabor rupture of membranes prior to 24 weeks and fetal death at 24 weeks or less

Maternal Conditions

Terminations of pregnancy to save the life or preserve the health of the mother are rare events. Some women with chronic medical conditions choose pregnancy termination only after discovering for the first time during pregnancy that continuing the pregnancy poses significant health risks for themselves. This failure of preconception counseling is unfortunately more common than it should be. For most chronic medical conditions, sufficient data exist to permit accurate decisions as to the likelihood and magnitude of risks associated with a continuing pregnancy, although it is often impossible to say precisely who will be affected. For example, although one can quote 30% to 50% mortality rate for pregnancy in association with Eisenmenger syndrome or pulmonary hypertension, half the women counseled will survive, and it is usually impossible to say which half. In the case of other medical indications for TOP, such as severe hypertensive vascular disease and certain malignancies, the prognosis can be given with more certainty.[168-170] Decision for TOP in this context should be based on the collaborative agreement of a multidisciplinary team. At minimum, the team should consist of the patient, the obstetrician, a medical specialist, and an expert in genetic counseling. Additional members may include family members, spiritual counselors, nurses, intensive care specialists, and ethicists. The decision must be individualized for each patient.

Legal Termination of Pregnancy Services

In the United States, only a few states provide public funding for TOP, and one third of private insurance plans provide limited or no coverage.[171] Women with federally funded medical care are covered for TOP services only if the woman's life is threatened, or in cases of rape or incest (32 states), when medically necessary (16 states), and in cases of life endangerment (2 states). Hence, cost considerations pose formidable barriers to women seeking TOP, even when there is gross fetal malformation.

Clinicians performing D&E procedures need training from an experienced mentor and the opportunity to maintain proficiency through ongoing experience. In the United States only 44% of all facilities providing TOP offer services at 14 weeks' gestation; the proportion declines dramatically as gestation advances, to 22% at 20 weeks and 7% at 24 weeks.[172] Moreover, only 7% of obstetrics and gynecology residency programs currently provide routine training in second-trimester TOP.[173] Labor induction is an integral part of obstetrics and gynecology training; training in D&E for second-trimester TOP is not. Among graduating obstetrics and gynecology residents in U.S. programs, 43% had never performed a D&E, and 81% had performed 10 or fewer procedures.[173] Therefore, despite the safety advantages of D&E, women requesting second-trimester TOP may be limited to labor induction methods simply because practitioners trained and willing to perform D&E are unavailable. Thus, the future availability of D&E, especially beyond 15 weeks of gestation, is uncertain. As the availability of D&E procedures decreases, the need for safe, efficacious methods of medical TOP will increase.

Patient Assessment and Counseling (See also Chapter 9)

Patient assessment should include history, physical examination, appropriate laboratory studies, and counseling.

History

The complete medical history should focus on the timing and reliability of the last normal menstrual period. If there is the slightest doubt about gestational age (for example, a discrepancy between the history and examination findings), assessment of fetal size with ultrasound is crucial. Knowledge of past reproductive history, sexual history, current medications, allergies, prior pelvic surgery, and any known uterine anomalies is important. Women with medical conditions severe enough to warrant TOP may require additional evaluation and stabilization prior to the procedure.

Physical Examination

Physical examination must include vital signs, weight, uterine size, and cardiopulmonary assessment. A sterile speculum examination should be done, seeking cervical pathologic problems, such as active cervicitis, deformities, and past trauma. A small, stenotic, or scarred cervical os may impair the cervical dilation necessary for safe surgical TOP.

Laboratory Studies

Few laboratory studies are required in young healthy women, but hematocrit, Rh status, indirect Coombs, and urinalysis results should be obtained.

- A complete blood count (CBC) and blood typing are the minimum laboratory studies required for surgical TOP.
  - A CBC is required to identify patients with significant anemia, who are at risk if excessive blood loss occurs. Transfusion may be needed, particularly in second-trimester TOPs. Patients with severe anemia are best treated in a setting where transfusion is available.
  - Blood typing is required so that Rh-negative women can be identified and given anti-D immunoglobulin (RhoGAM) to prevent Rh sensitization in subsequent pregnancies.
  - Screening for common sexually transmitted infections (STIs) should be addressed in geographic areas of high prevalence, in age groups at high risk (i.e., <25 years), and in at-risk groups (e.g., those with histories of STIs, multiple sex partners, substance abuse).
- Additional laboratory testing is dictated by the medical history and physical examination findings.

Coagulation studies are indicated for patients with conditions such as a history of coagulopathy, hematologic malignancies, hemorrhage with previous surgical procedures, petechiae, bruising, and hepatosplenomegaly.

Liver function tests are indicated for patients with conditions such as hepatitis, alcohol abuse, cancer, hepatomegaly, and jaundice. Renal function tests are indicated for patients with conditions such as renal disease, recurrent urinary tract infections, oliguria, hematuria, and proteinuria.

Electrolyte assays are necessary in patients who develop significant vomiting associated with the use of medical TOP techniques.

Ultrasound, in addition to its value for prenatal diagnosis, is used for determination of gestational age, placental location, and detection of uterine fibroids or the presence of uterine anomalies (e.g., uterus didelphys, unicornuate uterus, septate uterus).

Counseling

When a congenital fetal anomaly is diagnosed, the clinician should meet with the patient for the following reasons:

- To explain to the patient the nature and severity of the anomaly
- To discuss the treatment options available for the management of the anomaly
- To explain the implication(s) of the anomaly for the child and on the family
- To refer the patient for expert opinion if the clinician is uncertain about the congenital anomaly or its implication(s), treatment, and so on

The purpose of counseling is to help the patient understand her options regarding the pregnancy. In cases with severe anomaly, TOP may be offered as an option when there is a substantial risk that if the child were born, it would suffer from such physical or mental abnormality as to be seriously handicapped. If the clinician, based on his or her professional opinion, disagrees with the patient on her decision regarding TOP, the patient should be reminded that she can seek a second opinion.

At the minimum, the patient should know the diagnosis, purpose of the procedure, risks and possible complications, alternative treatments, and the likelihood of successful treatment.

Therefore, the woman should be given appropriate information related to the choice between TOP and continuing her pregnancy to viability, regardless of the physician's personal views about rearing a child with such an anomaly or about TOP. However, although physicians have a duty to give full and accurate information, they have no obligation to be involved in the procedure itself if they have ethical objections. For this reason, training in carrying out TOP should not be mandatory, although it

is mandatory for physicians to be knowledgeable about the procedure and its complications so that they can give accurate advice and make an appropriate referral to someone who is willing to perform it.[174]

Choice of Methods

Termination of pregnancy can be achieved by surgical means or with pharmacologic agents alone, in combination, or as an adjunct to a surgical method. The methods described refer to pregnancy termination at 13 to 24 weeks' gestation. The decision over which method to use is primarily determined by the following factors:

- The gestational age
- The expertise of the available medical staff
- Patient preference
- The clinical importance of obtaining an intact fetus
- Presence of other complicating clinical conditions

Generally, dilation and suction evacuation can be used up to 14 weeks' gestation, but thereafter, specific techniques of cervical preparation and special instruments for D&E need to be used. Modern methods of aggressive cervical preparation coupled with extensive clinical experience of the procedure have resulted in improved safety for D&E.[175] Moreover, there are limited data on the new labor induction agents compared to D&E.[166]

From a provider perspective, D&E allows predictable scheduling and avoids the prolonged period of medical observation typical of labor induction. Patients having a TOP for fetal anomaly may find that the prospect of a prolonged induction and delivery compounds the anguish of their decision and loss. A surgical TOP, possibly under general anesthesia, may be less traumatic emotionally. Shulman and colleagues observed recently that patients in their institution recovered more quickly after D&E and required fewer referrals for postoperative counseling than patients having a medical TOP.[176] However, D&E places a greater emotional burden on the surgeon and support staff.[177]

Although some women elect to have a medical TOP out of a desire to avoid surgery, the rate for the use of surgical aspiration or curettage to treat incomplete TOP is 15% to 30% or higher.[165–167]

On the other hand, grieving is important for many parents of a fetus with congenital abnormality, and seeing and holding the fetus are important components of healing.[178] In addition, medical TOP results in the delivery of an intact fetus and therefore allows optimal evaluation and confirmation of suspected genetic or structural abnormalities. This information is vital in counseling couples about the likelihood of recurrence.

Currently, medical TOP with misoprostol is a safe alternative to surgical TOP in patients with acute medical conditions and chronic debilitating illnesses. In our experience, misoprostol combined with mechanical cervical dilators such as a Foley catheter or laminaria tents can be used safely in patients with severe hypertensive disorders, cardiac disease, or asthma.[179]

In difficult or challenging cases, especially at or beyond 16 weeks, the physician, in consultation with the patient, must choose the most appropriate method based upon the patient's individual circumstances.[180,181]

Clincal Setting

Surgical D&E can be performed safely in a variety of outpatient settings, including a physician's office, provided there is an efficient system for emergency transfer.[182–184] In contrast, medical TOP services are usually provided in hospital settings.

Surgical Methods

Surgical methods include dilation and evacuation (D&E), dilation and intact extraction (D&X), hysterotomy, and hysterectomy. The use of real-time ultrasound scanning during D&E can reduce perforation rates.[185] Hysterotomy or hysterectomy is seldom used owing to higher rates of morbidity and mortality.[186] Prerequisites for surgical TOP include cervical preparation, adequate cervical dilation to use a 16-mm suction cannula, special grasping forceps, adequate anesthesia, oxytocic agents, antibiotic prophylaxis, and appropriate postoperative care.

Dilation and Evacuation

Anesthesia

The choice of anesthesia must be based on the medical, psychiatric, and emotional condition of the patient. Consultation with anesthetists, medical specialists, and psychiatric specialists may be necessary to determine the best choice for the individual patient. In general, paracervical block with light sedation provides sufficient anesthesia for many patients; however, the full range of anesthesia options must be available. Use of short-acting barbiturates by intravenous bolus infusion is a simple, effective form of general anesthesia that obviates the need for muscle relaxants, intubation, and halogenated gases.[187]

Cervical Preparation

A variety of mechanical and pharmacologic methods have been utilized (see –4).

Use of Osmotic Dilators

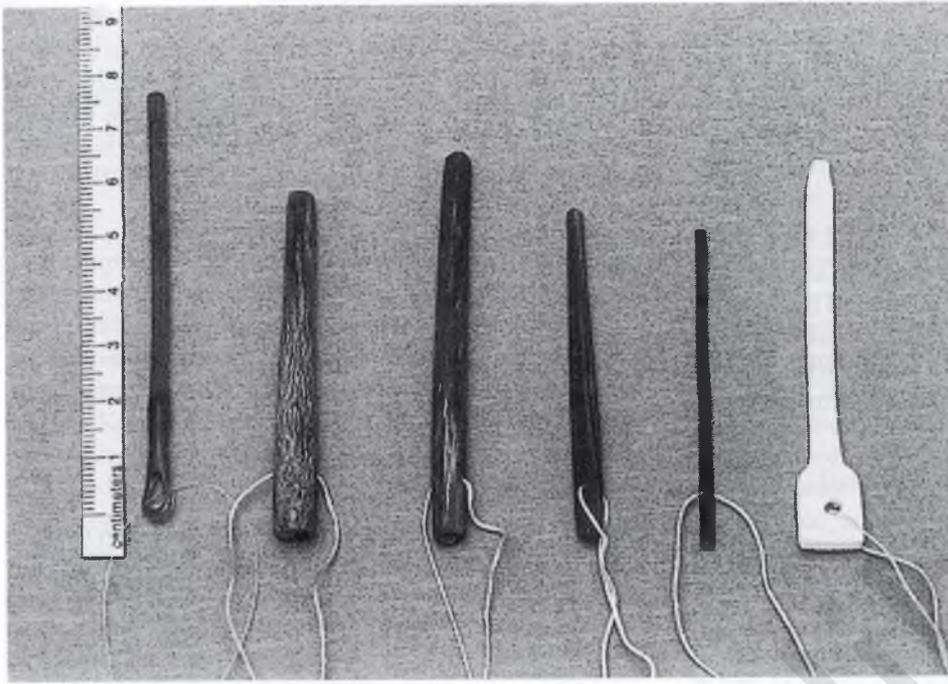
There are four types of osmotic dilators—laminaria japonica, two synthetic dilators (Lamicel, Dilapan) (Fig. 68–1),[188] and isaptent. Laminaria, derived from the seaweed genus *Laminaria* (*L. japonica*, *L. digitata*), are one of the oldest devices used for cervical ripening. Tents prepared from *L. japonica* are commercially available and are packaged in a variety of sizes. Although tents prepared from *L. digitata* are available, they are less


Figure 68–1
Osmotic dilators. Left to right: Dilapan, a single-sized synthetic polyacrylonitrile rod (hypan) currently available outside the United States; *Laminaria japonicum*, dried and compressed stalks of seaweed, four sizes (available in sizes ranging from 2 to 10 mm); Lamicel, a magnesium sulfate-impregnated polyvinyl alcohol sponge (available as 3 and 5 mm). (From Williamson DW: Resources for abortion providers. In Paul M, Lichtenberg ES, Borgatta L, et al [eds]: A Clinician's Guide to Medical and Surgical Abortion. New York, Churchill Livingstone, 1999, p 292, Fig. 20–13.)

useful clinically; they become gelatinous with expansion and are prone to fragment or become trapped in the cervix. The tents absorb water, swell, and ultimately dilate and soften the cervix. The tents expand most rapidly in the first 4 to 6 hours but continue to swell for up to 24 hours. In general, laminaria will expand up to four times their original diameter, resulting in concomitant dilation of the cervix. Placement of several smaller tents rather than one large tent may result in improved dilation and facilitate their later removal.

Compared to laminaria, Dilapan swells more rapidly and to a greater diameter, therefore, fewer Dilapan on average are needed for similar efficacy.[189] However, Dilapan is more likely to disintegrate, or retract, and it is no longer available in the United States.[190] Lamicel was found to be inferior to laminaria for midtrimester cervical ripening prior to D&E.[191] Lamicel is seldom used alone, as the sponges are difficult to insert in aggregate and become too soft on expansion to achieve the dilation needed.

Isaptent, although not used widely in the United States, is an alternative osmotic dilator that is effective for midtrimester cervical ripening. These commercially available tents (Dilex C.; Central Drug Research Institute, Lucknow, India) are prepared from granulated seed husk powder, derived from the isopgol plant (*Plantago ovata*), which is compressed and sealed into a cylindrical polythene sheath. The tents expand to a maximum diameter of 9 to 11 mm within 8 to 12 hours.[192] Comparison of isaptent to laminaria for cervical ripening demonstrates similar efficacy.[193]

Strategies may range from use of a single osmotic dilator with same-day surgery during the early second trimester to serial insertion of a variety of types and size of dilators for more advanced gestations. For procedures at up to 16

weeks' gestation, placing the dilators 4 to 8 hours prior to surgery may suffice. Beyond 16 weeks it is common practice to allow overnight dilation, and some mid to late second-trimester procedures call for a second insertion in 12 to 24 hours. Repeated laminaria applications significantly increase cervical dilation as compared to a single application, and therefore, treatment must be individualized.[190,194]

Adequate dilation is required in order to pass the 16-mm suction cannula and grasping forceps and to remove all the fetal parts. The minimum dilation required to insert grasping forceps depends on the type and size of the instrument used (13 mm for small Sopher, 14 to 15 mm for large Sopher, 16 mm for small Bierer, and 17 mm for large Bierer).[158] Prior to starting the procedure, sufficient cervical dilation must be confirmed. If cervical dilation is inadequate, additional osmotic dilators can be placed and the procedure delayed for at least 4 to 6 hours (or rescheduled to the next day).

Adequate pretreatment with laminaria may effect enough dilation prior to D&E to avoid the need for additional forced dilation in the operating room. Laminaria is the current mainstay in the United States for achieving cervical dilation for second-trimester TOP. Dilapan is still used widely in countries where it is available.

Methods of Insertion

After placing the speculum in the vagina and exposing the cervix, the cervix should be cleaned with antiseptic solution. Some women require no anesthesia or analgesia, but local anesthesia is helpful in women who are anxious or when the procedure is technically difficult. Use of a 50:50 mixture of lidocaine (1% or 0.5%) and bupiva-

caine (0.25%) provides rapid onset and a longer duration of action than does lidocaine alone.

The anterior lip of the cervix is grasped with a long Allis clamp. The cervical canal is carefully sounded, without rupturing the membranes, to identify its length. If desired, the cervix can be dilated mechanically using finely tapered dilators (such as Pratt and Denniston), and this allows insertion of more or larger osmotic dilators.

The large end of each osmotic dilator is grasped with a ring, packing, or ovum forceps and inserted into the cervical canal, laying successive dilators on top or next to the previous ones. Coating the dilators with lubricating jelly may ease insertion. Laminaria should be inserted leaving a 2- to 4-mm length protruding from the external os to facilitate its removal. The surgeon should ensure that the tips of the osmotic dilators pass through the internal os (Fig. 68–2).[158] If not, the result is a funnel-shaped canal and an inadequately dilated internal os (Fig. 68–3).[180] After inserting the dilators, they can be kept in place while the speculum is removed by placing a gauze sponge in a sponge holder over the cervix. The number and type of osmotic dilators inserted should be recorded.

In the event of inadvertent or spontaneous membrane rupture, the osmotic dilators should still be placed, but left in place for only 12 hours rather than 24 hours. The patient may resume normal activities, depending on how she feels.

Cervical Priming with Prostaglandins Prior to D&E

Lauersen and colleagues found a superior dilating effect with four to six laminaria tents placed 12 hours prior to D&E than with either PGE_2 vaginal suppositories (30 or 60 mg) or 15(S)-methyl $PGF_{2\alpha}$ (0.5 or 1.0 mg).[195] Vaginal and oral misoprostol have also been found useful in this setting.[196,197] More recently, buccal administration of misoprostol (600 µg given 2 to 4 hours prior to the procedure) was found to be as effective as laminaria tent for cervical preparation.[198]

PROCEDURE: DILATION AND EVACUATION

This procedure consists of removal of the osmotic dilators, assessment of cervical dilation, and insertion of a 16-mm suction cannula to rupture the membranes and evacuate the amniotic fluid and fetal elements, followed by mechanical destruction and evacuation of fetal parts using special grasping forceps (preferably under ultrasound guidance).

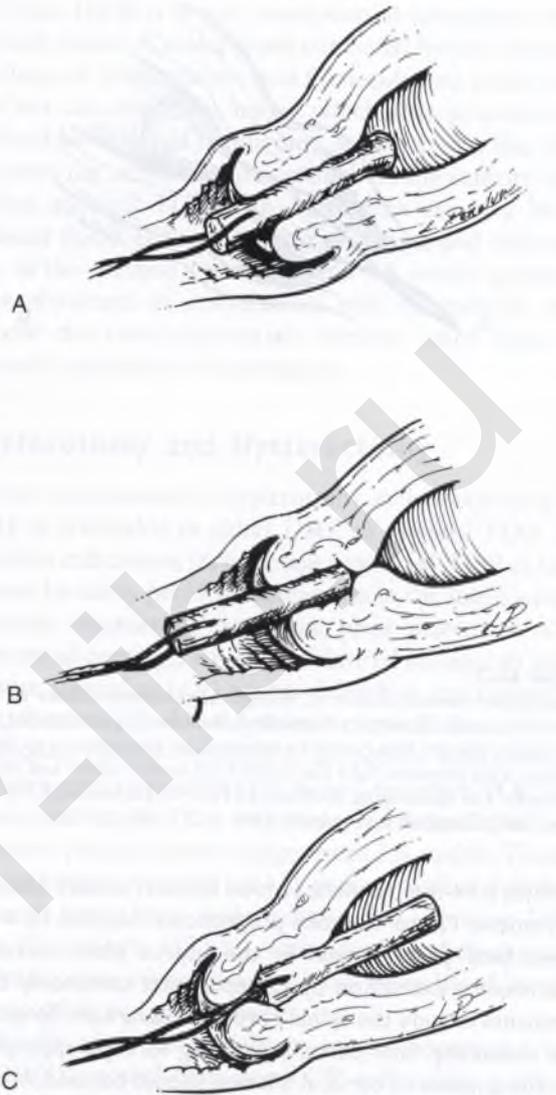
The osmotic dilators are removed digitally or with packing forceps. The number of dilators should be counted to ensure they are all removed. Following this, a gentle digital examination will establish the extent of cervical dilation (particularly at the internal os). If sufficient dilation cannot be accomplished, the procedure should be delayed to repeat the osmotic dilation, or consideration should be given to admitting the patient for a medical TOP.


Figure 68–2
Osmotic dilator insertion. *A*, Laminaria placed appropriately through the internal os. *B*, Laminaria does not pass through the internal os. Swelling results in funneling of the endocervical canal and inadequate dilation of the internal os. *C*, Laminaria inserted too far into the endocervical canal. This placement may result in rupture of the membranes and difficult removal. (From Haskell WM, Easterling TR, Lichtenberg ES: Surgical abortion after the first trimester. In Paul M, Lichtenberg ES, Borgatta L, et al [eds]: A Clinician's Guide to Medical and Surgical Abortion. New York, Churchill Livingstone, 1999, p 130, Fig. 10–2.)

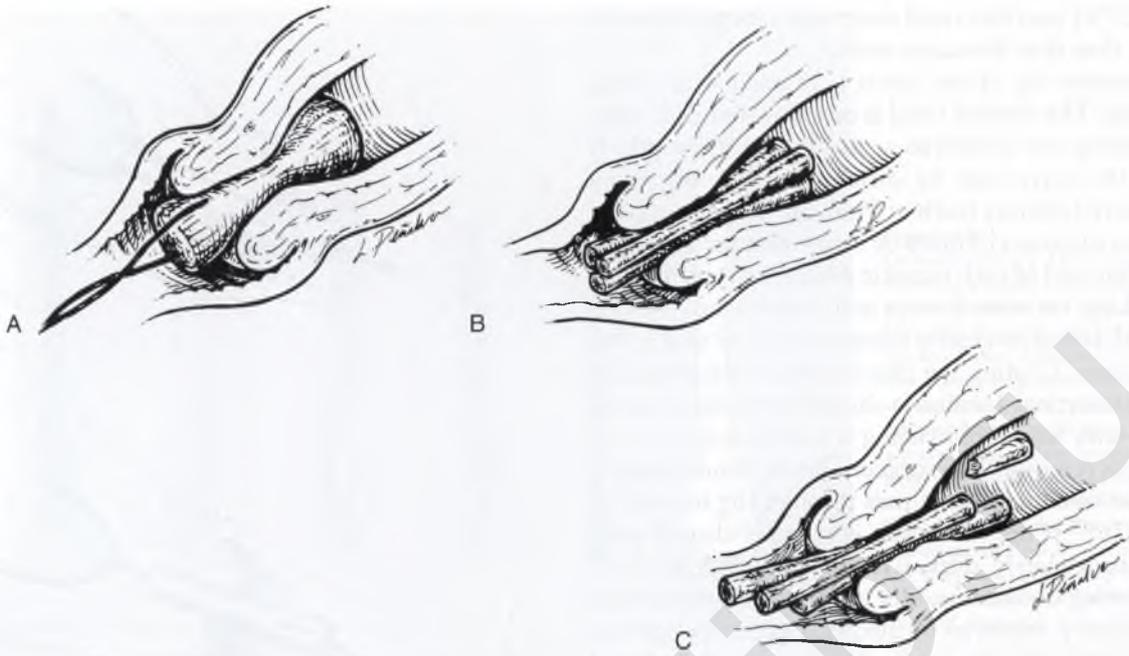
Once dilation is deemed adequate, the bladder should be emptied with a rubber catheter before D&E is started. The cervix is grasped with a long Allis clamp and a cannula is passed into the uterine cavity to rupture the membranes and evacuate as much amniotic fluid as possible with vacuum suction. The suction cannula should always be advanced fully into the uterine cavity before suction is applied. Up to 15 weeks' gestation, a 14-mm cannula should suffice, but gestations of 16 weeks and more require a 16-mm cannula. During removal of the amniotic fluid it is common for some membranes and placental tissue to be evacuated. However, complete placental extraction is generally delayed until the fetal parts have been removed.


Figure 68–3

Dumbbelled osmotic dilator. *A*, A single large osmotic dilator is "dumbbelled" by the stiff internal os. Removal of this dilator may be difficult. *B*, Several small dilators are dumbbelled. Because they are smaller, it may be possible to remove one. The others are then looser. *C*, When there are several dilators that cannot be removed, an alternative is to fracture one deliberately. The other dilators are then loosened and easier to remove. One fragment here has entered the uterine cavity and must be removed by suction or other means. (From Borgatta L, Burnhill MS, Karlin E: The challenging abortion. In Paul M, Lichtenberg ES, Borgatta L, et al [eds]: A Clinician's Guide to Medical and Surgical Abortion. New York, Churchill Livingstone, 1999, p 177, Fig. 13–5.)

With a 14-mm cannula, suction alone is usually adequate to remove 13- to 16-week pregnancies. Beyond 16 weeks some fetal parts remain in the uterus after suctioning and require extraction by forceps; most commonly these remnants include the spinal cord and calvarium. To extract the remaining fetal parts, a grasping forceps appropriate for the amount of cervical dilation should be used. In cases past 16 weeks, the fetus is extracted, usually in parts, using Sopher or similar forceps and other destructive instruments.

The choice of forceps (Fig. 68–4)[199] depends on operator preference and the extent of cervical dilation. We prefer Sopher forceps with its long shafts and bulkier grasping surfaces with sheltered serrations.

Once inserted, the forceps should be opened widely and one blade inserted along the anterior uterine wall in order to grasp the fetal parts. When fetal parts are felt between the blades on closing the handles, they are removed with a gentle twisting motion. The calvarium is the part most likely to be left behind. If fetal parts remain in the uterus, gentle probing with a small sharp curette may locate and retrieve them, although use of a sharp curette always carries the risk of perforating the uterine wall. Alternatively, sonography can be used to locate any remaining fetal parts and aid in their evacuation. In one study, use of intraoperative ultrasonography reduced the incidence of uterine perforation at D&E from 1.4% to 0.2%.[185]

Complete removal of the placenta generally requires one or more passes with the 14- to 16-mm suction curette. Before concluding the procedure, the fetal parts should be assembled to determine whether TOP was complete. Similarly, the quantity of placental tissue should be visually assessed to ensure that it is commensurate with the gestation.

USE OF OXYTOCIC AGENTS

The use of uterotonic agents during surgical TOP is a matter of preference. We use an intravenous infusion of oxytocin 20 to 40 units in 500 mL crystalloids given intraoperatively after rupture of membranes and continued postoperatively for 30 minutes. If the full 40 units is given, care should be taken to avoid excessive further infusion of crystalloid, because of the risk of water intoxication due to the antidiuretic effect of oxytocin.

ANTIBIOTIC PROPHYLAXIS

Routine oral antibiotic prophylaxis reduces the risk of infection after surgical TOP.[200–202] It is commonly started on the first day of osmotic dilator placement. Antibiotics such as tetracycline, clindamycin, and metronidazole have all been used to good effect.

POSTOPERATIVE CARE

Minimum observation periods for recovering D&E patients are 1 hour for early and mid second-trimester cases and 2 hours for late D&E, usually defined as more than 19 to 20 weeks' gestation.

Figure 68–4
Instruments for D&E. Kelly placental forceps, Sopher forceps, and Bierer forceps (left to right). (From Ludmir J, Stubblefield PG: Surgical procedures in pregnancy. In Gabbe SG, Niebyl JR, Simpson JL [eds]: Obstetrics: Normal and Problem Pregnancies. New York, Churchill Livingstone, 2002, p 639, Fig. 19–25.)

Intact Dilation and Extraction

The American College of Obstetricians and Gynecologists in its general policy statement related to TOP described "intact dilation and extraction" (intact D&X) as containing all the following four elements.[203]

- Deliberate dilation of the cervix, generally accomplished with multiple, serial osmotic dilators over 2 days or more
- Instrumental conversion of the fetus to a footling breech
- Breech extraction of the body excepting the head
- Partial evacuation of the intracranial contents of a living fetus to effect vaginal delivery of a dead but otherwise intact fetus

According to the Centers for Disease Control, only 5.6% of TOP performed in the United States in 2001 (the most recent data available) were performed after the 16th week of pregnancy.[156] It is unknown how many of these were performed using intact D&X.

Intact D&X is a very controversial procedure in the United States. A select panel convened by the American College of Obstetricians and Gynecologists could identify no circumstances under which this procedure, as defined here, would be the only option to save the life or preserve the health of the woman.[203] In the authors' institution, medical TOP, with concurrent use of a 30-mL balloon Foley catheter or laminaria tents and misoprostol, is the method of choice after 18 weeks' gestation. The physician, in consultation with the patient, must choose the most appropriate method based upon the patient's individual circumstances.

Hysterotomy and Hysterectomy

In rare circumstances, hysterotomy or hysterectomy for TOP is preferable to either D&E or medical TOP. The possible indications include failed medical TOP if D&E cannot be safely performed, myomas in the lower uterine segment obstructing extraction, prior placement of an abdominal cerclage, which it is desired to leave in place, uterine anomalies (e.g., uterus didelphys, unicornuate or septate uterus), and some cases of cervical cancer.[180]

Another clinical challenge is the patient with complete placenta previa presenting for second trimester TOP.[204] In ultrasound studies, the reported prevalence of second-trimester placenta previa ranges from 2% to 6%. Thomas and colleagues reported on 131 patients with and without placenta previa who underwent second-trimester D&E. The 23 patients (17.6%) with ultrasound-documented placenta previa averaged only 21 mL more blood loss and had no other complications.[205]

On the other hand, placenta accreta occurs in 1 to 2 per 10,000 second-trimester TOP and usually results in heavy bleeding during the procedure. Placenta accreta is frequently associated with previous uterine surgery, suggesting a preexisting defect in the basal layer of the endometrium (decidua basalis).[206] Occasionally, patients with placenta accreta or placenta percreta require laparotomy with hysterotomy or hysterectomy despite the increased morbidity and mortality risks associated with these procedures.[207] These patients may benefit from preoperative placement of embolization balloon catheters using interventional radiology techniques.[208,209]

Medical Termination of Pregnancy

The introduction of prostaglandin analogues and mifepristone has revolutionized the management of second-trimester TOP and fetal death in the last 2 decades. Gemeprost and misoprostol are the two most extensively studied prostaglandin analogues that are used in this period. Gemeprost is the only licensed synthetic prostaglandin analogue for second-trimester TOP in the United Kingdom. However, it is expensive and needs to be stored in a refrigerator. Misoprostol is inexpensive and can be stored at room temperature. It has been widely

used for induction of labor in cases of fetal death and second-trimester TOP for fetal anomaly. The combination of either gemeprost or misoprostol with mifepristone is most effective. With these regimens, over 90% of women abort within 24 hours and the mean induction-to-delivery interval is about 6 hours. Mifepristone is expensive and is not available in many countries. Therefore, prostaglandin analogue-only regimens can be the only option. These regimens are still effective, with TOP rate above 90% in 48 hours; however, the induction to TOP interval (15 hours) is much longer. Intracervical tents can be used to shorten the induction-to-delivery interval.[163,164]

Instillation into the uterine cavity through the intra-amniotic or extra-amniotic routes of substances designed to kill the fetus and promote delivery (such as hypertonic saline, hyperosmolar urea, $PGF_{2\alpha}$, ethacride lactate) is obsolete.[162–164] A recent review by Ramsey and coworkers detailed the limited role of vaginal PGE_2 and intramuscular $PGF_{2\alpha}$ as well as high-dose oxytocin infusion for second-trimester TOP.[210]

Fetocidal Procedures

Use of medical TOP has been associated with live birth rates from 4% to 10%.[167,211] In borderline viable gestations, patients, physicians, and nurses express concern about the dilemma of resuscitation in the event of a live birth after a PG-induced TOP. Moreover, such live birth is beset with ethical, medical, and legal implications. Because of concern among patients, practitioners, and hospitals, many TOP services perform a fetocidal procedure prior to or concomitantly with PG-induced TOP at 20 weeks' gestation or more.

The most common fetocidal agents used in developed countries are potassium chloride (KCl) and digoxin.[212,213] The procedure involves transabdominal insertion of a 20-gauge spinal needle into the fetal cardiac chambers by ultrasound guidance and instillation of 2 to 3 mL of potassium chloride in a concentration of 2 mEq/mL. Cardiac standstill is usually observed within 1 to 3 minutes. An alternative is the instillation of digoxin in doses varying from 0.25 to 2 mg, by the intracardiac, intrathoracic, intrafetal, and intra-amniotic routes.

Cervical Preparation

PHYSICAL METHODS

Osmotic dilators can be useful before induction of labor (see earlier discussion). There has been a resurgence of interest in catheter-based techniques, specifically in relation to the concurrent use of extra-amniotic saline infusion and misoprostol. A variety of balloon-catheter devices have been shown to be effective for cervical ripening.[210] Foley catheters with a 30-mL balloon are more commonly used in the United States. Extra-amniotic saline infusion (EASI) is an effective adjuvant to both midtrimester and term labor inductions.[214] Using aseptic technique and

countertraction, a lubricated 26F Foley catheter with a 30- to 50-mL balloon is grasped with ring forceps and inserted through the internal os, after which the catheter balloon is inflated in the lower uterine segment. For the tightly closed, nulliparous cervix, a smaller diameter catheter (e.g., 18F) can also be used. Normal saline is infused through the catheter lumen at a nominal rate of 30 to 60 mL/hour, and traction is not used. Overall, EASI appears to be a safe and effective alternative to laminaria for midtrimester cervical priming. Advantages of EASI include low cost, reversibility, and lack of systemic side effects. Although EASI and laminaria appear to be equally efficacious, EASI offers the potential advantage of easier placement and less patient discomfort.

PHARMACOLOGIC CERVICAL RIPENING

Mifepristone (RU-486; Mifeprex) received Food and Drug Administration (FDA) approval in the United States in September 2000. Mifepristone was found to be more effective than laminaria tents in shortening the induction-to-delivery interval in a study using gemeprost.[215,216] The value of intracervical tents in regimens using misoprostol is less clear.[217] The World Health Organization (WHO) recommended that cervical preparation should precede all TOPs induced after 14 weeks.[218] Whenever possible, mifepristone should be used as the cervical priming agent before second-trimester TOP. If mifepristone is not available, an intra-cervical tent should be used.

Prostaglandins and Their Analogues

Prostaglandin receptors are present throughout all stages of pregnancy, and thus, PGs and their analogues are effective in terminating both first- and second-trimester pregnancy. The natural PGs, $PGF_{2\alpha}$ and PGE_2, were the first to be tested clinically for medical TOP but they were soon replaced by synthetic PG analogues because of the high incidence of gastrointestinal side effects when given parenterally or vaginally.[162–165]

The PGE and PGF analogues have been used clinically for second-trimester TOP. The PGE analogue is preferable as it has a more selective action on the myometrium and causes less gastrointestinal side effects. The most extensively studied PGE and PGF analogues for second-trimester TOP are carboprost, meteneprost, sulprostone, gemeprost, and misoprostol.

PROSTAGLANDIN E_2 (PGE_2) ANALOGUES

Two PGE_2 analogues, dinoprostone (Prostin) and meteneprost (9-methylene PGE_2), are commercially available and have been investigated for midtrimester TOP. Of these, only Prostin is FDA approved in the United States as an abortifacient in the midtrimester and for fetal death up to 28 weeks' gestation. The recommended dosage regimen of Prostin for second-trimester termination is 20 mg administered as a vaginal suppository every 3 to 4 hours (maximal exposure: 24 hours). In a series of midtrimester TOPs with vaginal PGE_2, 20 mg

every 4 hours with osmotic dilators, the mean induction-to-delivery interval was 17 hours.[163,164] PGE_2 is not thermally stable and must be kept refrigerated. It has been widely investigated and has been proved effective for second-trimester TOP. However, intravaginal misoprostol was at least as effective as PGE_2 and without the cost and side effects associated with PGE_2 use.[100]

PROSTAGLANDIN $F_{2\alpha}$ (PGF$_{2\alpha}$) ANALOGUE

A synthetic $PGF_{2\alpha}$ analogue, carboprost tromethamine (15S)-15-methyl-$PGF_{2\alpha}$ tromethamine (Hemabate), is the only other commercially available PG that is FDA-approved and marketed in the United States as a midtrimester abortifacient at 13 to 20 weeks of gestation. The recommended dosage regimen of carboprost for second-trimester TOP is 250 µg, administered by intramuscular injection every 1.5 to 3.5 hours (maximal exposure: 12 mg or 48 hours). A test dose of 100 µg may be administered to confirm patient tolerance before administration of the full 250 µg dose. The successful TOP rate with intramuscular carboprost reached 80% to 90% in 36 hours, but it was associated with a high rate of gastrointestinal side effects.[163,164]

PROSTAGLANDIN E_1 (PGE$_1$) ANALOGUES

The three most extensively studied PGE analogues are sulprostone, gemeprost, and misoprostol. Sulprostone (16-phenoxy-(ω)-17-18,19,20-tetranor PGE_2 methyl sulphonylamide) was studied in the early 1980s for medical termination of second-trimester pregnancies. However, intramuscular sulprostone is no longer used clinically for medical TOP because of its association with myocardial infarction.[219] Therefore, gemeprost and misoprostol are the principal drugs used for second-trimester medical TOP today.

GEMEPROST

Gemeprost (16,16-dimethyl trans-Δ^2 PGE_1 methyl ester) is a PGE_1 analogue. It is the only prostaglandin licensed in the United Kingdom for medical TOP. It is administered as a vaginal pessary. Studies using a vaginal gemeprost-only regimen gave a complete TOP rate of 80% to 96.5% in 48 hours.[220-223] The commonest regimen is 1 mg every 3 to 6 hours for five doses in 24 hours. It is repeated if delivery does not occur in this time. The mean induction-to-delivery interval ranged from 14 to 18 hours. The commonest side effects were vomiting, diarrhea, and fever. Cost and the need for refrigeration are the drawbacks with gemeprost; these factors make its use practical only in developed countries.

MISOPROSTOL

Misoprostol (15-deoxy-16-hydroxy-16-methyl PGE_1) is a synthetic PGE_1 analogue. It was discovered that it could be used "off-label" as an abortifacient. It is cheap, stable at room temperature, and readily available in many developing countries. Vaginal misoprostol is as effective as gemeprost.[221-223]

Recent studies mainly focus on the optimization of misoprostol dosing regimens by comparing various dosages, dosing intervals, and routes of administration.[224-229] The dosage of misoprostol used ranged from 100 to 800 µg with dosing intervals of 3 to 12 hours. The efficacy of misoprostol is improved when a higher dose (400 to 800 µg) is given at a shorter intervals (3 to 4 hours) (Table 68-5). The vaginal route is more effective than the oral route.[228,230] The greater bioavailability of vaginal misoprostol probably explains the clinical results. Zieman and colleagues compared the absorption kinetics of misoprostol with oral versus vaginal (400 µg) administration in pregnant women.[120] It was shown that the systemic bioavailability of vaginally administered misoprostol is three times higher than that of the oral route. The plasma level was sustained up to 4 hours after vaginal administration. However, women preferred the oral route because it was less painful, gave more privacy, and was more convenient.[230]

A randomized study demonstrated that misoprostol 600 µg given vaginally, then 200 µg orally every 3 hours was probably the optimal regimen for second-trimester TOP.[231] A regimen that involves the administration of the first dose of misoprostol vaginally and subsequent doses orally might have a number of beneficial effects. It will minimize the number of vaginal examinations required to insert subsequent doses while preserving the possible direct cervical priming effect of the first dose.

Recently, sublingual administration of misoprostol has been developed. The sublingual route was chosen because it was considered as the most vascular area of the buccal cavity. It also avoids the first-pass effect through the liver in oral administration and the uncomfortable vaginal administration. One pilot study using 400 µg misoprostol every 3 hours for a maximum of five doses achieved a 100% second-trimester abortion rate with a median induction-to-abortion interval of 11.6 hours.[232] It was shorter than a similar dose regimen of vaginal misoprostol alone (15.2 hours), as shown in Table 68-5.[226]

MIFEPRISTONE AND SYNTHETIC PROSTAGLANDIN ANALOGUES

Mifepristone is the anti-progestin that is approved for use clinically for induction of TOP. It increases the sensitivity of the uterus to PGs. The use of oral mifepristone 36 to 48 hours before PG administration can increase the successful TOP rate, shorten the induction-to-delivery interval, and reduce the total dose of PGs required (see Table 68-6).[233-242] The first recommended dose of mifepristone was 600 mg, but it has been shown in a randomized trial that the successful TOP rate and induction-to-delivery interval were the same even if the dose was reduced to 200 mg.[239]

If mifepristone pretreatment is used before gemeprost (1 mg every 6 hours), the induction-to-delivery interval can be decreased from 15.7 hours to 6.6 hours and the successful TOP rate in 24 hours is increased from 72% to 95% (see Table 68-6).[237]

TABLE 68–6

Second-Trimester Termination of Pregnancy (TOP) by using Mifepristone Prior to Misoprostol

TREATMENT WITH ORAL MIFEPRISTONE 36–48 HOURS BEFORE MISOPROSTOL/GEMEPROST REGIMEN	NO. OF SUBJECTS	GESTATIONAL AGE (WEEKS)	TOP RATE IN 24 h (%)	INDUCTION-TOP INTERVAL (h)	REFERENCES

2. Mifepristone 200 mg + misoprostol 800 μg vaginal; then misoprostol 400 μg oral q3h × 4	50			6.1	

To improve patient acceptability and to maintain the efficacy, a combination regimen including both the oral and vaginal routes has been developed. El-Refaey and Templeton (1995) compared two misoprostol regimens in women pretreated with 600 mg mifepristone for 36 to 48 hours.[238] The first group received 800 μg vaginal misoprostol as the first dose and 400 μg vaginal misoprostol every 3 hours. The second group received 800 μg vaginal misoprostol as the first dose and 400 μg oral misoprostol every 3 hours. The mean induction-to-TOP interval was 6.0 and 6.7 hours, respectively. The 24-hour TOP rate was 97% in both groups (see Table 68–6). Ashok and associates (1999) used mifepristone 200 mg followed by 800 μg vaginal misoprostol as the first dose and 400 μg oral misoprostol every 3 hours. They achieved 97% abortion rate; the median induction-to-abortion interval was 6.5 hours.[241] Pretreatment with mifepristone significantly reduced the induction-to-TOP interval when compared with a misoprostol-only regimen. It was thought that vaginal misoprostol as the first dose could have a cervical priming effect.

Current evidence shows that the combination of oral mifepristone and vaginal misoprostol is an effective method for termination of second-trimester pregnancy. If mifepristone is not available, vaginal misoprostol alone can be used but the induction-to-TOP interval will be slightly longer.

USE OF PROSTAGLANDIN WITH A SCARRED UTERUS

With the rising cesarean delivery rate, an increasing number of women undergoing second-trimester TOP will have a previous uterine scar. No matter what method is used, the risk of uterine rupture is higher than for those without a scar. The reported risk of scar rupture at the time of medical termination in the presence of a previous uterine scar varies from 3.8%[243] to 4.3%.[244] This rate compares with a uterine rupture rate of 0.2% in patients with an intact uterus.[245,246] Uterine scar rupture has been reported with both gemeprost and misoprostol regimens with or without priming by mifepristone.[247–255] No well-controlled study has shown any method as being better than the others. All oxytocic agents should be used with caution in patients with previous cesarean deliveries. Women should be appropriately counseled about the risks and consequences, and practitioners should be prepared to deal with a rupture if and when it occurs. The optimum chance for successful outcome is provided by an informed and alert clinician who appreciates the potential risks of the procedure and who is prepared to deal with those risks.

Side Effects and Complications

Second-trimester TOP is a relatively safe procedure in countries where it is legal, accessible, and performed under modern medical conditions. However, both the patient and practitioner must be aware of procedure- and medication-related side effects and complications, including acute medical events and potential long-term reproductive risks.

SIDE EFFECTS OF PROSTAGLANDIN-INDUCED TOP

The use of PGs gemeprost and misoprostol, with or without mifepristone, is a safe and effective method of second-trimester TOP. Side effects including nausea, vomiting,

and diarrhea are characteristics of prostaglandin administration and are due to prostaglandin's stimulatory effect on the gastrointestinal tract. Diarrhea is more common in women using gemeprost, whereas fever is more common with misoprostol.[163,164] The advantages of using misoprostol for second-trimester TOP compared with other PG agents are the relatively low incidence of reported side effects (Table 68–7). Side effects reported from the use of high-dose oxytocin regimens include nausea and vomiting. Prolonged usage may cause water intoxication. The suggested high-dose oxytocin regimen includes an alternating period of oxytocin infusion and a drug-free interval to allow for clearance of the oxytocin to avoid water intoxication.

COMPLICATIONS ASSOCIATED WITH MEDICAL TOP

Complications common to most medical TOP include retained placenta and associated hemorrhage or infection, failed TOP, live birth, and serious complications such as uterine rupture.

Retained Placenta (incomplete abortion). Patients who underwent medical TOP compared to those who had D&E were more likely to have retained products of conception that required operative intervention (21% versus 0.7%). Although patients who underwent medical TOP with misoprostol were less likely to have complications than patients who underwent medical TOP by other methods (22% versus 55%), these patients still had more complications than surgical patients (22% versus 4%).

Patients who elect to undergo second-trimester medical abortion should be advised that they have a significant risk (21%) of requiring surgery for retained products of conception because this knowledge may assist them in making an informed decision.[166]

Sixty percent of subjects passed the placenta spontaneously within 2 hours, with approximately two-thirds of the expulsions occurring within the first 30 minutes. The rate of complications (hemorrhage and febrile morbidity) increased over time, reaching 4% at 30 minutes and 9% at 2 hours.[256] Retained tissues can lead to hemorrhage, infection, or both and usually manifests itself within several days of the TOP. Cramping and bleeding can be accompanied by fever. If complete placental expulsion did not occur within 2 hours of fetal delivery, the placenta was removed manually or by forceps or curettage.[256]

Infection. During the second trimester infection rates for both medical and surgical TOP methods have remained within the narrow range of 0.4% to 2.0% in North America and Great Britain.[165,166] Infection is usually associated with retained products of conception, but there are no data to analyze the incidence of infection separately in cases with or without retained tissue. Typically, signs and symptoms of post-TOP infection arise within the first 48 to 96 hours. The patient may present with pain, fever, and pelvic tenderness. The cervix should be cultured for sexually transmitted pathogens—*Neisseria* (gonorrhea) and *Chlamydia*. Established risk factors for post-TOP infection

---

TABLE 68–7

Induction Agents and Reported Adverse Effect (% occurrence)

AGENT	INDUCTION-ABORTION INTERVAL (h)	ADVERSE EFFECTS (%)	COMMENTS
Hypertonic saline	20–46	Fever, vomiting (5–12%) Hemorrhage	Intraamnotic injection; used with oxytocin augmentation
Oxytocin	8–13	Water intoxication (rare) Nausea and vomiting (less than with PGs)	Inexpensive Significantly fewer gastrointestinal side effects than prostaglandins (PGs) Requires intravenous infusion
PGF$_{2\alpha}$	14–37 (dose-dependent)	Incomplete abortion Hemorrhage Live-born fetus (rates higher than with saline) Nausea, vomiting, diarrhea (30%)	Intraamniotic instillation; most patients require oxytocin augmentation No longer available in United States in form used for induction Potent bronchoconstrictor
15-Methyl PGF$_{2\alpha}$	8–16	Vomiting, diarrhea, fever (2–3 episodes per patient)	Intramuscular (has also been used via intra-amniotic, extra-amniotic, vaginal routes)
Dinoprostone (PGE$_2$)	11–14 (6–7 h with cervical ripening)	Fever, nausea, vomiting, diarrhea (most patients experience at least one side effect)	Vaginal suppositories Must be refrigerated
Sulprostone (PGE$_2$)	11	Vomiting (12–46%) Diarrhea (6–17%)	Given intramuscular or intravenously Not available in United States
Gemeprost (PGE$_1$) + mifepristone	15 6–8	Vomiting (1–14%) Diarrhea (2–20%)	Vaginal pessary Not available in United States
Misoprostol (PGE$_1$) + mifepristone + laminaria	9–14 6–10 10–22	Vomiting (4–10%) Diarrhea (4–15%)	Oral or vaginal routes Inexpensive; no refrigeration required

include age younger than 20 years, nulliparity, previous pelvic inflammatory disease, and presence of pathogens in the cervix at the time of TOP. The latter association has been reported with documented *Chlamydia* infection, gonorrhea, and bacterial vaginosis.[201] Most post-TOP infections, however, occur in women without these risk factors. Routine antibiotic prophylaxis may prevent up to half of all post-TOP infections in the United States and is highly cost-effective. Tetracyclines or nitroimidazoles (metronidazole or tinidazole) were equally efficacious for preventing infection.[200] Ascending genital tract infections are typically polymicrobial. Patients who present with post-TOP metritis should receive a full course of broad-spectrum antibiotic therapy. When retained tissue is evident or suspected, prompt evacuation is indicated.

Failure of Medical TOP. Failed induction has been defined as a failure to achieve TOP within 24 to 48 hours and is a significant clinical problem. Management options include deferring TOP when membranes are intact for a predetermined time, aggressive cervical dilation with sequential laminaria application and another trial of induction, changing the induction agent used, or recommending D&E.

Uterine Rupture. Serious complications including uterine rupture, major hemorrhage, and cervical tear are rare.[163,164] Cases of uterine rupture were reported to occur with both gemeprost and misoprostol, and the use of mifepristone did not exclude the possibility.[243-255] The incidence of uterine rupture was estimated to be 0.2% in the second trimester. Risk factors for uterine rupture include previous cesarean delivery, grand multipara, advanced gestation, prolonged PG therapy, and use of oxytocin in addition to PGs.[252]

Live Birth. Second-trimester medical TOP with PG analogues has been associated with live birth rates of 4% to 10%.[167,211] Physicians should have a protocol to induce fetal death (e.g., fetal intracardiac potassium chloride or digoxin) before induction, and patients should be apprised of the risk for live birth and should understand the plan in advance.

COMPLICATIONS ASSOCIATED WITH D&E (Table 68–8)

Based on the data from the 1970s and 1980s, D&E is clearly safer than intra-amniotic instillation methods and hysterotomy or hysterectomy for second-trimester TOP through 16 weeks' gestation.[159,165,182-184] In these investigations most of the specific complications associated with D&E occurred at rates well below 1%. A recent report by Autry and colleagues confirmed both the low complication rate that is associated with D&E and its superiority over medical TOP.[166] When skilled operators are available, D&E after cervical preparation with laminaria should be considered the preferred method for second-trimester TOP. Hence, the choice of TOP method at this later stage usually hinges on nonmedical considerations: cost, convenience, comfort, and compassion.

In challenging or difficult cases, careful assessment and choice of TOP method should be made to minimize complications. Intraoperative ultrasonography may be helpful in difficult cases.[185] Previous cesarean delivery scar does not seem to increase the perioperative risk of late termination (14 to 22 weeks) by the laminaria and evacuation technique.[207]

Hemorrhage. Reported rates of hemorrhage vary widely, reflecting both diverse definitions and imprecise estimation of blood loss. Hemorrhage associated with TOP is not common and the RCOG guideline group reported this complication as 1.5 per 1000 TOPs overall.[161] Factors associated with increased risk of uterine hemorrhage were operator inexperience, advanced gestational age, advanced maternal age and parity, prior cesarean delivery, uterine fibroids, and past history of post-TOP or postpartum bleeding.[159,162] Hemorrhage associated with D&E may indicate cervical laceration, perforation, retained tissue, uterine atony, placental abnormalities, or coagulopathy. Advances in operative technique and use of uterotonic agents have resulted in reduction of both mean and median blood loss in North America.

Intraoperative use of oxytocin, ergots, and PGs reduces blood loss from uterine atony during D&E.

TABLE 68–8

Comparison of Complication Rates among Medical and Surgical TOP Study Subjects

COMPLICATION	MEDICAL (*n* = 158)	SURGICAL (*n* = 139)	P VALUE
Patients with any complication	45 ± 28.5	5 ± 3.6	<.001
Failed initial method	11 ± 7.0	0 ± 0	<.01
Hemorrhage with transfusion	1 ± 0.6	1 ± 0.7	NS
Infection with intravenous antibiotics	2 ± 1.3	0 ± 0	NS
Retained products of conception	33 ± 20.9	1 ± 0.7	<.001
Cervical laceration with repair	2 ± 1.3	3 ± 2.2	NS
Organ damage	2 ± 1.3	0 ± 0	NS
Hospital readmission	1 ± 0.6	1 ± 0.7	NS

Modified from Autry AM, Hayes EC, Jacobson GF, Kirby RS: A comparison of medical induction and dilation and evacuation for second-trimester abortion. Am J Obstet Gynecol 2002;187:393–397.

Treatment of uterine atony includes manual uterine compression, oxytocin infusion, ergot derivatives, and PGs (15-methyl $PGF_{2\alpha}$, PGE_1).

Second-trimester TOP by D&E in the presence of placenta previa appears to be safe and apparently does not increase maternal morbidity as compared with the outcome in patients without placenta previa undergoing the same procedure.[204] All placenta accreta patients had at least one cesarean delivery (mean 1.7), and prior to a preoperative sonogram demonstrating some form of placenta previa. The prevalence of clinical placenta accreta encountered during D&Es in the second trimester was 0.04%, the same as that reported for placenta accreta diagnosed clinically in the third trimester. Placenta accreta can be a potential complicating factor in the patient undergoing D&E in the second trimester.

Cervical Injury. The most common type of cervical injury is a superficial laceration caused by the tenaculum or Allis forceps tearing off during dilation. At the other extreme are the cervicovaginal fistula and the longitudinal laceration ascending to the level of the uterine vessels. Rates of cervical injury range from 0.01 to 1.6 per 100 suction curettage TOP.[157,158]

Several risk factors of cervical injury during suction curettage have emerged. Among factors within the control of the physician, use of laminaria and performance of the TOP by an attending physician (rather than a resident) lower the risk significantly. Among factors beyond the control of the physician, a history of prior abortion lowers the risk, and age of 17 years or under increases the risk. Use of laminaria and performance of the TOP under local anesthesia by an attending physician together yield a 27-fold protective effect.[159] Cervical preparation with misoprostol may confer similar benefits as laminaria, although more extensive experience will be needed to confirm this.

Perforation. Perforation is a potentially serious, but infrequent, complication of D&E. According to most reports, the incidence of perforation is about 0.2 per 100 suction curettage TOP.[157]

Several risk factors for perforation exist. Performance of a curettage TOP by a resident rather than an attending physician increases the risk more than fivefold; on the other hand, cervical dilation by laminaria decreases the risk about fivefold. The risk of perforation increases significantly with advancing gestational age. Previous gynecologic surgery including TOP, cesarean delivery, and large loop excision of the transformation zone of the cervix (LLETZ) procedure is a risk factor for tearing of the internal os leading to perforation of the uterus during subsequent D&E procedures.[257] Dilation of the cervix particularly for these "at-risk" procedures should be predominantly passive by the use of oral prostaglandins such as misoprostol and osmotic dilators. The overall perforation rate was 0.029%.[258]

The use of real-time ultrasound scanning during D&E can reduce perforation rates. The routine intraoperative use of ultrasonographic imaging to guide intrauterine forceps during uterine evacuation for second-trimester TOP resulted in a significant reduction in uterine perforation, the rate declining from 1.4% to 0.2%.[185] These findings support the routine use of intraoperative ultrasonography for second-trimester TOP to reduce the incidence of uterine perforation and make the procedure a safer one.

The two principal dangers of perforation are hemorrhage and damage to the abdominal contents. Lateral perforations in the cervico-isthmic region are particularly hazardous because of the proximity of the uterine vessels. Perforations of the fundus are more likely to be innocuous. Many suspected or documented perforations require only observation. Perforation with a dilator or sound is unlikely to damage abdominal contents. On the other hand, a suction cannula or forceps in the abdominal cavity can be devastating.

If the physician suspects a perforation, the procedure should stop immediately. If unmanageable hemorrhage, expanding hematoma, or injury to abdominal content occurs, prompt laparotomy is necessary. Laparoscopy can be useful in documenting perforation and assessing damage; if necessary, the physician can complete the abortion under laparoscopic visualization. Any woman with severe pain within hours after D&E should be evaluated for possible perforation with bowel injury.

Acute Medical Events

Acute medical events, such as vasovagal reaction, asthmatic reactions, amniotic fluid embolism, anaphylaxis, and seizures to anesthetic agents or laminaria can occur at the time of TOP.[259–261] The safety of PG agents used for TOP has been established. Side effects are usually of a minor nature, although life-threatening complications can occur and include cardiac arrest.[262] This severity emphasizes the importance of medical supervision when the procedure is carried out.[238]

Long-Term Reproductive Risks

The bulk of evidence would suggest that D&E is a very safe procedure with few long-term problems. There is no proven association between D&E and subsequent fertility difficulty.[263] Second-trimester D&E is not a risk factor for midtrimester pregnancy loss or spontaneous preterm birth. Preterm delivery in future gestations appears less likely when greater preoperative cervical dilation is achieved with laminaria, possibly because of a decrease in cervical trauma.[264–266] Published studies have not been prospective and have not been able to control for competing risk factors, such as smoking or exposure to sexually transmitted infections that might overestimate the

impact of induced TOP on poor reproductive outcome. Long-term complications associated with medical TOP in the second trimester using gemeprost and misoprostol with or without mifepristone are rarely reported.

CONCLUSIONS

GENERAL

- The introduction of prostaglandin analogues and mifepristone has revolutionized the management of second-trimester TOP and fetal death in the last 2 decades.
- Prostaglandin analogues provide a safe and effective method for induction of second-trimester TOP and intrauterine death.
- Gemeprost is the drug licensed for this purpose but misoprostol is a cheaper alternative and can be stored and transferred at room temperature. It provides a suitable alternative of particular relevance to resource-poor areas of the world.

GENERAL

- Prostaglandin analogues can also be used as cervical priming agents prior to D&E. D&E is safe and effective. TOP services can be difficult to organize; the skill and expertise to provide a safe D&E may not always be available.
- The choice of TOP methods continues to extend with new developments in medical termination across all gestations. There is no comparative trial evidence of late D&E against modern methods of midtrimester medical termination.
- Debate continues regarding appropriate techniques for terminating more advanced pregnancies.
- Practitioners should be specifically trained, competent, and comfortable with the procedure they provide.
- Clinical preassessment, counseling, and informed choice form the basis of good practice.
- Ultrasound is useful, but there is no randomized trial evidence of its value.
- Health care professionals should be aware of choices for TOP methods, and women should receive information that helps them to choose a method that is right for them.

DILATION AND EVACUATION

- Cervical ripening facilitates cervical dilation and reduces risk for certain complications.
- Antibiotic prophylaxis reduces short-term infective morbidity rate and should be offered as a minimum, but a screen-and-treat policy for infection is an alternative; both together might confer even greater health advantage.
- Aseptic technique should be observed for D&E with careful and gentle instrumentation to avoid injury to cervix or uterus.
- D&E needs specific training and requires special cervical preparation and instruments.
- Patients must have access to services for post-TOP advice and management of complications.

MEDICAL TOP

- Gemeprost and misoprostol are the two most extensively studied prostaglandin analogues that are used for mid-trimester TOP.
- The combination of either gemeprost or misoprostol with mifepristone is most effective. With these regimens, TOP rate within 24 hours is over 90% and the mean induction-to-TOP interval is about 6 hours. Mifepristone is expensive and is not available in many countries.
- Therefore, prostaglandin analogue-only regimens might be the only option. These regimens are still effective with a TOP rate of over 90% in 48 hours. However, the induction-to-TOP interval (15 hours) is much longer.
- Intracervical tents can be used to shorten the induction-to-TOP intervals.

FUTURE RESEARCH AGENDA

- Comparison of late D&E and modern midtrimester medical TOP with mifepristone and prostaglandin
- Prospective studies on the influence of medical and surgical TOP on future reproductive health (fertility and obstetric outcome)

SUMMARY OF MANAGEMENT OPTIONS
Second-Trimester Termination of Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—General			
Accurate estimation of gestational age	III	C	160,161
Accurate diagnosis	–	GPP	–
Patient assessment and counseling	–	GPP	–
Dilation and Evacuation (D&E)			
Cervical preparation			
Laminaria	IIa	B	190,191,194
Misoprostol	IIb	B	195,196,197
Use of prophylactic antibiotics	–	GPP	–
Use of intraoperative ultrasound	–	GPP	–
Use of intraoperative oxytocin	–	GPP	–
Medical Abortion			
Fetocidal agent – KCl or digoxin	III	B	212,213
Mifepristone 36–48 h, then vaginal misoprostol followed by oral misoprostol	Ia	A	238,241
Laminaria/Foley + vaginal misoprostol, then oral misoprostol concurrently	IIb	B	217
Failed Medical Abortion	III	B	180
D&E or			
Hysterotomy or hysterectomy

Poor Progress in Labor

Harry Gee

INTRODUCTION

Parturition is a physiologic process; therefore, it might be expected that the great majority of cases would progress normally and should not require medical intervention. However, the relatively high incidence of abnormal outcomes in the absence of intervention indicates that the physiology is not robust. The possible evolutionary reasons why this might be so are covered in Chapter 67.

Poor progress in labor is associated with increased morbidity and mortality rates for both the fetus and mother.[1] Poor progress, however, is rarely causative of itself, but is a sign of underlying pathology. Ideally, the recognition of poor progress in labor would result in the diagnosis of the specific underlying cause, and cause-specific treatment would follow, but with our current knowledge and diagnostic ability this is often not possible. Under these circumstances it has become a pragmatic necessity to use interventions on a trial-and-error basis. Such interventions should be validated by properly controlled clinical trials. Unfortunately, such trials have rarely been performed, and even when they have been, many popular and widely adopted interventions have failed to meet expectations. A common response to this failure has all too often been to question whether the intervention had been correctly applied rather than to review the value of the intervention itself or its indication. This failure to acknowledge our ignorance has severely limited our ability to improve the management of labor.

This chapter aims to provide a critical analysis of the following:

- The physiology of labor
- The methods of monitoring progress of labor
- Our ability to define the boundaries between normal and abnormal progress of labor
- The pathology underlying poor progress of labor, and its consequences
- The effectiveness of interventions

THE ONSET AND DIAGNOSIS OF LABOR

Onset of Labor

In the human, no single trigger for the onset of labor has been identified. Figure 69–1 represents a possible mechanism. Within the fetoplacental unit lies the placental corticotropin model[2,3] that generates the appropriate endocrine environment for the onset of labor via the pituitary-adrenal axis and the placenta. Within the mother, the hormonal environment precipitating labor is created by changes in placental function resulting in the generation of a number of proinflammatory agents (cytokines and interleukins), while the synthesis of prostaglandins and oxytocin integrate myometrial and cervical response.

These positive feedback systems promote change, not homeostasis. The steady-state pregnancy mode is changed to active labor, which is terminated ultimately by delivery. Stimulating or obstructing such a system carries risk: hyperstimulation from uterotonics and uterine rupture from obstruction (in this respect nulliparous women behave differently from multiparous ones, although the reasons for this are not fully understood). When labor is obstructed in nulliparas the uterus tends to become inert, but in multiparas it continues to contract, resulting in an increased risk of rupture.

Efficient labor requires the coordination of myometrium and cervix. The overt nature of myometrial activity has attracted the attention—perhaps to an inordinate degree. Cervical function is much more subtle but no less important. The function of the cervix in pregnancy is to prevent delivery and its collagenous composition with fibers wound tightly in a tubular configuration are ideally suited to retaining the fetus in utero. It is reasonable to propose that some instances of poor progress in the first stage of labor may be due to asynchrony in the coordination between cervical ripening and myometrial contaction,[4] in particular, a cervix that remains

Mother   Fetus

unripe despite the onset of regular coordinated uterine contractions.

The move from pregnancy to labor mode in the cervix is characterized by "ripening." The resultant increase in tissue compliance permits deformation. Effacement and formation of the lower segment are the initial manifestations of this, followed by dilation. In nulliparous women, these processes are usually sequential, but in parous women dilation may take place before effacement is complete. Either way, effacement redistributes tissue from the cervix to the lower segment and decreases cervical resistance.

Throughout pregnancy, the myometrium is spontaneously active, but before the onset of labor, contractions originating in any particular muscle cell or group of muscle cells are not propagated throughout the myometrium. Under the influence of estrogens and prostaglandins, spontaneous activity rises throughout gestation; in addition, gap junctions (*nexuses*) form between muscle cells.[5] These junctions provide preferential pathways for electrical activity to pass from cell to cell, producing a coordinated response from the myometrium. As coordination increases, contractility becomes sufficient to raise the intrauterine pressure and Braxton Hicks contractions can be perceived by both the mother and an observer palpating the uterus. However, until they are strong enough, and the cervix ripe enough, for cervical dilation to accompany these contractions, they are usually relatively painless.

By the time of the onset of labor, oxytocin is already in high concentrations in the maternal circulation, and oxytocin receptors have developed on the membranes of smooth muscle cells. Thus, oxytocin is thought to facilitate labor rather than initiate it.[6]

Prostaglandins *potentiate* the action of oxytocin. This potentiation results in a greater tonic effect from the combination of prostaglandin and oxytocin than would be achieved from the additive effect of either on its own. Estrogens promote the production of prostaglandins in the decidua, between the fetal membranes and the myometrium.[7] These and other agents, such as interleukins and cytokines, that are involved in the inflammatory cascade[8] characterizing labor have paracrine effects,[7,9] meaning that they act over short distances, stimulating the maternal positive feedback loop, with the result that uterine activity rises exponentially at the beginning of labor and continues to rise thereafter.

Many of the agents involved in the initiation of labor affect both myometrium and cervix in different ways, but all these changes have the net effect of creating the right local environment for labor to occur. Oxytocin is a very unusual hormone in that it is almost entirely specific in its effect on myometrial contractility. There are oxytocin receptors and a small amount of smooth muscle in the cervix that are active in labor,[10] but the effect of oxytocin on the cervix is minimal compared to its effect on the myometrium.

Diagnosis of Labor

Diagnosis of labor is crucial because incorrect diagnosis leads to unwarranted and potentially dangerous interventions. Precise identification of the onset of labor is

problematic. Two essential characteristics must be considered:

- The onset of regular uterine contractions
- Progressive change in the cervix

A subsidiary characteristic is spontaneous rupture of the amniotic membranes. Friedman's graphic analysis of labor laid the foundations for current practice.[11–13] Relying for the diagnosis of labor upon recognizing the onset of regular uterine contractions is problematic, because labor is an exponential escalation of uterine activity that can take place over several days, occasionally even weeks. Precise delineation of a transition point from Braxton Hicks contractions to contractions leading to progressive dilation of the cervix is not possible without examining the cervix, as up to the time of writing it has not proved possible to identify any substantial change in the characteristics of the uterine contractions themselves between pregnancy and labor. Measurements assessing the onset, peak, and offset of contractions and the propagation of contractions across the myometrium using electromyography do not show any important differences that would clearly delineate contractions associated with cervical dilation. Thus, fundamentally, the diagnosis of progressive labor relies upon identifying changes in the cervix. Friedman used assessment of the cervix to divide the first stage of labor into latent and active phases (Fig. 69–2).

During the latent phase the cervix is changing (primarily by effacement, and to a lesser extent by softening) but showing little dilation. The active phase is characterized by progressive cervical dilation.

Other definitions of the onset of labor have been used for research purposes and will be found in the literature, including, for example, the time of admission to delivery suite.[14] This is temporally precise but of little physiologic importance. Clinically, it makes good sense to restrict the diagnosis to evidence of cervical dilation[15] because of the following points:

- Dilation is relatively easy to recognize and record (on a cervicogram).
- Available techniques and limits for monitoring labor apply primarily to the active phase of labor.

A good practice point is that for clinical purposes, all else being normal, only diagnose labor and thereby commence the monitoring of labor when progressive cervical dilation is demonstrable (usually beyond 3 cm dilation).

It should be noted that although regular uterine contractions with intact membranes and without evidence of progressive cervical dilation should probably not be classified as labor, they are still associated with interruptions of the maternal intervillous blood supply and therefore represent a hypoxic challenge to the fetus. Thus, fetuses with poor reserve, such as those suffering from intrauterine growth restriction, should always be monitored carefully when there are contractions, even when there is no progressive cervical dilation.

LABOR MECHANISMS AND PROCESSES

Progress in labor results from the interaction of three factors:

- Powers
- Passages
- Passenger

Powers

Efficient uterine activity is crucial to promote the formation of the birth canal and impart flexion and rotation to the passenger so that it can pass through the complex geometry of the canal.

In the first stage of labor, there is little change in uterine volume. Thus, myometrial contractions are, to all intents and purpose, isometric (i.e., there is minimal shortening of the muscle fibers as they develop tension). Wall tension is required to dilate the cervix. However, it is important that the muscle fibers do not shorten significantly, as this would carry the risk of continuously compressing the blood vessels traversing the myometrium. This in turn would reduce placental perfusion continuously rather than the intermittent reduction associated with the contractions themselves.

Progress is determined by the equilibrium between force (myometrial contractions, especially at the fundus) and resistance (cervix and lower segment). This is almost self-evident, but there is a more subtle effect. The "give" from a compliant cervix attenuates the tension generated by the myometrium.[16,17] Thus, a compliant cervix not only dilates quickly but does so with less uterine activity (as measured by the rise in pressure in the amniotic fluid). The converse is also true.

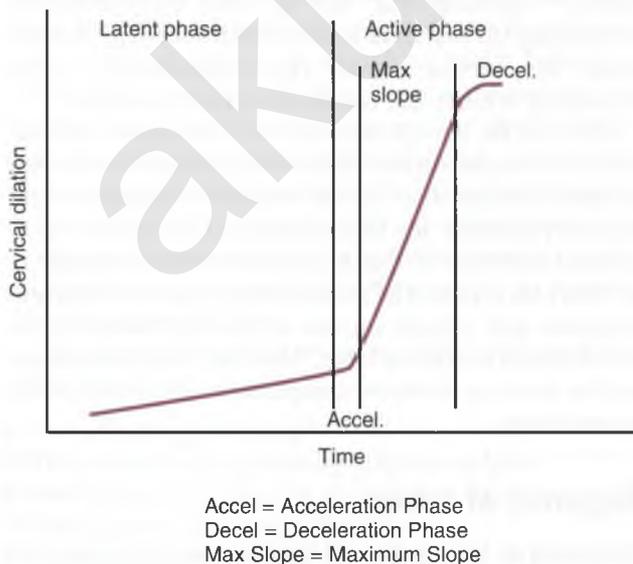
Accel = Acceleration Phase
Decel = Deceleration Phase
Max Slope = Maximum Slope


FIGURE 69–2
Friedman's representation of cervical dilation in labor.

One apparent paradox is that multiparous women demonstrate faster rates of cervical dilation than nulliparous women but do so with lower uterine activity.[18] This is becuase of their lower resistance.

Assessment of uterine Activity

Uterine activity can be quantified by measurement of intrauterine pressure (IUP), which is directly proportional to wall tension and indirectly proportional to uterine size. Four variables must be taken into account to assess uterine activity, the first three being associated with the contractions themselves: amplitude, duration, repetition frequency, and basal pressure or *tone* (the last one is associated with the elastic recoil and muscular tone of the uterus itself). Measurement of basal tone in absolute terms is sensitive to hydrostatic pressure. Hydrostatic pressure in turn is related to the position of the transducer in relation to the upper fluid level within the uterus. This relationship is affected by posture, and therefore, correct measurement of the baseline tone over and above the hydrostatic pressure requires knowledge of the position of the transducer in relation to the uterus. In current practice, transducers placed at the tip of an intrauterine catheter are often used, and their precise location within the uterus is unknown. Changes in baseline tone can be assessed if the recorded pressure is "zeroed" at the beginning of a recording, but this means that the absolute level always remains uncertain. For this reason, the assessment of uterine activity usually relies upon measuring changes in pressure above baseline tone, ignoring the effect of baseline tone itself. In fact, in the absence of placental abruption or the use of oxytocics (the two most common causes of abnormally elevated baseline tone) most workers have found that the level of baseline tone does not contribute significantly to the rate of cervical dilation and can therefore reasonably be ignored when assessing whether any particular level of uterine activity is likely to be associated with progressive cervical dilation.

IUP monitoring is invasive, requiring insertion of either a fluid-filled catheter connected to an external transducer, or a transducer-tipped catheter, into the amniotic sac. This carries a small risk, from incorrect placement, of abruption, uterine perforation, entanglement, and infection, although these risks are minimal with the modern designs of soft-tipped catheters. IUP monitoring has never been shown in prospective randomized trials to improve the management of labor, but it has been shown repeatedly that under some circumstances, clinical assessment of uterine activity by palpation is unreliable. For this reason, IUP monitoring may be useful in the following circumstances:

- Contractions are difficult to palpate, such occurs in obese patients.
- There is uncertainty as to whether augmentation of labor (for example, with an oxytocin infusion) is producing appropriate increases in uterine activity.

- The data from this labor will be used for research purposes.

Also, in some circumstances it may be of medicolegal value to be able to demonstrate close and accurate monitoring of uterine activity, for example, with induction or augmentation of labor in the presence of a uterine scar, or the use of Syntocinon in grand multiparas, or when the fetus is particularly at risk from uterine hyperstimulation (e.g., when there is evidence of intrauterine growth restriction). The argument is made that if one is prepared to allow spontaneous uterine activity in such cases, then logically one should be prepared to correct low levels of uterine activity up to a physiologic level, provided this can be assessed objectively. However, no studies clearly demonstrate any advantages to IUP monitoring in these circumstances, and some would counsel against such use in case they provide a false sense of security. An equally valid management option at the present time is not to use an oxytocic at all in such cases, resorting instead to cesarean section if there is poor progress.

Because amplitude of contractions correlates with the palpable duration of contractions (most contractions only become palpable when the IUP exceeds baseline tone by more than 15 mm Hg) and overall activity is dependent on repetition frequency, palpation of contractions with timing of duration, and particularly frequency, can give an adequate, semiquantitative assessment of uterine activity for most clinical purposes, including oxytocin augmentation.[19] For these reasons palpation remains the standard method of monitoring uterine activity for clinical purposes.

Normal Range

If progressive cervical dilation is taking place, there is no need for a lower limit to be placed on acceptable uterine activity. Only when there is perceived delay in labor should the adequacy of uterine activity be questioned.

- A contraction frequency of three to four contractions every 10 minutes is optimal.
- Palpable contractions should last for minimum of 40 seconds.

Contractions occurring more frequently than five every 10 minutes with little or no relaxation between them constitute tachysystole (Fig. 69–3).

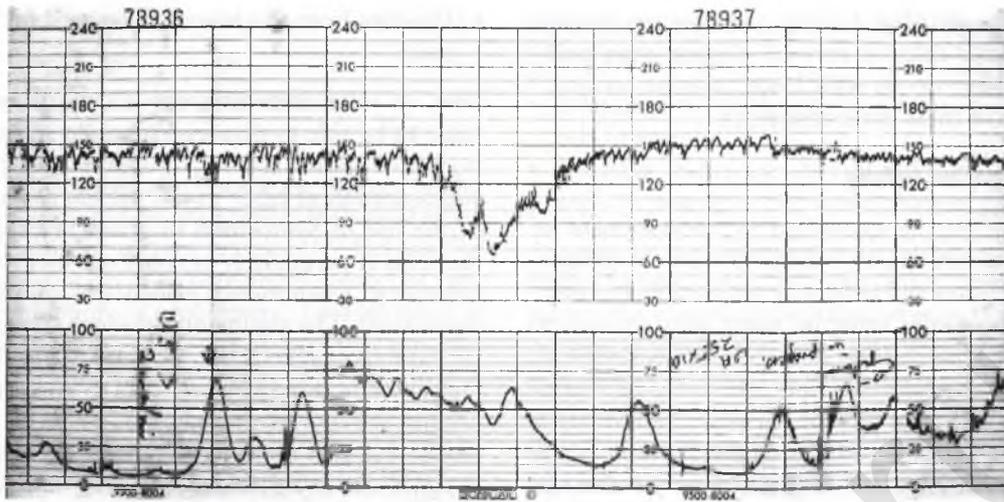
Uterine activity increases as labor progresses due to prostaglandin release from the decidua and secretion of oxytocin from the maternal posterior pituitary. Spontaneous uterine activity at the end of the first stage can be in excess of levels considered safe for induced or augmented labor.[20,21] The well-being of the fetus in labor is finely balanced. The stronger the contractions, the better the progress but the greater the effect on placental perfusion. The stress of high levels of uterine activity and rapid progress is usually self-limited by early delivery before there is any adverse cumulative effect on the fetus. Poor progress, on the other hand, may result in the


FIGURE 69–3
Hyperstimulation due to oxytocin showing effect on fetal heart rate. Note the frequent small-amplitude contractions and rise in basal tone.

cumulative effects of uterine contractions exceeding the tolerance of the fetus. A compromized fetus will have lower tolerances, and augmented uterine activity will then have a greater and more rapid impact.

Passages

The passages have often been equated solely with the bony pelvis, but the soft tissues are also important, including the cervix and lower segment in the first stage and the pelvic floor in the second stage.

Assessment of the Pelvis

Absolute cephalopelvic disproportion is today rare in well-nourished populations. Childhood rickets used to be a relatively common cause of brim dystocia, hence the importance obstetricians have traditionally given to "engagement," because in previous generations passage of the largest part of the fetus through the narrowest part of the bony pelvis usually guaranteed delivery.

In today's practice, however, clinical and x-ray pelvimetry have poor predictive values[22] and should not be used. More sophisticated imaging techniques, such as magnetic resonance imaging and computed tomography, coupled with ultrasound fetal biometry, have been used to improve diagnosis, and this approach is logical but further clinical research is required to establish their value.[23]

The shortcomings of pelvimetry, and the complex mechanism of labor that relies on flexion, rotation, molding, and even pelvic compliance, means that clinicians have to fall back on "try it and see."

It should be noted that two out of three women who require a cesarean section for failure to progress go on to deliver normally the next time despite birth weight rising with parity. This suggests that cephalopelvic disproportion is not a common cause for failure to progress.

Assessment of the Soft Tissues

The function of the cervix in pregnancy is to obstruct delivery. Failure of the cervix to undergo its correct biophysical preparation may carry its pregnancy function through to labor. Abnormal connective tissue biochemistry has been demonstrated in association with poor progress in labor.[24]

In the second stage of labor the soft tissues of the pelvic floor help to induce the rotational forces necessary for the complex mechanism of labor in the human, while, at the same time, they offer resistance to progress. It is perhaps paradoxical that the resistance necessary to impart rotation also offers resistance to descent.

Measurement of the forces between the cervix and the fetal head has shown differences between progressive and delayed labor.[25–27] These data do not fit simple mechanical relationships, emphasizing that cervical dilation is a more complex process than mere stretching. More work needs to be done to permit clinical application of these experimental techniques.

Clinical monitoring relies on the aggregate response of the cervix during labor. Digital estimation of cervical dilation is plotted against time (cervicography). This is simple and screens for deviation from a normal pattern, but because of the many variables that may be at play, it does not offer a diagnosis. For example, the complex interaction of the head to cervix forces with the stretching of the cervix cannot be assessed clinically at the present time.

Passengers

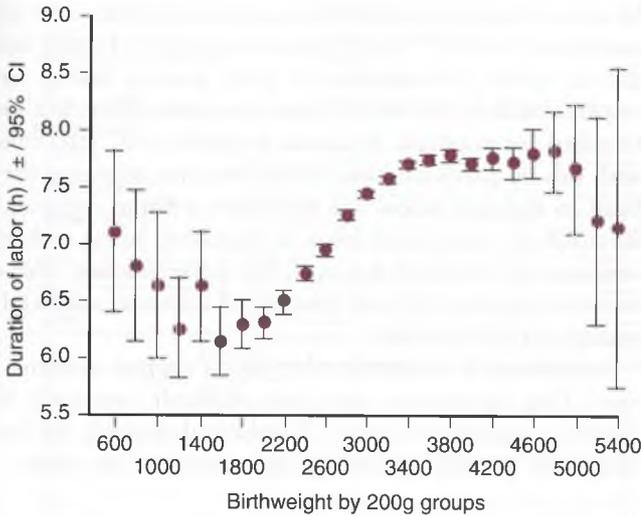
Birth weight within the normal range has poor predictive value for delivery complications. Figure 69–4 shows that there is some correlation of the duration of labor with birth weight, but the maximum variation over the


FIGURE 69-4
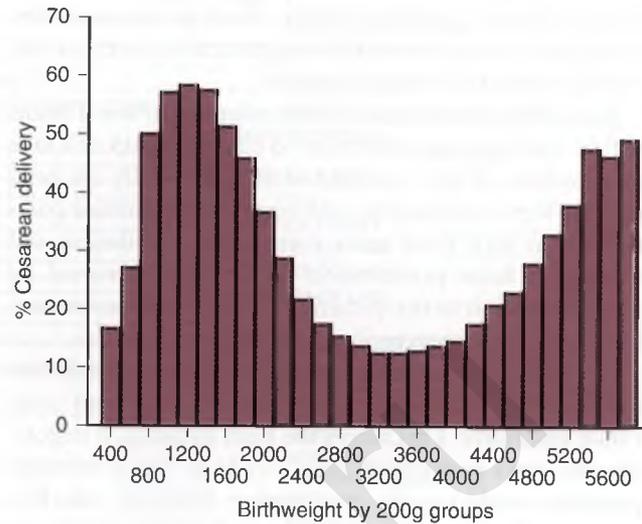
The duration of labor by birth weight. Data taken from 425,855 births with birth weight and duration of labor recorded in the North West region of London from 1988 to 2000.


FIGURE 69-5
Percentage of babies delivered by cesarean section, according to birth weight. Data taken from 513,381 births with birth weight and mode of delivery recorded in the North West region of London from 1988 to 2000.

extremes of birth weight is only 1.5 hours. The effects of flexion and rotation on the efficiency of the labor mechanisms are likely to be at least as important. The ability of the fetal head to mold is another important variable. Moreover, in terms of cephalopelvic disproportion, head size is not closely correlated with birth weight. For macrosomic fetuses the main risk is shoulder dystocia. Unlike cephalopelvic disproportion, shoulder dystocia is not reliably predicted by cervical dilation rates in the first stage, and even the descent of the presenting part in the second stage can be normal.[28]

Only the extremes of birth weight have much significance in relation to mode of delivery. In recent U.K. practice, cesarean section was used in up to 60% of pregnancies when the birth weight was less than 2.5 kg, and from 40% to 50% when the birth weight exceeded 5 kg (see Fig. 69-5). However, there was relatively little variation in the use of cesarean section when the birth weight lay between 2.5 kg and 4 kg (Fig. 69-5), and in 513,381 births in the North West region of London between 1988 and 2000, this range accounted for 83.2% of all births. Thus, for the majority of babies, birth weight contributes little to the mode of delivery.

Some evidence suggests that birth weight is rising[29]; even more important than the increasing mean birth weight is the increase in the proportion of babies weighing more than 4 kg, which in some European countries has now reached 30%. However, this increase in birth weight has to be viewed in the context of improved maternal nutrition and the general increase in maternal stature.

Assessment

Even if birth weight was of crucial importance in determining progress in labor, birth weight can only be predicted to an accuracy of ±10% to 15% by ultrasound fetal biometry. The poor predictive value of these estimates

means that they have to be factored in very cautiously when planning delivery. They should be taken into consideration, however, when delay is apparent. Other clinical features of cephalopelvic disproportion that should be sought include excessive molding, and failure of the presenting part to engage and descend. Generally speaking, it is reasonable to assume that pelvic capacity is adequate if a woman has delivered vaginally before, but birth weight increases with parity, and the increase may be substantial if the woman has developed gestational diabetes due to advancing maternal age. Therefore, it is wise to check previous birth weights and any features of the current pregnancy (such as glucose intolerance) that may indicate borderline disproportion. This baby may be just that bit too big.

Presentation: Flexion/Deflexion

Flexion and deflexion of the head determines the part that will present. Flexion results in a vertex presentation, that part of the head bounded by the occiput, the posterior part of the anterior fontanel, and the biparietal eminences. This results in the smallest dimensions of the head presenting themselves to the birth canal (9.5 cm × 9.5 cm). Flexion is promoted by efficient powers—uterine contractions in the first stage and the addition of maternal pushing in the second.

Deflexion of the head produces first a brow presentation and then, in complete deflexion, a face presentation. The dimensions of a brow in a term fetus are such (13.5 cm anteroposterior) that they cannot be accommodated by a normal pelvis. Thus, the head remains high, progress of labor may become obstructed with a secondary arrest pattern, or if full dilation is reached, there may be failure of descent. Brow presentation should be considered when a multiparous patient, who has delivered normal-sized

babies without a problem before, develops abnormalities of progress. Resort to oxytocin augmentation without this consideration risks uterine rupture.

Judicious prevarication can be adopted to see if there will be spontaneous conversion to either a vertex or a face presentation. If not, cesarean section is usually the only option. Very occasionally, with an occipitoposterior position of the fetal head and a roomy pelvis, deflexion will result in a brow presentation that can be corrected by forceps rotation to occipitoanterior. Such maneuvers are, however, rarely contemplated in modern practice.

Babies with a face presentation can deliver vaginally but only under favorable circumstances. The mentum must rotate anteriorly. This allows the head to flex as it negotiates the curve in the birth canal. To do so with a mentum posterior would require even further deflexion, which is anatomically impossible. A good-sized pelvis and efficient powers are necessary to deliver a face presentation spontaneously. Forceps can be used to add traction.

Assessment is undertaken by digital vaginal examination.

Position: Rotation

The vertex normally engages with the occiput in a lateral position. This allows congruence between the long axis of the head and the widest diameter of the brim of the pelvis from side to side. With descent, the lowest part (occiput) is forced forward by the levator ani muscles that form an inclined plane running from back to front. This occurs in the midpelvis, which when cut across presents a circular shape that is conducive to rotation. With the occiput anterior and the head flexed, the head is now able to fit the diamond-shaped pelvic outlet with matching of the long axes of the head and the outlet. Deflexion of the head is possible as it negotiates the curve of the birth canal.

If the head rotates and maintains a posterior position (OP), there is a tendency to deflex and present a larger dimension to the birth canal. To follow the curve of the birth canal the head has flex further. This is anatomically difficult and unlikely to occur. In the first stage, an OP position may present with any pattern of delay. The options are to wait and hope for spontaneous resolution, augment the powers with a view to encouraging flexion and rotation, or cesarean section if neither produces the desired result. If augmentation is undertaken, the side effects have to be recognized and safeguards employed, meaning continuous electronic fetal monitoring and timely reviews, particularly in a multiparous woman if progress is arrested.

Delay in the second stage can be addressed by instrumentation. For persistent OP, an OP ventouse cup can be used, not only to apply traction, but also to encourage rotation and flexion. Some skill is required to achieve this. Forceps (Kielland's) can be used for simple traction or rotation. These are not maneuvers for the inexperienced.

The head may stay in an occipitolateral position such that it cannot negotiate the diamond-shaped pelvic out-

let whose longest dimension lies anteroposterior. This is sometimes termed "deep transverse arrest." It may be due to pelvic abnormality or poor powers failing to impart rotation. Resistance from the pelvic floor is also required for rotation. Epidural analgesia may interfere with this by paralyzing the levator muscles, allowing the head to descend below the midcavity without rotation. Rotation to occipitoanterior is required, using either ventouse or rotational forceps. The latter is more effective but requires skill and practice if maternal and fetal trauma is to be avoided.

Assessment is undertaken by digital vaginal examination. This examination can prove difficult, especially if there is scalp edema (caput). Ultrasound imaging can be helpful by identifying midline structures and the orbits.

CLINICAL ASPECTS OF MANAGEMENT OF LABOR

If a woman delivers vaginally the first time, she is much more likely to do so in the future. Thus, good management of the first labor is crucial and has a bearing on the rest of her reproductive potential.

Active Management

This term carries a number of connotations. In its broadest sense it marked a change in philosophy from reacting to prolonged labor after the event, to prospective monitoring of labor to detect delay early, diagnose its cause, and instigate management.[30] This ideal is often not possible because a precise diagnosis is lacking. A more pragmatic approach emerged whereby prospective detection of departure from normal progress was automatically managed by augmenting the powers to accelerate progress because this was the only variable open to manipulation by the clinician.[15,31]

Whatever the clinician's view of active management, most agree that good management of labor[32] depends upon the following:

- Correct diagnosis of labor
- Use of a partogram
- Adherence to agreed policies of management based on best evidence regarding fetal and uterine contraction monitoring
- Appropriate intervention
- Auditing of outcomes

The Partogram

Figure 69-6 is a chart that represents the essential variables for monitoring both mother and fetus during labor. Graphic representation of data is used whenever possible because trends are important. The three sets of data concern maternal signs, fetal signs, and progress of labor.

FIGURE 69-6
Partogram.

Graphic representation of data is used whenever possible becasue trends are important. The three sets of data concern maternal signs, fetal signs, and progress of labor.

Maternal Signs

Maternal data comprise vital signs (pulse, blood pressure, temperature), urinalysis, and medical treatment (analgesia, uterotonics).

Fetal Signs

Fetal data comprise fetal heart rate, state of the membranes, color of the liquor, and descent and position of the presenting part.

Progress of Labor

The cervicogram is a component part of the partogram and, by definition, relates to the first stage. It represents, graphically, cervical dilation over time from the diagnosis of established labor. In practice this applies only to the active phase of dilation (although monitoring the change in the Bishop's score of the cervix may be of value in the latent phase). Because the usual concern is detection of delay, the lower limit of progress has received much attention, with little attention on setting upper limits. Precipitate labor has been associated with risk but this comes mainly from unexpected delivery rather than from the brevity of the process per se (although there is a reported increase in the incidence of Erb's palsy with precipitate labor – see Chapter 70).

MANAGEMENT OF THE FIRST STAGE OF LABOR

Diagnosis of Delay or Aberrance

Friedman selected 200 nulliparous women retrospectively from a larger heterogeneous group of patients[12] and a similar cohort of parous women[13] to identify "ideal" labor, namely, no iatrogenic interventions (apart from "prophylactic low forceps"), vaginal deliveries, and average-sized, healthy neonates. These patients' labor curves were analyzed to identify statistical limits as means and standard deviations.

From these data a lower limit of maximum slope dilation was produced (Fig. 69–7).

The value of 1 cm/hour has now become almost universally accepted for clinical practice. However, this rate may be an overestimate for the following reasons:

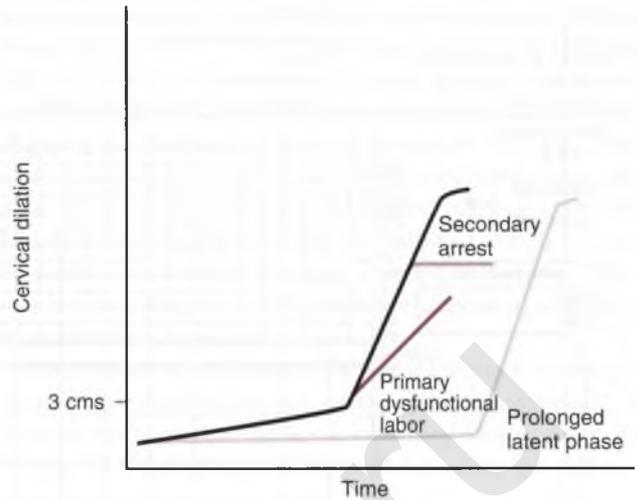
- The data are not normally distributed, but have a tail skewed toward higher rates of dilation, bringing into question the validity of the statistical analysis.
- Most clinicians use an average of 1 cm/hour for the whole of the active phase, including the slower phases of acceleration and deceleration and not just the phase of maximum slope.


FIGURE 69–7
Patterns of delay. (Data from Friedman.)

Better statistical analysis of progress in normal labor has confirmed these doubts (Fig. 69–8).[33] These data show lower rates of dilation in the early part of the active phase and no inflection points at the end of the phase of maximum slope. This pattern of progress may reflect physiology better, but more clinical evaluation is required.

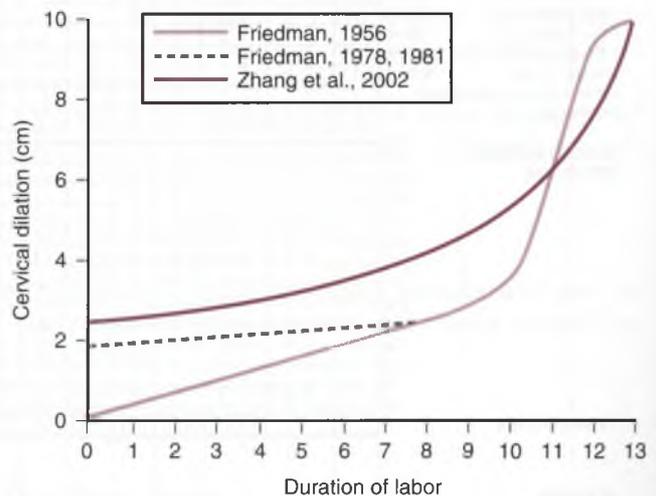
Several cervicograms have been produced for clinical use. Hendricks[34] produced similar patterns of dilation but chose the slowest 20% as the statistical divide. Philpott and Castle,[35] in a southern African population, demonstrated a marked difference in the rate of maximum slope compared with Friedman's data (median 1.25 cm/hour versus 2.75 cm/hour, respectively) based on data from an unspecified number of cases, representing the slowest 10% of primigravidas, suggesting that there may be significant popula-


FIGURE 69–8
Reanalysis of progress in nulliparous labor. (Data from Friedman EA: Cervimetry—an objective method for the study of cervical dilation in labor. Am J Obstet Gynecol 1956;71(16):1189–1193; Friedman EA: A cervimeter for continuous measurement of cervical dilatation in labour—preliminary results. Am J Obset Gynecol 2002;3(2):288–290.)

tion differences. They introduced the concept of an alert line followed 4 hours later by an action line.[36] This interval has been changed by other researchers, often without clear reason or benefit. Despite the earlier observation that there was a lower maximum slope gradient in their population, the lines were set with gradients of 1 cm/hour. Beazley and Kurjak[37] used a "low risk" population to produce a cervicogram whose limits differentiate progress above the line, resulting in an 80% chance of a favorable outcome, compared with only a 20% chance below it. This cervicogram acknowledges differing limits for nulliparous and parous women. Studd[38] devised a cervicogram from a multiracial population in the United Kingdom having "normal" labor. An S-shaped dilation curve was produced, with the steepest gradient between 4 cm and full dilation. The statistical methodology used to produce these curves was not specified, nor were the biologic limits.

All these cervicograms, in their various ways, attempt to define a boundary that can be used to define slow progress. However, they have been devised using data from specific populations with individual characteristics, and therefore, they may not be generalizable to different populations. Indeed, as they all differ, it is likely that they cannot be used without their clinical value being tested prospectively to determine their predictive value for any particular group. For example, it seems unlikely that the same cervicogram would be applicable to a black African population with their high assimilation pelves and high obstructed labor rates, compared with white Scandinavians with their wide pelves and low cesarean section rates. Prospective evaluation of these various cervicograms in different populations from those in which they were derived has not been done, and the available data does not allow their generalizability to be assessed from the original studies. Using data from later papers, the positive predictive value for operative delivery from an alert line set at 1 cm/hour gradient and an action line 2 hours later (values that are widely used today in the developed world) is only 43%. Use of standard cervicogram limits for the multiethnic populations of many of today's major cities seems unlikely to be adequate.

Thus, cervicography is only an aid to the management of labor and should not be used as a substitute for appropriate diagnosis. Transgression of a lower limit of progress should simply raise awareness of increasing risk, indicating the need to look for an explanation (diagnosis) of the slow progress.

Poor Progress

Friedman described three patterns of aberrance from normal labor[39] (see Fig. 69-7):

- Prolonged latent phase (PLP)
- Primary dysfunctional labor (PDL)
- Secondary arrest (SA)

None of these patterns is pathognomonic of a particular pathology. They are signs of pathology not diagnoses.

Prolonged Latent Phase

Friedman described the latent phase, from the onset of contractions to entry to the active phase of dilation, as lasting up to 20 hours in nulliparas (mean 8.6 hours, SD 6 hours) and 14 hours in parous women (mean 5.3 hours, SD 4.1 hours). The difficulties with defining the start and end of this phase have already been discussed. Thus, the true incidence of prolonged latent phase is difficult to determine, but 3.5 % has been proposed in nulliparas. It is less common in parous women.

The causes of this pattern of delay are uncertain but probably relate to delayed cervical ripening (absent or slow changes in cervical connective tissue biochemistry during the second half of pregnancy).

Augmentation of the powers with oxytocin to accelerate progress in the latent phase is not beneficial.[14,40,41] Such augmented labors still exhibit a 10-fold increase in cesarean section rates compared to normal labors, with a threefold increase in low Apgar scores in the neonates.

From a practical point of view, all else being equal, reassurance for the mother, analgesia, and time are often all that is necessary to allow cervical preparation to synchronize with that of the myometrium.

Primary Dysfunctional Labor

Primary dysfunctional labor is defined as progress slower than 1 cm/hour during the active phase slope with an incidence of 26% in nulliparas and 8% in parous women.[40] About 80% of nulliparas and 90% of parous women will respond to oxytocin, suggesting that poor uterine activity is a significant factor. Unfortunately, response in terms of improvement in cervical dilation rate does not always translate into uncomplicated vaginal delivery. Fetal distress may result from augmentation of the forces, and an increased incidence in instrumental delivery and perinatal morbidity suggest that mechanical factors may also operate. Five percent of augmented labors do not respond in terms of increasing their uterine activity or rates of progress, and these nonresponsive labors are associated with cesarean section rates of 77%. On the other hand, 23% still achieved a vaginal delivery,[14] so even failure of response cannot be seen as an automatic indication for cesarean section. Mechanical abnormalities can be postulated (particularly malposition, malrotation and deflexion, and slow molding of the fetal head) which correct themselves in time, but sound evidence for a single causal effect is hard to find. Other possibilities have not been extensively studied. Abnormalities of cervical mechanics and biochemical preparation have been documented and merit further study.

Secondary Arrest

Secondary arrest can be identified by cessation of progress after normal active phase dilation.[42] The incidence is 6% in nulliparas and 2% in parous women.

A subtle variant of secondary arrest is delay between 7 and 10 cm. Even though full dilation may be achieved, there is an increased risk of difficult instrumental delivery.[43]

Of the three patterns of arrest, secondary arrest has the most convincing link with etiology, namely disproportion and malposition. Although in one series 60% nulliparas and 70% of parous women showed improved progress with augmentation of contractions, cesarean section rates were over 10-fold greater than in normal labor. The effect of uterine stimulation may have been to encourage flexion and rotation of the head, promoting descent and progress along the birth canal.

Practice Point

Whatever the pattern of delay, identification of a clear, single etiologic factor is unlikely. This may be due to complex interactions between multiple factors, an inability detect the contributory factor because the diagnostic tools are imprecise, lack of knowledge of other factors, or finally a combination of all three. Treatment is more likely to be successful when a diagnosis of a single pathologic process is possible. Augmentation of the powers may be the only intervention available, and the "do nothing" arm of clinical trials has been woefully absent, leaving this option surrounded with uncertainty.

Thus, the obstetrician faced with evidence of delay should be conversant with the options available and be prepared to balance the risks and benefits of any intervention to be employed.

Interventions

Amniotomy

It is commonly stated that amniotomy increases uterine activity, although the evidence for this is weak, and there are good reasons to keep the membranes intact. For example, more fetal heart rate decelerations have been noted following amniotomy. Randomized clinical trials of routine amniotomy show that there is no improvement in clinical outcome, though labor may be shortened. Surgical intervention is not reduced, and there are no major benefits for the neonate.[44–46] However, if there is poor progress with intact membranes and uterine activity is thought to be suboptimal, a case for amniotomy can be made. Occasionally, it may also allow the presenting part to descend and press more effectively on the cervix. Perhaps more important than the physical forces induced by amniotomy are its pharmacologic effects. Rupture of the membranes provokes prostaglandin release from the decidua. Prostaglandins may stimulate the positive feedback loop to increase uterine activity and ripen the cervix. Amniotomy has also been advocated to allow early detection of meconium as an aid to the assessment of fetal well-being, and therefore may sometimes be useful if the fetal heart rate pattern is nonreassuring. In summary, all other features of labor being normal, there is no clinical benefit from routine amniotomy.

Oxytocin Augmentation

When oxytocin became readily available for clinical use in the 1960s, obstetricians were given some degree of control over one of the three variables that determine progress, namely the powers. As already stated, the powers also indirectly influence flexion and rotation of the passenger.

Oxytocin is a polypeptide hormone secreted from the posterior pituitary of both mother and fetus. The half-life of oxytocin is only 5 to 7 minutes. Therefore, its effect can be removed rapidly merely by stopping the infusion (Fig. 69–9).

Binding of oxytocin to its receptor[47] opens calcium-activated channels and results in membrane depolarization.[6] This, in turn, opens voltage-dependent channels, producing a rise in intracellular calcium that generates tension in the contractile filaments. The prime effect is to increase the frequency of contractions with a second effect of slowing conduction and recruiting more cells per contraction, thereby increasing duration and amplitude. Thus, palpation of frequency and duration is a logical, simple means of monitoring oxytocin's effect.[17]

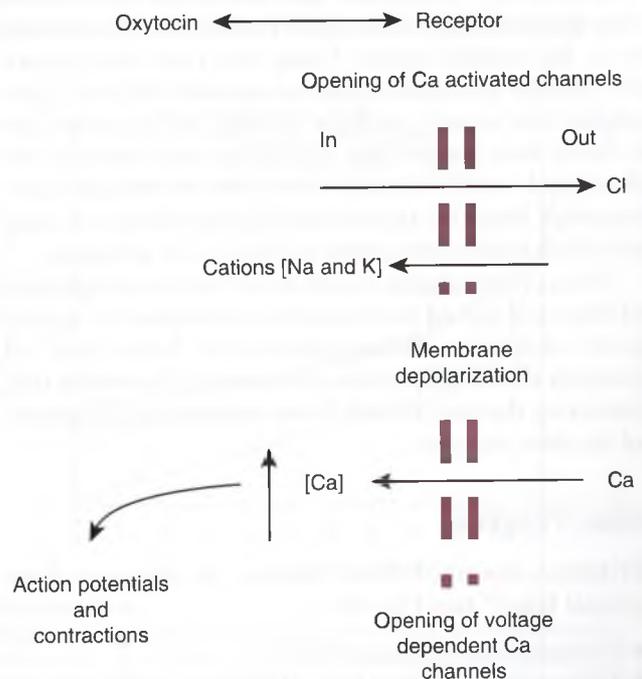
Both of these effects are beneficial when the myometrium is hypotonic, but addition of oxytocin to an already optimally acting myometrium frequently induces hypertonus, with resulting fetal hypoxia. Careful monitoring of uterine activity is essential and infusion rates may have to be reduced as labor proceeds. Titration of dosage against uterine activity should be performed using


FIGURE 69–9
Action of oxytocin.

regimens that allow time for activity to become stabilized between increments. An interval of 30 minutes between increments is recommended. Published protocols generally recommend a starting dose of 1 to 6 mU/minute; in current practice 1 to 2 mU/minute are usually used. Geometrically increasing regimens (e.g., 1, 2, 4, 8, 16, 32 mU/minute) reach effective doses more quickly but are more prone to cause hyperstimulation, and have therefore generally been replaced by predominantly arithmetic increases (e.g., 1, 2, 4, 6, 8, 10, 12 mU/minute). The majority of women will respond to dose rates of 8 mU/minute, and few will need more than 16 mU/minute.

When oxytocin is used in labor, it must be maintained for the third stage and for an hour thereafter to reduce the risk of uterine atony and postpartum hemorrhage. Postpartum hemorrhage is also associated with prolonged labor.

Meta-analysis[48] of clinical trials of oxytocin augmentation show an increase in the parturient's subjective experience of pain and some increase in the rate of cervical dilation but no reduction in cesarean section and instrumental delivery rates.

Cesarean Section

When interventions for poor progress fail, cesarean section is necessary.

The Active Management of Labor

The widespread availability of oxytocin was followed by the similarly widespread adoption of the use of cervicography to detect slow progress. It was argued by some[15] that the only variable the clinician could influence in the first stage of labor was the powers and that malposition or deflexion of the fetus could only be influenced indirectly via the powers. Hypotonic uterine activity, leading to these abnormalities, should be treated by augmentation. A package of care was proposed for nulliparous women that emphasized the importance of the correct diagnosis of labor (active phase), routine amniotomy, hourly cervical assessment per rectum to determine progress, and augmentation of the powers with intravenous oxytocin if slow active phase progress was detected (the lower limit of normal adopted was 1 cm/hour). This regimen permitted one-to-one midwifery care because within a short measure of time patients progressed normally, responded to augmentation, or underwent cesarean section if they did not progress. The results from uncontrolled cohort studies indicated low cesarean section rates associated with this policy. The simplicity of this approach appealed to many clinicians, and still does.

However, the same results could not be replicated elsewhere and concerns grew over rising cesarean section rates[49] for failure to progress despite the apparent adoption of this philosophy. Moreover, 25 years later, meta-analysis of the individual components of this approach has revealed that the medical interventions proposed are not effective in reducing operative intervention.[48]

Randomized controlled clinical trials have now been performed. The first of these[50] showed a decrease in cesarean section associated with the adoption of "active management" from the rate prior to the study, but there was also a decreased rate in the control arm of the study. This was almost certainly a Hawthorne effect (simply by doing the trial and focusing participants' minds on the management issues produced an effect). The end result was not statistically significant. The largest study[51] did not show any improvement in surgical delivery rates, though there was a reduction in maternal postnatal pyrexia. These two studies started with relatively high cesarean section rates, in the region of 20%. Early studies reported the use of oxytocin in up to 50% of nulliparas,[15,53] not a particularly surprising figure if a threshold of 1cm/hour of cervical dilation is chosen as a threshold for augmentation, as this is their average rate of cervical dilation. A third study[52] aimed to test if relaxation of the indications to augment uterine activity that had been adopted as part of a regimen of active management, thereby using less oxytocin, would risk raising a low cesarean section rate. This study reported cesarean section rates of 3.9% in the active management arm compared with 2.6% in the "selective use" arm and spontaneous vaginal delivery rates of 78% and 79%, respectively. Meta-analysis has been performed on clinical studies of active mangement.[54] This analysis combines controlled and uncontrolled trials and concludes that there is reduced operative intervention. Care must be exercized when combining such heterogeneous data. Meta-analysis of only the randomized trials fails to show any benefit. There does not appear to an increase in neonatal problems, probably due to the high degree of intrapartum surveillance that is employed. A study of the promptness with which oxytocin is used (crossing an action line set at 2 or 4 hours after the alert line) did indicate that there was a reduction in cesarean section (RR 0.68) using the more aggressive approach.[53] This trial, though showing benefit, had to be curtailed, and there were protocol violations in the aggressive arm of the study. Confirmation of these findings by similar studies would be helpful.

One-to-One Midwifery Care

This benefit was almost a side effect of the package of active management, but clinical benefit from such intensive care has been demonstrated.[48] Patient confidence and her feeling of control is improved in association with a reduction in the the need for pain relief and a lower incidence of cesarean section and operative vaginal delivery. Who provides the support appears to be less important. Some studies have employed nonclinical but trained lay supporters (doulas).

Interventions demonstrated to be effective are preparation of the mother and personal support during labor and correct diagnosis of labor (active phase) to permit appropriate application of limits of progress.

MANAGEMENT OF THE SECOND STAGE OF LABOR

The second stage of labor starts at full dilation of the cervix and ends with delivery of the fetus. Descent and rotation of the passenger are the main features. Before the advent of epidural analgesia, full dilation of the cervix was apparent because of an urge to push due to the descent of the presenting part onto the pelvic floor. Epidural analgesia may abolish this sensation completely. Thus, there may be no outward signs of entry to the second stage, and diagnosis will only follow vaginal examination. The duration of second stage has thereby become controversial.

Physiology of the Second Stage

Maternal Changes

At full dilation of the cervix, the uterus ceases to be a "closed vessel," cervical resistance is lost, and descent through the birth canal begins. Cervical resistance is necessary for the isometric generation of wall tension. After full dilation, myometrial activity progressively changes toward isotonic activity as the uterus empties. Reduction in uterine volume permits shortening of the myometrial fibers that becomes maximal during the third stage. This form of myometrial activity is crucial for effective hemostasis in the third stage but is potentially dangerous in the second stage.

The myometrium is "inserted" into the pelvis via the connective tissues that surround the cervix, with the round ligaments helping to tether and direct the uterine fundus. These connective tissue supports are elastic. If the force required to stretch them is greater than the resistance offered by the birth canal, there will be progress. The rate of progress will be determined by the equilibrium established between the elasticity of the supports and the resistance offered by the birth canal. Frank obstruction to progress from the bony pelvis will merely direct all force to stretching the cervical supports against this resistance. Descent can occur without pushing, but there is little evidence (other than anecdotal, for example, spontaneous delivery in paraplegic women) to show that delivery can be achieved without the voluntary use of the abdominal muscles to raise intra-abdominal pressure to increase the expulsive forces. Pushing increases maternal effort and interferes with breathing, inducing both respiratory and metabolic acidosis.

Fetal Changes

Studies on the acid-base balance in the fetus in the second stage show a decline in pH and a rise in lactate as pushing and descent progress.[55–57] To a degree, this is physiologic, and the metabolic changes will stimulate the neonate to breathe spontaneously. Too much, however, results in respiratory depression.

Divisions of the Second Stage

It is useful to split the second stage into passive and active sections, depending on whether pushing has commenced.[55]

Passive Section

In the passive section, prior to pushing, there is likely to be little descent to alter the character of myometrial activity, and the mother is not affecting her metabolic state by pushing. Thus, there is minimal effect on the fetus.[55] There does not appear to be a significant risk from waiting at this point prior to pushing, all else being equal. However, there does not appear to be any benefit, either.[58] Thus, whether to commence pushing or wait and the duration of this wait continues to be debated but is probably irrelevant to outcome.[59]

Active Section

The active section commences with pushing. From this point onward, the metabolic changes in the fetus described earlier begin and progress. Descent and rotation of the presenting part should be progressive, irrespective of the presence or not of an epidural anesthetic.

Monitoring Progress

Descent

Descent is monitored and represented on the partogram in two ways: abdominally by the amount of head palpable, usually in fifths, and vaginally as the station, estimated in terms of the level of the lowest point of the presenting part in relation to the ischial spines.

Friedman[60] described progress in terms of the number of expulsive efforts the mother makes; more commonly, time alone is used as the criterion. The former is more physiologic, the latter is easier. If contractions are occurring with the usual frequency of three to four every 10 minutes, the two are the same. No robust clinical trials have been conducted concerning the optimal time for pushing, but traditional limits of 30 minutes for parous and 45 minutes for nulliparous women are reasonable. These times may seem a little short, but it should be remembered that if the woman has not delivered by this time, it can take a further 20 to 30 minutes to prepare for, and carry out, instrumental delivery. There is unlikely to be a problem if delivery occurs within this time but if longer limits are allowed, the extra time may be critical. Progress can be recorded on the partogram, and a second stage nomogram has been produced.[61]

Rotation

Rotation is determined by vaginal examination and palpation of the sutures and fontanels on the fetal head in relation to the maternal pelvis. Scalp edema (caput), which often develops with delay, may make this difficult.

Interventions

Augmentation of the Powers

As with the first stage, efficient powers are paramount. Uterine inertia is not uncommon at full dilation when epidural analgesia is used, due to the abolition of the reflex release of maternal oxytocin produced by the sensation of stretching of the introitus and perineum (Ferguson reflex). Intravenous oxytocin may be required to restore uterine activity.

Use of the mother's abdominal muscles to raise intra-abdominal pressure (Valsalva maneuver) is important. Efficient pushing requires education and encouragement, particularly when epidural analgesia has removed sensation.

Maternal Posture

An upright posture of the mother reduces both the duration of the second stage and the incidence of operative delivery.[62] There are also reductions in the use of episiotomy, perception of pain, and fetal heart rate abnormalities. Maternal posture does not appear to affect malposition. Avoidance of the supine position is beneficial for the acid-base status of the fetus in the second stage.[63]

Manual Rotation

Manual manipulation is an effective way to correct malrotation for those adept at its practice.

Instrumental Delivery

Instrumentation is used to shorten the second stage, either when prolonged or to avoid fetal or maternal complications. The ventouse and variations on its design permit primarily traction on the fetal head from a vacuum applied via a cup. The design of the cup usually produces scalp edema within the lip of the cup that adds to the effect of the vacuum alone. By directing the traction, flexion and rotation can be imparted to the head.

There is less perineal trauma compared with forceps and, therefore, ventouse has been recommended as the instrument of choice for delivery of the head when in an OA position. Cephalhematoma and intraocular hemorrhages have been associated with this instrument, but birth trauma, overall, is no higher than with other instruments.

Forceps are used for traction or rotation according to their design. Correct identification of the position of the fetal head is crucial to avoid trauma. Rotational forceps (Kielland's) can produce spiral tears of the vagina during rotation, an injury that is almost specific to the instrument.

Episiotomy

Episiotomy is surgical reduction of resistance offered by the pelvic floor. There is no benefit from routine episiotomy.[64] Mediolateral episiotomies direct any tearing away from the rectum and anus, resulting in fewer third-degree tears, but cause more bleeding than those in the midline. They also cause more discomfort in the puerperium.

CONCLUSIONS

Principles of good management of labor are summarized as follows:

- Prepare women for labor both physically and mentally and give support.
- Make the correct diagnosis of labor:
  - Only apply cervicogram limits to the active phase.
  - If in doubt, do *not* diagnose labor.
- Understand fetal monitoring.
- Understand interventions and their consequences.
- Agree on a policy:
  - Set policy according to best evidence.
  - Consistently apply policy.
  - Audit the results.

SUMMARY OF MANAGEMENT OPTIONS
Conduct of Normal Labor

Management Options	Quality of Evidence	Strength of Recommendation	References
Use of partogram helps to detect abnormality of labor and poor progress early and thus allow timely intervention.	III	B	36

Continued

Conduct of Normal Labor *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Use of partogram with an agreed protocol for management reduces maternal morbidity and fetal morbidity and mortality rates.	IIb	B	65
The package of precise diagnosis of labor (active phase), early amniotomy, regular monitoring of cervical dilation rate, and correction with the empirical augmentation of uterine activity reduces the incidence of prolonged labor.	III	B	15
Compared to active management, a policy of no routine amniotomy and selective use of oxytocin does not adversely affect cesarean section rate or neonatal outcome.	Ia, Ib	A	46, 51, 52
Support in labor reduces operative delivery rate.	Ia	A	66

SUMMARY OF MANAGEMENT OPTIONS
Poor Progress in Labor

Management Options	Quality of Evidence	Strength of Recommendation	References
Poor progress in latent phase of first stage:			
Expectant management with careful watch of the fetal heart rate.	III	B	14, 40, 41
Augmentation may increase cesarean section rate.	III	B	14, 40, 41
Poor progress in active phase of first stage:			
Allowing 4 hours of grace after crossing alert line reduces need for augmentation and cesarean section.	Ib	A	53
Judicious augmentation with Syntocinon will reduce labor duration.	Ib	A	51
Studies favor 30-minute incremental intervals with oxytocin infusion.	Ib	A	48
Obstetric outcome is no better by use of intrauterine pressure catheters, compared with use of external tocography, for most cases.	Ib	A	19
Epidural analgesia is associated with prolongation of the first and second stages of labor, malposition, and increased operative vaginal delivery.	Ia	A	67
Poor progress in the second stage of labor:			
Flexibility in the duration of the second stage is permissible.	–	GPP	–
Upright posture of the mother reduces the duration of the second stage and need for operative delivery. It also reduces the need for episiotomy, perception of pain, and fetal heart rate abnormalities.	Ia	A	62
Use of episiotomy should be limited and selective.	Ia	A	64

Shoulder Dystocia

Robert B. Gherman

INTRODUCTION

Despite its infrequent occurrence (0.2% – 3% of all deliveries[1]), all health care providers attending vaginal deliveries must be prepared to handle this unpredictable obstetric emergency. Shoulder dystocia represents the failure of delivery of the fetal shoulder(s), whether it be the anterior, posterior, or both fetal shoulders.[2] Shoulder dystocia results from a size discrepancy between the fetal shoulders and the pelvic inlet, which may be absolute or relative (due to malposition). A persistent anterior-posterior location of the fetal shoulders at the pelvic brim occurs when there is increased resistance between the fetal skin and vaginal walls (e.g., with macrosomia), with a large fetal chest relative to the biparietal diameter, and when truncal rotation does not occur (e.g., precipitous labor.)[3] Shoulder dystocia can also occur from impaction of the posterior fetal shoulder on the maternal sacral promontory.

DEFINITION

Most authors have defined this obstetric emergency to include those deliveries requiring maneuvers in addition to gentle downward traction on the fetal head to effect delivery. Several studies have proposed defining shoulder dystocia as a prolonged head-to-body delivery interval (60 sec) or the use of ancillary obstetric maneuvers, as this time represented the mean plus two standard deviations.[4,5]

MATERNAL AND FETAL RISKS

Postpartum hemorrhage and the unintentional extension of the episiotomy or laceration into the rectum (fourth-degree laceration) are the most common maternal complications associated with shoulder dystocia (Table 70–1). In Gherman's study, these occurred in 11% and 3.8%, respectively, of the described shoulder dystocias.[6] Other reported complications have included vaginal lacerations, cervical tears, bladder atony, and uterine rupture. Maternal symphyseal separation and lateral femoral cutaneous neuropathy have also been associated with overly aggressive hyperflexion of the maternal legs.[7] Risks to the physician mainly involve litigation, as brachial plexus palsy, central neurologic dysfunction, and perinatal death account for most of the shoulder dystocia-related lawsuits. A clearly documented medical record may prove to be helpful in the medicolegal arena.[8]

A large retrospective study that evaluated 285 cases of shoulder dystocia found that the fetal injury rate was 24.9%, including 48 (16.8%) brachial plexus palsies, 27 (9.5%) clavicular fractures, and 12 (4.2%) humeral fractures.[9] Unilateral brachial plexus injuries are probably the most common neurologic injury sustained by the neonate. The right arm is more commonly affected (64.6%) due to the fact that the left occiput anterior presentation leaves the right shoulder impinged against the symphysis pubis.[9] Brachial plexus injury has been found to complicate up to 21% of all shoulder dystocia cases.[10] Most (80%) of these nerve injuries have been located within the C5–C6 nerve roots (Erb-Duchenne palsy). Other types of brachial plexus injuries that have been described include Klumpke's palsy (C8–T1), an intermediate palsy, and complete palsy of the entire brachial plexus. Diaphragmatic paralysis, Horner's syndrome, and facial nerve injuries have been reported occasionally to accompany brachial plexus palsy.[3] Approximately one third of brachial plexus palsies will be associated with a concomitant bone fracture, most commonly the clavicle (94%).[8] Neonatal radial fracture can also be associated with the shoulder dystocia or the maneuvers employed to alleviate it.[11]

Gherman's study compared shoulder dystocia cases based on the absence or presence of direct fetal manipulative maneuvers (Woods', posterior arm extraction, or Zavanelli maneuvers). He found that the overall incidence of fetal bone fracture (16.5% vs. 11.4%, *p* = 0.21) and brachial plexus palsy (21.3% vs. 13.3%, *p* = 0.1) were

Common Complications Associated with Shoulder Dystocia

MATERNAL	ACCOUCHEUR	NEONATAL
Third- or fourth-degree lacerations	Terror	Erb-Duchenne palsy
Postpartum hemorrhage	Medical liabilty	Klumpke's palsy
		Clavicular fracture
		Humeral fracture
		Hypoxia
		Permanent brain injury
		Death

not significantly different between the two groups.[9] Similar findings had previously been reported by Nocon, who grouped the techniques used to disimpact the shoulder into major treatment categories. None of the major categories revealed a statistically significant difference when compared with respect to fetal injury. In this study, the authors found incidences of injury of 14.9%, 14.3%, 37.9%, and 20%, respectively, associated with the McRoberts' maneuver, rotations, posterior arm delivery, and suprapubic pressure.[12]

PRENATAL: IDENTIFYING THE PREGNANCY AT RISK

It has been clearly shown that risk of shoulder dystocia increases significantly as birth weight increases. The percentages of births complicated by shoulder dystocia for unassisted births not complicated by diabetes were 5.2% for infants weighing 4000 to 4250 g, 9.1% for those 4250 to 4500 g, 14.3% for those 4500 to 4750 g, and 21.1% for those 4750 to 5000 g.[13] It must be remembered, however, that approximately 50% to 60% of shoulder dystocias occur in infants weighing less than 4000 g. Moreover, even if the birth weight of the infant is over 4000 g, shoulder dystocia will only complicate 3.3% of the deliveries.[14,15]

From a prospective point of view, prepregnancy and antepartum risk factors such as previous delivery of a macrosomic infant, preexisting or pregnancy-induced diabetes mellitus, multiparity, excessive maternal weight gain, and postdate gestation have exceedingly poor predictive value for the prediction of shoulder dystocia. For example, one study found that only 32% of patients were obese (>90 kg), 25% had excessive weight gain (>20 kg), 8% had short stature (<60 inches), 6% were more than 42 weeks' gestation, 3% were of advanced maternal age, and 2% had a personal history of diabetes mellitus.[16] In a case-control study from the Northern and Central Alberta Perinatal Outreach Program, maternal obesity (defined as >91 kg) was not associated with shoulder dystocia when multivariable logistic regression analysis was used to control for confounding effects.[17]

Ultrasonographic estimation of fetal weight, performed during either the late third trimester or the intrapartum period, has been commonly employed in order to estimate the risk of shoulder dystocia via prediction of birth weight. To date, however, no studies have specifically evaluated this relationship in a patient population where routine ultrasounds are performed. Late pregnancy ultrasound likewise displays low sensitivity (22% – 44%), poor positive predictive value (30% – 44%), decreasing accuracy with increasing birth weight, and an overall tendency to overestimate the birth weight. For this reason, the American College of Obstetricians and Gynecologists has recently noted that attempted vaginal delivery is not contraindicated for women with estimated fetal weights up to 5000 g in the absence of maternal diabetes.[18,19]

Patients with insulin-requiring diabetes mellitus appear to warrant special evaluation for shoulder dystocia. The risk of shoulder dystocia for unassisted births to diabetic mothers has been found to be 8.4%, 12.3%, 19.9%, and 23.5% when the birth weight is 4000 to 4250 g, 4250 to 4500 g, 4500 to 4750 g, or more than 4750 g, respectively.[13] These values are somewhat higher than for nondiabetics of similar build. Changes in fetal body configuration brought about by increased fat deposition in the fetuses of diabetic mothers, such as larger trunk and chest circumferences, increased bisacromial diameters, and chest-to-head disproportion, impede the rotation of the fetal shoulders into the oblique diameter.

In a similar fashion, patients with a history of shoulder dystocia complicating a prior vaginal delivery have a risk of recurrence, ranging between 11.9% and 16.7%. Maternal and fetal factors that have been shown to be significantly associated with recurrent shoulder dystocia include birth weight greater than the index pregnancy, duration of the second stage of labor, and birth weight more than 4000 g.[1] However, a policy of universal elective cesarean delivery has not been recommended for this cohort of patients because the risks outweigh the benefits.[19] Nonetheless, antepartum counseling and discussion of recurrence risks should be undertaken with consideration of the present estimate of fetal weight, the presence of maternal glucose intolerance, and whether the prior shoulder dystocia resulted in transient or permanent neurologic injury.

PRACTICAL MANAGEMENT OF SHOULDER DYSTOCIA (See Table 70–2)

The patient should be instructed to stop pushing after the shoulder dystocia is initially recognized. Maternal expulsive efforts, however, will need to be reinstituted after the fetal shoulders have been converted to the oblique diameter, in order to achieve delivery. If the provider is alone, additional assistance may be obtained by summoning other obstetricians, an anesthetist or anesthesiologist, additional nursing support, and a pediatrician.

Umbilical cord compression, most commonly between the fetal body and maternal pelvis, leads to a decrease in the fetal pH at a rate of 0.04 units per minute. If a nuchal cord is present and cannot be reduced easily over the fetal head, clamping and cutting of the cord should be avoided until the shoulder dystocia has been alleviated (Table 70–2).[20] Most, if not all, of the commonly encountered shoulder dystocia episodes can be relieved within several minutes. Although research studies have been unable to predict an exact time limit at which irreversible brain injury occurs, it is reasonable to assume that the risk of permanent central neurologic dysfunction is associated with prolongation of the head/shoulder interval thresholds. The length of delay that results in permanent brain injury will depend on the condition of the baby at the point at which the delivery is arrested. It may be as short as 4 to 5 minutes, or as long as 15 minutes.

At the time of delivery, if shoulder dystocia is a concern, some clinicians have empirically advocated proceeding immediately to delivery of the fetal shoulders, in order to maintain the forward momentum of the fetus. Others support a short delay in delivery of the shoulders, arguing that the endogenous rotational mechanics of the second stage may spontaneously alleviate the obstruction. Obstetricians may also employ the McRoberts' maneuver "prophylactically" in order to decrease the risk of shoulder dystocia or shorten the second stage of labor. One clinical trial randomized patients with estimated fetal weights over 3800 g to undergo either prophylactic maneuvers (McRoberts' maneuver and suprapubic pressure or to undergo maneuvers only after delivery of the fetal head, if shoulder dystocia was identified. This study, found that head-to-body delivery times, an indirect proxy for shoulder dystocia, did not differ between the prophylactic and control patients.[21]

Although many maneuvers have been described for the successful alleviation of shoulder dystocia, no randomized controlled trials or laboratory experiments have been conducted that directly compared these techniques. Most obstetricians currently employ the McRoberts' maneuver as their initial step for the disimpaction of the shoulder. In a retrospective review of 236 shoulder dystocia cases occurring between 1991 and 1994 at Los Angeles County/University of Southern California Medical Center, this maneuver alone alleviated 42% of cases. Moreover, trends toward lower rates of maternal and neonatal morbidity were associated with the McRoberts' maneuver.[6]

The McRoberts' maneuver, performed by sharply flexing the maternal thighs onto the abdomen, results in a straightening of the maternal sacrum relative to the lumbar spine with consequent cephalic rotation of the symphysis pubis.[22] Care should be taken to avoid prolonged or overly aggressive application of the McRoberts' maneuver as the fibrocartilaginous articular surfaces of the symphysis pubis and surrounding ligaments may be unduly stretched.

The overwhelming majority of patients can assume the proper position for the McRoberts' maneuver with little difficulty. Women may be instructed to grasp the posterior aspect of their thighs and pull themselves into position, with family members or health care professionals providing any assistance necessary. The obstetrician may also choose to flex both of the patient's legs. Problems may occur when moving an obese patient or a woman who has undergone a dense epidural motor blockade.

Because shoulder dystocia is considered to be a "bony dystocia," episiotomy alone will not release the impacted shoulder. The need for cutting a generous episiotomy or proctoepisiotomy must be based on clinical circumstances, such as a narrow vaginal fourchette in a nulliparous patient. This may allow the fetal rotational maneuvers to be performed with ease, as well as creating more room for attempted delivery of the posterior arm. Attendants should refrain from applying fundal pressure as a maneuver for the alleviation of the shoulder dystocia. Pushing on the fundus simply duplicates a maternal directional expulsive force that has already failed to deliver the fetal shoulder(s) and serves only to further impact the anterior shoulder behind the symphysis pubis. In addition, the use of fundal pressure has been associated with an increased risk of Erb-Duchenne palsy and thoracic spinal cord injury in the neonate.[23]

Suprapubic pressure, commonly administered by nursing personnel, is typically used immediately prior to or in direct conjunction with the McRoberts' maneuver. This pressure is usually directed posteriorly, in an attempt to force the anterior shoulder under the symphysis pubis. Other described techniques for suprapubic pressure have included lateral application from either side of the maternal abdomen or alternating between sides using a rocking pressure.[24]

Many cases of shoulder dystocia require the performance of several maneuvers to alleviate the impaction. Stallings has found that slightly more than a third of patients required more than two maneuvers.[25] When more complex maneuvers are required, either fetal rotational maneuvers or posterior arm extraction may be employed. In the Woods' corkscrew maneuver, the practitioner attempts to abduct the posterior shoulder by

TABLE 70–2

Maneuvers for the Alleviation of Shoulder Dystocia

Abdominal rescue through hysterotomy

exerting pressure onto the anterior surface of the posterior shoulder. In the Rubin's (reverse Woods') maneuver, pressure is applied to the posterior surface of the most accessible part of the fetal shoulder (i.e., either the anterior or posterior shoulder) to effect shoulder adduction. These rotational maneuvers, however, may be difficult to perform when the anterior shoulder is tightly wedged underneath the symphysis pubis. It may therefore be necessary to push the fetus slightly upwards in order to facilitate the rotation.

By replacing the bisacromial diameter with the axilloacromial diameter, posterior arm delivery creates a 20% reduction in shoulder diameter.[26] To perform delivery of the posterior fetal arm, pressure should be applied by the accoucheur at the antecubital fossa in order to flex the fetal forearm. The arm is subsequently swept out over the infant's chest and delivered over the perineum. Rotation of the fetal trunk to bring the posterior arm anteriorly is sometimes required. Grasping and pulling directly on the fetal arm, as well as application of pressure onto the midhumeral shaft, should be avoided as bone fracture may occur.

The previously mentioned maneuvers are typically able to be attempted within 4 to 5 minutes after identification of the shoulder dystocia. If the shoulder dystocia remains uncorrected, a bilateral shoulder dystocia or posterior arm shoulder dystocia may be present. The latter is suggested by the presence of the posterior arm being maintained at the level of the pelvic inlet and an inability to perform posterior arm extraction. These intractable shoulder dystocias warrant the use of heroic techniques, such as the Zavanelli maneuver, symphysiotomy, or hysterotomy.

Performance of these will be complicated by the provider's lack of clinical experience with these maneuvers, performance under emergent conditions, and the significant maternal and neonatal complications inherent in the procedures. In the Zavanelli maneuver, the head is rotated back to a prerestitution position and then gently flexed. Constant firm pressure is used to push the head back into the vagina and cesarean delivery is subsequently performed. Halothane or other general anesthetics, in conjunction with tocolytic agents, may be administered in preparation for and during the Zavanelli maneuver. Oral or intravenous nitroglycerin may be used as well. A modification of the original Zavanelli maneuver may be employed in order potentially to reduce maternal morbidity. As described by Zelig, maternal expulsive efforts were reinitiated after the obstetrician had observed that the biparietal diameter had passed back through the introitus and the shoulders were felt to disimpact.[27] This modification should only be attempted as long as there is no evidence of fetal compromise.

To perform a symphysiotomy, the patient should be placed in an exaggerated lithotomy position. Although its placement may be very difficult secondary to obstruction, a Foley catheter can help to identify the urethra. With the physician's index and middle finger displacing the urethra laterally, the cephalad portion of the symphysis is incised with a scalpel blade or Kelly clamp. The reader is also referred to Chapter 64 (Breech) for further description and discussion of symphysiotomy. Hysterotomy may also be performed to either resolve the shoulder dystocia primarily or assist with vaginal techniques. The abdominal surgeon can apply pressure on the anterior fetal shoulder to allow rotation to the oblique diameter. The posterior fetal arm may be manipulated through the transverse uterine incision with passage of the hand to a vaginal assistant.

Prior to performing these techniques, one may consider using the "all-fours" technique, in which the patient is rolled from her existing position onto her hands and knees.[28] The downward force of gravity or a favorable change in pelvic diameters produced by this maneuver may allow disimpaction of the fetal shoulder. Older textbooks have described deliberate clavicular fracture as a maneuver of last resort, performed by exerting direct upward pressure on the midportion of the fetal clavicle. However, this has not been reported in the recent literature because it is technically difficult to perform and risks serious injury to the underlying vascular and pulmonary structures in the fetus.

SHOULDER DYSTOCIA AND BRACHIAL PLEXUS INJURY

Brachial plexus palsy is currently a major cause of litigation, constituting 11% of the 370 obstetric claims closed by the Norwegian patient insurance system from 1988 to 1997.[29] In the past, textbooks have stated without evidence that brachial plexus palsy is caused by the accoucheur's application of excessive lateral traction on the fetal head and neck during attempts at alleviating the shoulder dystocia. Over the past several

Estimation of force of traction applied
Order, duration, and results of maneuvers employed
Duration of shoulder dystocia
Documentation of adequate pelvimetry prior to initiating labor induction or augmentation
Neonatal and obstetric impressions of the infant after delivery
Inform gravida that shoulder dystocia had occurred

From Acker DB: A shoulder dystocia intervention form. Obstet Gynecol 1991;78:150–151.

years, multiple lines of evidence have supported the concept that most brachial plexus palsies are not caused by the accoucheur.[3,30–31] This opinion is based on several findings:

- More than 50% of cases of brachial plexus injuries are associated with uncomplicated vaginal deliveries[32,33]
- Brachial plexus palsy can occur in the posterior arm of infants whose anterior arm was impacted behind the symphysis pubis and can also occur with a traumatic cesarean delivery
- There is no statistical correlation with the experience of the obstetric provider nor the number or type of maneuvers used

- Rapid second-stage and disproportionate descent of the head and body of the fetus have been implicated in the pathogenesis of the injury
- Mathematical and computer-simulated models have shown that maternal endogenous forces are far greater than clinician-applied exogenous delivery loads during a shoulder dystocia episode.[34,35]

Despite these observations it is good and prudent practice for obstetricians to make a detailed and accurate account of the procedure when they have managed a case of shoulder dystocia. This should be undertaken as close to the event as possible. Table 70–3 gives a suggested list of items that may be covered in such a report.

CONCLUSIONS

- Knowledge of the maneuvers employed for the alleviation of shoulder dystocia is relevant not only for obstetric residents and attending house staff, but also for family practitioners, nurses, and nurse midwives.
- The performance of shoulder dystocia "drills" can be helpful not only to coordinate a teamwork approach to this obstetric emergency but also to provide an opportunity to practice the maneuvers.
- Shoulder dystocia continues to represent an immense area of clinical interest, due to the fact that it typically occurs unexpectedly.
- All patients in labor should therefore be considered at risk for the development of shoulder dystocia.
- Brachial plexus palsy results from the significant endogenous forces associated with shoulder dystocia; it is not caused by iatrogenic excessive traction, but by an asymmetrical distribution of traction or propulsion forces acting on the fetus.[1,30,36]

SUMMARY OF MANAGEMENT OPTIONS
Shoulder Dystocia

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal Identification of At-Risk Pregnancy			
Estimation of fetal weight and risk of SD is of limited value.	III	B	13,14
May be of more use in diabetic pregnancies or those with previous SD.	IIb	B	15
Limited accuracy of ultrasound in estimating fetal weight	III	B	39
ACOG Guidelines:	IV	C	18,19
Vaginal delivery is reasonable with estimated fetal weights up to 5 kg in the absence of diabetes because risks of elective cesarean section			
Despite this guideline women with previous delivery complicated by SD may prefer to have elective cesarean section, especially if estimated fetal weight similar or greater than previously	–	GPP	–
The following are poor predictors of SD:	IIa	B	16,17
Previous macrosomia/large-for-dates			
Diabetes (preexisting or gestational)			
Multiparity			
Excessive weight gain in pregnancy			
Postdates pregnancy			
If vaginal delivery is to be attempted following a discussion with an at-risk patient, make a clear record in the patient's notes	–	GPP	–

Fetal Distress in Labor

Philip J. Steer / Peter Danielian

WHAT IS FETAL DISTRESS?

Fetal distress is a term that is commonly used, but difficult to define. It is probably best taken to mean "an absence of fetal well-being," in a similar way that the expression "a flat baby" means a neonate in need of resuscitation and "an ill person" means someone who is unwell. Thus, its use encompasses many different pathologies affecting the fetus, such as chronic hypoxia leading to a metabolic acidosis, mechanical trauma (e.g., excessive head compression), hyperthermia, meconium aspiration, and sepsis. Hypoxia with acidosis (often referred to as "asphyxia," although originally the term simply meant born without an evident pulse, from the Greek *a-sphyxos*) is widely perceived to be the most important cause, but does not have a simple relationship with the condition of the baby at birth. Beard[1] pointed out as early as 1967 that the Apgar score (a clinical measure of condition at birth) "does not differentiate between asphyxial and non-asphyxial depression of the newborn." In 1982 Sykes and colleagues[2] reported that only 27% of babies with a severe acidosis (umbilical artery pH <7.1 and a base deficit > 12 mmol/L) had a 1-minute Apgar score <7. Similarly, only 21% with a 1-minute Apgar score <7 had a severe acidosis. Lissauer and Steer[3] subsequently noted that more than half of babies born at 32 weeks' gestation or later, and needing resuscitation by intubation and positive pressure ventilation, had either entirely normal fetal heart rate (FHR) patterns throughout labor or normal values for umbilical cord blood pH measurement. In their study, the nonasphyxial associations with depression at birth included operative delivery, anesthetic agents given to the mother, meconium-stained liquor, and tight nuchal cord. Steer and associates[4] subsequently reported that acidosis in the fetus (as measured by cord umbilical artery pH) only accounted for 7.5% of the variation in the 1-minute Apgar score, and 1.8% of the variation in the 5-minute Apgar score. Thorp and colleagues[5]

reported that umbilical artery cord pH was normal in 80% of clinically depressed newborns. Chorioamnionitis has in recent years been recognized as an important antecedent of cerebral palsy,[6] but it is not directly associated with asphyxia. Maberry and associates[7] reported that chorioamnionitis does not increase the likelihood of metabolic acidosis at birth; there were no babies with a significant metabolic acidosis or pH <7.0 in 123 cases of confirmed intra-amniotic infection during labor. Instead, the brain damage that later manifests as cerebral palsy may be caused by cytokine release. Nonetheless, chorioamnionitis, or even noninfective fever during labor (see Chapter 72) may potentiate the damaging effects of hypoxia-ischemia on the brain by increasing its metabolic requirements for oxygen.[8]

What Constitutes "Birth Asphyxia"?

Saling's initial publication[9] reported on 306 babies born in vigorous condition and reported their mean capillary fetal blood sample (FBS) pH to be 7.33 with a range (± two standard deviations) of 7.2 to 7.5. An FBS pH of 7.2 subsequently became a widely accepted lower limit of normal, below which values were taken to indicate the need for urgent delivery. However, it has become appreciated over the last 15 years that acidosis has to be very severe (values well below 2 standard deviations from the mean) before it is associated with long-term sequelae. For example, Winkler and colleagues[10] reported that none of 335 infants born with an umbilical artery pH <7.2 but >7.0 had any neonatal complications, and only two of 23 born with a pH <7.0 had any complications attributable to asphyxia. Goodwin and associates[11] reviewed 129 full-term, normally formed, singleton infants born with an umbilical artery pH <7.0 and found that 78% were entirely normal at follow-up, with only 8% having a major neurologic defect. Nagel and colleagues[12] reported 30 newborns with an umbilical artery

pH <7.0. All but three had an Apgar score of 6 or more at 5 minutes. In the neonatal period, two babies died, five had mild and two severe encephalopathy. Using the Denver Developmental Screening Test at ages ranging from 14 to 33 months, 23 surviving babies were normal, 2 questionable, and none had major abnormalities (31 lost to follow-up). However, these reports should not be taken as meaning that acidosis is always benign. Severe acidosis (pH <7.0) is still likely to be associated with a much higher incidence of depression at birth than a pH >7.2. Van den Berg and colleagues[13] reviewed the neonatal complications of 84 nonanomalous babies with an umbilical artery pH <7.0 and compared them with a nonacidotic (pH >7.24) matched control group. They found highly significant differences in the proportions of babies requiring intubation (29% cf. 2.4%), and having pulmonary (31% cf. 11%), cardiovascular (15% cf. 8%), and neurologic (23% cf. 7%) complications. Low and associates[14] studied the effect of metabolic acidosis on newborn complications at 10 days of life. Fifty-nine babies had a severe metabolic acidosis (umbilical artery buffer base <30 mmol/L) and were six times more likely to have complications than a control group without acidosis (85% cf. 14%). Neonatal encephalopathy was observed in 61% of the acidotic group cf. 17% of the control group. Socol and colleagues[15] studied 28 newborns with an Apgar score of ≤3 at 5 minutes. They found that 11 of 17 neonates with an umbilical cord arterial pH >7.0 had an uncomplicated neonatal course compared with only 1 of 11 with a pH <7.0. Low's group have subsequently studied the threshold of fetal metabolic acidosis at delivery above which moderate or severe newborn complications may be expected; they found this to be an umbilical artery base deficit of 12 mmol/L.[16] Thereafter, increasing metabolic acidosis is associated with a progression of severity of newborn complications.

On the basis of these findings, it seems reasonable to categorize asphyxia as a cord artery pH <7.0 and a base deficit >12 mMol/L. However, because the large majority of babies with asphyxia by this definition have a normal long-term outcome, it has been suggested that the term *birth asphyxia* should be used to indicate an even more severe situation in which, in addition to acidosis, generalized neonatal dysfunction is evident. Thus, Thorp[17] suggested the inclusion of neonatal depression as measured by the Apgar score, as well as evidence of hypoxic end organ damage such as early neonatal seizures and renal or cardiac dysfunction. Subsequently, the American College of Obstetricians and Gynecologists recommended that birth asphyxia be regarded as resulting from "intrapartum hypoxia sufficient to cause neurological damage," defined by an umbilical artery pH <7.0, a 5-minute Apgar score ≤3, moderate or severe neonatal encephalopathy, and evidence of multiorgan dysfunction (affecting the cardiovascular, renal, and/or pulmonary systems)[18] (Table 71–1). Few depressed neonates fulfill these stringent conditions.[19]

Do Intrapartum Events Lead to Cerebral Palsy?

It is clear that the majority of mental handicap is not caused by intrapartum events. In 1985, the U.S. National Institutes of Health reported that "the causes of severe mental retardation are primarily genetic, biochemical, viral and developmental, and not related to birth events. Associated factors include maternal lifestyle, such as poor nutrition, cigarette smoking, and alcohol and drug abuse."[20] For example, the single most prevalent cause of mental retardation is Down syndrome. However, some forms of mental handicap are likely to be the consequence of birth asphyxia and other adverse intrapartum events. The International Cerebral Palsy Task Force suggested that birth asphyxia was a significant cause of cerebral palsy characterized by nonprogressive abnormal control of movement or posture.[21] The percentage of such cases caused by birth asphyxia remains controversial. It is widely accepted that at least some acute intrapartum events (e.g., placental abruption, cord prolapse) can cause brain injury in previously normal fetuses. In a recent review of 351 babies investigated by MRI or at postmortem, Cowan and colleagues showed that more than 90% of full-term infants with neonatal encephalopathy, seizures, or both, but without specific syndromes or major congenital defects, had evidence of perinatally acquired insults, and in only a few babies was there any evidence of established brain injury acquired before birth.[22] Their data do not exclude the possibility that antenatal factors could initiate a causal pathway for perinatal brain injury and that they might, possibly together with genetic predispositions to hypoxic-ischemic injury, make some infants more susceptible than others to the stresses of labor and delivery. However, although their study was not population-based, it strongly suggests that the potential for avoiding intrapartum brain damage by improved management is substantial. The Western Australia case–control study of neonatal encephalopathy[23] (which was population-based) clearly showed a protective effect of elective cesarean section (adjusted odds ratio [OR] 0.17, 95% confidence

interval [CI] 0.05–0.56). This demonstrates that intrapartum events play a role in the etiology of neonatal encephalopathy. The question of the proportion of babies with brain injury but no evidence of chromosomal anomaly or congenital anomaly that are due to intrapartum events has been addressed recently by Johnston,[24] who concluded that it was between 30% and 60%, depending on the setting and the efficiency of intrapartum surveillance and the risk status of the population. When addressing the likelihood of perinatal events as a cause of cerebral palsy, the criteria of Nelson can be recommended (Table 71–2).

MANAGEMENT ISSUES

Diagnosis of Fetal Distress

Diagnosis is difficult because of the problems of accessing the fetus in utero. Before the introduction of the Pinard stethoscope, the condition of the fetus remained unknown until the moment of birth. However, once the FHR could be detected with some reliability, it was discovered that both persistent fetal tachycardia and bradycardia were associated with an increased likelihood of poor condition at birth, and that meconium staining of the amniotic fluid could also be an adverse sign. Once continuous electronic fetal monitoring (EFM) was introduced in the 1960s, it was possible to detect reduced FHR variability, which is also associated with an increased risk of depression at birth. The introduction of fetal blood sampling and pH estimation by Saling[9] allowed further assessment of fetal condition. Unfortunately, fetal blood sampling is a complicated and time-consuming technique, which is uncomfortable for the mother. As a result, the approach that developed was to use EFM as a screening tool for asphyxia, and then use fetal blood sampling to confirm or reject the diagnosis. Beard and associates, in their landmark paper of 1971,[25] showed that a normal FHR pattern is associated with a very low risk of acidosis (<2% of fetuses with a normal FHR pattern will have a pH <7.2). However, although increasing abnormality of the FHR is associated with an increasing chance that the fetus is acidotic, even with the most abnormal pattern (a complicated baseline tachycardia), the risk of acidosis is only about 60% (Fig. 71–1). This explains the increased intervention rates for the diagnosis of fetal distress if FHR monitoring is used without the backup of FBS and pH estimation.[26,27] Reviews indicate that the use of FBS and pH measurement not only limits the increase in operative delivery rate seen with EFM, but also improves its ability to reduce the neonatal seizure rate.[28]

Most studies of EFM have examined the relationship between the heart rate pattern and asphyxia. Cardiotocogram (CTG) interpretation can, however, also indicate other pathologies, such as pyrexia (and therefore indirectly, sepsis), which is associated with a fetal tachycardia.[29] Recurrent variable decelerations with a maintained normal FBS pH suggest intermittent cord compression. Repeated umbilical cord compression may cause brain damage without asphyxia because of the major swings in blood pressure induced by repeated occlusion and release.[30] The damage may be exacerbated by nuchal entanglement (cord around the neck) because occlusion of the venous return from the brain increases intracranial pressure. Damage to the hippocampus from intermittent occlusion of the cord has been seen in fetal sheep.[31]

Does Electronic Fetal Monitoring Improve Outcome?

The widespread introduction of EFM in the 1970s was associated with substantial falls in perinatal mortality as reported by a number of retrospective observational

---

TABLE 71–2
Criteria To Be Fulfilled before Long-term Outcome Can Be Linked with Intrapartum Events
1. Was there evidence of severe, prolonged intrapartum dysfunction?
2. Was the child severely ill as a newborn? Were there disturbances of feeding, tone, and consciousness, and evidence of involvement of other organ systems, of which renal involvement may be especially significant?
3. Is cerebral palsy present?
4. Have other potential explanations been excluded, such as the following:
Congenital malformation
Infection
Metabolic abnormality
Familial disease
Microcephaly in the neonatal period
Abnormal CT or MRI scan suggesting discrete lesions
Maternal substance abuse (especially cocaine)
Thyroid disease

CT- computed tomography; MRI- magnetic resonance imaging.

Fetal heart rate pattern and the associated risk of acidosis.

studies.[32,33] However, during the same period, major advances were being made in neonatal intensive care, and the cesarean section rate also rose substantially. It has proved impossible to establish which of these changes, if any, were responsible for the improvement in outcome. This uncertainty led to calls for prospective randomized controlled trials. None of these trials were, on their own, large enough to have sufficient power to address the long-term outcome of most interest, namely cerebral palsy. Accordingly, there have been a series of meta-analyses, although these are dominated by the effect of the single largest trial, carried out in Dublin in the early 1980s.[34] Vintzileos and associates[26] reviewed nine, including in total 18,561 patients (of which 12,964 were in the Dublin trial). This confirmed a substantial increase in the cesarean section rate associated with EFM (OR 1.53, 95% CI 1.17–2.01) but disappointingly for the advocates of EFM, the reduction in the overall perinatal mortality rate was not significant (4.2/1000 in the EFM group cf. 4.9/1000 in the intermittent auscultation (IA) group). However, in a post hoc analysis, Vintzileos and associates commented that there was a significant reduction in the deaths attributed to hypoxia in the EFM groups, being 0.7/1000 compared with 1.8/1000 in the auscultation group (OR 0.41, 95% CI 0.17–0.98). A similar meta-analysis was performed by Thacker and colleageus[27] with the inclusion of three further studies but with similar conclusions, except that they reported a significant reduction in the incidence of neonatal seizures in the group where EFM had been used (relative risk [RR] 0.5, 95% CI 0.30–0.82). Thus, the studies suggest some improvement in short-term outcome at the expense of an increased operative delivery rate, but were unable to address the issue of long-term outcome (a follow-up study of the Dublin trial showed that three babies in each group developed cerebral palsy[35]; however, even if the number had been doubled in the auscultation group, this would still not have been statistically significant). It should be noted that many authorities, including the National Institute for Clinical Excellence (NICE) in the United Kingdom, state in relation to the meta-analyses that "there was no apparent difference in perinatal death rates between the two groups."[36] This is not actually correct, as most studies show a difference in favor of EFM, which is not, however, statistically significant. As already pointed out, even the meta-analyses are underpowered to address the question of perinatal mortality, let alone long-term outcome. It should always be remembered that absence of evidence is not evidence of absence, and one needs to be aware of the possibility of a type II error (i.e., there is a difference which by chance has not been found to be significant).

Fetal Heart Rate Monitoring and Fetal Blood Sampling

It will be appreciated from the previous discussion that monitoring the heart rate of the fetus should not be expected to detect all pathologies affecting the fetus during labor. For example, maternal intrapartum cardiac arrest, fetal skull fracture with brain infarct, intrapartum fetal stroke, and uterine rupture have been reported as causes of subsequent childhood handicap,[37] but none of these can be predicted reliably beforehand by FHR monitoring (in a recent study of 36 cases of intrapartum rupture of a previous cesarean section scar,[38] no significant differences were noted in rates of mild or severe variable decelerations, late decelerations, prolonged decelerations, fetal tachycardia, or loss of uterine tone. Fetal bradycardia in the first and second stage was the only finding consistently associated with uterine rupture). Equally, although intrapartum infection and meconium aspiration may be associated with fetal tachycardia, neither are consistently associated with acidosis[4,39]; therefore a normal FBS pH may be actively misleading in their management if a normal value is taken as reassurance about fetal condition. Nevertheless, hypoxia and acidosis pose a significant threat to the fetus during labor (accounting for perhaps 20–40% of poor condition at birth), and FHR monitoring remains the best available screening tool for its detection. The best way to detect developing acidosis in the fetus is to measure its pH on an FBS. Clues about other pathologies (e.g., variable decelerations with nuchal cord, FHR tachycardia with infection, sinusoidal variability with fetal anemia) can be obtained from EFM, but its use in these conditions should not be regarded as sensitive or specific.

Human Factors in the Use of Cardiotocography

A human element may factor into our inability to demonstrate that the use of EFM produces an improved outcome to the degree anticipated by the pioneers of the technique. For example, in the Dublin trial, the fetal monitors used were of a relatively primitive design, staff were previously unfamiliar with their use, and during the trial a marked Hawthorne effect was evident, which would have reduced its apparent efficacy. In a later case–control study, the intrapartum treatment of 38 babies severely asphyxiated at birth was compared with 120 controls.[40] In the control group, 29% of babies had an abnormal intrapartum FHR tracing, but in only 9% was the abnormality severe. In contrast, in the babies asphyxiated at birth, 87% had an abnormal FHR tracing, and in 61% of cases the abnormality was severe. The most striking finding, however, was the length of time required for the staff to recognize the FHR abnormality. With moderate abnormalities, the mean time to recognition was 71 minutes, and paradoxically, with severe abnormalities it was 118 minutes. The authors could give no plausible reason why the standard of FHR tracing interpretation was so poor. However, it was clear from this study that if the quality of interpretation of the intrapartum FHR pattern had been higher, the benefits from

EFM would almost certainly have been significantly and substantially enhanced.

In 1990, Ennis and Vincent published the results of their study of 64 cases of poor perinatal outcome from the archives of the Medical Protection Society.[41] In 11 cases, although indicated, continuous EFM was not performed. In six cases, the technical quality of the tracing was inadequate. In 14 cases, a significant abnormality in the FHR pattern was present, but this was either not noticed, or no action was taken upon it. In only 14 cases was appropriate monitoring and action performed (the CTG was missing in 19 cases). In only 16 cases was a consultant involved in the interpretation of the tracing. In a further study from Oxford published in 1994,[19] intrapartum care was assessed in 141 cases of cerebral palsy and 62 perinatal deaths with a potential intrapartum cause. They found that abnormal FHR patterns were 2.3 times as common in babies who went on to develop cerebral palsy compared with controls, and 6.7 times as common in perinatal deaths. They found that failure to respond to these clear signs of abnormality occurred in 26% of cerebral palsy cases and 50% of perinatal deaths, compared with 7% of controls. On the basis of these figures, it can be calculated that there will be approximately one case of potentially preventable cerebral palsy and one potentially preventable perinatal death in every 4000 deliveries. If one assumes 700,000 births per annum in the United Kingdom, 174 cases of cerebral palsy and 158 cases of perinatal death would be preventable.

More recently, Stewart and associates have reported that perinatal mortality in Wales is twice as high at night as during the day, and twice as high in July/August as in the rest of the year.[42] They suggested that the excess of deaths may represent overreliance on inexperienced staff at night and a shortage of staff during the peak summer holiday months, and also that it might be related to physical and mental fatigue of the caregivers. The Confidential Inquiry into Stillbirths and Deaths in Infancy (CESDI) was a U.K. national survey of perinatal deaths, now subsumed into the Confidential Inquiry into Maternal and Child Health (CEMACH, www.cemach.org.uk). The fourth annual report[43] showed that failures in the use and interpretation of CTG were present in more than half of intrapartum-related deaths. The fifth report[44] studied the proportion of 567 cases where there was evidence of suboptimal care in labor, and then classified this by whether improved care could possibly or probably have prevented the adverse outcome. Suboptimal care was identified in 71% of cases, and a better outcome could possibly or probably have been anticipated in 28% and 22% of cases, respectively, if care had been adequate. The report commented that "fetal surveillance problems were the commonest cause (of problems in labor), with CTG interpretation . . . the most frequent criticism."

Maternity care accounts for some 60% of the U.K. National Health Service (NHS) medical litigation bill, with individual settlements reaching £4.6 million and even successful defense costing up to £0.5 million.

Possible Interventions to Improve the Quality of Care

Young and associates[45] have studied the efficacy of intrapartum intervention and found that in cases of low Apgar scores, there was evidence of substandard care in labor in 74%. Following the introduction of regular audit of low Apgar scores, with feedback to clinical staff, this proportion fell to 23%, but crept back up to 32% over the following year. However, following the introduction of compulsory training in FHR pattern interpretation for all staff, the proportion of low Apgar score cases associated with substandard care fell back once again to only 9%.

Indications for Electronic Fetal Monitoring

Intrapartum EFM was intended to be a screening tool for fetal hypoxia, with FBS used as the confirmatory test. Accordingly, many authorities have advocated universal continuous EFM. However, with the growth of the "natural childbirth" movement, and the difficulty in establishing the efficacy of EFM in randomized trials, most guidelines now suggest that intermittent auscultation is an adequate form of FHR monitoring for "low risk" labors and that continuous EFM should be reserved for "high risk" labors. Unfortunately, it is difficult to define "low risk" labor. The guidelines of the NICE in the United Kingdom[36] approach this problem by listing high risk factors that they consider indicate the need for continuous EFM (Table 71–3). I have analyzed 29,443 births at the Chelsea and Westminster Hospital (London, UK) from 1988 thru 1998 inclusive and coded them as low risk if: the mother's age was <40; there was no diabetes, cardiac disease, renal disease, or antepartum hemorrhage; the highest blood pressure at any time during pregnancy was <90 mm Hg diastolic; presentation was cephalic; gestation was 37 to 42 weeks; labor onset was spontaneous; the labor duration was <12 hours; epidural anesthesia was not used; and there was no oxytocin augmentation, meconium staining of the amniotic fluid, or pyrexia. Using these criteria, labors were low risk throughout labor in only 26%. Therefore, according to the NICE guidelines, intermittent auscultation throughout labor was only applicable in about a quarter of labors. In fact, only 11% had no EFM during labor, and the incidence of abnormal FHR pattern was 7.8%. In contrast, in the "high risk" 74%, 4.3% had no EFM during labor, and the incidence of abnormal FHR pattern was 22.8%. A similar analysis of the data from 15 other maternity units in the North West Thames region of London showed a median value for "low risk" labors of 25%, with the highest proportion of low risk labor being 34%, and the lowest 16%. In only one of these units did the proportion of low risk labor where EFM was not used exceed 50%.

TABLE 71-3

Indications for Continuous Electronic Fetal Monitoring

Labor Abnormalities
  Induced labor
  Augmented labor
  Prolonged labor
  Prolonged membrane rupture
  Regional analgesia
  Previous cesarean delivery
  Abnormal uterine activity

Suspected Fetal Distress in Labor
  Meconium staining of the amniotic fluid
  Suspicious fetal heart rate on auscultation
  Abnormal fetal heart rate on admission cardiotocography
  Vaginal bleeding during labor
  Intrauterine infection

Fetal Problems
  Multiple pregnancies (all fetuses)
  Small fetus
  Preterm fetus
  Breech presentation
  Oligohydramnios
  Post-term pregnancy
  Rhesus isoimmunization

Maternal Medical Disease
  Hypertension
  Diabetes
  Cardiac disease (especially cyanotic)
  Hemoglobinopathy
  Severe anemia
  Hyperthyroidism
  Collagen disease
  Renal disease

Mires and colleagues recently reported on a randomized controlled trial of CTG versus Doppler auscultation of the fetal heart at admission in labor in low risk obstetric population.[46] They commented that "as the trial progressed, it became clear that . . . more women had complications that required continuous monitoring than had been predicted"; the overall proportion was 63% and was similar in both groups. In an even more recent study of low risk labors in Dublin, Impey and associates[47] reported that if an admission CTG was performed, 58% of women had continuous EFM during labor, but that even if intermittent auscultation was used from the outset, 42% of women had continuous EFM. Accordingly, using current guidelines, continuous EFM is likely to be used in most settings in over 80% of labors.

Fetal Monitoring by Intermittent Auscultation

Evidence regarding the value of EFM is limited, but the evidence regarding the use of intermittent auscultation is even worse. Recommendations therefore have to depend entirely on custom and practice, and "expert" opinion. These have been summarized in the NICE guidelines.[36] They have followed the American College of Obstetricians and Gynecologists, and the Society of Obstetricians and Gynaecologists of Canada in recommending that (1) during the active phase of the first stage of labor, the FHR should be auscultated and recorded every 15 minutes and (2) during the second stage of labor, the FHR should be auscultated and recorded every 5 minutes. Ideally, the heart rate should be counted over 30 to 60 seconds, in the minute after a contraction (to detect late decelerations).

The "Admission" Cardiotocogram

The incidence of emergency cesarean section for fetal distress is higher in the first hour of labor than in any subsequent single hour. This is because the onset of contractions reveals the fetus that is unable to cope with the relative hypoxia of labor. For this reason, performing EFM for the first hour of labor even in low risk pregnancies ("admission test") has become popular in some maternity units. Unfortunately, no studies of sufficient size have been conducted to enable an evaluation of the usefulness of this approach.[36]

Technical Aspects of Electronic Fetal Monitoring

A cardiotocograph machine is used to produce a continuous recording of FHR and uterine contractions, known as a CTG. It reveals information about aspects of FHR such as baseline variability, which cannot be measured using intermittent auscultation. It also produces recordings of FHR decelerations in relation to contractions, which are easier to detect and analyze, and an automatic paper recording is produced for archival purposes (optical discs are increasingly being used for convenient storage). This record is available for subsequent independent review, which is valuable for audit and teaching, although it may be a mixed blessing in medico-legal terms if it reveals abnormalities previously overlooked.

EFMs can measure the FHR and uterine contractions via external transducers using Doppler ultrasound and a tocodynamometer (strain gauge attached to a belt) or via internal sensors such as a fetal electrode and an intrauterine catheter. Despite the fact that the latter methods are more reliable and accurate, and probably more comfortable for the average woman in labor than the belts necessary to attach the external transducers, they are more invasive and thus most EFM is performed using external devices. This mode of EFM has a number of problems. First, modern machines generally use a form of autocorrelation or cross-correlation analysis to produce the FHR from ultrasound signals, but the systems are now so sensitive that if the fetus is dead they sometimes produce a recording of the maternal rate, which can be mistaken for that of the fetus. This is particularly likely if the mother is anxious and has a tachycardia so that her heart rate is similar to that expected of her fetus and can even lead to the erroneous emergency delivery of a dead baby.[48] To

avoid this problem, it is good practice always to ensure that rate calculation is derived from the characteristic signals of the fetal heart (sharp and distinct, sometimes sounding like the hooves of a galloping horse), rather than to rely on the "whooshing" sound produced by reflections from fetal blood vessels.

Second, good recording of the FHR depends greatly on correct placement of the transducers on the abdomen. This is not always achieved, and constant readjustment is often necessary if the mother is very active. Unfortunately, it is often the mothers who wish to have an active birth and who are very mobile who decline the use of internal monitoring. This commonly results in loss of adequate signal and FHR information at a most critical time in the labor, the second stage.

Third, the information obtained about uterine contractions using an external transducer is essentially limited to timing them. The external contraction transducer (tocodynamometer) gives only a relative indication of contraction strength, and the recording is attenuated if, for example, the mother is obese or the transducer is poorly placed. This may mislead the birth attendant into underestimating the strength of contractions, particularly in a stoical woman, and thus lead to overdosage with uterine stimulants such as oxytocin. By comparison, the recordings obtained from a directly applied fetal electrode and an intrauterine catheter are much more accurate and less susceptible to recording failure.

One factor that militates against the use of scalp electrodes is the increasing prevalence of the HIV virus. The Royal College of Obstetricians (UK) advise that women who carry the HIV virus should not have their fetuses monitored using an electrode that breaches its skin, for fear of increasing the risk of transmission of the virus to the fetus. Although women with a detectable viral load are now advised to have their babies delivered by cesarean section, and HIV-infected women only normally choose vaginal delivery if their viral load is undetectable, anonymous testing reveals that in about 25% of cases, women positive for HIV choose not to have antenatal testing and therefore go through labor unaware they are at risk.

Interpretation of Fetal Heart Rate Recordings

The key to reliable and consistent interpretation of FHR tracings from CTG machines is a systematic approach. Four main aspects of the FHR should be assessed: the baseline rate, baseline variability, the presence or absence of accelerations, and the presence and classification of decelerations (slowings of the FHR, or "dips"). Many errors of interpretation occur because of an excessive concern with decelerations and a consequent failure to appreciate the significance of the other three aspects of the FHR. A detailed account of how the FHR can be assessed using CTG is given in Table 71–4.

A normal CTG pattern is highly reassuring that the fetus is not acidotic; the significance of an abnormal pattern is much more difficult to judge. In general, the more of the four basic aspects of the FHR (baseline rate, baseline variability, accelerations, decelerations) that are abnormal, the more likely the fetus is to be acidotic. However, other factors should modulate the response to such a pattern.

The Time Factor

The fetus does not become acidotic as soon as the FHR becomes abnormal; Fleischer and associates[49] showed that a well-grown fetus can cope with hypoxic stress for as long as 90 minutes before the pH of fetal blood starts to fall. Thus, a normal fetal scalp blood pH 60 minutes after the CTG has become abnormal does not indicate that the abnormality is a "false-positive." The pH of the fetus may begin to fall at any subsequent time; accordingly the only safe plan is to repeat the FBS at hourly intervals (more often if the pattern is severely abnormal) or deliver the baby.

In contrast, a low pH may be an acute response to temporary interference with maternal placental blood flow and gas exchange. This can occur, for example, after an epidural top-up (with or without maternal hypotension) or because of uterine hyperstimulation with oxytocics. Action should be taken to correct the problem. This can include turning the mother to the left lateral position to correct supine hypotension, stopping any infusions of oxytocic drugs, and giving the mother oxygen by face mask; persisting hypotension from epidural anesthesia can usually be corrected by intravenous injection of a vasoconstrictor such as ephedrine, and excessive uterine activity may be corrected by an infusion of a tocolytic drug such as ritodrine or salbutamol. If the FHR pattern returns to normal, then a low pH is often corrected, and immediate delivery of the fetus would be inappropriate. Therefore, it is probably unnecessary to take an FBS in response to an acute FHR abnormality unless the resuscitative measures described earlier do not correct the abnormality of the FHR within 15 to 20 minutes.

Intrauterine Growth Restriction

Any baby thought to be seriously small for gestational age on antenatal assessment or with intrauterine growth restriction seen on serial ultrasound scanning should be treated as particularly at risk during labor.[50] There is an increased likelihood of abnormal FHR patterns and acidosis, so FBSs should be taken more readily and more often than with well-grown babies, and the threshold for operative delivery should be reduced.

Early Gestational Age

Preterm babies are more susceptible to the effects of intrauterine hypoxia than full-term babies; in particular

TABLE 71-4

Interpretation of Fetal Heart Rate Pattern (Cardiotocogram)

Admission Test

Normal, reassuring, or reactive
  Two or more accelerations (>15 beats/min for 15 sec) in 20 min
  Baseline FHR 110–150 beats/min
  Baseline variability 5–25 beats/min
  Absence of decelerations
  Moderate tachycardia/bradycardia and accelerations
Interpretation/action: Risk of fetal hypoxia in next 2–3 hr in spontaneous labor, is low other than following acute events

Suspicious, equivocal, or nonreactive
  Absence of accelerations, reduced baseline variability (5–10 beats/min), or silent pattern (5 beats/min), for >40 min, although baseline rate normal (110–150 beats/min)
  Baseline FHR <100 beats/min or >150 beats/min
  Variable decelerations (depth <60 beats/min, duration <60 sec)
Interpretation/action: Continue CTG, consider vibroacoustic stimulation/fetal scalp pH estimation if CTG not normal in 1 hr

Pathologic/ominous
  Silent pattern and baseline FHR >150 beats/min or <110 beats/min with no acceleration
  Repetitive late decelerations and/or complicated variable decelerations
  Baseline FHR <100 beats/min or prolonged bradycardia (>10 min)
Interpretation/action: Exclude cord prolapse, placental abruption and scar dehiscence. If small fetus, or thick meconium, or previously abnormal trace, consider immediate delivery. In other situations, consider fetal scalp pH estimation (and, for example, tocolysis if uterine hyperstimulation, IV fluids if related to epidural 'top-up')

First-Stage Intrapartum CTG

Normal, reassuring, or reactive
  Two or more accelerations (>15 beats/min for >15 sec) in 20 min
  Baseline FHR 110–150 beats/min
  Baseline variability 5–25 beats/min
  Early decelerations (in late first stage)

Suspicious, equivocal, or nonreactive
  Absence of accelerations for >40 min
  Baseline FHR 150–170 beats/min or 100–110 beats/min (normal baseline variability, no decelerations)
  Silent pattern >40 min (normal baseline rate, no decelerations)
  Baseline variability >25 beats/min in the absence of accelerations
  Variable decelerations (depth <60 beats/min, duration <60 sec)
  Occasional transient prolonged bradycardia (FHR drops to <80 beats/min for >2 min or <100 beats/min for >3 min)
Interpretation/action: Continue CTG, vibroacoustic stimulation or fetal scalp pH estimation if CTG not normal in 1 hr

Pathologic/ominous
  Baseline FHR >150 beats/min and silent pattern and/or repetitive late or variable decelerations
  Silent pattern for >90 min
  Complicated variable decelerations (depth ≥60 beats/min, duration ≥60 sec) and changes in shape (overshoot, decreased or increased baseline heart rate following the deceleration, absence of baseline variability, slow recovery)
  Combined/biphasic decelerations (variable followed by late)
  Prolonged bradycardia (FHR drops to <80 beats/min for >2 min or <100 beats/min for >3 min) in a suspicious trace
  Prolonged bradycardia (FHR drops to <80 beats/min for >2 min or <100 beats/min for >3 min) >10 min
  Repetitive late decelerations
  Pronounced loss of baseline variability
  Sinusoidal pattern with no accelerations
Interpretation/action: Consider fetal scalp pH estimation

Second-Stage Intrapartum CTG

Normal, reassuring, or reactive
  Normal baseline heart rate, normal baseline variability and no decelerations, frequent accelerations, both periodic and scattered
  Baseline heart rate 110–150 beats/min and baseline variability 5–25 beats/min or >25 beats/min, with or without early and/or variable decelerations

Suspicious, equivocal, or nonreactive
  Baseline heart rate >150 beats/min, persisting or compensatory following each deceleration
  Reduced baseline variability or silent pattern decelerations of >60 sec duration
  Mild bradycardia, heart rate catches up between contractions and may reach above 100 beats/min, especially when baseline variability is normal
Interpretation/action: Observe trace for increasing baseline heart rate or bradycardia

Pathologic/ominous
  Baseline heart rate <100 beats/min of different patterns
    Progressive bradycardia: baseline heart rate gradually decreases between contractions; absence of baseline variability can be seen especially when heart rate is <80 beats/min
    Persisting bradycardia, baseline <80 beats/min. The additional absence of baseline variability represents a more ominous feature
  Baseline tachycardia (>150 beats/min) with reduced variability and severe variable and late decelerations
Interpretation/action: Expedite delivery if not imminent

---

hypoxia has a damaging effect on the type 2 pneumocytes that produce surfactant in the lungs, increasing the incidence and severity of the neonatal respiratory distress syndrome (hyaline membrane disease).[51] However, the incidence of hypoxia and acidosis in fetuses in preterm labor is not increased compared with fetuses in full-term labor.[52] Preterm babies are more likely to have low Apgar scores than full-term babies, but this is due to functional immaturity and not to the effects of hypoxia.[53] A baby born at 28 weeks' gestation is likely to have poor respiratory effort, to have reduced tone, and to have less reflex irritability, and thus a lower Apgar score than its full-term counterpart; however, given a normal FHR pattern, it is no more likely to be hypoxic or acidotic.[52] The interpretation of the FHR pattern of the preterm fetus in labor is similar to that of its full-term counterpart.[54] However, some subtle differences may be seen in the FHR pattern.[55] Short-term baseline variability is often rather less, and FHR accelerations less frequent (the differentiation between quiet and active sleep patterns sometimes does not develop until 28 to 32 weeks' gestation). Small, brief (<20 seconds) decelerations are often seen and are insignificant (cause unknown).

Presentation of the Fetus

Although current recommendations favor elective cesarean delivery for babies in breech position,[56] there is still a place for vaginal delivery if this is what the mother requests (see Chapter 64). The second stage of labor is prolonged when the fetus is in breech presentation, and therefore it is probably wise not to embark on a vaginal breech delivery if there is any suggestion of fetal compromise at the onset of the second stage. Thus, if the FHR pattern is entirely normal, vaginal delivery can proceed, but if the FHR is abnormal, fetal condition should be checked by an FBS pH measurement. This can readily be taken from the buttock, and pH values are the same as for babies in cephalic presentation.[57] If the FBS pH is normal, then the delivery can be allowed to proceed, but if the FHR abnormality persists the FBS should probably be repeated if delivery has not occurred within 30 minutes. The passage of meconium is common with a breech presentation and unless it occurs very early in labor is not a useful monitoring variable.

Twins or Higher Order Pregnancy

Because of the increased risk of perinatal mortality associated with being a second twin, there is an increasing trend for elective cesarean delivery. However, vaginal delivery is a reasonable option if that is the parents' preference.[58] The use of ultrasound allows the heart rate of the second twin to be recorded accurately, and in view of the higher mortality rates for the second twins, such monitoring is recommended. The second twin may have heart rate changes suggestive of hypoxia while that of the first twin remains normal.[59] In this case, since FBS is impossible until the first twin has been delivered, cesarean section is probably appropriate.

Instrumental Delivery

Fetal distress is commonly cited as an indication for urgent instrumental vaginal delivery. However, great caution should be applied if the fetal head needs to be rotated. Hypoxia and acidosis can cause cerebral edema, and an edematous brain is stiffer and less flexible than normal. Twisting forces applied in this situation may cause tentorial tears, which would otherwise not occur. Thus, rotational deliveries when the FHR pattern is abnormal should probably only be undertaken after an FBS pH has been measured and found to be normal.[60]

Maternal Preference

A scientific basis for deciding when labor should be terminated operatively for fetal indications remains elusive. Such decisions cannot therefore be taken in isolation from the social context, and the wishes and anxieties of the parents should always be taken into account. Some parents have particular anxieties about labor; for example

they may have a sibling with residual damage attributed to birth asphyxia or trauma. In such cases, they may request delivery by cesarean section if there is any sign of fetal dysfunction or delay in labor. In view of the very low mortality and morbidity rates associated with cesarean section in modern practice, especially in the absence of any acute emergency, it is probably wise to accede to such requests unless delivery is imminent and the obstetrician very confident of a successful outcome.

PROCEDURE

FETAL BLOOD SAMPLING

Position

The use of the lithotomy position should be avoided because of the risk of supine hypotension. This can produce iatrogenic hypoxia and acidosis in the fetus, leading to unnecessary operative delivery. The sampling is most comfortably performed with the woman in the left (or right) lateral position.

Procedure

Under aseptic conditions, an amnioscope is passed up the vagina to rest on the presenting part of the fetus. Sufficient pressure must be used to exclude amniotic fluid, which will otherwise contaminate the sample. The fetal skin is then dried with a dental swab in a holder, and sprayed with ethyl chloride. The evaporation of the ethyl chloride cools the skin, and as it warms up again, a reactive hyperemia is produced, which aids bleeding. The skin is smeared with a water-repellent gel (often silicone) so that when the skin is stabbed with a guarded 2-mm blade a droplet of blood forms. This droplet is allowed to flow into a preheparinized thin glass tube by capillary action (it helps to tilt the tube slightly downward at the operator's end). Mouth operated suction should not be used because of the risk of the operator ingesting potentially infected blood.

Analysis

The sample is then transferred to a blood gas analyzer for measurement. It is preferable to measure PO_2, PCO_2, pH, and calculate the base deficit. If the values are normal, but the FHR pattern remains abnormal, it will usually be necessary to repeat the sampling within 15 to 30 minutes.

Use of Intravenous Fluids during Labor and Its Effect on Fetal Acid–Base Balance

Women in labor are commonly advised not to eat, because of the risk of Mendelson's syndrome (aspiration of stomach contents) should they unexpectedly need general anesthesia. As a result, they often develop ketonemia. For this reason, it is common practice to give parenteral fluid containing glucose and electrolytes, particularly if labor lasts more than a few hours. However, Ames and colleagues reported in 1975 that infusion of glucose-containing solutions could give rise to maternal lactic acidosis.[61] This is because the rise in

maternal blood glucose concentration increases the production rate of lactate, according to Michaelis-Menton kinetics. Subsequently, it was confirmed that maternal infusion of glucose at 100 g/hour (1 L of 10% glucose over 1 hr) produced a significant fall in average pH and rise in lactate in fetal as well as maternal blood.[62] However, lactic acidosis does not occur if the glucose infusion rate is restricted to 30 g/hour,[63,64] and there is some evidence to suggest that physiologic amounts of glucose in infused fluids (i.e., 5%) may be associated with less fetal acidosis than glucose-free solutions.[65] These studies indicate that in labor, as at other times, care must be taken to monitor the volume and content of intravenous infusions to ensure they are compatible with the maintenance of normal physiology.

IATROGENIC CAUSES OF FETAL DISTRESS

Excessive Oxytocin Augmentation of Labor

Every uterine contraction above 4 to 6 kPa causes a cessation of maternal intervillous placental blood flow.[66] This produces a period of relative hypoxia for the fetus, such that the fetal PO_2 falls by about 0.5 to 0.75 kPa during each contraction, reaching its lowest level at the end of the contraction, after which the flow is restored and the PO_2 recovers. Because it takes some time for the oxygen-depleted maternal pool of blood to be replaced, recovery takes about 60 to 90 seconds. The total period of reduced oxygenation is therefore 120 to 150 seconds, emphasizing the importance of an adequate intercontraction interval to ensure fetal oxygenation. Poorly controlled oxytocin infusions, which produce excessively frequent contractions, can cause iatrogenic fetal hypoxia and acidosis (see Chapter 69). In practical terms, this means that if the FHR becomes abnormal, oxytocin infusions should be stopped immediately.

Epidural Anesthesia

Before preloading of the circulation with colloid came into practice, abnormalities of the FHR occurred in approximately one third of cases following insertion of an epidural anesthetic. With preloading, this can be reduced by two thirds.[67]

Epidural anesthetics may also cause a fetal tachycardia by inducing hyperthermia in the mother (see Chapter 72). Such tachycardia is not likely to be associated with significant fetal hypoxia, and fetal pH is not affected, but it can give rise to an erroneous diagnosis of fetal distress. It may also lead to a false diagnosis of intrauterine infection, greatly increasing the proportion of newborns investigated with cultures and treated with antibiotics.[68] Probably, the correct response is to cool the mother with tepid sponging.

Drugs

Drugs given to the mother may cross the placenta and affect the fetus. Beta-blockers such as propranolol, and α- and β-blockers such as labetalol may interfere with the reflex responsiveness of the fetal circulation and impair its response to hypoxia. Other hypotensives such as hydralazine can cause hypoxia by producing maternal hypotension. Sedatives such as pethidine (meperidine) and diazepam (Valium) may depress the fetal central nervous system, reducing the variability of the FHR and producing neonatal depression. Care must be taken to give the minimum of any necessary drug in labor, and the effects on the fetus must always be considered.

OTHER METHODS OF MONITORING FOR FETAL DISTRESS

Transcutaneous Gas Measurements

In the late 1970s, transcutaneous PO_2 measurements using a modified Clark electrode became possible. However, the technique was difficult; the scalp had to be shaved, dried, and readily accessible to a fairly large probe, which then had to be glued to the skin or held on by suction. The probe had to be heated to arterialize the circulation and allow oxygen to diffuse out of the fetal arterioles. There were problems with trauma and heat injury. In addition, the measurement of PO_2 is a measure of hypoxic stress but does not quantify response (acid–base buffer reserve) in the way that measuring pH does; it is very susceptible to local and acute changes.

Further attempts to improve acceptability have been made by using pulse oximetry, which does not require the probe to be heated; instead, it uses infrared light to detect changes in oxygenated hemoglobin concentration in the tissues during the arterial pulsation cycle. However, this system also has problems; it cannot work through hair (which leads to practical difficulties with placement) or meconium, it is susceptible to maternal and fetal movement, and sometimes produces inconsistent results. Results suggest that 30% to 60% saturations are the normal range in the human fetus, indicating that prolonged desaturation is physiologic in the human fetus.[69] This makes the significance of the readings difficult to assess clinically. If a cutoff of 30% saturation is used, then values below this have a sensitivity of 94% in detecting pH <7.13, but the specificity is only 38%.[69] This means that the technique is similar to, but not better than, continuous FHR monitoring as a screening test for acidosis.

Near-infrared spectroscopy is a related technique that uses infrared light at two frequencies to assess the difference in concentrations between oxygenated and deoxygenated hemoglobin concentrations and, hence, the oxygen saturation of the blood. However, the method is

expensive and presents many technical difficulties, including frequent probe detachment. No published trials have examined the ability of near-infrared spectroscopy in assessing fetal condition during labor.[70]

Fetal Scalp Lactate Measurement

In theory, lactate measurement assesses hypoxic and anaerobic metabolism leading to a metabolic acidosis, which is very similar to that obtained by measuring base deficit. In practice, a randomized controlled trial using lactate compared with pH to assess metabolic acidosis showed no significant differences in clinical performance.[71] The practical advantages in measuring lactate are that very small sample volumes are needed (5 μL compared with 25 μL for pH estimation), and the values are not significantly altered by contamination of the sample with air bubbles.[72]

Electrocardiographic Waveform Analysis

Since the fetal electrocardiogram (ECG) was first demonstrated by Cremer in 1904, attempts have been made to assess fetal well-being by assessing changes in ECG waveform.[73] One approach has been to analyze changes in the PR/RR interval ratio but this has not been found to be of value in a prospective, randomized, controlled trial.[74] Another approach used the T/QRS ratio as a measure of acidosis (based on the hypothesis that it is altered by the production of lactate in the fetal heart secondary to hypoxia) and can reduce the need for FBS.[75,76] Two prospective, randomized, controlled trials[77,78] suggested that it can reduce the need for operative delivery for fetal distress, as well as the incidence of both of metabolic acidosis at delivery and neonatal encephalopathy. However, a recent study of its introduction into routine clinical practice did not show the expected benefits.[79] A particular problem with the use of the ECG waveform analysis is that it requires the application of a fetal scalp electrode.

Expert Systems

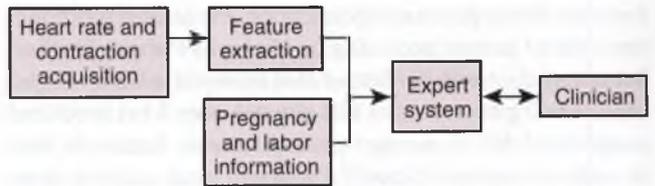
Studies of the efficacy of EFM have consistently found the human component to be the weakest link. Computerized analysis is now commonplace in the evaluation of the adult ECG waveform. Keith and associates reported a study in which the ability of an "expert" computer system (Fig. 71–2) designed for the interpretation of FHR and FBS data was compared with the opinions of 17 clinicians experienced in fetal monitoring from 16 centers in the United Kingdom.[80] Fifty cases with


FIGURE 71–2
Principles of expert system cardiotocogram interpretation. (From Keith RDF, Beckley S, Garibaldi JM, et al: A multicentre comparative study of 17 experts and an intelligent computer system for managing labor using the cardiotocogram BJOG 1995;102:688–700.)

complete intrapartum CTGs and clinical data were reviewed by the system and each expert independently on two occasions, at least 1 month apart. The system agreed with the experts well and significantly better than chance (67.3%, κ = 0.31, P << 0.001). It was highly consistent (99.16%, κ = 0.98, P << 0.001) when used by two operators independently. It recommended no unnecessary intervention in cases that ended with a normal delivery of a baby in good condition (cord artery pH >7.15, vein pH >7.20, 5 min Apgar ≥9, and no resuscitation). This was better than all but two of the experts. It recommended delivery by cesarean section in 11 cases; at least 15 of the 17 experts in each review also recommended cesarean section delivery in these cases. Most did so within 15 minutes of the system, and two thirds did so within 30 minutes. It identified as many of the birth-asphyxiated cases (cord arterial pH <7.05 and base deficit ≥12, and Apgar score at 5 minutes ≤7 with neonatal morbidity) as the majority of the experts, and one more than was acted upon clinically. The experts were found to be consistent and to agree; with the exception of expert "Q." This expert was the only one who declined all information from FBS and attempted to make all decisions on the basis of the FHR alone. In fact, (s)he was the second most inconsistent expert in scoring and obtained the lowest agreement with the other experts (58%, κ = 0.12). (S)he was also the most inconsistent in recommending cesarean section; in nine cases cesarean section was recommended in the first review and not the second or vice versa. "Q" also recommended two cesarean sections and one second-stage intervention unnecessarily in cases with a normal delivery and a good outcome. Keith and associates commented "in the hands of the experts, this additional information (FBS) clearly adds to the accuracy of decision-making. This information supports the current RCOG (Royal College of Obstetricians and Gynaecologists, 1993) recommendations for using FBS appropriately." This system is currently being prepared for its first clinical trials and shows considerable promise. The outcome of the trials are awaited with interest.

Screening for Fetal Distress in Labor

Management Options	Quality of Evidence	Strength of Recommendation	References
Prevention of Fetal Hypoxia			
Avoid unnecessary induction of labor and excessive use of oxtocic agents.	III	B	36
Preload with IV fluids in women who are having epidural analgesia in labor to reduce the risk of maternal hypotension.	Ib	A	67
Remember the effect of maternal drugs on fetal heart rate patterns.	–	GPP	–
Indications for Continuous Electronic Fetal Heart Rate Monitoring (EFM)			
See Table 71–3 for conditions associated with an increased risk of intrapartum fetal hypoxia. These indications may classify up to 80% of women as at-risk.	III	B	36
Fetal Monitoring in "Low risk" Labor			
The advice from the American, Canadian, and British Colleges is that intermittent auscultation can be used in such labors; however, there are no studies of sufficient size to evaluate this approach.	III	B	36
Use of EFM in "High risk" Labor			
Meta-analysis of randomized controlled trials shows significant reductions in the short-term neonatal morbidity rate and a significant reduction in perinatal deaths due to hypoxia, but a significant increase in cesarean delivery rates. However, studies are under powered to show an effect on overall perinatal mortality or cerebral palsy rates.	Ia	A	26,27
Concomitant use of fetal blood sampling (FBS) to estimate pH significantly reduces rates of cesarean delivery.	Ia	A	26–28
Admission EFM Recording ("Admission Test")			
Common practice, but no studies of sufficient size to evaluate this approach.	Ib	A	36, 46, 47
Interpretation of EFM Findings			
Human factors that adversely affect the outcome of EFM are delays in response times and failure to interpret the findings accurately. Education improves human responses, but this benefit is lost with time.	III	B	19,40–43,45
Because of the rate of decline in fetal pH after fetal hypoxia, FBS should be performed at least hourly if EFM abnormality is detected. Shorter intervals are advisable with intrauterine growth restriction.	III	B	49,50
If EFM abnormality is detected: • Correct caval compression. • Give maternal facial oxygen. • Correct hyperstimulation (stop oxytocics, use tocolytics). • Give IV fluids if the patient has epidural-induced hypotension.	III	B	36
EFM in a preterm fetus requires the use of slightly different criteria.	IV	C	55
The maternal pulse may be mistakenly recorded as fetal. The maternal pulse should be regularly recorded clinically by palpation to reduce this risk.	IV	C	48
FBS can be used in breech presentations.	IV	C	57
EFM in twins requires careful confirmation of separate fetal recordings.	IV	C	59
The use of rotational forceps with abnormal EFM is controversial and they should not be used if the fetal scalp pH is <7.15.	IV	C	60

Continued

CORD PROLAPSE

Prolapse of the umbilical cord in labor is an uncommon event; reported incidences vary from 1 in 265 to 426 labors. The occurrence of cord prolapse is most commonly associated with breech and other malpresentations, a high head at the onset of labor, multiple gestation, grand multiparity, abnormal placentation, preterm labor, polyhydramnios, and obstetric manipulations such as forceps delivery.[81] The diagnosis is commonly made during a vaginal examination, the examiner feeling a soft, usually pulsatile structure. In one series,[82] in 4% the cord was presenting, in 11% it was alongside the presenting part, in 45% it was in the vagina, and in 39% the cord appeared at the introitus. The last mentioned is more likely to occur after artificial, or sudden spontaneous rupture of the forewaters, than in association with a hindwater leak. Occasionally, the diagnosis may be suggested by the sudden appearance of large variable decelerations on the CTG. The mode of delivery remains controversial. As neonatal care has improved, so has the perinatal mortality associated with cord prolapse steadily declined, irrespective of the mode of delivery. For example, in one series reported in 1977, the perinatal mortality rate was 430 per 1000 births,[82] in 1985 162 per 1000 births, and in 1988 55 per 1000 births[83]; although a recent report from Israel found a perinatal mortality of 83 per 1000.[81] Some studies emphasized the danger of prolonged prolapse to delivery interval and urged prompt cesarean section unless the cervix is fully dilated and the presenting part is at or below the ischial spines so that the fetus is immediately deliverable by forceps (which is the case in about 20%–30%). While the woman is being prepared for the operation, it is usually recommended that she be nursed in the traditional knee-chest position facing downward, or alternatively (and often more practically) in steep Trendelenburg's position. It may be necessary for a birth attendant to keep a gloved hand in the vagina to elevate the presenting part and relieve pressure on the cord. One technique first suggested by Vago in 1970 and since commended by others[84] is to fill the urinary bladder with 500 to 700 mL of saline, elevating the presenting part and relieving pressure on the cord. However, more recently one paper championed manual replacement of the cord[83] (termed funic reduction), describing a successful vaginal delivery in seven of eight cases so treated (one was too far advanced in labor for this to be feasible and a cesarean section was performed). The interval between replacement of the cord and final delivery ranged from 14 to 512 minutes (8.5 hours!).

SUMMARY OF MANAGEMENT OPTIONS

Cord Prolapse

Management Options	Quality of Evidence	Strength of Recommendation	References
Cesarean section while pressure on the cord is relieved until delivery.	III	B	84
Manual elevation of the head away from the cord.			
Knee-chest position.			
Steep Trendelenburg position.			
Filling of the bladder with up to 700 mL normal saline.			
Instrumental delivery if the patient is in the second stage of labor, the presenting part is below the level of the ischial spines, and easy, prompt vaginal delivery is anticipated.	III	B	84
The value of funic reduction (manual replacement) is uncertain because few patients have been studied.	III	B	83

INTRAPARTUM FETAL RESUSCITATION

In general, if acute fetal hypoxia is evident and acidosis is rapidly developing, the best management is emergency cesarean section, preferably within 15 minutes. If the presentation is occipitoanterior, the presenting part is at or below the spine, and there is no obvious evidence of disproportion, then a nonrotational forceps delivery is an appropriate alternative. Various studies have reported attempts at intrauterine resuscitation of the fetus, and maneuvers recommended include turning the mother to the left side, giving her oxygen by face mask, stopping any oxytocic infusion, uterine tocolysis, and correction of any hypotension. While there is anecdotal evidence that these maneuvers may be effective in appropriate circumstances, no randomized studies attest to their efficacy.

MECONIUM STAINING OF THE AMNIOTIC FLUID

Aspiration of meconium by the fetus remains a relatively common cause of perinatal mortality and morbidity because it is difficult to prevent. The fetus passes meconium into the amniotic fluid in approximately 10% of all pregnancies; in up to 5% of these (i.e., in 1:200 of all pregnancies) the meconium is aspirated and can then lead to meconium aspiration syndrome (MAS). MAS can cause, or contribute to, neonatal death in up to 0.05% (i.e., 1:2000 of all pregnancies).[85,86] In addition, up to one third of all cases in which aspiration occurs develop long-term respiratory compromise.[87,88] The incidence of MAS may be falling in developed countries: fewer pregnancies are proceeding beyond 42 weeks because of increased use of ultrasound dating of pregnancy and induction between 41 and 42 weeks.[89]

It seems likely that the causes of meconium passage by the fetus are not necessarily the same as those that cause aspiration, and so in the account that follows, the two aspects will be addressed separately.

Passage of Meconium

Mechanism

Meconium is passed into the amniotic fluid by peristalsis of the fetal gut accompanied by relaxation of the internal and external anal sphincters. In the adult this process is a complex interaction of hormonal, myogenic, and neurogenic factors. Peristalsis is principally controlled by local reflexes acting via the neural complexes in the gut wall, but is usually modified by extrinsic innervation. Sympathetic activity inhibits rectal activity and causes constriction of the internal anal sphincter, whereas parasympathetic activity has the opposite effects. In the resting state the internal and external sphincters are constricted. In the adult, involuntary defecation can occur in response to stress ("flight-or-fight reaction"). This is mediated centrally by the hypothalamus (and possibly the amygdala), which in turn causes stimulation of the visceral parasympathetics.[90,91] In contrast, pathophysiologic stresses such as pain, heat, cold, injury, exercise, and nonintestinal infections all produce gut stasis and constipation.[90] It is attractive to suggest that the fetus may exhibit a similar response to the "emotional" stress of labor, but this concept is likely to remain an untested theory. The fetus is stressed pathophysiologically in labor by hypoxia, pyrexia, or compression, which by extrapolation from adult physiology would be more likely to produce gut stasis than increased motility. However, fetal physiology differs in many ways from that of the adult, and our knowledge of the mechanisms of gut motility and meconium passage in the fetus is poor.

The Effect of Maturity and Gestation on Passage of Meconium

Meconium is found in the fetal gut from 10 weeks' gestation,[92] but passage of meconium is rare before 34 weeks.[93] The incidence of meconium passage increases with gestational age and reaches approximately 30% at 40 weeks' gestation and 50% at 42 weeks.[93,94] The presence of meconium in the amniotic fluid may reflect fetal gastrointestinal maturity.[95] Fetal gut transit time does decrease with gestational age, and gut motility increases.[96] The low gut motility in the preterm fetus has been attributed to a lack of gut wall musculature, but this is unlikely because peristalsis has been reported before 12 weeks' gestation, and muscle development must have occurred before this.[97]

Immature innervation of the fetal gut is more likely, with preterm fetuses having fewer myelinated axons and ganglion cells in the colon than full-term infants. Meconium passage in the preterm fetus can occur if it becomes infected with organisms that can cause a fetal enteritis (e.g., *Listeria monocytogenes*, *Ureaplasma urealyticum*, rotaviruses).[98] The fetal gut must be sufficiently developed for peristalsis to occur and meconium to be passed even in the preterm fetus.

Hormonal Control of the Passage of Meconium

The intestinal hormone motilin has been implicated in the passage of meconium in utero; it causes contraction of smooth muscle in the gut wall. Motilin levels in umbilical venous blood increase with gestation, and if they reflect levels in the fetal gut, could be a factor in explaining the tendency for the mature fetus to pass meconium.[99] Cord levels are also higher in infants that have passed meconium prenatally,[99,100] and one study found that they were also higher if an FHR abnormality had occurred in labor.[99] This latter finding was not confirmed in a later study,[100] but different definitions of FHR abnormality were used. It is possible that stress on the fetus could cause release of motilin and thus passage of meconium, but this remains conjectural. The hormonal and other factors that control gut motility are largely unknown, even in the adult.

Infection and the Passage of Meconium

Meconium-stained amniotic fluid is associated with increased peripartum infection rates, independent of other risk factors for infection. Thick meconium, in particular, is associated with a marked increase in peripartum infectious morbidity.[101-103] It is not yet clear whether the presence of meconium encourages infection, or whether infection promotes the passage of meconium by the fetus. In favor of the former, prophylactic intravenous ampicillin-sulbactam significantly reduces intra-amniotic infection in patients with meconium-stained amniotic fluid,[104] although the possibility remains that the presence of the infection antedated the appearance of the meconium and was unrecognized. In addition meconium is a chemoattractant and activator of polymorphonuclear leukocytes in vitro, and for cytokines such as TNF-α, IL-1, and IL-8.[105] It may be that meconium increases the damaging effects of infection by increasing the presence of these inflammatory mediators.

Obstetric Cholestasis

The risk of meconium passage increases in association with cholestasis of pregnancy.[106] This may be secondary to elevated levels of bile acids in the maternal circulation, which cross the placenta and affect the fetus. Cholestasis of pregnancy also increases the bile acid content of meconium.[107] The same study also found that although maternal ursodeoxycholic acid (UDCA) therapy caused a reduction in serum bile acid levels in the mother, there was no associated reduction in the levels of meconium passage in the fetus. The implications of this are unclear, but it is possible that if UDCA does not affect fetal bile acid levels significantly, perinatal loss rates associated with cholestasis of pregnancy will not improve.

Risks

Fetal Hypoxia

An association between meconium passage in utero and poor condition of the neonate has been suggested since ancient times. Aristotle reported opium-like effects in neonates born through meconium-stained fluid, and there have been references to meconium in association with perinatal death from as early as 1676 (quoted in Schulze).[108] Subsequently many authors have suggested that fetal hypoxia causes intestinal peristalsis, relaxation of the anal sphincter, and thus passage of meconium. This view has largely been assumption, with little or no direct evidence to support such a hypothesis. Stander[109] claimed that meconium was a sign of impending fetal "asphyxia" due to "relaxation of the sphincter ani muscle induced by faulty aeration of the blood" and proposed prompt delivery whenever meconium was seen. Desmond and colleagues[110] claimed that meconium staining of the amniotic fluid was a marker of fetal hypoxia, but no blood gas analysis of either fetal or neonatal blood was performed; the diagnosis of hypoxia being made on clinical grounds alone. These observations were made despite the report of Schulze,[108] who had concluded from a study of a series of more than 5500 births in California, that passage of meconium during labor "is in the large majority of cases independent of fetal asphyxia" and that the presence of old meconium in the amniotic fluid was of no prognostic significance for the later development of asphyxia (asphyxia here was not defined but appears to mean lack of respiratory effort at birth). She also observed that in cases associated with asphyxia there were always changes of the FHR during labor, and that these changes should be the sole guide to the necessity for delivery. However in a later study,

meconium passage was associated with low umbilical vein oxygen saturation, and thick meconium with lower levels of PO_2 than thin meconium.[111] This remained the principal experimental evidence linking fetal hypoxia with meconium passage and was widely quoted, often as the sole evidence, for at least the subsequent 20 years.

Fenton and Steer[112] made one of the first attempts to separate meconium passage from other markers of fetal compromise such as abnormality of heart rate, but again had only presumptive evidence of hypoxia in the fetus. They stated that there were other, benign causes of meconium passage and suggested that the passage of meconium was not significant if the FHR was greater than 110 beats/minute. The introduction of FBS began to clarify the situation. Miller and associates[113] found no difference in scalp blood pH, umbilical cord artery and vein pH, and neonatal arterial pH up to 64 minutes of life, between meconium and nonmeconium groups, if the FHR during labor had been normal. They concluded that meconium in the absence of other signs was not a sign of fetal distress (defined as late decelerations on the CTG and umbilical artery acidosis). More recent studies confirmed that infants who have normal FHR patterns have similar outcomes whether or not meconium is present, at least as far as acid–base status is concerned.[114]

If the FHR pattern is abnormal, however, the presence of meconium is associated with an increased chance of a baby being acidotic, born in poor condition, and needing resuscitation at birth.[93,113] In the data presented by Steer and colleagues,[93] 140 babies had an abnormal CTG pattern in the first stage of labor. The mean cord artery pH was 7.22 (SD = 0.10) in the 108 cases with clear amniotic fluid, compared with 7.17 (SD = 0.12) in the 32 cases with meconium-stained amniotic fluid (t = 2.37, P = 0.0096, one-tailed). The incidence of 1-minute Apgar scores <7 was 19% (3% at 5 minutes) if the amniotic fluid was clear, compared with 56% (9% at 5 minutes) if the amniotic fluid was meconium-stained. The difference was significant at 1 minute (P = 0.0001; Fisher's exact test). However, they commented that the reduction in the 1-minute Apgar score may have been due at least in part to the use of pharyngeal suction or endotracheal intubation by the attending pediatrician suppressing spontaneous respiration and thus iatrogenically reducing the Apgar score.

Despite the lack of a clear relationship between meconium staining of the amniotic fluid and fetal acidosis in the absence of FHR changes, we cannot conclude that the presence of meconium is not a threat to the fetus or neonate even if the FHR is normal. Yeomans and associates[115] studied 323 pregnancies with meconium-stained amniotic fluid at 36 to 42 weeks' gestation. Although there was a significantly higher incidence of meconium below the vocal cords if an umbilical artery pH was <7.20 compared with when the umbilical artery pH was ≥7.20 (34% compared with 23%), the difference in the incidence of clinical meconium aspiration syndrome

according to pH was not significant. Moreover, 69% of babies with meconium below the cords had cord arterial pH of ≥7.2. Thus a normal pH does not exclude the possibility of meconium aspiration, and most babies with meconium aspiration do not have acidosis. These data do not support the hypothesis that fetal hypoxia is a major cause of meconium passage in labor, and indeed Naeye and colleagues[116] reported that meconium staining of the amniotic fluid was not more common, even when the neonate was hypoxic.

Evidence that hypoxia per se does not lead to passage of meconium has been available for many years. Becker and associates[95] showed reduced peristalsis in the fetal guinea pig after induction of maternal hypoxemia, and a similar result was seen in the monkey fetus. In the adult with spinal shock, although the external sphincter relaxes, constipation occurs due to the loss of the other defecation reflexes. If meconium passage does occur in response to reduced intestinal blood flow, it must be an early event for the neurogenic reflexes still to be present. Meconium passage may occur as a result of vagal stimulation, and this could account for coexisting reduction in the FHR.[112] Parasympathetic stimulation is known to occur with cord compression, and this is supported by meconium passage being more common with increasing gestational age. Emmanouilides and colleagues[64] found that in the sheep fetus, if one umbilical artery was ligated, passage of meconium only occurred as a very late phenomenon, after chronic fetal wasting had developed. Although it is widely stated that fetal hypoxia leads to meconium passage in laboratory animals, the studies usually cited were concerned with the investigation of fetal breathing movements and do not state that meconium was passed in response to hypoxia.[66,117]

Meconium Aspiration

The passage of meconium is not a risk to the fetus, but aspiration of the meconium into the fetal or neonatal lung is associated with clinical disease ranging from mild transitory respiratory distress to severe respiratory compromise and occurs in up to one third of cases. Meconium aspiration is commonly defined as the presence of meconium below the vocal cords and occurs in up to 35% of live births with meconium-stained liquor.

Aspiration of meconium was thought by many authors to occur at delivery as the newborn infant took its first breath. Oropharyngeal suction, and endotracheal intubation of the infant before the first breath were widely promoted, to prevent meconium aspiration. However it now seems likely that meconium aspiration is largely an intrauterine event. This change of view has occurred because of compelling evidence that severe meconium aspiration syndrome still occurs despite adequate suction at delivery.[115,118,119]

The current view is that meconium aspiration occurs due to fetal breathing movements, causing inhalation of

amniotic fluid, with meconium if present. Two types of breathing movements cause inhalation of amniotic fluid: gasping and deep breathing. Gasping is a normal response to hypoxemia and can be induced experimentally by occluding the umbilical cord or by occluding the maternal aorta.[66,117]

The fetus may also inhale meconium by deep irregular breathing in utero, not initiated by hypoxia. These breaths become more frequent as gestation advances and comprise 10% of all fetal breathing movements.[117] The passage of amniotic fluid deep into the lung has been demonstrated by radiolabeling experiments that also showed that the human fetus inhales 200 mL/kg/24 hours of amniotic fluid.[120] Fetal hypercapnia and acidemia also increase these breathing movements, but they still occur in most, if not all, normal fetuses.[117,121] Although some infants with meconium aspiration are severely compromised at birth, there is little or no difference in umbilical cord acid–base status between infants with meconium below the cords and those without.[115] Meconium aspiration is more common if the meconium is thick rather than thin. This may be a reflection of the fact that oligohydramnios (and therefore thick undiluted meconium) is more likely to lead to fetal hypoxia due to cord compression and, consequently, increased fetal breathing.

Meconium Aspiration Syndrome

GENERAL

MAS represents a wide spectrum of disease ranging from transient respiratory distress with little therapy required, to severe respiratory compromise requiring prolonged mechanical ventilation and high levels of oxygen administration. Neonatal death occurs in up to 40% of cases.[118]

Severe MAS is associated with profound hypoxia, which is secondary to right-to-left shunting, a persistent fetal circulation, resistant pulmonary hypertension, pulmonary hemorrhage, necrosis of pulmonary vessels, and muscularization of distal pulmonary arterioles.[86,122,123] These changes may be due to intrauterine hypoxia, rather than to the meconium itself, although the inhalation of meconium exacerbates the problem in several ways in the neonatal period.

Meconium inhaled in an infant who has not been subjected to hypoxia usually causes mild disease only, and is asymptomatic in 90% of cases. Exposure to intrauterine hypoxia causes pulmonary vasoreactivity that persists after birth. Large increases in pulmonary artery pressure in response to very small falls in oxygen tension then result. The severity of this pulmonary vasospasm seems to depend on the severity of the fetal hypoxia and may be fixed (completely unresponsive) in the most severe cases. These changes have been demonstrated experimentally and observed clinically. A vicious cycle of hypoxia, pulmonary vasospasm, shunting, and therefore worsening hypoxia can develop. Jovanovic and Nguyen[124] showed in the guinea pig that meconium or amniotic fluid aspiration in the absence of hypoxia caused minimal damage, whereas lung damage (necrosis of alveoli and diffuse hemorrhage) in the hypoxic cases was severe whether the amniotic fluid contained meconium or not. The degree of lung destruction seems to depend primarily on the length and degree of hypoxia, not simply the aspiration of meconium. Hypoxic damage also reduces the clearance of aspirated meconium or amniotic fluid.[125] Meconium does, however, exacerbate the problems faced by the neonate. It displaces surfactant, causing atelectasis and hyaline membrane formation[126–128] and causes a chemical pneumonitis possibly due to cytotoxicity to the type II pneumocytes caused by bile salt-induced accumulation of calcium.[129] In addition it enhances bacterial growth and is associated with intrauterine infections. Aspiration may lead to infectious pneumonitis.

Some bacterial toxins cause pulmonary vascular spasm, exacerbating the effects of hypoxia.[98,130,131] Meconium has been demonstrated to cause vascular necrosis and vasoconstriction in the umbilical cord and may cause similar damage in the lung.[132] The umbilical vasoconstriction may cause hypoxia in utero, leading to aspiration. Inhaled thick meconium may cause a physical obstruction to the airways, leading to distal lung collapse, with hyperinflation in other areas of the lung. In total, 95% of severe cases of MAS occur when the meconium is thick, which is more common in post-term pregnancies when a relative oligohydramnios develops. Oligohydramnios may also be due to hypoxia, causing reduced fetal urine output[133] or may be a sign of uteroplacental insufficiency.

METHODS OF PREVENTING MAS

During the 1950s and 1960s, it was thought that meconium-stained amniotic fluid was a marker of fetal compromise, and efforts were made to detect meconium in the amniotic fluid in late pregnancy and to deliver the fetus either before, or as soon as, meconium appeared. Amnioscopy was introduced for pregnancies more than 10 days past the expected date of confinement. It was stated that the finding of meconium indicated "impending danger," and that immediate amniotomy and fetal blood sampling should be performed; the ensuing uterine contractions were thought to be therapeutic for the fetus. A threefold reduction in perinatal mortality was claimed, but other investigators have been unable to reproduce these results.[134,135] Saldana and associates[136] showed no benefit from amnioscopy and delivery. Amnioscopy has not been shown to be beneficial, is uncomfortable for the mother, may result in accidental rupture of the membranes or induce labor, can cause infection, and has to be repeated at regular arbitrary intervals until delivery.

Benacerraf and colleagues[137] reported the detection of thick meconium by ultrasonography, but further studies showed that vernix can produce an ultrasonically indistinguishable image in the absence of meconium.[138,139]

Because meconium passage is more common with advanced gestational age, many studies have investigated the effect of inducing labor at an earlier gestation. In a controlled trial Cole and associates[140] significantly reduced the incidence of meconium-stained liquor by inducing at 39 to 40 weeks' gestation, but no effect on perinatal mortality or respiratory disease was seen. Other studies of induction of labor have not shown a decrease in meconium aspiration, even if the incidence of meconium staining of the liquor was reduced.[141-143] There is thus no evident benefit from induction of labor before meconium appears, or from the routine use of amnioscopy, and disadvantages to both procedures exist.

In the 1970s it was widely believed that meconium aspiration developed by inhalation of the meconium at delivery when the infant took its first breath. To prevent this, aggressive policies of oropharyngeal suction, endotracheal intubation, and splinting of the thorax to prevent aspiration were proposed. Despite these interventions, cases of meconium aspiration still occurred, and further studies showed little or no reduction in MAS. A decline in the mortality from meconium aspiration is probably due to concurrent advances in perinatal medicine, rather than to the introduction of suction protocols. Suction and intubation are not free of risk. Cordero and Hon[144] reported apnea and bradycardia in infants having nasopharyngeal suction, and Linder and colleagues[145] found no benefit from the intubation at birth of meconium-stained but otherwise normal infants. All cases of meconium aspiration in this study occurred in the intubated group, and two cases of laryngeal stridor also required repeated hospitalization with residual hoarseness at 6 months of age. Cunningham and associates[119] recommended routine oropharyngeal suction but not intubation. There is now widespread acceptance that routine suctioning and intubation of neonates that have passed meconium have little if any effect on aspiration and may have deleterious side effects.

Amnioinfusion, the instillation of normal saline into the uterus during labor, has been proposed as a method to reduce meconium concentration and therefore the effects of aspiration. It may reduce cord compression in cases of oligohydramnios and therefore fetal gasping. Recent meta-analysis of the randomized studies investigating amnioinfusion has shown a significant reduction in overall cesarean section rate and in the rate specifically for fetal distress.[146] The incidence of meconium aspiration, MAS, and umbilical artery pH <7.20 appear to be reduced. The beneficial effect of amnioinfusion may be due to a reduction in cord compression during uterine contractions and therefore possible fetal hypoxia, or directly to a reduction in the concentration of meconium. However, because thick meconium is often associated with oligohydramnios, the benefits of amnioinfusion may be due solely to correction of amniotic fluid volume. Although amnioinfusion is a promising technique for reducing the incidence and severity of MAS, one study found that amnioinfusion is not clinically feasible in 53% of cases, and no benefit was seen.[147]

Attempts have been made to classify meconium in labor according to its concentration, because thick meconium has been associated with increased incidence and severity of the aspiration syndrome. However, any grading system is subjective because amniotic fluid draining during labor may not be representative of the fluid in utero, and no fluid may drain at all in cases of oligohydramnios, masking the presence of meconium. Quantifying the meconium concentration by centrifuging samples of amniotic fluid and measuring the amount of solid matter in the sample has been attempted,[148,149] but the same problems of obtaining amniotic fluid representative of the intrauterine milieu exist. In addition, neither author addressed the problem of vernix, and solid matter other than meconium in the liquor, producing false-positive results.

Two reports suggested that social support during labor reduces the incidence of meconium staining,[150,151] but in both cases more oxytocin was used in the group with no support, which could have lead to unphysiologic contractions and fetal hypoxia.

Evidence linking fetal distress and meconium should be viewed with caution because the events during labor and delivery do not represent the intrauterine environment at the time of meconium passage. In addition it is unlikely that prevention of meconium passage or aspiration will be successful until there is some elucidation of the underlying causes. Intrauterine probes to measure meconium concentration in the amniotic fluid continuously during labor, using a light-reflectance method have been developed.[152] Although this enabled observation of the events at the time of meconium passage (e.g., FHR changes, epidural top-ups) and was able to detect meconium not otherwise visible to the birth attendants, it is unlikely to be clinically useful in the foreseeable future.

Management Options with Meconium Staining of the Amniotic Fluid

When amniotic fluid is seen to drain, it should always be inspected carefully for the presence of meconium. If meconium is detected, continuous electronic FHR monitoring is recommended. If the FHR pattern remains normal, no specific action is necessary, except to avoid actions that might precipitate acute fetal hypoxia (supine hypotension, epidural hypotension, uterine hyperstimulation with oxytocics). In particular, there is no indication for routine FBS and pH estimation as long as the FHR pattern is normal. At delivery, a pediatrician should be present. If the baby is vigorous and cries promptly, there is no need for further action. Although there is no proof of efficacy, some pediatricians prefer to suction the pharynx as soon as possible after delivery of the head, and this is acceptable as long as care is taken not to traumatize the pharynx or larynx, as this may precipitate meconium aspiration.

If the FHR pattern is abnormal during labor, the likelihood of acidosis is substantially increased. Consideration should be given to immediate delivery, if necessary by cesarean section. If rapid progress in cervical dilation is occurring, it may be appropriate to take an FBS and allow the labor to continue if the pH is above 7.20, but this decision must take into account other factors such as the wishes of the mother, and whether there are other risk factors, such as intrauterine growth restriction. Amnioinfusion should be considered if it is decided to allow the labor to continue. Amnioinfusion can also be considered even if the FHR pattern is normal, as a preventive measure.

SUMMARY OF MANAGEMENT OPTIONS
Meconium Staining of the Amniotic Fluid

Management Options	Quality of Evidence	Strength of Recommendation	References
Incidence			
Meconium aspiration syndrome contributes to neonatal death in approximately 1 in 2000 births.	III	B	85–87
The main influence on the passage of meconium is gestational age.	III	B	94–96
Meconium aspiration is associated with infection, particularly in the lungs.	III	B	101–104
Fetal passage of meconium is more common in cholestasis of pregnancy.	III	B	106,107
Hypoxia and acidosis do not per se lead to the passage of meconium.	III	B	114,115
The combination of severe hypoxia and meconium aspiration causes lung damage.	III	B	125–127
Prevention			
A pediatrician should be present for delivery, but should not perform routine oropharyngeal suction in the absence of evidence of fetal hypoxia because suction does not reduce the incidence of meconium aspiration syndrome.	IIa	B	144,145
Meconium aspiration and acidosis are reduced by amnioinfusion of normal saline.	Ia	A	146

CONCLUSIONS

FETAL HEART RATE MONITORING

- Intermittent fetal heart rate auscultation is advocated as adequate screening for intrapartum fetal hypoxia in low risk women; however, the trials are of insufficient size.
- Electronic fetal heart rate monitoring in high risk labors produces significant reductions in short-term neonatal morbidity and a significant reduction in perinatal deaths due to hypoxia but a significant increase in cesarean section rates; but all studies were insufficiently robust to be able to demonstrate any effect on perinatal mortality or cerebral palsy rates.
- Concomitant use of fetal blood sampling to estimate pH significantly reduces cesarean section rates.
- An "admission test" is commonly used in practice, but there are no studies of sufficient size to evaluate this approach.
- Human error (especially delays in response times and misinterpretation) contributes to poor outcome in monitored labors.
- Corrective actions to consider with an abnormality in electronic fetal monitoring are
  - Correcting caval compression
  - Maternal facial oxygen
  - Correct hyperstimulation (stop oxytocics, use tocolytics)
  - Intravenous fluids if epidural induced hypotension

CONCLUSIONS *(Continued)*

CORD PROLAPSE

- Conventional approaches to this problem are
  - If diagnosed in first stage—relief of pressure on cord while performing an emergency cesarean section
  - If diagnosed in the second stage—expedite vaginal delivery

MECONIUM STAINING OF THE AMNIOTIC FLUID

- Most cases are a reflection of fetal gestational maturity.
- Hypoxia is the cause in a minority and thus this is an indication for continuous electronic fetal monitoring.
- Hypoxia and aspiration of meconium can lead to lung damage.
- The incidence of meconium aspiration and acidosis are reduced by amnioinfusion of normal saline.
- A pediatrician should be present for delivery, but routine oropharyngeal suction in the absence of evidence of fetal hypoxia should not be performed as it does not reduce the incidence of meconium aspiration syndrome.

Central Neuraxial, Analgesia, and Anesthesia in Obstetrics

Lawrence C. Tsen

INTRODUCTION

With the application of diethyl ether to aid in a vaginal delivery in 1847, James Young Simpson, an obstetrician, ushered in the use of anesthetic agents for obstetrics. Over the next half-century, inhaled agents would enable the use and evolution of other agents and techniques in the setting of labor and delivery. Regional anesthetic techniques, which deliver pain relief to a discrete region of the body, were introduced to obstetrics in 1900, when Oskar Kreis described the use of spinal anesthesia. Since that time, central neuraxial techniques, which comprise regional techniques that reversibly interrupt the central neuraxial system, have evolved from single, limited duration injections into the intrathecal sac (spinal) to titratable, controlled infusions through flexible catheters most commonly placed into the epidural space. The combined spinal-epidural (CSE) technique, first introduced to obstetrics in the 1980s, consists of a spinal blockade and an epidural catheter placement during the same procedure (Fig. 72–1).[1] Now rivaling the popularity of the epidural technique, the CSE technique provides rapid and profound initial pain relief with virtually no motor blockade when opioids, sometimes with small amounts of local anesthetics, are used for the spinal injection. Together, the use of the epidural, spinal, and CSE techniques has increased dramatically; in major part, this success has been driven by the quality and safety of the analgesia and anesthesia produced, the ability to titrate the degree and duration of pain relief as required by the circumstances, and an expanding number of situations in which their use is appropriate. Currently, in developed countries, central neuraxial techniques provide labor analgesia for 30% to 50% of all parturients, and the anes-thesia for the majority of instrumental and operative deliveries.[2–4]

In this chapter, the indications and implications of central neuraxial techniques to provide obstetric analgesia and anesthesia will be discussed. Emphasis will be placed on the novel indications for these techniques as well as the association of these techniques with two outcomes of common obstetric and anesthetic concern: progress and outcome of labor and maternal temperature alterations.

INDICATIONS

The use of epidural, spinal, and CSE techniques for vaginal, instrumental, and operative deliveries has been well described in numerous texts and articles.[5–7] The use of these techniques, as well as nonpharmacologic modalities, systemic medications, and peripheral nerve blocks, will be discussed in the obstetric setting. The philosophical shift favoring the use of regional versus general anesthesia will be further elucidated, and two novel obstetric applications of these techniques will be discussed in greater detail: external cephalic version and postoperative pain management.

Although the quality, titratability, and patient satisfaction associated with the use of neuraxial analgesia and anesthesia have increased the use of such techniques, perhaps an even more important reason is the reduction in maternal mortality. In relation to anesthetic interventions, maternal death is overwhelmingly the result of airway management difficulties during the provision of sedative or general anesthetic agents.[8–10] Although in the United States the number of deaths involving general anesthesia has remained stable, the estimated rate of maternal deaths from complications of general anesthesia increased from

Combined spinal-epidural (CSE) technique. *A*, The spinal needle is introduced through the epidural needle and punctures the dura matter. The initial medication is dosed into the subarachnoid (spinal) space. *B*, After the withdrawal of the spinal needle, a catheter is introduced into the epidural space and secured in place. (From Rawal N, Holmström B, Zundert A, et al: The combined spinal-epidural technique. In Birnbach DJ, Gatt SP, Datta S [eds]: Textbook of Obstetric Anesthesia. Philadelphia, Churchill Livingstone, 2000, p 159.)

20.0 to 32.3 deaths per million in the time periods of 1979–1984 to 1985–1990, respectively (Fig. 72–2).[11] In addition, the case fatality ratio for general versus regional anesthesia over the same periods increased from 2.3:1 to 16.7:1. These changes have occurred primarily through an increase in the use of central neuraxial anesthesia and a decrease in its associated maternal mortality rate, and the fact that general anesthesia is now used mainly for high risk emergent cases in which regional anesthesia is avoided owing to the urgency of the case, the failure of neuraxial techniques, or the presence of comorbid conditions.

Despite these trends, central neuraxial techniques may still be underutilized in patients who would benefit from the avoidance of systemic sedation or general anesthesia. This group includes parturients with a high likelihood of having a difficult airway and an operative delivery (e.g., obesity, placenta previa, vaginal births after cesarean [VBACs]). In such parturients, consultation optimally should occur early in the third trimester and shortly following their arrival on the labor and delivery ward. If they are admitted in labor, evaluation should be made regarding the suitability of a neuraxial technique (Table 72–1) and early placement of an epidural catheter should be considered, even if the birth attendants or the woman herself are not sure that a regional block will definitely be required. The catheter need not be dosed immediately; such dosing can occur at a later time when an analgesic or anesthetic is required. This approach will decrease the incidence of "perceived lack of time" as a reason for administering a sedative (such as meperidine) or general anesthetic.[4]

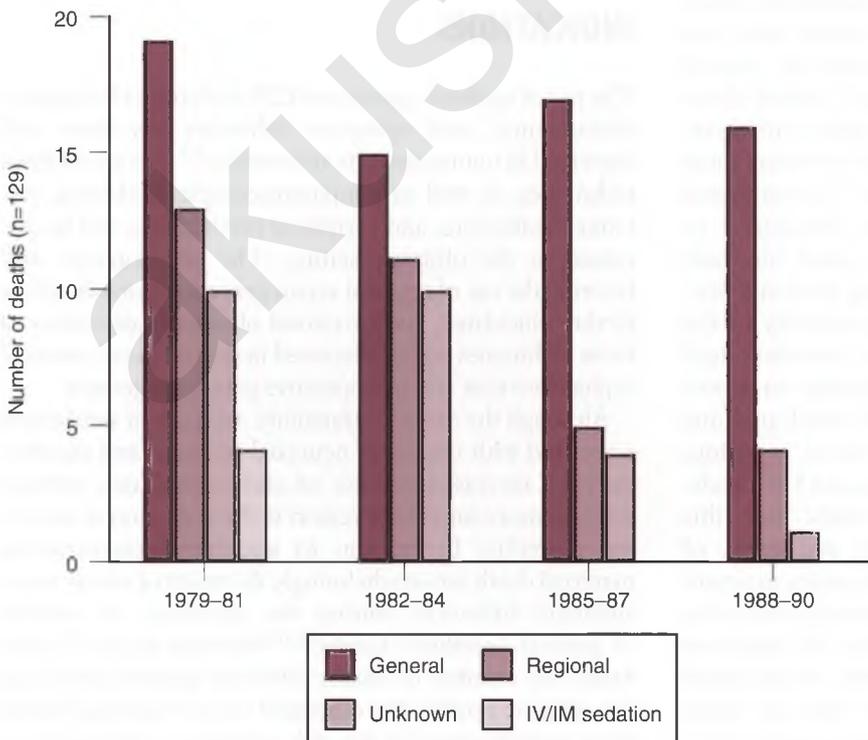
The antenatal consultation should focus on the physiologic changes of pregnancy that can make airway management more difficult. As early as the fourth week of gestation, and particularly with preeclampsia/eclampsia,[12]


FIGURE 72–2

Anesthesia-related maternal deaths by types of anesthesia, United States, 1979–1990. (From Hawkins JL, Koonin LM, Palmer SK, et al: Anesthesia-related deaths during obstetric delivery in the United States, 1979–1990. Anesthesiology 1997;86:277–284.)

TABLE 72-1

Contraindications to Central Neuraxial Anesthesia

Absolute Contraindications
  Patient refusal or inability to cooperate
  Localized infection at the insertion site
  Sepsis
  Severe coagulopathy
  Uncorrected hypovolemia
Relative Contraindications
  Mild coagulopathy
  Severe maternal cardiac disease (including congenital and
    acquired disorders)
  Neurologic disease (including intracranial and spinal cord
    disorders)
  Severe fetal depression

capillary engorgement of the oropharyngeal and respiratory mucosa makes these structures more friable, vascular, and edematous.[13] With labor, the airway structures become further engorged, making the oropharyngeal area even smaller.[14] In addition, the anteroposterior and transverse diameters of the thorax increase during pregnancy, resulting in a substernal angle that, in combination with increases in breast tissue, serve to make laryngoscopy more challenging. Finally, arterial oxygen desaturation occurs more quickly in apneic parturients due to a smaller functional residual capacity and increased oxygen consumption. These alterations make the provision of general anesthesia more challenging; difficult intubations with the need for special airway management devices and techniques were observed in up to 16% of the cases in a 6-year report of general anesthesia performed for cesarean delivery in a tertiary care hospital.[4] Complications such as these have promoted the use of central neuraxial techniques for labor and delivery.

MANAGEMENT OPTIONS FOR PAIN DURING PARTURITION

Nonpharmacologic Techniques

Psychological support and sensory stimulation are two basic classifications of nonpharmacologic modalities for the reduction of pain during labor. The most popular forms of psychological support are "natural childbirth" and "psychoprophylaxis," which were popularized by Dick-Read and Fernand Lamaze, respectively. These methods, which utilize a series of preparative classes to explain the process of labor and teach methods for relaxation and allaying pain, have been observed to reduce the amount of analgesia used,[15] but the degree of pain relief experienced appears limited.[16,17] Potential problems with these techniques include hyperventilation[18] and postpartum depression if analgesic techniques are eventually utilized.[19] Hypnosis, a temporary alteration in consciousness characterized by increased suggestibility, focuses on producing physical and mental relaxation and changing the interpretation of physical stimuli. Although few randomized controlled trials have evaluated the modality, a recent meta-analysis[20] reports that hypnosis can be successful in the management of labor pain. Trained individuals called doulas can also be a source of emotional and physical support during labor. When doulas provide continuous, rather than intermittent, support during labor and delivery, a decrease in analgesia, labor duration, and instrumented deliveries has been observed.[21]

Sensory stimulation, including massage, superficial application of heat and cold, hydrotherapy, acupuncture and acupressure, transcutaneous electrical nerve stimulation (TENS), intradermal sterile water blocks, and music and audio analgesia are all methods of sensory stimulation and have been used with some success during labor. These methods are hypothesized to use innocuous stimuli, such as touch, vibration, and pressure, to compete with painful stimuli at the site of their convergence in the substantia gelatinosa of the dorsal horn of the spinal cord. This competitive inhibition, accompanied by descending messages from the brain cortex and brainstem, is believed to modulate the transmission of pain information. To date, few randomized controlled trials have been performed with these modalities, and thus, only limited conclusions can be drawn. Reviews of trials with labor analgesia produced by acupuncture and TENS demonstrate a high degree of patient acceptability and satisfaction, despite a weak analgesic-sparing effect.[20,22] The novel use of TENS as an adjuvant to other modalities has been investigated. Tsen and associates found that TENS was ineffective in augmenting the duration or quality of analgesia produced by small amounts of spinal or epidural local anesthetics and opiates during labor.[23,24] Overall, despite the limited scientific evidence supporting the analgesic value of these psychological and sensory stimulation modalities, many patients consider them to be an integral and helpful part of their labor experience.

Systemic Medications

Medications given by injection were among the first agents routinely utilized for childbirth pain relief. The combination of scopolamine, an anticholinergic, and morphine to induce a combination of analgesia, sedation, and amnesia termed "twilight sleep" was utilized routinely in the 1950s and 1960s for labor and delivery.[25] Scopolamine, now more commonly utilized as an antiemetic, eventually lost favor to other more effective forms of analgesia with fewer side effects such as delirium, agitation, and excitement.

Oral, subcutaneous, intramuscular, and intravenous injection techniques have all been utilized for administration of systemic labor analgesia. Owing to their more rapid onset and ease of administration, intramuscular

(IM) and intravenous (IV) routes have emerged as the most popular forms. Time to onset, duration, and degree of analgesia with IM analgesic agents can be affected by the habitus of the patient and the site of the injection. Injection into the deltoid muscle, for instance, will result in better absorption than injection into the less perfused gluteus muscle. Patient-controlled analgesia (PCA), which utilizes a pump programmed to give a dose of an IV analgesic on demand outside a defined lock-out period, has created interest, especially when neuraxial analgesia is not available or is contraindicated.[26]

Opioids, despite their side effects of nausea, emesis, drowsiness, dysphoria, hypoventilation, and neonatal respiratory depression, are the most widely used medications for labor analgesia because of their availability and the degree of analgesia produced. Although frequently substituted with meperidine, an agent which results in less neonatal depression at equianalgesic doses,[27] morphine is given in doses of 5 to 10 mg IM or 2 to 3 mg IV for a peak effect in 2 hours and 20 minutes, respectively. Meperidine (trade name Demerol; known as pethidine in Europe), the most commonly used narcotic for labor analgesia, is given in dosages of 50 to 100 mg IM or 10 to 50 mg IV to produce 2 to 4 hours of pain relief. To minimize neonatal respiratory depression, IM administration of meperidine should be avoided within a window of 1 to 3 hours before delivery.[28] (Of course, that is easier said than done; many women thought to be hours away from giving birth deliver suddenly and unexpectedly. In practice, provided that bag and mask ventilation of the neonate and IM naloxone are given, the risk to the baby from IM meperidine is minimal.) Fentanyl, alfentanil, and sufentanil are potent synthetic morphine analogues that are generally not used intramuscularly due to their short duration of action and narrow therapeutic index; with the advent of PCA, however, these agents are being used more frequently.[26] Opioids with agonist/antagonist properties have the advantage of a "ceiling effect" for maternal respiratory depression, and include pentazocine, nalbuphine and butorphanol. Pentazocine is utilized less commonly because of its potential for the psychomimetic effects of dysphoria and a perception of impending death.[29] Nalbuphine and butorphanol are given in IM or IV doses of 3 to 5 mg or 1 to 2 mg, respectively, and are equianalgesic to meperidine with less nausea and emesis.[30]

Tranquilizers such as benzodiazepines and phenothiazines are occasionally used to reduce anxiety during labor and delivery. Diazepam can be used in doses up to 10 mg,[31] but lorazepam and midazolam should be avoided owing to their pronounced neonatal depressant and maternal amnesic effects, respectively. Phenothiazines can be used synergistically to reduce the dose of opioids, thereby increasing sedation and reducing side effects. Hydroxyzine given in doses of 50 to 100 mg IM and promethazine given in doses of 24 to 50 mg IM or 15 to 25 mg IV have been observed to improve maternal analgesia without significant neonatal effects.[32] Promazine, chloropromazine, and prochlorperazine are avoided because of their strong alpha-adrenergic blocking activity, which can produce hypotension.[33]

Barbiturates, such as secobarbital and pentobarbital, can allay anxiety. However, as a class, the efficacy of these agents during labor is limited owing to their lack of analgesic properties, their potential to increase the sensation of pain, and the presence of protracted effects on the newborn.[34] In low doses of 0.2 to 0.5 mg/kg IV, ketamine can produce intense analgesia with limited neonatal effects; however, maternal dysphoric reactions may result.[35] Midazolam 2 to 4 mg IV can decrease these effects. In higher doses of 1 to 2 mg/kg, ketamine can be used as induction agent for general anesthesia; however, when the dose exceeds 2 mg/kg, increases in uterine tone may occur and be associated with lower Apgar scores or abnormally increased neonatal muscle tone.[35]

Inhalational Analgesia

The first form of analgesia used for labor in modern medicine, inhalational analgesia remains popular in many institutions, particularly in Europe. Inhalation of subanesthetic doses of nitrous oxide, trichloroethylene, methoxyflurane, enflurane, isoflurane, and recently, sevoflurane has been used to provide safe and effective analgesia during labor and delivery. Most effective during the early stages of labor, inhaled analgesics are administered either intermittently (i.e., during contractions only) or continuously with the dose regulated according to the patient's response. The most common formulation in current use, a mixture of 50% nitrous oxide and 50% oxygen (Entonox),[36] has been demonstrated to bring relief to approximately 50% of parturients and can be used as an adjuvant, but not a complete analgesic, to a pudendal nerve block for forceps delivery, perineal suturing, or manual removal of the placenta.[37] Advocates who embrace the inhalational technique suggest that it safely provides amnesia and analgesia; those who do not use the technique, cite the possible loss of consciousness, diminished airway reflexes with the associated risk for aspiration and hypoxia, and unscavenged gas pollution of the labor suite. The risk for loss of consciousness and airway reflexes are more commonly witnessed with halogenated agents.

In rare instances, general anesthesia is induced with inhalational halogenated agents (e.g., isoflurane) for vaginal delivery. Two of the more common scenarios include a need for greater anesthesia without time to administer a regional anesthetic (i.e., fetal distress requiring forceps delivery) or a need for maximum uterine relaxation (i.e., need for intrauterine manipulation). In contrast to regional anesthetics, halogenated agents cause uterine relaxation in a dose-dependent manner,[38] with the administration of greater than 0.5% minimum alveolar concentration (MAC) potentially decreasing uterine smooth muscle responses to oxytocin.[39]

Regional Analgesia and Anesthesia

A variety of regional techniques can provide pain relief for labor and delivery. As both expected and unexpected physiologic sequelae may occur following these techniques, intravenous access should be established and resuscitation equipment should be readily available.

Paracervical Block

A technique that relies on blocking the nerve ganglion located immediately lateral and posterior to the cervicouterine junction, the paracervical block is primarily effective for the first stage of labor. Owing to the frequent occurrence of fetal bradycardia, which may result from local anesthetic-induced uteroplacental vasoconstriction or direct fetal myocardial depression, this technique is now used infrequently.[40]

Lumbar Sympathetic Block

By blocking the visceral afferent sensory fibers that accompany the lumbar sympathetic chain, lumbar sympathetic block provides analgesia limited primarily to the first stage of labor. Although seldom used due to the need for multiple injections, this technique has been advocated for labor analgesia due to the near absence of motor blockade.[26,41]

Pudendal Block

Effective for the second stage of labor, the use of outlet forceps, and episiotomy repairs, this block interrupts the terminal nerve transmissions of the pudendal nerve. Owing to the distal nature of the nerve blockade, this form of anesthesia is not effective for midforceps delivery, postpartum examination or repair of the upper vagina or cervix, or exploration of the uterine cavity.[42] Maternal and neonatal blood levels of local anesthetic following a pudendal block are comparable to those seen following an epidural technique.[43]

Perineal Infiltration

Perhaps the most commonly performed local anesthetic technique for labor and delivery, perineal infiltration interrupts pain transmissions from the terminal nerves in the posterior fourchette. Because direct injection into the fetal scalp can occur, the quickly metabolized agent 2-chloroprocaine may be preferable to lidocaine or longer-acting local anesthetics.[44]

Caudal Block

A technique that uses the lowermost segment of the epidural space, the caudal block has lost favor to the higher, more approachable lumbar block. The change to the lumbar approach was also motivated by the association of the caudal block with inadvertent injections of anesthetic into the fetal head, the theoretical increased risks of infection due to a closer proximity to the rectum, and difficulty in extending the cephalad level of the blockade for cesarean delivery.

Antenatal Use of Regional Techniques: External Cephalic Version

Epidural, spinal, and combined spinal-epidural (CSE) techniques have all been used to promote external cephalic version (ECV) and have all been reported to improve success rates compared with control subjects. Schorr and associates[45] randomized 69 patients (all of whom received tocolytics to relax the uterus) to undergo an ECV attempt either with or without epidural anesthesia. In demographically and obstetrically similar groups, the success on the first attempt as well as the overall success rate of ECV was higher in the epidural group (69% versus 32%). No cases of fetal distress or abruptio placentae were observed in either group, and ultimately, vaginal delivery occurred in 66% of the epidural group versus 21% in the control group. In comparison to tocolytics, a preliminary report by Samuels and associates[46] noted greater success with an epidural anesthetic versus ritodrine (29 of 38, 76.3% versus 23 of 38, 60.1%).

Spinal techniques have also been used for ECV attempts, with varying analgesic doses resulting in contrasting results. Dugoff and associates[47] noted no improvement with the spinal administration of bupivacaine 2.5 mg with sufentanil 10 μg (44% versus 42%), whereas Birnbach and associates[48] noted a significant improvement (80% versus 33%) with the use of sufentanil 10 μg alone. Reasons for these contrasting outcomes may reflect differences in obstetric or patient factors, including the amount of force applied or the degree of maternal discomfort tolerated for a given level of analgesia. As a consequence, the ability of spinal analgesia to improve ECV version success requires further investigation. By contrast, when spinal anesthesia (lidocaine 45 mg with fentanyl 10 μg) was used, even in the more difficult setting of previously failed ECV attempts, a high success rate (83%) has been reported.[49]

Whether utilized for primary or failed ECV attempts, a CSE technique with a short duration spinal anesthetic may represent the optimal technique.[49] The short anesthetic duration allows for a timely discharge from hospital in the event of a successful version, and if success or failure results in either a trial of labor or an operative delivery on the same day, the epidural catheter can be left in place to allow additional analgesia or anesthesia to be administered.

Central neuraxial analgesic and anesthetic techniques most likely improve ECV success by relaxing the abdominal wall muscles, improving patient comfort during the ECV attempt, and allowing the obstetrician to make

a more concerted attempt.[48,50] The use of anesthetic techniques for ECV attempts has been associated with an improved maternal and fetal outcome, a reduced need for emergent operative deliveries, and a favorable cost-benefit analysis.[50,51]

Anesthesia for Vaginal Delivery

Spinal Anesthesia

The finite duration of action of a single injection, and an increased risk of a postdural puncture headache with multiple injections, limit the utility of spinal anesthesia for the management of labor. Spinal techniques, however, can be used successfully during delivery, especially in the event of an assisted vaginal breech delivery, the need to use outlet forceps or vacuum extraction, or the repair of extensive tears or lacerations. For these procedures, a low level spinal anesthetic block can be used; in the event of a "trial of forceps," consideration should be given to providing a dose appropriate for a cesarean delivery. Clear communication between the obstetrician and anesthetist on their expectations regarding delivery is essential if the optimal technique is to be chosen. Applications of the spinal technique that offer more flexibility include its use as part of a CSE technique (discussed later) or the placement of a catheter into the spinal space, called a "spinal catheter" or "continuous spinal anesthesia" technique. The benefits of these techniques have been observed particularly in patients with conditions such as morbid obesity and cardiac disorders, or following an unintentional dural puncture with an attempted epidural catheter placement as a method for providing a reliable, precisely titratable blockade.[52] For most patients, however, the spinal catheter option is less attractive, as it most often accompanies the use of epidural equipment (17-gauge Touhy needle to place a 20-gauge catheter), which results in a large dural puncture and a significant risk of a postdural puncture headache. Current trials with smaller needles and catheters for labor and delivery are currently being conducted in the United States and Europe, with the hope that a better understanding of the technique and the medications utilized will avoid the complications observed with earlier trials of microcatheters.[53,54]

COMPLICATIONS

A number of complications may occur following a spinal technique. Hypotension, defined as a 20% to 30% decrease in systolic blood pressure from baseline, can be observed in 20% to 100% of pregnant women and is due to the sympathetic vasomotor blockade produced.[55] If left uncorrected for even a brief period of time, hypotension may result in decreased uteroplacental perfusion with resulting hypoxia and fall in pH of the fetus.[56] Preventive measures include maternal intravascular volume expansion (preloading with IV fluid, usually 500 to 1000 mL of crystalloid such as Hartmann's solution) and avoidance of aortocaval compression, and treatment includes titrated doses of vasopressors such as ephedrine (5–10 mg) and phenylephrine (40–100 μg) given intravenously. The nausea and vomiting following a spinal technique may be associated with reductions in sympathetic tone, blood pressure, and cerebral blood flow and can be reduced significantly with vasopressor use.[57] Postdural puncture headache (PDPH) occurs in approximately 1% to 3% of the obstetric population following a spinal technique and is most likely related to the needle size and tip design, with larger, cutting needles associated with a greater incidence.[58] Typically, a PDPH presents as a positional headache that worsens in the upright position and improves in the recumbent position. The differential diagnosis should include other types of headache, hypertensive disorders, infectious diseases, dural venous sinus thromboses, and other intracranial pathologies. If the diagnosis is a PDPH, bed rest may aid in pain relief,[59] and conservative measures of hydration and oral intake of caffeinated and analgesic products (including Fioricet or Fiorinal) may be used for 24 to 48 hours. An epidural blood patch, whereby 10 to 20 mL of autologous blood is placed in the epidural space, has been associated with a greater than 80% incidence of success in most trials.[58,60] Although the incidence of neurologic complications as a result of spinal anesthesia in the obstetric population is extremely rare,[60] consultation with a neurologist may assist in diagnosis and treatment. Finally, an unexpected high level of anesthesia can result in hypotension, dyspnea, the inability to speak, and a loss of consciousness; ventilatory and circulatory support should always be readily available when this technique is provided.

Epidural Analgesia and Anesthesia

One of the most effective methods of pain relief for labor and delivery,[5] the epidural technique with an indwelling catheter provides a reliable form of analgesia that can be titrated as the situation evolves. Should the need arise for surgical anesthesia for an instrumental or operative delivery, laceration repair, or postpartum tubal ligation, this can be provided with a change in the local anesthetics used through the catheter.

The choice of agents for use in the epidural space depends on the degree of pain relief required. During labor and delivery, adequate sensory analgesia with minimal motor blockade is the goal. Optimally, this would allow the pregnant woman to appreciate a sense of pressure, without pain, during each contraction. Almost every local anesthetic developed has been tested for its value in obstetric analgesia. Of the shorter-acting agents, mepivacaine has been reported as having a prolonged half-life and causing neonatal depression. Chloroprocaine 3% and lidocaine 2% produce surgical anesthesia, and the dense sensory and motor block they produce make them less appropriate for vaginal delivery. The longer-acting agents

are best suited for labor analgesia when used in low concentrations. Bupivacaine, with a high degree of sensory to motor block, is the most commonly used agent for labor epidural analgesia worldwide. Concentrations of 0.0625% to 0.125% are commonly used to initiate and maintain the block. Ropivacaine and levo-bupivacaine are two newer longer-acting agents that, when given in equipotent concentrations to bupivacaine, may result in slightly less motor blockade and cardiotoxic effects.[61,62] The dose, onset, and duration of various local anesthetics for epidural labor analgesia are well characterized (Table 72–2). Although sufficient for many parturients in the first stage of labor, epidural narcotics alone routinely fail during the second and third stages of labor.[63,64] The combination of narcotics with local anesthetics in the epidural space, however, enhances the quality of analgesia and allows a decrease in the total dose of local anesthetic required. Epidural administration of small doses of sufentanil (0.2–0.3 μg/mL) or fentanyl (0.2 μg/mL) combined with the low doses of bupivacaine 0.0625% or 0.125% result in excellent analgesia for vaginal delivery. In addition, an epidural fentanyl bolus of 50 μg, with or without local anesthetic, can be of assistance during the second stage of labor when patchy analgesia or perineal sparing cannot be remedied with local anesthetics alone.[65]

Once the initial sensory blockade has been established, epidural analgesia can be maintained by intermittent bolus injections, a continuous infusion, or both techniques simultaneously. The development of inexpensive infusion pumps has offered perhaps the optimal method: a continuous infusion coupled with patient-controlled intermittent bolus top-up injections through the epidural catheter. This combined method reduces the total amount of medication used, decreases the amount of motor blockade, and increases patient satisfaction when compared to continuous infusions or intermittent bolus methodologies alone.[66,67]

Combined Spinal-Epidural Analgesia

Introduced in the early 1980s for surgical procedures, the CSE technique, with a few modifications, has become one of the most popular techniques for labor analgesia. The technique consists of epidural needle placement, intraspinal medication administered via a spinal needle placed through the shaft of the epidural needle into the subarachnoid space, and then placement of an epidural catheter. In comparison to the epidural or spinal techniques alone, the CSE technique has a number of advantages (Table 72–3). A mixture of local anesthetics with narcotics appears to be the optimal combination for initial labor analgesia with this technique, and its application, even early in labor, may have beneficial effects on the progress of labor.[68] Used later in labor, the CSE technique can provide quick onset of analgesia and the ability to extend the duration or level of the blockade should delivery methods mandate such augmentation.

COMPLICATIONS

Relatively few complications are inherent to the CSE technique. The risks of a dural puncture with the epidural needle may actually be reduced, as the spinal needle, when placed in through the shaft of the epidural needle, emerges 10 to 15 mm beyond the tip of the epidural needle.[69] The emergence of cerebrospinal fluid through the spinal needle indicates that the dura has been traversed and thus serves to locate the relative position of the tip of the larger epidural needle. The likelihood of the epidural catheter passing through the spinal needle dural puncture site is low, based on laboratory-based and clinical studies.[70] Drugs placed in the epidural space can pass through the dural hole created by the spinal needle and there is a theoretical possibility of producing a dense or high spinal blockade. In the majority of cases, however, the amount of medication is very

TABLE 72-3

Advantages of the Combined Spinal-Epidural Technique for Labor Analgesia

Advantages over an Epidural Technique

More rapid onset

Lower maternal, fetal, and neonatal blood concentrations of local anesthetic than with epidural techniques alone.

Better sacral analgesia

Assists in identification of the epidural space in technically difficult placements

Advantages over a Spinal Technique

Allows ability to titrate the level, density, and duration of the blockade

Catheter can be used for postoperative pain management

---

limited and may actually improve sacral or perineal analgesia[71]; the risk of a high spinal blockade appears in practice to be negligible.

The failure of subsequent medication given through the epidural catheter to produce adequate analgesia/anesthesia is of greater concern. Because the spinal portion of a CSE technique gives an initial period of analgesia, the epidural catheter that has been placed is "untested" and may not be reliable as a route for further injection of anesthetic should an emergency arise. Although epidemiologic evidence suggests that the epidural catheter following a CSE technique has a lower failure rate than a solely epidural technique,[72] in those parturients with a difficult airway or a high probability of an instrumental or operative delivery, a standard epidural technique, which tests the function of the catheter at the time of placement, may be safer.

MANAGEMENT OPTIONS FOR ANESTHESIA FOR CESAREAN DELIVERY

Despite repeated calls to reduce the rate of cesarean deliveries from both lay and professional organizations in the United States and Europe, the incidence of surgical delivery continues to increase. Although there is now a long history of safety improvements for general anesthesia for cesarean delivery, the majority of maternal deaths due to anesthesia still occur during the actual or attempted provision of general anesthesia. However, in deciding between regional and general anesthetic techniques, the urgency of the procedure, the health and comorbidities of the mother and fetus, and the desires of the mother and health care providers all need to be considered.

Spinal Anesthesia

A simple and reliable technique with rapid onset, spinal anesthesia optimally provides an awake and comfortable patient with minimal risks for aspiration. Despite the lower abdominal incision, a T4 dermatome level is required to prevent referred pain from traction on the peritoneum and uterus. The type and dose of local anes-

thetic medications used to provide the spinal anesthetic must include consideration of the level of medication desired, the duration of the surgery, the postoperative analgesia plan, and the preference of the anesthesiologist. Hyperbaric bupivacaine is the agent most commonly used because it provides a blockade of long duration while avoiding the extensive motor block produced by tetracaine. The potential toxicity advantages of ropivacaine and levo-bupivacaine are limited given the extremely small doses of agent used. The use of adjuvant spinal medications, such as narcotics and epinephrine, may augment the quality and duration of the anesthesia and analgesia.[73,74]

Following the administration of a spinal technique, the patient may complain of dyspnea. Dyspnea can be due to several factors, including the blunting of thoracic proprioception, the partial blockade of abdominal and intercostal muscles, and the recumbent position increasing the pressure of the abdominal contents against the diaphragm. Despite these changes, significant respiratory compromise is unlikely as the blockade rarely affects the cervical nerves that control the diaphragm. Should the patient lose the ability to vocalize, give a strong hand grip, or demonstrate normal oxygen saturation by pulse oximetry, a rapid sequence induction with cricoid pressure and placement of an endotracheal tube can be performed to maintain ventilation and prevent pulmonary soiling with gastrointestinal contents.

The most common complications of spinal anesthesia have been described earlier and include hypotension, nausea and vomiting, and the risk of a postdural puncture headache. Hypotension presents the greatest risk to maternal and fetal comfort and health[55]; prevention and prompt treatment with infusion of IV fluid and administration of vasopressors have been noted to be beneficial but, on occasion, not completely successful.[75,76] In terms of volume expansion, spinal anesthesia in the urgent setting should not be delayed until a fixed, arbitrary volume has been infused. In addition, aggressive hydration with large fluid volumes (greater than 20 mL/kg crystalloid) may increase the risk of edema with only limited reductions in hypotension.[75] Colloid solutions appear more effective than crystalloids in preventing the hemodynamic consequences of spinal anesthesia[77] but have allergic,

cost, and coagulation implications. Current investigations in vasopressors for prevention and treatment of hypotension in this setting include the use of phenylephrine, sometimes in combination with ephedrine, and the use of infusion pumps.[78]

Epidural Anesthesia

Epidural anesthesia for cesarean delivery has increased since the 1980s, primarily due to the widespread use of the epidural technique for labor analgesia; the use of epidural anesthesia for cesarean section has also increased. Although medications used in the spinal and epidural space are identical, epidural doses are 5 to 10 times greater and of much larger volumes to encourage adequate blockade and spread. These dose alterations can be explained primarily by anatomic differences in nerve exposure and the capacity of the spaces.

Advantages of the epidural technique include a lower incidence and degree of maternal hypotension due to the ability of the compensatory mechanisms to respond to the more slowly developing sympathetic blockade. In addition, if a catheter is used, the level, density, and duration of the anesthesia can be titrated. The greater sensitivity of nerves to local anesthetics during pregnancy has been observed clinically through a decrease in anesthetic requirements for epidural blockade.[79,80] For cesarean delivery, the most common agents used are 2% lidocaine with epinephrine 1:200,000 and 3% 2-chloroprocaine. Chloroprocaine is the agent of choice for emergency cesarean deliveries because of its rapid onset and rapid maternal and fetal metabolism; fetal accumulation, especially when acidosis is present, is therefore minimized.[81] By contrast, chloroprocaine is avoided for routine, nonurgent deliveries as the short duration requires multiple doses, and its use can adversely affect the efficacy of subsequent epidural opioid analgesia.[82] In addition, when used in higher total volumes (>40 mL), chloroprocaine can increase the incidence of back pain.[83] Alkalinization with sodium bicarbonate hastens the onset time of local anesthetics significantly and is recommended for use in urgent cesarean deliveries;[84] caution must be applied in its use, however, as certain local anesthetics (particularly bupivacaine) have a low threshold for precipitation.[85]

The complications of epidural anesthesia have been described previously and include hypotension, risk of postdural puncture headache, systemic toxic reactions, and rarely, neurologic complications. Epidural techniques can provide patchy or inadequate blockade due to anatomic or technical reasons;[86] often, these failures can be identified a priori through observation of the degree of labor epidural analgesia, or quickly after partial augmentation of the blockade. Alternative techniques, such as supplementation with intravenous or inhalational agents, spinal anesthesia, or general anesthesia, must always be considered as options.

Combined Spinal-Epidural Anesthesia

The principal advantage of the CSE technique is the ability to augment the density or duration of the anesthesia through the use of the epidural catheter. This is particularly useful in obstetrics, in which a delay in the timing prior to or during surgery can potentially occur (e.g., possible placenta accreta, history of multiple abdominal surgeries, high index of suspicion for gravid hysterectomy). A guiding principle in the selection of the CSE technique is whether the parturient appears to have an airway that would be difficult to intubate; a patient who presents as an intubation risk would perhaps be better served by avoiding the CSE technique, as the epidural catheter is "untested" and may not provide optimal anesthesia when needed.

Contraindications to Regional Anesthesia

Although regional anesthesia is used whenever possible to avoid the potential airway complications associated with general anesthesia, certain conditions or time constraints may contraindicate its use.[4] Such comorbidities include localized infection or generalized sepsis, coagulations disorders, severe hypovolemia, or cardiac disorders in which hypotension may be detrimental. Severe obstetric hemorrhage in the antepartum period, including uterine rupture and acute, severe fetal distress, may also contraindicate regional anesthesia procedures because of the time necessary to establish a surgical anesthetic.

Patients with severe preeclampsia or hypertension may undergo rapid hemodynamic changes with regional techniques; however, both epidural and spinal techniques can and have been used successfully in this setting.[87,88] In addition, gravid hysterectomies have been performed safely with regional techniques.[89] Overall, however, if questions exist regarding the ability of maternal compensatory mechanisms to react to the regional anesthetic or surgery, general anesthesia should be considered.

General Anesthesia

There are few, if any, absolute contraindications to general anesthesia; however, regional anesthesia remains a preferred method to avoid the risks of airway management and allow the patient the ability to witness the delivery. General anesthesia, however, may offer advantages when uterine relaxation would be beneficial; such cases include difficult breech extractions, retained placenta, uterine inversion, or in utero fetal surgery.

The importance of proper airway evaluation, during the antenatal period or in early labor if possible, cannot be overemphasized, as failed intubation, failed ventilation and oxygenation, and pulmonary aspiration of gastric contents are the leading anesthetic causes of maternal death.[90,91] If the airway evaluation suggests the possibility of a difficult intubation, strong consideration should be

given to the establishment of a continuous neuraxial technique early in labor.[92] If a difficult airway is discovered upon an intubation attempt, options include allowing the patient to awaken, using alternate techniques to place an endotracheal tube, or using alternative airway devices. The laryngeal mask airway (LMA), although not able to prevent pulmonary soiling with gastric contents as efficiently as an endotracheal tube, can be a lifesaving measure in failed intubation situations,[93] and has been used safely in elective cesarean deliveries.[94]

Attempts should be made to minimize the risk of maternal aspiration, even when the need for intubation is not anticipated. With an elective cesarean delivery, adherence to a nil per os (NPO, nil by mouth) policy for 8 hours prior to surgery is advised. A nonparticulate antacid is believed to decrease the damage to the respiratory epithelium if aspiration occurs,[95] and H_2 antagonists (cimetidine, ranitidine) and promotility agents (metoclopramide) can reduce gastric acid secretion and facilitate emptying, respectively.[96,97]

Preoxygenation and denitrogenation with 100% oxygen reduces the rapidity of onset of any hypoxemia due to the parturient's decreased functional residual capacity and increased oxygen consumption. In urgent situations, four vital capacity breaths of 100% oxygen will provide adequate preoxygenation.[98] Succinylcholine is given with a defasciculating dose of a nondepolarizing agent and can be continued as an infusion, or a short-acting nondepolarizing agent can be used alone. Although nitrous oxide is often used in concentrations of 50% until delivery, the addition of halogenated volatile anesthetics reduces the response to surgical stimulation, although it also reduces awareness, which may be less desirable.[99] The 25% to 40% increase in sensitivity to halogenated agents during pregnancy allows lower doses to be used;[100] this may be of benefit in attenuating the side effects of volatile agents, which reduce uterine tone and interfere with the action of oxytocin.[101] Comparisons of neonatal outcomes following general versus epidural anesthesia for cesarean delivery suggest small, transient differences;[102] however, with either technique, when the uterine incision to delivery is greater than 180 seconds, lower Apgar scores and greater fetal acidosis have been observed (although this may reflect relative difficulty in delivery of the baby rather than the direct effects of the anesthetic agents).[103] Later redistribution of general anesthetic agents from the fetal fat to the circulation can result in secondary depression of neonatal ventilatory effort; and the presence of a pediatrician in such cases is probably advisable until a normal ventilatory pattern is observed.

MANAGEMENT OPTIONS FOR POSTOPERATIVE PAIN

Since 1979, when Wang and associates[104] published the first report of spinal opioid administration in humans,

the analgesic efficacy of epidural and spinal opioids has been demonstrated by numerous investigations.[105] By directly activating spinal and supraspinal opioid receptors, epidural and spinal opioids blunt nociceptive input and produce analgesia of greater intensity than doses administered parenterally or intramuscularly (Fig. 72–3).[106,107] As such, a number of opioids, including meperidine, fentanyl, sufentanil, hydromorphone, diamorphine, methadone, buprenorphine, and butorphanol, have been utilized in the epidural and spinal spaces (Table 72–4). Morphine, however, has emerged as the most common agent used internationally for postcesarean delivery pain management owing to its long duration of action and low cost.

In the epidural space, the low lipid solubility of morphine slows the penetration into the spinal tissues. This results in peak analgesic effects that are delayed 60 to 90 minutes[108] but persist to provide reliable analgesia for up to 24 hours.[108,109] Up to 5 mg of epidural morphine has been used for postcesarean analgesia, although lower amounts have been utilized with similar success.[109–111] In a prospective, randomized manner, Palmer and associates[111] performed a dose ranging study of 1.25 to 5 mg of morphine used epidurally for postcesarean analgesia, and observed that the quality of analgesia increased to a dose of 3.75 mg; increasing the dose further to 5 mg did not further improve analgesia. Of interest, the side effects of pruritus and nausea were not dose-related. The use of an infusion of naloxone, a narcotic antagonist, can reduce the severity but not the incidence of pruritus following epidural morphine.[112]

The choice of local anesthetic for epidural anesthesia may influence the efficacy of epidural morphine. Kotelko

TABLE 72-4

Neuraxial Opioids

OPIOID	EPIDURAL DOSE	SPINAL DOSE	DURATION (H)	COMMENTS
Morphine	2.5–5 mg	0.1–0.2 mg	18–24	Gold standard
Fentanyl	50–100 μg	10–20 μg	3–4	Useful as an intraoperative adjuvant
Sufentanil	10–20 μg	5–10 μg	3–4	Useful as an intraoperative adjuvant
Meperidine	25 mg		2–3	
Hydromorphone	1 mg		12	
Methadone	4–5 mg		5–6	
Diamorphine	2.5–5 mg		5–15	Not available in United States

and associates[113] observed that postcesarean analgesia was significantly reduced, usually to less than 3 hours, in patients who received 2-chloroprocaine (a short-acting, rapid-onset local anesthetic used primarily for emergent cesarean deliveries) versus other local anesthetics.

Continuous, low concentration epidural infusions of local anesthetics with opioids may also offer an analgesic option in patients in whom prolonged duration and level of analgesia are desired.[114] The infusion of low doses of bupivacaine combined with either fentanyl or morphine has been noted to provide good postcesarean analgesia and can be operated via patient-controlled infusion pumps.[115]

The delivery of a single spinal dose of opioid has also become an attractive option for postcesarean analgesia. With a duration of action (18 to 24 hours) and side effect profile similar to its use in the epidural space, morphine has also become the leading opioid utilized spinally.[116,117] Owing to the direct access to opioid receptors, such agents are given spinally at approximately one tenth of their epidural dose. Despite this degree of access, morphine still requires 45 to 60 minutes for peak effect. Palmer and associates[73] observed little advantage in utilizing greater than 0.1 mg of morphine for postcesarean analgesia when compared to doses up to 0.5 mg; a greater incidence of pruritus, but not nausea and vomiting, was noted with higher doses.

Postoperative analgesia has been greatly improved through the use of central neuraxial techniques, most commonly provided through a single-dose administration of morphine. Given in the spinal and epidural compartments, opioids provide an enhanced quality and duration with a very acceptable side effect profile when compared to oral or intravenous analgesics.

MANAGEMENT OPTIONS FOR ANALGESIA AND ANESTHESIA IN HIGH RISK PARTURIENTS

Invasive Monitoring (See also Chapter 80)

Although the noninvasive measurement of blood pressure, heart rate, oxygen saturation, urinary output, and fetal cardiotocography is standard practice in most modern labor and delivery facilities, the use of invasive monitors is variable and controversial. Monitoring data, and particularly those from invasive hemodynamic monitors, are best interpreted in relation to all pertinent medical history and physical findings. However, the interpretation of data from cardiovascular monitors remains difficult, despite practice guidelines written by a number of professional organizations, including the joint task force of the American College of Physicians, the American College of Cardiology, and the American Heart Association.[118] A number of studies suggest that the poor collection and incorrect interpretation of hemodynamic data from invasive monitors remain the key problem with their use.[119,120]

In addition to understanding the data produced, knowing when to use invasive monitoring is a vital clinical skill. The indications for invasive arterial blood pressure monitoring during pregnancy are relatively straightforward and include a desire to more carefully manage blood pressure, the lack of reliable noninvasive cuff measurements, the need for vascular access for blood studies, and the planned use of certain hemodynamic agents. By contrast, the indications for invasive central monitoring are not as clear or uniformly accepted. A central venous pressure (CVP) catheter is often placed to yield an approximation of volume status (or to follow a trend in blood loss or replacement therapy) and give a greater understanding of the mechanical phases of the cardiac cycle. Management of oliguria unresponsive to a fluid challenge, pulmonary edema, and refractory hypertension are clinical situations in which some clinicians desire CVP monitoring.

Although a pulmonary artery (PA) catheter can also assist in determining the etiology of pulmonary edema, oliguria with a normal CVP, or cardiovascular failure, its use is the most controversial. Advocates of PA catheter use suggest that it can provide information on left and right ventricular function, systemic vascular resistance, and cardiac output. Detractors question the validity of the data, noting that in the setting of preeclampsia, for example, the correlation between CVP and the pulmonary capillary wedge pressure (PCWP) is unreliable

TABLE 72–5

Pulmonary Artery (PA) Pressures Observed with Different Etiologies of Pulmonary Edema

ETIOLOGY	PA WEDGE PRESSURE	STROKE WORK INDEX
Left ventricular dysfunction	Increased	Decreased
Altered capillary permeability	Normal	Normal or increased
Low hydrostatic-oncotic pressure	Increased	Normal

From Benedetti TJ, Kates R, Williams V: Hemodynamic observations in severe preeclampsia complicated by pulmonary edema. Am J Obstet Gynecol 1985;152:330–334.

when the CVP reading exceeds 6 cm H_2O.[121] In deciding between a PA versus CVP catheter, the clinician should recognize that although the insertion-related complications are similar,[124] the PA catheter is associated with more use-related complications including balloon rupture, pulmonary infarction, valvular damage, and erosion of the pulmonary artery. Thus, the benefits of PA catheter use should clearly outweigh its inherent risks before it can be recommended; the 1999 practice guidelines of the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia state that "the decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors."[125] To date, although PA catheter use has been reported in parturients (primarily with cardiac disease), no controlled trials are available that confirm the benefit of PA catheter monitoring on maternal or fetal outcome. This being noted, the PA pressures observed with different etiologies of pulmonary edema are shown in Table 72–5.[122] Similarly, the PA pressures observed with different etiologies of oliguria are shown in Table 72–6.[123]

Despite being noninvasive (unless a transthoracic probe is placed for echocardiography), future modalities for hemodynamic monitoring may offer greater advantages than currently available. These monitors include Doppler ultrasound and two-dimensional echocardiography, which are able to give detailed, dynamic information on cardiac structures and function.[126]

Hypertensive Disorders of Pregnancy

Whether preexisting, gestational, or a function of preeclampsia or eclampsia, hypertension is a common medical problem in parturients and is associated with higher maternal, fetal, and neonatal mortality and morbidity. Preeclampsia, with its systemic vasoconstriction, intravascular volume and protein depletion, and simultaneous retention of extravascular sodium and water, is of particular concern to anesthesiologists. In addition to individual organ dysfunction, abnormalities in coagulation, and edema of the brain, larynx, and lungs may occur. Medical management of blood pressure should be optimized prior to obstetric or anesthetic interventions if possible, and control with labetalol and hydralazine or infusions of nitroglycerin or nitroprusside should be commenced with arterial and central venous monitoring in severe cases. Prehydration to maintain CVP has been demonstrated to improve urine output, maintain mean arterial pressure, and decrease diastolic pressure.[127] If oliguria persists after normalization of the CVP (usually between 2 and 3 cm H_2O), or the physiologic state is complicated with pulmonary edema or cardiovascular decompensation, a PA catheter may be helpful. A cardiology consultation and an assessment of cardiopulmonary function with a transthoracic echocardiogram may also assist with the diagnosis and management. The course of preeclampsia can be complicated by mild to severe coagulopathy even in the presence of a normal platelet

TABLE 72–6

Pulmonary Artery (PA) Pressures Observed with Different Etiologies of Oliguria

ETIOLOGY	PA WEDGE PRESSURE	LEFT VENTICULAR FUNCTION	SYSTEMIC VASCULAR RESISTANCE	TREATMENT
Low volume	Low	Increased	Increased	Fluid
Renal arteriospasm	Normal	Normal	Normal	Hydralazine
Decreased cardiac output	Increased	Decreased	Increased	Decrease/restrict fluid

count.[128,129] For the benefit of both obstetric and anesthetic management, if the initial platelet count is less than an arbitrary 70 to 75 cells/L^{-9}, the clinical history and the results of additional studies such as a PT/PTT (prothrombin time/partial thromboplastin time) or a thromboelastograph should be reviewed. A risk-benefit analysis will ultimately determine the anesthetic technique of choice and whether the administration of blood products such as fresh frozen plasma or pooled platelets should commence prior to any intervention.

During labor, epidural analgesia offers the advantage of limiting pain or stress, thus reducing catecholamine release, decreasing maternal blood pressure, and indirectly increasing placental perfusion.[127] Epidural anesthesia can also be a preferred technique for cesarean delivery due to the ability to slowly titrate the dose of medications as an aid to the management of blood pressure. The possibility of spinal technique–induced hypotension should not necessarily eliminate this anesthetic option. Although data are limited, one small prospective randomized study of preeclamptic women did not reveal significant blood pressure differences between spinal and epidural anesthesia.[130] A retrospective study of women with severe preeclampsia also observed that the incidence of hypotension was not different between spinal or epidural anesthesia use.[131] As a method of avoiding general anesthesia, spinal anesthesia is a viable option.

Because of the hypovolemia associated with preeclampsia, the use of antihypertensive medications, and the administration of magnesium as seizure prophylaxis, marked hypotension may develop as a result of the sympathectomy produced by neuraxial techniques. Restraint, however, is advocated when responding pharmacologically to hypotension; patients with hypertensive disorders may be exquisitely sensitive to these agents. The induction and emergence from general anesthesia can be associated with reflex hypertension and result in ruptured aneurysms and pulmonary edema.[132] This hypertension can be blunted with a number of agents, including β-blockers, calcium-channel blockers, hydralazine, nitroprusside, nitroglycerine, trimethaphan, and narcotics. Finally, airway changes, including worsening edema, may be encountered in preeclamptic patients and preparations for the management of a potentially difficult airway should be made.

Cardiac Disease

Cardiac disease is becoming increasingly prevalent during pregnancy. Although stable in overall adult prevalence, coronary heart diseases (including those associated with hypertension) and valvular pathologies have become more relevant as the parturient population ages. More significant, however, is the dramatic increase in adult patients who have benefited from improvements in the diagnosis, treatment, and surgical correction of congenital heart disorders (CHDs). In the United States alone,

adults with CHDs have grown from an estimated 300,000 in the 1980s to an anticipated 1.4 million in the year 2020.[133] Many of these individuals are women of childbearing age, and with pregnancy, CHD can have profound effects on maternal and fetal outcome.

At one time, general anesthesia was regarded as the method of choice for all cesarean deliveries in patients with both acquired and congenital heart disorders. However, with advances in the understanding of cardiac disorders and the effects of anesthesia, especially in the relation to the anomalous or diseased myocardium, regional techniques have been reconsidered. Regional anesthesia has many beneficial effects, including the ability to provide pain relief, decrease the release and effects of catecholamines, and avoid airway manipulation. General anesthesia can result in moderate, sometimes detrimental inotropic and chronotropic alterations in heart physiology, especially during the induction, intubation, and extubation periods.

The independent and related complexities of cardiac disorders and pregnancy make the sharing of patient data with all interested parties of vital importance. As the cardiac alterations of pregnancy usually plateau from the 20th to 24th gestational weeks until the onset of labor, this represents an ideal time to assess whether adequate compensation is occurring. This is not to say that decompensation cannot occur prior to this period or at any time during the peripartum experience. Although benign arrhythmias occur commonly without symptoms or sequelae during pregnancy,[134] in the setting of corrected congenital cardiac lesions, hemodynamic compromise may result. Communication with the patient's cardiologist is vital, and a full analysis of prior diagnostic studies should be made. Despite the presence of CHD, other causes of arrhythmias or decompensation (electrolyte and thyroid abnormalities, magnesium use, etc.) should be evaluated. Should complete cardiopulmonary arrest occur late (after the 24th week) in pregnancy, an event that occurs in approximately 1 in 30,000 pregnancies,[135] resuscitation must consider both maternal and fetal health. Rapid CPR (cardiopulmonary resuscitation), intubation, prevention of aortocaval compression with uterine displacement, and immediate delivery within 4 to 5 minutes of maternal cardiac arrest may maximize the chances of maternal and fetal survival.[136] In terms of medications, intubation, and defibrillation protocols, there are no alterations to the basic ACLS (advanced cardiorespiratory life support) algorithms.[136]

Acquired Cardiac Disorders

Despite the widespread use of antibiotics, in many parts of the developing world rheumatic heart disease remains the leading cause of cardiac abnormalities in women of childbearing age.[137] Valvular lesions include mitral stenosis (75%–90%), mitral regurgitation (6%–12%), aortic regurgitation (2%–5%), and aortic stenosis (1%).

In general, the primary goal with stenotic lesions is to maintain a normal to slow sinus heart rate with preservation of systemic vascular resistance (SVR). These goals are particularly important when controlling the physiologic responses to central neuraxial blockade, which can often dramatically reduce the SVR (i.e., cause hypotension) and result in compensatory tachycardia. Incremental titration of catheter-based epidural or spinal techniques, or initial use of spinal analgesia with narcotics alone, can limit the sympathetic blockade produced by local anesthetics. Treatment of hypotension with phenylephrine (an α-adrenergic vasopressor) may avoid the tachycardia observed with the use of ephedrine (a combined α- and β-adrenergic vasopressor). In contrast to stenotic lesions, regurgitant valvular disorders, such as mitral and aortic insufficiency, are best managed with normal to slight increases in sinus heart rate and reductions in SVR. Thus, the sympathetic blockade observed with central neuraxial blockade can be beneficial in providing afterload reduction and minimizing the influences of stress catecholamines on SVR. Preserving venous return and intravascular volume are important; however, on occasion, the normally helpful increased intravascular volume of pregnancy or the rapid return of SVR following delivery can result in left ventricular failure and pulmonary edema.[138]

Congenital Cardiac Disorders

Congenital heart disease in the adult is not simply a continuation of the childhood experience. The growth of the cardiac chambers allows arrhythmias to change in character and frequency and ventricular dysfunction and failure to occur. Bioprosthetic replacement valves and conduits can also fail over time, often as a result of adult comorbidities or conditions, including pregnancy. With some congenital disorders, a complete repair is made and cardiovascular function, pressures, and blood flow patterns develop relatively normally. For the most part, these individuals require no special treatment. However, three important differences should be recognized: First, as some cardiac disorders are inherited, fetal echocardiography at 20 to 24 weeks' gestation is desirable. Second, antibiotic prophylaxis may be warranted. Third, arrhythmias are more common as the scar tissue in the heart can act as an arrhythmogenic focus. Other disorders, however, may present as uncorrected or partially corrected lesions in decompensated or poorly compensated states, thereby making the anesthetic management more challenging. The most commonly observed congenital heart disorders during pregnancy include left-to-right shunts, tetralogy of Fallot, Eisenmenger syndrome, and aortic coarctation (see Chapter 37).

The physiologic impact of a small septal defect or a patent ductus arteriosus is usually a trivial to modest left-to-right intracardiac shunt. In general, modest left-to-right shunts are well tolerated during pregnancy, although several alterations in management have been suggested.[139] Because air embolization may occur through intravenous lines, or with the loss-of-resistance-to-air technique of epidural placement, the use of air filters and alternate (loss-of-resistance-to-saline) epidural placement techniques is recommended.[140] In addition, as increases in pulmonary vascular resistance with hypoxia, hypercarbia, and acidosis may allow for reversal of shunt flow, the application of supplemental oxygen appears prudent. Finally, the overall management goal for these defects should focus on limiting maternal catecholamine and systemic vascular resistance (SVR) increases. In this regard, the use of central neuraxial analgesia provides exceptional control; however, the block should be administered slowly, as rapid decreases in SVR may result in a pronounced right-to-left shunt with maternal hypoxemia.[139]

Parturients with uncorrected or partially corrected cyanotic congenital heart disease (i.e., right-to-left shunts) may tolerate pregnancy poorly. Management focuses on maintaining adequate SVR, intravascular volume, and venous return and preventing increases in PVR (often due to pain, hypoxemia, hypercarbia, and acidosis). The use of supplemental oxygen and the use of arterial and central venous catheters may facilitate care and hemodynamic management. The use of pulmonary artery catheters remains controversial owing to difficulties in placement, the risk of pulmonary artery rupture and cardiac arrhythmias, and the limited information obtained in the setting of a severe fixed pulmonary hypertension and a large intracardiac shunt.[141] Neuraxial analgesia produced with intrathecal opioid administration may minimize decreases in SVR, and if provided with a CSE technique, the judicious addition of epidural local anesthetics can be titrated as needed. In the event of a cesarean delivery, regional anesthesia remains preferable to general anesthesia owing to the diminished cardiac output that can occur from halogenated agents and positive pressure ventilation. If regional anesthesia is contraindicated, a controlled versus rapid sequence induction of general anesthesia minimizes critical decreases in SVR and myocardial function. Regardless of the technique employed, hemodynamic alterations must be promptly resolved, and ephedrine and dopamine, rather than phenylephrine, are vasopressors of choice because of their maintenance of both SVR and heart rate.

Diabetes

Analgesic and anesthetic management of diabetic parturients should focus on glucose management and the responses of the physiologic systems most affected: coronary, cerebral and peripheral vascular, gastrointestinal, renal, and autonomic systems. The analgesia and anesthesia produced by neuraxial techniques can increase placental perfusion through reductions in maternal catecholamines and decrease the incidence of fetal acidosis occurring with maternal labor hyperventilation. The

cardiovascular, autonomic, and uteroplacental blood flow changes caused by diabetes make the prevention and early treatment of hypotension a significant concern. The frequent and severe maternal hypotension witnessed in diabetics can be associated with spinal and epidural anesthesia for cesarean delivery;[142] however, it is possible that dextrose-containing IV fluids may have played a role. With strict observation and reaction to maternal blood pressure, volume expansion with a non-dextrose-containing solution, and maternal glucose control, spinal anesthesia can be performed without an associated fetal acidosis.[143]

In addition to the improved hemodynamic control seen with the slow initiation of epidural analgesia and anesthesia, this technique may offer other beneficial effects during labor and delivery. Insulin resistance has been demonstrated to occur in a dose-response relationship with the amount of stress following surgery, burns, trauma, and sepsis. More recently, pain per se has been demonstrated to impair insulin sensitivity by affecting nonoxidative glucose metabolism.[144] Although studies have not been performed in laboring diabetic parturients or even in females, this suggests that glucose regulation can be improved by the administration of pain relief in stressful states. Indeed, when epidural anesthesia was compared to general anesthesia as a control group, an attenuation of the hyperglycemic response to abdominal surgery was observed through a modification of glucose production, without affecting glucose utilization.[145] Protein metabolism, by contrast, was not influenced by epidural blockade. These investigations suggest a possible benefit from the use of neuraxial analgesia and anesthesia in parturients with diabetes.

If general anesthesia is required, the possibilities of gastroparesis, limited atlanto-occipital joint extension, and impaired counterregulatory hormone responses to hypoglycemia should be considered and integrated into the management.[146]

EFFECTS OF NEURAXIAL ANALGESIA ON PROGRESS AND OUTCOME OF LABOR

Whether central neuraxial analgesia affects the progress and outcome of labor remains a controversial topic. The myriad of maternal and fetal variables adds complexity to the issue, as well as differing institutional and individual anesthetic and obstetric practices. Moreover, the contemporary pattern and progress of labor appears slower than previously described a half a century earlier by Friedman.[147] Zhang and associates,[148] noting a significant delay in the progress of labor in nulliparous women, pointed to several factors possibly responsible including higher maternal age and weight, increasing fetal size, and higher induction and epidural use rates. Together, these changes make practice patterns and outcomes difficult to compare.

Study Design Issues

The greatest challenge in uncovering an association between neuraxial analgesia and progress of labor is that the ideal prospective, randomized, double-blinded, placebo-controlled study is exceptionally difficult, if not impossible, to perform. Retrospective or nonrandomized studies may underestimate the importance of confounders. For instance, women requesting epidural labor analgesia may be inherently different from those choosing natural childbirth; such differences have included having smaller pelves, more occiput posterior fetal presentations,[149] greater use of oxytocin for induction or augmentation, and more painful labors (which may be associated with slower labor and instrumental delivery).[150] Moreover, in nulliparous parturients with larger fetuses and eventual dystocia, a requirement for larger amounts of epidural local anesthetic for pain relief has been reported.[151–153]

The complexity of assessing prospective studies begins with enrollment procedures, as women open to randomization of the timing and technique of analgesia may not be representative of the majority of parturients. In addition, parturients who deliver either very slowly or very quickly may not remain in their randomized group. Blinding the obstetrician, anesthesiologist, nurse, and patient to central neuraxial versus other analgesic forms is also difficult. Such blinding is necessary to remove any subtle or overt influences on decision-making; for example, instrumental deliveries may be more common in those patients with epidural analgesia because they can more comfortably accept forceps delivery.[154] Finally, women utilizing parenteral opioids, commonly used as a control group, may not progress in a manner representative of the natural progress of labor,[155] thus not giving a true comparison of epidural techniques with the natural birth experience. No study has so far succeeded in meeting all these objectives; however, certain insights can be gained from the literature to date.

Study Results

The American College of Obstetricians and Gynecologists (ACOG) recently issued guidelines on the use of obstetric anesthesia services. Among the recommendations to reduce the incidence of cesarean delivery was delaying epidural analgesia initiation until cervical dilation of 5 cm or greater was achieved.[156] The data cited, primarily observational and nonrandomized, found an association between earlier epidural placement and dystocia. Using a case-control methodology, investigators at the National Maternity Hospital in Dublin (the pioneers of the active management of labor) observed that epidural initiation at greater than 2 cm dilation was a significant risk factor for prolonging labor in nulliparous women.[157] Thorp and associates,[158] in nulliparous women with cervical dilation less than 5 cm and dilation rate less than 1 cm/hour, observed a sixfold increase in cesarean delivery for dystocia

in association with the use of regional analgesia. Similarly, Lieberman and associates,[159] using a multivariate regression technique on observational data, noted cervical dilation less than 5 cm and station less than 0 at time of epidural initiation as strong risk factors for cesarean delivery. Such cohort studies, however, have not uniformly supported differences in progress and outcome with epidural analgesia; Ohel and Harats[160] failed to show any difference in labor outcome when epidural analgesia was initiated prior to or after 3 cm cervical dilation. Holt, and associates,[161] in a prospective cohort study, found an association between cesarean delivery and higher station, but not cervical dilation, at the time of epidural placement.

An interesting form of retrospective analysis evaluates those institutions in which epidural analgesia becomes suddenly available. These studies, though nonrandomized, offer an analysis of an entire patient cohort in which a "sentinel event" has occurred but other variables, such as obstetric practice styles, are unlikely to change dramatically. A meta-analysis of such studies found no association between a sudden increase in the utilization of epidural analgesia and higher rates of cesarean delivery.[162]

The majority of randomized controlled trials indicate little overall effect of epidural analgesia on the progress and outcome of labor. Luxman and associates[163] found no difference in length of labor or mode of delivery in 60 nulliparous parturients randomized to receive epidural analgesia prior to or after 4 cm cervical dilation (mean 2.3 cm versus 4.5 cm). Chestnut and associates, in evaluating women closer to 5 cm cervical dilation (mean 4 cm versus 5 cm), demonstrated no differences in labor outcome in either spontaneous[164] or induced[165] labors. A recent meta-analysis of 10 trials comparing parturients of mixed parity randomized to epidural analgesia or parenteral opioids noted a prolongation of the first and second stages of labor by 42 minutes and 14 minutes, respectively, in association with the use of epidurals.[166]

Specific studies, however, do appear to indicate that anesthetic practice differences may influence the progress and outcome of labor. Although the COMET trial found no differences in the incidence of cesarean delivery, a higher proportion of instrumental deliveries was observed in patients with "traditional" epidurals versus CSE or parenteral narcotics. In the "traditional" epidural group, intermittent boluses of 0.25% bupivacaine were administered, a method not commonly used in contemporary practice in which lower concentrations and continuous infusion pumps are usual. Regardless, the findings suggest that differences in neuraxial technique may alter outcomes; this conclusion has been supported by other studies comparing CSE and epidural techniques. In nulliparous parturients at less than 3 cm cervical dilation, Tsen and associates,[68] using 1 mL versus 12 to 15 mL of 0.25% bupivacaine in the spinal and epidural spaces, respectively, observed faster cervical dilation and progress of labor in the spinal group.

Obstetric practice style may also influence the outcome and progress of labor. Meta-analyses of randomized trials have found that although instrumental delivery rates increased in patients receiving epidural analgesia, the resulting incidences were widely divergent, perhaps reflecting substantial practice style differences.[166,167] In terms of cesarean delivery, one study noted that apart from nulliparity, the identity of the individual obstetrician was the variable with the greatest influence on cesarean delivery rates.[168] Moreover, the use of peer review and education have been demonstrated to result in a 50% decrease in cesarean rates despite a simultaneous doubling of epidural analgesia use.[169,170]

In summary, although problems with methodology make an association difficult to evaluate, the use of epidural analgesia appears to affect the progress and outcome of labor remarkably little. Although the risk of cesarean delivery does not appear to be influenced, instrumental vaginal delivery appears to be increased with the use of epidural analgesia. It is possible that these associations may reflect variances in patient demographics or differences in anesthetic and obstetric practice styles.

TEMPERATURE CHANGES IN LABOR

Humans have the ability to maintain body temperature within a narrow range despite changes in environmental temperature. Although the extremities and skin can vary over several degrees, the average core body temperature of healthy adults is 37°C with diurnal variations of ± 0.5°C.[171] Thermoregulation is centered in the hypothalamus and responds to receptors found predominantly in the skin and spinal cord. Established through a balance of heat uptake, production, and loss, temperature equilibrium can be distorted by processes that change the thermoregulatory threshold (set value) or the response to temperatures above or below this value.

Clinically, a temperature greater than 38°C represents a fever. Most commonly, fever is the result of exogenous or endogenous pyrogens that disturb the "thermostat" set value to allow thermoregulatory mechanisms to maintain an elevated temperature. Less commonly, thermoregulatory responses to hyperthermia are prevented (such as a blockade of sympathetically mediated vasodilation or sweating) or overwhelmed (such as immersion in hot water). Of interest, endogenous pyrogens, which act on the thermoregulatory center and are triggered by the release of interleukins 1 and 6 from macrophages, are partially mediated by prostaglandin metabolism;[172] the relationship of this finding to the many pregnancy-induced alterations in the production and distribution of prostaglandins has yet to be elucidated.[173]

Thermoregulation During Pregnancy

During pregnancy, the mother attempts to maintain a normal temperature. The fetus relies on the uteroplacental circulation and the amniotic fluid interface for heat exchange; these limited routes for heat egress result in a normal fetal temperature approximately 0.5°C to

0.75°C higher than maternal body temperature.[174] With extreme hyperthermia, experimental evidence suggests that fetal deterioration may occur. Morishima and associates,[175] utilizing radiant heat to produce maternal hyperthermia of 107°F in anesthetized baboons, observed increased uterine activity and deterioration in fetal condition. Similarly, Cefalo and Hellegers[176] demonstrated fetal deterioration in anesthetized gravid ewes with levels of hyperthermia that produced maternal cardiovascular collapse. Although these extreme degrees of hyperthermia are unlikely to be clinically applicable, lesser increases of temperature may have various effects, including changes in umbilical blood flow.[176]

In terms of neonatal effects, epidemiologic evidence suggests that mild maternal fever may not be as benign as previously assumed based on the animal data. Lieberman and associates,[177] in a retrospective review of 1218 nulliparous women with singleton, term pregnancies in spontaneous labor who were afebrile on admission, noted that 1-minute Apgar scores less than 7, hypotonia, and the need for bag and mask ventilation were more common in parturients with a body temperature greater than 101°F. Although it remains unclear whether temperature per se, independent from underlying infectious or inflammatory processes, can cause neurologic injury, an association between maternal intrapartum fever and neonatal encephalopathy,[178] cerebral palsy,[179] and persistent developmental cognitive deficits[180] has been observed. Moreover, maternal outcome may be directly or indirectly influenced by the presence of even low-grade fever. Lieberman and associates[181] retrospectively observed a twofold higher incidence in operative vaginal and cesarean deliveries in nulliparous women who were afebrile at admission and subsequently developed a fever greater than 99.5°F, compared to those who remained afebrile, even when controlled for birth weight, length of labor, and analgesic choice. More recently, Shipp and associates[182] noted an association between postpartum fever after cesarean delivery and an increased risk of uterine rupture in a subsequent trial of labor.

Epidural Analgesia and Maternal Pyrexia

Study Design Issues

To date, nearly all the clinical studies of maternal fever associated with epidural analgesia have been nonrandomized. Similar to the progress and outcome of labor studies, it is possible that women who request epidural labor analgesia have risk factors that predispose them to fever, including greater rates of nulliparity,[183] prolonged rupture of membranes,[183,184] prolonged labor,[183,185,186] higher temperature on admission,[183] early chorioamnionitis,[183] and frequent cervical examinations.[187] Using a case-control methodology, Vallejo and associates[186] compared women with histologically confirmed chorioamnionitis with two groups of women who received epidural analge-

sia (with and without chorioamnionitis). Fever was more common in infected women in all groups; however, the incidence of fever in uninfected women with epidurals was only 1%. In a similar study of 149 women who delivered greater than 6 hours following membrane rupture, Dashe and associates[188] noted an increased incidence of fever in 54% of parturients who received epidurals. However, when parturients with evidence of placental inflammation were excluded, the incidence of fever was similar in women with and without epidural analgesia (11% versus 9%).

Study Results

Although an infection is the most common reason for fever during pregnancy, the influence of neuraxial techniques on maternal temperature is of interest. Regional anesthesia administered for surgery, including cesarean delivery, typically results in peripheral vasodilation, redistribution of body heat, and hypothermia.[189] By contrast, in laboring women receiving regional analgesia, a rise in temperature has been noted. Fusi and associates[190] reported an increase in vaginal temperatures of approximately 1°C over 7 hours in 18 parturients receiving epidural analgesia with no evidence of infection; this contrasted to stable temperatures in 15 parturients who received intramuscular meperidine. Using a method perhaps more reflective of core temperature, Camann and associates[185] measured tympanic membrane temperature in 53 laboring parturients divided into three groups. One group received intravenous nalbuphine; the other two groups, composed of women who chose epidural analgesia, were randomized to receive epidural bupivacaine with or without fentanyl. With ambient room temperature maintained at 20°C to 22°C, epidural analgesia did not affect maternal temperature for the first 4 hours. Thereafter, the mean tympanic membrane temperature increased by 0.07°C/hour in both epidural groups, with no differences observed in those receiving epidural fentanyl (Fig. 72–4).

Macaulay and associates[191] evaluated maternal oral and intrauterine and fetal skin temperatures in 33 and 27 parturients undergoing labor with and without epidurals, respectively. With an ambient temperature ranging from 23.3°C to 29°C, 10 fetuses within mothers with epidurals reached a maximum fetal skin temperature of greater than 38°C versus none in the group without epidurals. Of interest, only two women, both in the epidural group, reached an oral temperature greater than 37.5°C. Ultimately, no differences in Apgar scoring or umbilical cord blood gases were found. Overall, a number of investigators have observed an incidence of clinical fever (greater than 38°C) in 1% to 36% of laboring women receiving epidural analgesia, with a temperature elevation rate of approximately 0.1°C/hour of epidural analgesia, usually after a 4- to 5-hour delay.[183,184,192,193]

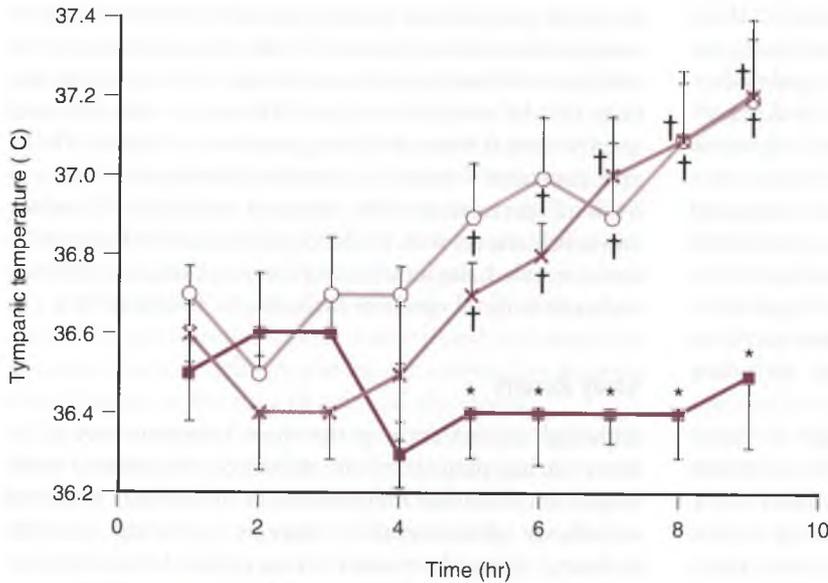
The mechanisms by which epidural analgesia may produce changes in maternal temperature during labor


FIGURE 72–4
Mean tympanic temperatures during labor in three groups of patients: Epidural bupivacaine-fentanyl (0), epidural bupivacaine only (X), and parenteral opioids (v) groups. *$P < 0.01$ compared with the epidural group. [†]$P < 0.01$ compared with the preepidural temperature. (From Camann WR, Hortvet LA, Hughes N, et al: Maternal temperature regulation during extradural analgesia for labour. Br J Anaesth 1991;67:565–568.)

remain unclear. Although high ambient temperatures (24°C to 26°C) have been suggested as a possible etiology,[190] an association between ambient temperature and maternal or fetal temperatures has not been uniformly demonstrated.[184,191] A second possibility could be epidural-induced reductions in heat loss mechanisms, including an increase in sweating thresholds (by 0.55°C in volunteers)[194] and a reduction in hyperventilation during labor.[195,196] A third possibility could be alterations that result in, or are related to, shivering; in those parturients who shivered following the initiation of epidural analgesia versus those who do not, pyrexia developed as early as 1 hour later, in comparison to greater than 4 hours later.[197] In addition, shivering parturients ultimately attained higher maximum temperatures and had a threefold increase in clinical fever. A final possibility could be alterations in the parturients not receiving an epidural technique; the opioids frequently utilized in these groups may suppress temperature elevations.[198] A retrospective study of systemic use[199] and a prospective, randomized study of epidural use[185] of opioids, however, failed to demonstrate temperature curve changes with the addition of opioids.

Impact and Interventions

In addition to the fetal concerns discussed earlier, temperature elevations may alter neonatal exposure to antibiotics and subsequent care. Mayer and associates[200] retrospectively evaluated 300 low risk nulliparous women who received systemic opioids, epidural analgesia, or both (n = 100 in each group). The incidence of maternal fever (2%, 16%, and 24% in the preceding groups, respectively) and intrapartum maternal antibiotics (6%, 19%, 22%) was highest in the combined opioid and epidural group. Of note, in the 10 patients who ultimately demonstrated laboratory evidence of chorioamnionitis, maternal fever was not the only presenting symptom; fetal tachycardia and meconium-stained or abnormal amniotic fluid

were also found. This suggests that the administration of antibiotics should not be guided by maternal fever alone. In a secondary analysis of 1657 low risk nulliparous women enrolled in a trial of active management of labor, the incidence of maternal fever (15% versus 1%), neonatal sepsis evaluation (34% versus 10%), and antibiotic treatment (15% versus 4%) was increased when epidural analgesia was used.[192] However, the incidence of actual neonatal sepsis was exceedingly low in epidural and nonepidural groups (0.3% versus 0.2%), and of interest, although the indications for sepsis evaluations was not provided, was the finding that two thirds of the evaluations occurred in infants of mothers who did not have intrapartum fevers. Moreover, the mothers who received epidural analgesia had larger infants, longer labors, and a twofold increase in the labor induction rate. Although it is possible that the active management protocol of frequent cervical examinations and early amniotomy may have influenced the risk of fever, a subsequent study evaluated nonrandomized parturients whose temperature remained below 100.4°C throughout labor.[201] Neonatal sepsis evaluations were more common in parturients who had epidural analgesia (20.4% versus 8.9%) even after controlling for gestational age, birth weight, maternal smoking history, active labor management, premature rupture of membranes, and admission cervical dilation. Epidural analgesia was associated with both major (rupture of membranes >24 hours, fetal heart rate >160) and minor criteria (maternal temperature >99.5°F, rupture of membranes 12 to 24 hours) for sepsis evaluation. These data suggest that multiple factors should be present prior to initiating a sepsis evaluation; moreover, of those babies investigated for sepsis because of risk factors, few will ultimately prove to have been infected.

The rate of neonatal sepsis evaluation and treatment can be modified by neonatology admission criteria and practice style. Yancey and associates,[202] reviewing the effects of an on-demand epidural analgesia service

where epidural use increased overnight (because of a change in policy in the unit) from 1% to 83%, observed that maternal temperatures greater than 99.5°F and 100.4°F increased threefold and 18-fold, respectively. Despite this increase in maternal temperatures, neonatal blood counts and cultures increased modestly (RR 1.5–1.7), and no changes in the proportion of infants who received antibiotic treatment for presumed sepsis were observed. Similarly, Kaul and associates[203] noted in a retrospective review of the delivery records of 1177 nulliparous women that the incidence of neonatal sepsis evaluations was no different (7.5% versus 9.4%) despite women with epidural analgesia having more fever. Both investigators cited more stringent neonatal sepsis treatment guidelines, which did not include the treatment for maternal fever in the absence of chorioamnionitis, as being responsible for their results.

Attempts to diminish maternal temperature increases during labor have thus far been limited. Goetzl and associates[204] randomized 42 nulliparous women to receive acetaminophen 650 mg every 4 hours versus placebo in women receiving epidural analgesia. The incidence of fever did not differ between groups (23.8%). Of note, despite all neonatal blood cultures being negative, maternal serum and cord blood markers of inflammation (IL-6) were higher in mothers who had fever. This suggests that inflammatory markers can be elevated in the absence of neonatal infection.

In conclusion, epidural analgesia does appear associated with increases in temperature, although most of these increases are mild. This being said, maternal fever has been linked with adverse neonatal outcomes. Further studies of the mechanism of these temperature elevations with epidural use and a reanalysis of maternal and neonatal evaluation and treatment policies are warranted.

CONCLUSIONS

- Central neuraxial techniques, including spinal, epidural, and combined spinal-epidural techniques, are commonly used in modern obstetric care for the provision of labor analgesia and anesthesia for instrumental and operative deliveries.
- Philosophical and clinical shifts in practice have expanded the indications for the use of these techniques. Most recently, these techniques have been applied to the following:
  - External cephalic version: Success has been improved significantly with all central neuraxial techniques for both primary attempts and reattempts.
  - Postoperative pain management: The use of long-acting opioids such as morphine via spinal and epidural techniques has dramatically improved the postoperative analgesia and recovery following cesarean delivery.
- The basic properties of epidural, spinal, and CSE techniques may indicate advantages for specific situations.
- All three techniques can utilize a catheter to allow flexibility in titrating the onset and duration of the blockade; however, this is less commonly done with the spinal technique because of the size of the dural puncture and the resulting high incidence of headache.
- A number of analgesic and anesthetic options exist for labor and delivery, including nonpharmacologic modalities, systemic agents, and peripheral nerve blocks.
- A number of disease processes are being seen more commonly during pregnancy. Hypertensive disorders, cardiac diseases including acquired and congenital heart disorders, and diabetes are comorbid conditions that have implications for obstetric and anesthetic care. On occasion, invasive monitoring may be required for the optimal care of the parturient with these significant disease states, and a risk-benefit analysis for their use should be considered in advance.
- Whether central neuraxial analgesia affects the progress and outcome of labor remains controversial, in part due to the complexity in study design. However, the following should be noted:
  - The majority of studies appear to indicate little overall effect of epidural analgesia on progress and outcome of labor.
  - Anesthetic and obstetric practice styles may influence who ultimately receives an instrumental or operative delivery.
- Although the etiology remains unclear, epidural labor analgesia appears to increase maternal temperature; however, the following should be noted:
  - Study design issues also exist.
  - A delay of 4 to 5 hours is observed prior to a mean increase of approximately 0.1°C/hour following epidural initiation.
  - The impact of these changes remains controversial, and the direct and indirect implications of these changes on neonatal sepsis evaluations deserve further investigation.
- Awareness and communication of the indications and implications of central neuraxial techniques among the entire obstetric care team, including obstetric, anesthetic, neonatal, and nursing care providers, remain of paramount importance to the continued welfare of the expectant mother and fetus.

SUMMARY OF MANAGEMENT OPTIONS
Central Neuraxial Analgesia and Anesthesia

Management Options	Quality of Evidence	Strength of Recommendation	References
External Cephalic Version			
Epidural use is associated with higher success rates compared to no epidural; it is not clear whether spinal or combined-spinal epidural (CSE) has the same effect.	Ib	A	45–49
Pain Relief during Parturition			
Nonpharmacologic methods:			
All nonpharmacologic methods have limited analgesic action.	Ib	A	15–17
Psychological support is of benefit and reduces the need for pain relief.	Ia	A	20
Hypnosis can be beneficial.	Ia	A	21
The presence of a doula or other nonprofessional support in labor reduces need for pain relief.	Ia	A	20,22
Sensory stimulation (e.g., acupuncture, TENS) is claimed to be of some benefit in early labor.	III	B	26–28
Pharmacological methods:			
Systemic medications shown to be effective include opioids and patient-controlled anesthesia.	III	B	36,37
Inhalational analgesia: Entonox—50% NO/50% oxygen—is widely used, but evidence mainly observational.	Ib	A	42
Regional analgesia/anesthesia:			
Most often used are pudendal block and perineal block.	IIb	B	44
Paracervical, caudal, and lumbar sympathetic blocks are infrequently used.	Ib	A	40,41
Pain Relief during Parturition			
Neuraxial analgesia:			
Spinal block is effective for assisted vaginal delivery and cesarean section (CS) but not labor.	IV	C	52
Epidural block is effective for assisted vaginal delivery, and CS; addition of fentanyl and local anesthetic improves short-term effectiveness (especially for an assisted vaginal delivery).	IIa	B	65
CSE technique is effective for assisted vaginal delivery and CS; possibly it has a lower complication rate than epidural alone.	Ib	A	68
Dural puncture managed by:			
analgesia	Ib	A	75
IV fluids	Ia	A	76
blood patch	IV	C	58
Cesarean Section			
Spinal, epidural, and CSE are preferred to general anesthesia; addition of narcotics and ephedrine may result in increased effectiveness.	Ib	A	56,73,74, 79,80
With general anesthesia (GA):			
Use laryngeal mask if intubation is difficult.	IIb	B	94
Use nonparticulate antacid and/or H_2 antagonist in advance of all CS in case GA necessary.	Ib	A	95–97
Use pre- and perioperative oxygenation.	III	B	98

Perineal Repair and Pelvic Floor Injury

Colm O'Herlihy / Rohna Kearney

INTRODUCTION

Pelvic floor injury at the time of vaginal delivery can result in the later development of urinary incontinence, pelvic organ prolapse and fecal incontinence. In the United States the direct annual cost of pelvic organ prolapse surgery alone is estimated to be over $1 billion, with 22 women per 10,000 requiring surgical correction for this indication.[1,2] The annual direct cost of urinary incontinence is even higher, at $12.4 billion.[3] The lifetime risk of a woman in the United States undergoing surgery for incontinence or prolapse by the age of 80 is 11%.[4] With growing awareness of the impact of pelvic floor injury, attention is now increasingly focused on the prevention of these problems. Vaginal delivery is the factor most subject to modification in the etiology of pelvic floor injury.[5–7] In order to prevent injury and minimize the impact of delivery on the pelvic floor, it is necessary to have an understanding of the anatomy and the pathophysiology of injury.

Anatomy

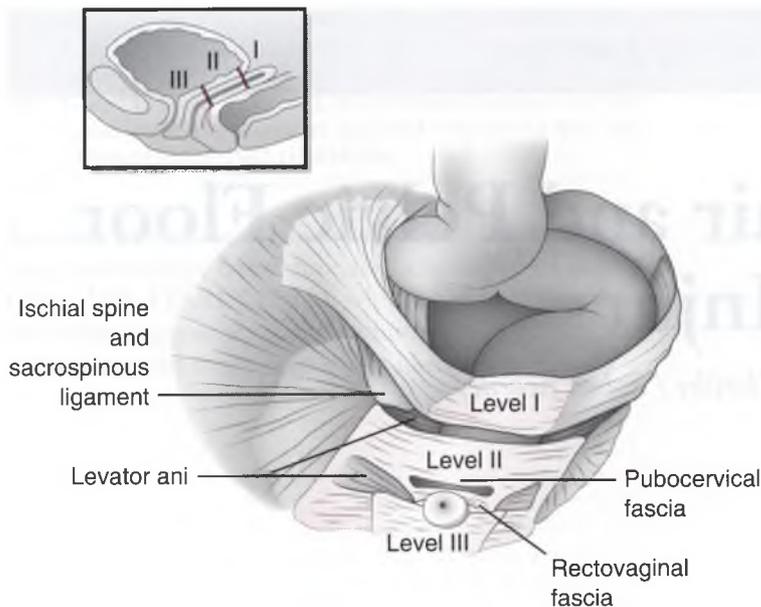
The primary function of the pelvic floor is to prevent the pelvic organs from downward displacement in the upright position, while at the same time allowing parturition and elimination. The levator ani muscles, which are composites of the pubococcygeus, puborectalis, and iliococcygeus on each side, are the most important constituents of the pelvic floor and resemble a horizontal shelf that acts to close like a valve when the female assumes the upright position.[8] The pubococcygeus comprises the puboanalis, pubovaginalis, and puboperineus subdivisions.[9] The pubococcygeus and puborectalis arise from the inner surface of the pubic bone, whereas the iliococcygeus arises from the arcus tendineus levator ani. The pubococcygeus inserts into the vaginal wall (pubo-

vaginalis), perineal body (puboperineus), and intersphincteric groove (puboanalis). The puborectalis forms a sling around the rectum and inserts into the deep external sphincter and the iliococcygeus inserts into the iliococcygeal raphe.

The perineal membrane is a triangular sheet of fibromuscular tissue with the striated urogenital sphincter lying above. It provides support by attaching the vagina, urethra and perineal body to the ischiopubic rami. Above it the striated urogenital sphincter consists of the compressor urethra urethrovaginal sphincter, and the sphincter urethra.

The endopelvic fascia refers to the condensation of the adventitial layers of the pelvic organs. This connective tissue layer attaches the pelvic organs to the lateral pelvic walls and, together with the levator ani, shares the load on the pelvic floor. Support for the vagina has been identified at three levels[10,11] (Fig. 73–1). Level I consists of the uterosacral and cardinal ligaments, which represent a medial and lateral thickening of the endopelvic fascia connecting the cervix and upper vagina to the pelvic sidewalls. These structures are vertical in the standing position and serve to keep the uterus, cervix, and upper vagina tethered in a posterior position over the levator ani muscles.

At level II, the middle third of the vagina is attached by the paracolpium to the arcus tendineus and levator ani muscle fascia. The arcus tendineus fascia pelvis runs from the pubic bone anteriorly to the ischial spines posteriorly. At level III, the lower third of the vagina is attached directly to the perineal membrane, perineal body, and levator ani.

The proximal urethra is supported by the endopelvic fascia and anterior vaginal wall, which act like a hammock and attach it to the arcus tendineus fascia and levator ani, thus resulting in compression and closure of the urethral lumen in response to increases in intra-abdominal pressure.[12]


The perineal body is covered by skin and lies between the lower vagina and the anus. It is attached by the perineal membrane to the inferior pubic rami and ischial tuberosities. The perineal body receives the insertion of the bulbocavernosus muscles and posteriorly is attached to the coccyx by the external anal sphincter.

The anal sphincters are located in the posterior compartment of the pelvic floor. The external anal sphincter is a voluntary muscle consisting of three components, a subcutaneous part, a superficial part connecting the perineal body to the coccyx, and a deep part, which surrounds the rectum. The internal anal sphincter is a downward extension and thickening of the circular smooth muscle of the rectum. The intersphincteric groove runs between the internal and external anal sphincters. The ischiorectal fossas lie between the levator ani and the obturator internus muscles. The external anal sphincter and bulbocavernosus muscles are supplied by the pudendal nerve, which arises from the anterior primary rami of S2, S3, and S4. The nerve leaves the pelvis through the greater sciatic foramen and runs in the pelvic side wall close to the ischial spine and sacrospinous ligament to enter the pudendal (Alcock's) canal through the lesser sciatic foramen. It divides into three terminal branches—the clitoral, perineal, and inferior rectal. Autonomic nerves from the pelvic plexus supply the internal anal sphincter.

Pathophysiology

Pelvic floor injury can result from damage to the nerve supply, muscles, or connective tissue, which together maintain pelvic floor function. There is good evidence that damage to the innervation of the pelvic floor is a causative factor in the development of urinary and fecal incontinence following vaginal delivery.[13,14] Partial denervation of the pelvic floor has been shown in 80% of women following a single vaginal delivery.[15] Fetal macrosomia and a pro-

longed second stage (either active or passive) are associated with an increased risk of neuropathic damage.[16]

The levator ani and endopelvic fascia act together to maintain urinary continence and pelvic organ support. If the muscle is damaged, the connective tissue has to play a greater compensatory role, and this frequently fails over time, most commonly after the menopause. The arcus tendineus fascia is found to be detached (most commonly from the ischial spines) in women with anterior vaginal wall prolapse,[10] and histologic studies have documented levator ani muscle fibrosis following vaginal delivery.[17] Such changes are also seen in women with stress urinary incontinence and pelvic organ prolapse.[18] Magnetic resonance imaging is providing increasing information about pelvic floor injury following childbirth, demonstrating, for example, abnormalities in the levator ani in women with stress urinary incontinence and prolapse.[19,20] A recent study has shown levator ani muscle abnormality in 20% of women following their first vaginal delivery,[21] although it has not yet been established whether these defects are related to muscle or nerve injury or a combination of insults. As well as a prolonged second stage of labor and fetal macrosomia, instrumental delivery, midline episiotomy, and occipitoposterior fetal position have also been implicated in pelvic floor injury.[15,16,22–24]

UTEROVAGINAL PROLAPSE

Effects of Pregnancy, Childbirth, and Parity

Nulliparous pregnant women have been shown to exhibit altered pelvic floor support when compared with nulliparous nonpregnant women. In the nonpregnant group, 43% had stage 0 prolapse and 57% had stage 1, but in the pregnant group 10% had stage 0, 43% had stage 1, and

48% had stage 2.[25] Interestingly, the greatest changes observed were in the length of the anterior wall and the perineal body, which may explain the common occurrence of urinary incontinence during pregnancy. The increase in perineal body length may represent an adaptation that reduces the occurrence of anal sphincter damage. Another study of nulliparous women delivered at term showed that at 36 weeks' gestation 46% had prolapse, with 26% having a stage 2 prolapse[26]; at 6 weeks postpartum there was a similar incidence of new prolapse in women delivered vaginally and by cesarean section. Thus, regardless of the mode of delivery, being pregnant of itself impairs pelvic floor support.

That the risk of prolapse increases with the number of vaginal deliveries is well documented. Mant and associates have shown that a woman after two vaginal deliveries has an eightfold increased risk of developing pelvic organ prolapse compared with the nulliparous woman and that this risk rises to 12-fold after four vaginal deliveries.[5]

Risks

Uterine prolapse occurring for the first time during pregnancy is rare, occcuring in 1 in 10,000 to 15,000 deliveries.[27] It can occur acutely following a fall or trauma in nulliparous women[27] but is more commonly seen in parous women with prolapse prior to pregnancy. Much of the literature relating to uterine prolapse in pregnancy consists of case reports prior to 1970,[27–31] when the condition was seen more frequently owing to higher average parity.[32] Thus, current data on maternal and fetal risks are lacking. A large review up to 1940 reported a substantial fetal and maternal complication rate,[27] which included a 10% risk of miscarriage[28] and an increased risk of preterm birth.[29] Fetal and maternal death have also been reported.[29] Cervical elongation, hypertrophy, and edema are present in all cases in which the pregnancy progresses to term.[27] Urinary obstruction can occur and may require catheterization. Abnormalities of labor are common. On the one hand, weakness of the pelvic floor can lead to precipitate delivery with resultant cervical lacerations. On the other hand, cervical infection and bleeding during pregnancy are common and can lead to scarring and fibrosis with resultant cervical dystocia. This typically manifests as secondary arrest in cervical dilation, usually between 5 and 7 cm.[30] At one time it would have been managed by Duhrssen's cervical inci-

sions with or without the use of forceps, but presently cesarean section is preferred. Accordingly, although spontaneous vaginal delivery rates of 40% to 80% have been reported,[29,30] cesarean or instrumental deliveries are more common. Primary postpartum hemorrhage, due to uterine atony, may be difficult to control, as manual uterine compression is hindered by the prolapse.

Management Options

Prenatal

Uterine prolapse occurring prenatally requires admission to hospital if it is not possible to reduce the prolapse in the clinic. Treatment consists of bed rest in the Trendelenburg position combined with an indwelling urinary catheter and saline soaks to reduce cervical edema. Once edema has been reduced, the prolapse can usually be manually replaced and a pessary then inserted to prevent reccurrence; a Hodge pessary is the one most commonly used. Antibiotic creams are often prescribed to reduce associated cervicitis. There is no evidence that systemic antibiotics are beneficial. In the past vaginal packing and even surgical closure of the introitus have been described as effective.[32] The introitus is reopened at term to allow vaginal delivery. Pessary treatment is often required only until the fifth month of pregnancy, when the uterus lifts out of the pelvis, thereby alleviating prolapse symptoms.[33]

Labor and Delivery

Careful intrapartum monitoring of the rate of cervical dilation is essential for early detection of both precipitate delivery and cervical dystocia. In the event of the latter, (Duhrssen's) intracervical incisions can be considered, but today cesarean section is usually more appropriate.

Postnatal

If the prolapse is untreated, it will almost certainly recur in future pregnancies. Surgery is the definitive cure, but a vaginal pessary is an appropriate immediate treatment during postnatal genital involution. Longer term use of a pessary should be considered if more pregnancies are desired, as a surgical repair is likely to be undone by another vaginal delivery, and an elective cesarean to avoid recurrent prolapse carries its own risks.

PREVIOUS PELVIC FLOOR REPAIR/ VAGINAL SURGERY

Maternal Risks

Despite a general decline in family size, the combined effects of increasing rates of surgical intervention for pelvic organ prolapse and urinary incontinence and delayed childbearing mean that many women are becoming pregnant having previously undergone reconstructive surgery. This poses a dilemma for the obstetrician. Both pregnancy and especially delivery can pose a threat to the continued efficacy of successful surgical repair. It is important to provide the woman with information on the likelihood of symptoms recurring during pregnancy, persisting following delivery and necessitating further treatment. However, published evidence on which to base management is scanty. The urethra lengthens during pregnancy,[34] and the bladder becomes an abdominal organ. Stress incontinence occurs commonly in pregnancy[35] and is a risk factor for persistent urinary incontinence. Thus, pregnancy of itself poses a risk of prolapse recurring. However, the main obstetric concern following previous successful pelvic floor surgery is mode of delivery. Reported outcomes among women delivered abdominally or vaginally following previous surgery for pelvic organ prolapse and stress urinary incontinence provide conflicting results. In the largest series of 89 women who conceived following colporrhaphy (66 of whom had undergone cervical amputation), 34 miscarried or delivered prior to 32 weeks. Twenty-four had a cesarean section to preserve pelvic floor function. At 6 to 8 weeks post partum, there was recurrence of symptoms in 7% of women, but at 1 year postpartum, 22% had symptoms severe enough to require further surgery.[36] Cesarean section failed to prevent recurrence, with 9 of the 25 (36%) delivered abdominally suffering recurrence at 5 years compared to 7 of the 49 (14%) delivered vaginally. On the other hand, in another series of 78 women who had surgery for prolapse, 31 were followed up after subsequent pregnancy. Twenty-five had vaginal deliveries and four of them had recurrent prolapse,[37] six had cesarean section, and none had any recurrence of prolapse (although this difference is not statistically significant). Another study of five women who delivered vaginally following a previous Burch colposuspension reported that three suffered recurrent incontinence,[38] whereas all the women delivered by cesarean section had maintained continence at 1 year post cesarean (despite a majority having had incontinence in the third trimester). Of six reported vaginal deliveries following uterosacral sacrospinous suspension for prolapse, one patient suffered a recurrence of symptoms requiring further surgery.[39]

Fetal Risks

The Manchester repair (Fothergill) operation performed prior to pregnancy has been associated with greater miscarriage and preterm delivery rates, but this operation is now rarely performed.

Management Options

Prepregnancy

All women planning a pregnancy after previous pelvic floor surgery for urinary incontinence or prolapse should

be advised of a possible functional deterioration during pregnancy that may persist, even if an elective cesarean section is performed.

Prenatal

Timely assessment of symptom recurrence and reassurance of probable resolution of symptoms following delivery are important. Intensive pelvic floor physiotherapy may be indicated, but there are inadequate data on its effectiveness in this situation for it to be recommended with confidence.

Labor and Delivery

If symptoms have been largely cured by a prolapse or incontinence repair procedure, current consensus would favor performing an elective cesarean section in order to minimize the risk of recurrent symptoms. There have, however, been many reports of women delivering vaginally with no recurrence of symptoms. If a vaginal delivery is planned, an episiotomy may be beneficial to reduce stretching of rigid or scarred tissues.[36]

Postnatal

Pelvic floor exercises should be continued. A decision regarding further surgical management should ideally be deferred until 6 months following delivery, as recovery of function continues to occur until then.[40] Any plans for further childbearing should be discussed; the woman should be made aware that any subsequent pregnancy risks producing a recurrence of symptoms requiring further surgery once childbearing is complete.

PERINEAL INJURY

Trauma to the perineum, of varying degree, constitutes the most common form of obstetric injury. Its severity is generally classified according to the degree of perineal disruption:

- First-degree tear involves only perineal or vaginal skin.
- Second-degree tear occurs when perineal skin and muscles are torn.
- Third-degree tear occurs when, in addition to perineal skin and muscle, the anal sphincter muscle is torn.
- Fourth-degree tear occurs when sphincter muscle disruption is complete with additional extension into the anal mucosa; this implies that both external and internal anal sphincter muscles have been severed.

Further subdivision of third-degree tears, in particular, has been proposed[41] according to the depth of torn

sphincter muscle, but such differentiation can be difficult in clinical practice.

First- and Second-Degree Tears

General

First- and second-degree perineal tears are very common. The incidence of intact perineum following delivery after a first vaginal birth is very low, approximately 6%.[42] The maternal position at delivery may be important; one study reported an overall 66% intact perineum rate associated with the lateral position at delivery, compared to 42% in the squatting position.[43] Because of the frequent need for suturing of tears and the limited availability of experienced surgeons, repair is often performed by relatively inexperienced personnel. All staff supervising even the most normal births should therefore receive early and thorough training in perineal repair. The principles of management include immediate assessment to exclude deeper injury involving the anal sphincter, appropriate surgical repair, and effective postpartum analgesia and advice.

Maternal Risks

Second-degree tears can result in significant morbidity. Women who sustain them resume sexual intercourse later and report greater frequency of dyspareunia than women who have intact perineums or first-degree tears.[44] Use of teaching models for instruction of midwifery and medical staff in repair technique is effective in reducing such complications.[45]

Management Options

PRENATAL

Prenatal and intrapartum perineal massage have been advocated as interventions to reduce the incidence of second- and greater-degree tears, but the evidence in its favor is conflicting. In one study of 1340 women, massage and stretching during the second stage of labor did not increase the rate of perineums intact after delivery.[46]

However, a second study of 861 nulliparas randomized to antenatal perineal massage demonstrated a reduction in episiotomy, and second- and third-degree lacerations, with the greatest benefit among women over 30 years old.[47] Pelvic floor muscle exercises performed prenatally and postnatally have been shown to reduce self-reported incontinence in late pregnancy and up to 6 months postpartum.[48]

LABOR AND DELIVERY

Several studies have examined the method of perineal repair. Use of polyglactin suture material is associated with less perineal pain lower resuture rates compared to chromic catgut.[49,50] A two-stage continuous repair leaving the skin unsutured also seems to be associated with less pain.[50,51]

THE ROLE OF CESAREAN SECTION

There is no consensus about the role of elective cesarean section in the prevention of obstetric pelvic floor injury. However, some are so convinced of its benefit that they even advocate obtaining "informed consent" regarding the risks of perineal injury before women elect to have a vaginal birth.[52] Although traumatic mechanical injury to the anal sphincter occurs only with vaginal delivery, evidence exists to show that if performed late in labor cesarean section may fail entirely to protect the anal sphincter mechanism, with one study showing neurologic injury in women delivered by cesarean section after 8 cm dilation.[53] Parous women delivered only by cesarean section still have a 3.5-fold increased relative risk of urinary incontinence compared to women who have never been pregnant, although the risk is higher still after vaginal delivery.[54] These data suggest that the pregnant state of itself (regardless of mode of delivery) can influence function and indicate that more research is required into the pathogenesis of obstetric pelvic floor injury before definitive advice on mode of delivery can be offered.

POSTNATAL

Analgesia is the main priority.

Third-Degree Anal Sphincter Injury

General

Altered fecal continence is common following primary repair of third- and fourth-degree perineal injury, that is, when anal sphincter muscle disruption is clinically recognized after vaginal delivery. Up to 50% of women experience some incontinence symptoms within the weeks and months after a third-degree tear.[55,56] These symptoms do not correlate with the mode of sphincter repair. Consequently, all women known to have sustained anal sphincter trauma should have their continence routinely assessed at the conclusion of the puerperium.

Postnatal continence assessment should include direct questioning using a standardized bowel function questionnaire (Table 73–1)[57] so that a reliable continence score can be allotted to facilitate monitoring of the progress of symptoms over time. Continence of flatus, liquid, and solid feces should be documented, together with inquiry concerning fecal urgency, a socially debilitating symptom defined as an inability to defer defecation for longer than 5 minutes; the complaint of urgency incontinence may reflect external anal sphincter dysfunction.

Digital examination of the anal canal may provide an approximation of the integrity of the sphincter and perineal body but is not otherwise diagnostically reliable. On the other hand, palpable defects in the levator ani mus-culature have been shown to correlate with magnetic resonance images of the pelvic floor.[21] Nevertheless, anorectal physiologic testing is necessary to determine objectively the nature and prognosis of any residual anal sphincter damage and routinely consists of the following investigations:

- Anal manometry is performed to evaluate sphincter tone and contractile function.
- Endoanal ultrasound is used to examine the anatomic integrity of the sphincter.
- Neurophysiologic testing of the pelvic floor is done to identify pudendal neuropathy.

These tests should be applied not only to women who have sustained third- and fourth-degree tears but also to other puerperal patients complaining of fecal incontinence. Disturbance of resting tone on anal manometry is indicative of predominant internal anal sphincter dysfunction, whereas a reduction in squeeze incremental pressure on voluntary contraction is consistent with reduced external sphincter muscle power. Manometry is performed using a multichannel, water-perfused catheter in the left lateral position, and reductions in the pressure profile, while diagnostically reliable, do not differentiate traumatic muscular from neurologic injury. High-quality endoanal endosonography provides clear and reproducible images of both internal and external

TABLE 73–1

Add one score from each row. A score of 0 implies complete continence. A score of 20 implies complete incontinence.

sphincters [58,59] but may overestimate the significance of muscular defects. Many women are found to have small defects that do not correlate with antecedent obstetric events or fecal incontinence symptoms.[60]

Pudendal nerve assessment should include testing both conduction along the entire length of the nerve, for example, using clitoral-anal reflex assessment, and anal sphincter electromyography (EMG), which assesses motor unit recruitment and action potential morphology. Neuropathy is responsible for at least one third of fecal continence disturbances, and its assessment provides essential information on prognosis and appropriate management.[61]

Risk Factors for Anal Sphincter Injury (Table 73–2)

VAGINAL DELIVERY

Normal vaginal delivery inevitably increases the risk of damage to the sphincter mechanism, compared with prelabor cesarean section. Nonetheless, intrapartum cesarean section can be followed by continence disturbance, consistent with first stage influences on anal sphincter function.[53] Prelabor cesarean section should, therefore, be chosen when any risk to the pelvic floor is to be avoided.

PRIMIPARITY

Because first labors are most often associated with inefficient uterine contractility, dystocia, prolonged labor, use of epidural anesthesia and episiotomy, puerperal fecal incontinence most often follows first vaginal delivery. Risk is increased between two- and fivefold,[62] which reflects the reduced elasticity of the pelvic floor among nulliparas.

INSTRUMENTAL DELIVERY

Both forceps and vacuum extraction significantly increase the risk to the fecal continence mechanism two- to sevenfold.[16,62] Although vacuum extraction is somewhat less commonly traumatic, completion of the delivery with forceps when a vacuum attempt fails, generally due to poor adhesion of the vacuum cup, compounds the incontinence risk.[63]

PROLONGED SECOND STAGE OF LABOR AND EPIDURAL ANALGESIA

Effective epidural analgesia, now a very widely applied form of intrapartum pain relief, abolishes the maternal bearing down reflex in late labor. As a consequence, the passive phase of the second stage of labor is prolonged, sometimes for several hours, before maternal pushing is encouraged. Such a prolonged passive second stage doubles the risk of subsequent incontinence, apparently secondary to pudendal neuropathy. Randomized evidence does not support an expectant policy in the second stage under epidural blockade, because the instrumental delivery rate is not reduced and the duration of labor is needlessly prolonged.[64]

INTRAPARTUM MECHANICAL FACTORS

Third-degree tears occur three times more frequently when the fetus is macrosomic (birth weight >4 kg) compared with lower birth weights. Shoulder dystocia also predisposes to anal sphincter injury, as does persistent occipitoposterior position of the fetal head in the second stage of labor.[22]

MIDLINE EPISIOTOMY

Episiotomy is performed with the objective of preventing deep perineal lacerations and anal sphincter trauma, and is one of the most frequent surgical interventions. The perineal incision can be made either mediolaterally or in the midline posteriorly. Although there is a widespread assumption that it can do more harm than good,[65–67] recent population data suggest that selective mediolateral episiotomy may be protective of the sphincter mechanism.[68,69] On the other hand, there is little doubt that midline episiotomy, which is particularly favored in North America, greatly increases the risk of third-degree tear[70] to the extent that its use should probably be abandoned. This risk is compounded when midline episiotomy is combined with other interventions, such as epidural analgesia and instrumental delivery.

PREVIOUS ANAL SPHINCTER DISRUPTION

The incidence of third-degree tears of varying severity is about 2.5% of primiparous and 0.5% of multiparous vaginal deliveries, with an overall average rate of about 1.5%.[59] Following satisfactory postnatal repair, at subsequent vaginal delivery the risk of a further tear increases fourfold to about 4%[71] if mediolateral episiotomy is practiced and to over 10% with midline episiotomy.[72]

Management Options

Bearing in mind the inherent anatomic vulnerability of the anal sphincter during childbirth, some risk of trauma exists even when obstetric management is optimal. Avoidance of postpartum fecal incontinence rests partly with measures to avoid occurrence of third-degree tears but even more significantly, in the appropriate management of anal sphincter injury when it occurs at delivery.

TABLE 73–2

Obstetric Risk Factors for Anal Sphincter Injury

First vaginal delivery
Instrumental delivery (forceps > vacuum)
Prolonged second stage of labor (>1 hour)
Epidural anesthesia
Persistent occipitoposterior position
Macrosomia (birth weight > 4 kg)
Shoulder dystocia
Previous third-degree perineal tear
Midline episiotomy

PRIMARY PREVENTION

Primary preventive measures include augmentation of myometrial contractions during first labors, using intravenous oxytocin to correct dystocia; in this way the incidences of instrumental delivery, occipitoposterior position, and prolonged first and second stages of labor can be minimized (for a somewhat different view, see Chapter 69). Vacuum extraction should be the first choice for low-cavity instrumental delivery, although the potentially traumatic sequence of failed vacuum followed by forceps delivery should not be ignored. Abbreviation of the passive, nonpushing second stage of labor is advisable, even in the presence of effective epidural anesthesia (again, for a somewhat different view, see Chapter 72). When episiotomy is performed, midline procedures should be eschewed in favor of mediolateral incisions approximating as closely as possible to 45 degrees.

OPTIMIZING PERINEAL REPAIR

A standard classification of the severity of anal sphincter injury has not been generally adopted. It is inevitable that the functional outcome following repair of extensive tears involving the internal anal sphincter and anal mucosa (fourth-degree tears) will be intrinsically more predisposed to continence sequelae than when only partial-thickness external sphincter trauma has occurred. Nevertheless, well-trained obstetric surgeons using appropriate operative techniques will produce the best functional outcomes, regardless of the extent of injury.

MANAGEMENT OF OBSTETRIC SPHINCTER DISRUPTION

Timing of Repair Procedure. It is standard obstetric practice to repair anal sphincter tears immediately or within a few hours of vaginal delivery—the so-called primary repair. Early repair abbreviates the patient's inconvenience and discomfort but should not preclude performance of the repair procedure by an appropriately trained obstetric surgeon. If a skilled operator is not immediately available, then delayed primary repair within 24 hours has much to recommend it, provided that hemostasis and analgesia have been produced. Delayed repair will, however, almost inevitably enhance the patient's anxiety and sense of grievance concerning her injury, with a potential incremental effect on resort to complaint and litigation.

Surgical Technique. Anal sphincter repair should be conducted with full surgical precautions, instrumentation, and lighting in an operating room setting. Slowly absorbed synthetic monofilament suture materials such as polyglyconate (Maxon) or polydioxone (PDS) should be used. Although coloproctologists employ an overlapping "figure-of-eight" approximation of the anal sphincter muscle stumps when performing secondary repairs following an interval of fibrosis and cicatrization, direct approximation of the disrupted sphincter appears to provide equally effective functional results in the well-

perfused muscle found immediately after injury at primary repair.[55] Distortion of the normal anal anatomic relationships following deep perineal lacerations means that endoanal ultrasound does not appear to offer useful intraoperative assistance in improving surgical muscle realignment. Ultrasound may have a potential role, however, in the early postnatal screening of women with ostensibly intact anal sphincters so as to facilitate selective monitoring of fecal continence among those who sustain occult forms of anal sphincter injury.

Postnatal Management. Although firm evidence is scanty, it appears likely that prophylactic broad-spectrum antibiotic therapy (e.g., co-amoxyclavulanic acid) enhances the integrity of primary anal sphincter repair during the first 3 to 5 postnatal days. On the other hand, firm randomized, controlled data exist to support the use of a laxative rather than a constipating postoperative regimen during the early puerperium.[73] Use of lactulose or ispaghula to soften the stool is associated with a shorter and less painful recovery period when compared with codeine phosphate treatment as employed by coloproctologists following elective anal surgery.

Routine Postnatal Review of Fecal Continence. Because up to 50% of women who sustain a third- or fourth-degree tear experience some puerperal symptoms of fecal incontinence, routine follow-up assessment of anal sphincter function is advisable once postnatal healing is complete. Such a review is probably best performed at 8 to 12 weeks following delivery and should consist, as delineated previously, of an assessment of fecal continence symptoms, anal manometry, and endoanal ultrasound combined with pudendal nerve evaluation, if indicated. The examination should optimally take place in an obstetric setting because it provides the patient with an opportunity to discuss not only her current continence status but also the antecedent circumstances surrounding her anal injury. The results of the anal physiology investigations facilitate the planning of further treatment and provide invaluable insights into prognosis.

Symptomatic Therapy. Minor postnatal fecal incontinence symptoms such as intermittent fecal urgency or constipation are frequently transient in nature and can often be effectively managed using loperamide or ispaghula, respectively. Perineal pain, secondary to discomfort in the sutured tissues, is amenable to targeted local injection of a combination of 2% bupivicaine, hyaluronidase, and methylprednisolone acetate. More significant tenderness and dyspareunia associated with perineal anatomic distortion can be corrected by minor surgical intervention under local or general anesthesia. Associated psychosexual dysfunction responds to early psychotherapeutic counseling initiated before secondary deterioration in sexual interaction has developed.

Postnatal Physiotherapy. Even without active treatment, fecal incontinence symptoms of minor degree are frequently transient and disappear or attenuate within a few

TABLE 73–3

Proposed Management of Multiparas in Pregnancies after Anal Sphincter Injury

TYPE OF INJURY	INVESTIGATION PROFILE	MANAGEMENT
1. Previous third-degree tear—asymptomatic	Normal manometry and ultrasound	Allow vaginal delivery

3. Successful secondary sphincter repair	Normal manometry and ultrasound	Prelabor cesarean section
4. Previous third-degree tear or "occult" injury—asymptomatic	Abnormal manometry and ultrasound	Discuss vaginal or cesarean delivery

months of delivery. Kegel pelvic floor exercises are not effective in alleviating incontinence, but the addition of operant conditioning through biofeedback physiotherapy using an endoanal stimulating probe[74] significantly improves anal sphincter function. Biofeedback therapy is particularly effective in maintaining muscle bulk while healing occurs and neuropathy recovers.

Secondary Anal Sphincter Repair. Persistent symptoms of fecal incontinence lasting for more than 6 months following delivery usually necessitate surgical repair of the damaged anal sphincter muscle. Before considering surgery, it is mandatory to exclude a coexistent neuropathic cause for the symptoms and to confirm pudendal nerve integrity. If severe neuropathy is identified, then colostomy diversion or an artificial sphincter procedure may be necessary.

Counseling during Subsequent Pregnancies. Women who suffer persistent and debilitating fecal incontinence after childbirth are likely to experience deterioration in their symptoms after further vaginal deliveries.[75] Transient symptoms that do not persist but are associated with abnormally low resting and squeeze manometric pressures and a large residual anal sphincter defect may recur following further vaginal deliveries. On the other hand, the continence of asymptomatic women with relatively normal manometric profiles is not likely to deteriorate, even in the presence of documented anal sphincter scarring on endoanal ultrasound examination. Ultrasound tends to overdiagnose functional deficits in continence[60] but should, nonetheless, be performed, together with anal manometry, when planning the mode of next delivery in women with a history of third- or fourth-degree anal sphincter injury.

As a generalization, in the absence of clear evidence of the optimal approach in such women, it is probably best to individualize the management. An empiric approach is suggested in Table 73–3.

In women who have achieved normal continence following primary obstetric anal sphincter injury and repair, further vaginal delivery is a reasonable option. However, elective prelabor cesarean section is advisable to protect the continence mechanism following successful secondary repair of the anal sphincter. The use of prophylactic cesarean delivery in women with asymptomatic ultrasonically identified sphincter defects is not justified by the published evidence.

FEMALE CIRCUMCISION (FEMALE GENITAL MUTILATION)

The World Health Organization defines female genital mutilation (FGM) as including all procedures involving partial or total removal of the external female genitalia or other injury to the female genital organs for cultural, religious, or nontherapeutic reasons.[76] This practice occurs predominantly in Africa, although affected women and girls may present anywhere in the world as immigrants from these countries. Consequently, FGM is now a global concern with human rights organizations devoted to the elimination of this practice and many countries prohibiting it by law. Medical professionals caring for affected women require knowledge and understanding of FGM.[77] Countries where there is a high prevalence of FGM include Egypt, Sudan, Eritrea, Ethiopa, Djibouti, Somalia, Mali, Senegal, Guinea, and Sierra Leone, and the WHO estimates that currently 100 million to 140 million women live with the consequences of this procedure, with a further 2 million girls at risk each year.

There are several forms of FGM that carry differing health implications:

- Type I: excision of the prepuce with or without excision of the entire clitoris
- Type II: excision of the clitoris with partial or total excision of the labia minora
- Type III: excision of part or all of the external genitalia and stitching or narrowing of the vaginal opening (infibulation)
- Type IV: pricking, piercing, or incising of the clitoris or labia, stretching of the clitoris and labia, or cauteri-

zation of the clitoris and surrounding tissue including scraping of the introital skin (angurya cuts) or cutting the vagina (gishiri cuts) and the introduction of corrosive substances or herbs into the vagina to cause bleeding and cicatrization

The greatest health risks are in women who have undergone infibulation, which accounts for about 15% of cases. FGM is usually performed on women between 5 and 8 years of age and has physical, psychological, and sexual consequences.

General Risks

Immediate risks of the FGM procedure itself when performed by a traditional practitioner using crude instruments and no anesthesia include shock, hemorrhage, sepsis, and death. There are few reliable figures of FGM-related mortality rate. Ulceration of the genitalia and acute urinary retention can also follow, as can transmission of HIV and hepatitis.

Delayed complications include urinary and vaginal infections, large epidermal cysts, abscesses, keloid scarring, obstructed menstruation, urinary incontinence, and coital and psychosexual problems which may lead to infertility.[78]

Maternal Risks

The incidence of pregnancy complications or maternal deaths related to FGM is unknown. The risks depend on the type of FGM performed; infibulation in particular can cause tender introital scarring which precludes

adequate prenatal examination, investigation, and treatment. Vaginitis is common, as are urinary tract infections. Miscarriage may be complicated by retention of products in the vagina, leading to sepsis. When labor occurs, assessment of cervical dilation may be difficult or impossible. Urinary retention in labor is common. Dystocia, usually due to soft tissue obstruction in the second stage, can have serious consequences for the mother and fetus if undetected or improperly managed. Vaginal delivery is associated with increased risks of perineal damage and hemorrhage.[79] The increased incidence of postpartum hemorrhage is mainly due to the need for anterior episiotomy or lacerations extending to the urethra, bladder, or rectum. Postpartum pain is also more severe due to a greater degree of perineal injury. Postnatal wound infections, dehiscence, and fistulas can occur.

Fetal Risks

Stillbirth and neonatal death have been reported with higher frequency in circumcised women, secondary to fetal asphyxia due to prolonged obstructed labor.[80] This sequence is generally confined to women with severe types of FGM.

Management

Prenatal

Sensitive prenatal care is essential. Women may not volunteer that they are affected by FGM, necessitating an increased awareness when treating women originating from countries where FGM is practiced. Early recognition provides sufficient time for assessment, discussion, and the development of a management plan. The extent of damage, scar tissue, and physical obstruction to vaginal delivery should be clearly documented so that unnecessary repeated examinations can be avoided. Women with a tight introitus, 1 cm or less, have the greatest risk of perineal damage. However, if the urinary meatus can be observed or two fingers can be inserted on digital examination, significant delivery problems are unlikely to ensue. Parous women who have been sutured at a previous delivery are at risk of developing significant scar tissue with subsequent infection and wound problems. Antenatal assessment also provides an opportunity to establish if the woman would wish introital dilation to allow comfortable intercourse, or to undergo a complete reversal of the procedure. Ideally, complete reversal should be avoided during pregnancy or immediately post-partum owing to the greater likelihood of hemorrhage at that time. Optimally, an anterior episiotomy sufficient only to expose the urethra should be performed during the late second stage, but occasionally this procedure must be performed earlier to allow adequate investigation or treatment during pregnancy, for example, in the case of pain and bleeding in early pregnancy. Antenatally, the health care provider can also educate affected women so as to eliminate the practice of FGM in her offspring.

Labor and Delivery

The diagnosis of labor may be difficult in the presence of a small introitus. In this case defibulation may need to be performed to allow adequate assessment. In skilled hands, intrapartum defibulation is a safe and effective procedure.[80] This procedure can be done under local anesthesia. If the opening is large enough to permit digital examination, then the decision on defibulation can be deferred to the second stage. Extra care is essential in the second stage as the delivery of the fetal head may be obstructed by scar tissue. This can result in fetal asphyxia or severe tearing in the mother, leading to hemorrhage and fistula development. If introital obstruction develops, a timely anterior episiotomy should be performed to the urethra but not beyond because of the risk of hemorrhage.

Following delivery of the placenta, a careful examination of the genital tract is necessary. In particular, the presence of high vaginal lacerations and damage to the anal sphincter, rectum, or bladder should be noted. The sides of the midline anterior incision should be oversewn to secure hemostasis, leaving the urethra exposed. Reinfibulation should not be performed, irrespective of the wishes of the woman, as this will result in further scarring and problems; ideally, this issue will have been discussed prenatally.

Postnatal

Good postnatal analgesia is important because anterior divisions are associated with more pain. Affected women may need education in relation to differences in urination, menstruation, and coital function. A specific postnatal visit should be arranged to assess healing and to discuss sexual activity.

DEFIBULATION PROCEDURE

1. Locate opening and paint with antiseptic solution.
2. Administer local anesthetic to the introitus if epidural anesthesia is not present.
3. Raise scar tissue from underlying area and incise in midline to expose urethral meatus. Do not incise beyond this.
4. Suture raw edges for hemostasis.

SUMMARY OF MANAGEMENT OPTIONS
Female Genital Mutilation or Circumcision

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Identify women at risk.	–	GPP	–
Sensitive approach: Educate couple and obtain consent for examination and treatment.	–	GPP	–
Establish type of female genital mutilation and determine if defibulation is required.	III	B	80
Discuss timing of defibulation and postnatal result.	III	B	80
Labor/Delivery			
Observe for obstructed second stage.	–	GPP	–
Perform timely defibulation or episiotomy if required.	–	GPP	–
Inspect genital tract after delivery of placenta for extension of lacerations.	–	GPP	–
Repair perineal damage and provide hemostasis.	–	GPP	–
Postnatal			
Provide analgesia and follow-up and education.	–	GPP	–

CONCLUSIONS

UTEROVAGINAL PROLAPSE IN PREGNANCY

- Troublesome prolapse is rare in pregnancy but more common during the puerperium.
- Vaginal pessary treatment is the first, and usually most effective, choice of treatment for pregnancy and postnatal prolapse.
- Persistent prolapse carries an increased risk of preterm birth.
- Delivery by prelabor cesarean section is recommended in pregnancies following previous successful repair of prolapse or urinary or fecal incontinence.

OBSTETRIC ANAL SPHINCTER INJURY

- Anal sphincter disruption follows 1% to 2% of vaginal births, more commonly first deliveries.
- Other obstetric risk factors include instrumental delivery, prolonged second stage of labor, midline episiotomy, and previous sphincter disruption.
- Enquiry about fecal continence should form part of the routine postnatal assessment.

POSTPARTUM FECAL INCONTINENCE

- Damage to the anal sphincter mechanisms can be traumatic/muscular (especially primiparas) or neurologic or a combined injury.
- Fecal incontinence symptoms require appropriate postpartum anal physiologic investigation to define both the type of injury and the most appropriate management.
- Many fecal continence disturbances are transient and can be managed effectively with drugs and biofeedback physiotherapy.
- Secondary surgical repair is necessary for women with fecal incontinence persisting for some months post-partum.

FEMALE GENITAL MUTILATION

- Medical professionals should not be involved in supervising or performing genital mutilation procedures.
- The degree of mutilation is variable and, if extensive, can interfere with management of subsequent pregnancy and delivery.
- Counseling should be provided during pregnancy with a view to postnatal surgical correction of symptomatic genital distortion.

Assisted Vaginal Delivery*

Robert Hayashi

INTRODUCTION

Assisted vaginal delivery (AVD) offers the option of an operative procedure to safely and quickly remove the infant, mother, and obstetrician from a difficult or even hazardous situation. When spontaneous vaginal delivery does not occur within a reasonable time, a successful assisted or operative vaginal delivery trial avoids cesarean section with its attendant uterine scar and implications for a future pregnancy, and avoids potential birth asphyxia from prolonged fetal and cord compression. Reviews of delivery statistics[1] show considerable variation in the incidence of AVD, but the range is usually between 10% and 20% of all deliveries. Whether the method employed is the ventouse (vacuum extractor) or obstetric forceps, the operator can expect optimal results only when careful attention is given to the indications, prerequisites, and performance of the procedure.

INDICATIONS

Maternal indications are most commonly those of maternal distress, maternal exhaustion, or undue prolongation of the second stage of labor. Prolongation of the second stage of labor is a relative indication. Many have argued that specific time limits are not needed if monitoring of the fetus shows no evidence of distress and progress is not obviously arrested. However, in cases without regional anesthesia and with reassuring fetal monitoring parameters (e.g., a normal fetal heart rate pattern) it is probably appropriate to consider intervention if the second stage in a nullipara lasts longer than 2 hours (1 hour in a multipara). A further hour is often allowed in the presence of regional anesthesia, provided the mother wishes it and fetal condition is satisfactory. The increased need for intervention following epidural anesthesia has been well documented.[2,3] This approach conforms to the ACOG (American College of Obstetricians and Gynecologists) guidelines.[4] Less common but more medically significant indications for AVD include cardiopulmonary or vascular conditions in which the stresses of the second stage should be minimized. With vaginal birth after previous cesarean section, decreasing the stress on the uterine scar may be a relative indication, although dehiscence or rupture is rare if the ACOG guidelines are followed. It has been suggested that if use of the ventouse has failed to deliver the infant but the fetal head has been brought down sufficiently, a cautious low or outlet forceps procedure is safe.[5] Significant bleeding per vaginam is also an indication for terminating labor; the source of the bleeding may be maternal or fetal (for example, placental abruption or vasa previa).

Fetal indications commonly encountered are malpositions of the fetal head, with relative dystocia. The occiput posterior (OP) and occiput transverse (OT) positions occur more frequently with regional anesthesia.[3,6] This may result from disturbance of the tone of the musculature of the pelvic floor impeding spontaneous rotation to the optimal occiput anterior (OA) position. Similarly, the maternal expulsive (bearing down) force may be compromised. Intervention with forceps for protection of the premature infant remains controversial. In the infant weighing below 1500 g, forceps delivery offers no advantage[7] and may in fact be deleterious,[8] owing to an increased incidence of intracranial bleeding. Use of the ventouse carries the same risk; vacuum extraction is probably best avoided at less than 34 weeks. Spontaneous delivery (with a generous episiotomy if delivery is delayed at the perineum, or the outlet appears tight) and manual control of the head appear preferable, with abdominal delivery if operative intervention is needed.[8]

In the low-birth-weight infant (1500–2500 g) assisted vaginal delivery is more widely accepted but should be managed with caution and minimal force.[9,10]

Fetal distress is a commonly cited indication. This expression is subject to varied interpretation, which may range from a brief bradycardia to prolonged late decelerations with acidosis. "Presumed fetal jeopardy" may be a preferable term, in conjunction with recording of as precise a description of the situation as possible in order to validate the indication.[4]

Vaginal delivery of the breech is considered by some to be an indication for forceps to the aftercoming head.[11,12] When the management decision is made to deliver vaginally (see Chapter 64), forceps to the aftercoming head may be considered routinely. The procedure becomes mandatory if the body has delivered and the Mauriceau-Smellie-Veit maneuver has failed. A putative advantage is the avoidance of traction force on the trunk and cervical spine, together with automatic control of the flexion of the fetal head. This may decrease the risk of hyperextension[13] and cervical plexus injuries.[14]

CONTRAINDICATIONS

Lack of engagement (leading bony point at or above the level of the ischial spines) suggests pelvic inlet dystocia and is usually considered an absolute contraindication to AVD. Conditions in which vaginal delivery per se is contraindicated include known pelvic abnormality with fetopelvic disproportion and fetal anomalies if obstructive or subject to damage from vaginal delivery. Certain fetal malpositions, such as a brow presentation or a face presentation in other than chin anterior position, are not suitable cases, nor is the dead fetus with postmortem changes. Inability to diagnose the position of the fetal head accurately or to apply the instrument properly are major contraindications.[1,15,16]

Several factors are relative contraindications. Fetal macrosomia may be such a factor. In general, the higher the head, the greater the difficulty and the need for performance skill. An increased risk of shoulder dystocia with midcavity procedures with macrosomia and an arrest has been reported.[17] The proficiency and experience of the operator are also factors to be considered. Finally, caution should be used with a ventouse procedure on a fetus who has had fetal scalp blood samplings performed because of the possibility of enhanced fetal scalp bleeding.[11]

DEFINITIONS

Significant comparative statistics have always been difficult to collect owing to differences in the classification, initially of forceps, but now of all assisted vaginal deliveries. ACOG has proposed a more specific classification,[4,18]

which has proved to be of clinical value[19,20] and deserves universal adoption. This classification is given in Table 74-1. It applies equally to vacuum extractor and forceps procedures.[4] To the classification of low forceps, a significant clinical addition would be the observation that, on examination, the head must fill the hollow of the sacrum.[21] Station of the head is measured in plus or minus centimeters of distance between the leading bony point of the skull and the ischial spines.

Neonatal results comparable to those of spontaneous delivery can be expected, with procedures categorized as outlet or low with rotation less than 45 degrees.[1,22,23-26] Midpelvic and rotational procedures are generally associated with a higher rate of morbidity than spontaneous delivery.[27] However, when compared more properly with appropriate alternatives of management, namely, manual rotation followed by forceps or ventouse extraction or delivery by cesarean section, results are equivalent.[23,27-31] It is clear that abdominal delivery is associated with a much higher rate of maternal febrile morbidity. The controversy continues; appropriate selection and proficiency in execution of the maneuver remain the unmeasurable variables that often determine the results of trials.

"Failed forceps" and "failed ventouse" are terms that have a pejorative implication. They can carry the stigma of poor judgment, poor obstetrics, and perhaps negligence in that disproportion was unrecognized. Alternatively, a "trial" (psychologically a better term) of forceps or ventouse connotes a cautious attempt at vaginal delivery with the option of altering management if unusual difficulty is met.[13] A trial of forceps or ventouse is appropriately carried out in an operating theater with immediate recourse to cesarean section if vaginal delivery is not achieved. The

TABLE 74-1
Classification of Forceps Deliveries According to Station and Rotation

TYPE OF PROCEDURE	CLASSIFICATION
Outlet forceps	Scalp is visible at the introitus without separating labia
	Fetal skull has reached pelvic floor
	Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position
	Fetal head is at or on perineum
	Rotation does not exceed 45 degrees
Low forceps	Leading point of fetal skull is at station ≥ + 2 cm, and not on the pelvic floor
	Rotation ≤45 degrees (left or right occiput anterior to occiput anterior, or left or right occiput posterior to occiput posterior)
Midforceps	Rotation >45 degrees
	Station above +2 cm but head engaged
High forceps	Not included in classification

procedure deserves greater utilization.[32] A gentle negative trial should not alter outcome.[33,34]

PREREQUISITES

In management of an AVD certain prerequisites must be met.[4] The head must be engaged (as defined by the biparietal diameter having passed through the plane of the inlet of the pelvis (Fig. 74–1)). Generally this will have occurred when the leading bony point has reached the ischial spines. It must be remembered that certain conditions may lead to a higher than anticipated level of the biparietal diameter.[21] This is true with molding, particularly with macrosomia. Asynclitism and occiput posterior positions are associated with a higher level of the biparietal diameter, as is any extension of the fetal vertex away from a well-flexed position. These factors must always be considered when estimating engagement of the head if the assessment is to be accurate.

The position and attitude of the head must also be known if an accurate and effective application of the chosen instrument is to be made. Should the operator be unable to diagnose the position of the fetal head from the fontanels and suture lines, feeling for the location of an ear can be helpful. This can, however, produce a loss of station and backward rotation of the head due to the necessary displacement of the vertex, which may then mitigate against delivery. The use of ultrasound (with the transducer placed just above the symphysis pubis) may also help determine fetal head position.

The maternal pelvis should be evaluated for the adequacy of the fetopelvic relationship. Factors such as maternal overweight or diabetes with related fetal macrosomia should be considered. An obvious disproportion contraindicating vaginal delivery must not be present. Clinical evaluation rather than radiographic pelvimetry should be adequate for estimation of the midpelvis and the pelvic outlet.

The bladder should be empty for procedures at other than outlet level. Membranes must be ruptured and the cervix must be fully dilated and retracted, or marked obstruction to rotation or decent of the head will result. There is no place in modern obstetrics for manual or mechanical dilation of the cervix or for cervical incisions to facilitate an operative procedure.[13] The rare exception may be the trapped head in a breech delivery.[35] Appropriate anesthesia is needed for any AVD, although applying the ventouse usually causes less maternal discomfort and the requirement for anesthesia may therefore be less. Although outlet and possibly some low forceps procedures may be performed with local perineal infiltration, a pudendal block is usually more appropriate. For any rotational procedure a regional block (epidural or spinal) is necessary.[35] In rare circumstances, a general anesthetic may be necessary. In the UK, it has been suggested to be medicolegally advisable to have an anesthesiologist attend and confirm that adequate analgesia has been produced before proceeding with any but the most urgent operative vaginal delivery. This does not happen in the majority of units.

Although the simplest operations may be undertaken in an informal birthing room setting, most procedures deserve a delivery room/operating theater. Facilities, equipment, and personnel should be adequate for support of patient, infant, and operator in case of any adverse development. A negative trial of AVD should result swiftly in abdominal delivery instead.[4]

Because complications tend to increase in inverse ratio to the technical skill and experience of the operator, physician knowledge of the instruments and the physical forces involved in their use is essential. The operator must know his or her limitations and be prepared to abandon the procedure in case of difficulty. The use of greater force is the worst of the available options.

COMPLICATIONS

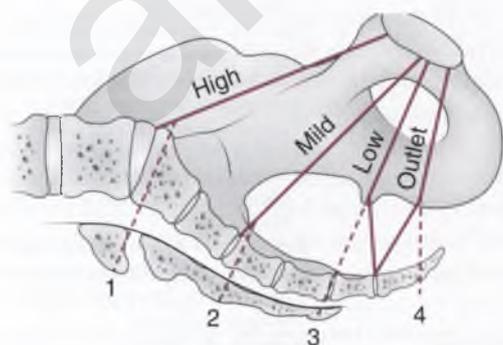
Most of the complications of AVD have also been reported following spontaneous vaginal and even abdominal delivery, but their incidence is greater with AVD. Assessment of causation is frequently problematic because this type of delivery is so often accompanied by other fetal and labor factors that commonly are associated with birth injury. However, it is obviously difficult for the operator to disclaim responsibility for an injury subsequent to an instrumental delivery. Maternal complications are usually those of soft tissue trauma and tend to be reported more frequently with the use of forceps than with ventouse. They can include uterine, cervical, or vaginal injury, laceration, or hematoma. Bladder or urethral injury may occur, including postpartum urinary retention and late fistula formation. Rectal laceration (with or without episiotomy) and subsequent fistula may occur, as well as later problems in defecation.[1] Increased blood loss is common with more difficult procedures. Maternal injury with use of the ventouse includes inadvertent entrapment of the


FIGURE 74–1

cervix or vaginal wall between the cup edge and fetal head with consequent laceration of the maternal periurethral and vaginal tissues. Placement of the cup should never be done carelessly or forcefully.

Fetal complications of forceps delivery include transient facial marks, facial palsies, and fracture of facial bones or skull. Severe cervical cord damage following midforceps rotation has been reported,[36] but such serious trauma is extremely rare. Injury from the ventouse includes minor, and occasionally severe, scalp injury, including scalp bruising, abrasion, laceration, cephalhematoma, subgaleal hematoma, and intracranial hemorrhage. Subgaleal hematomas are thought to be due to disruption of the diploic vessels in the loose subaponeurotic scalp tissue that allows a large volume of bleeding to occur over time.[19] The entire scalp can be elevated. Tentorial tears have been associated with mechanical injury to the fetal cranium and are thought to be related to the shearing forces on the tentorium, resulting in rupture of the deep venous system or laceration of the inferior surface of the cerebellum.[20] Although the pathophysiology is not clearly understood, the vacuum extractor may produce stress on the fetal cranium in the occipital frontal diameter, with tension on the tentorium. The tentorium may then rupture, causing intracranial hemorrhage. Because of these uncommon, but serious, sequelae in infants following a ventouse delivery, all such infants should be carefully observed following birth for any neurologic signs of irritability, drowsiness, tachypnea, seizure activity, or an enlarging head size.[37] Any such signs should be carefully investigated.

Cephalhematoma may be associated with an underlying skull fracture.[38] Fortunately, most documented series of vacuum extractions report no such serious complications. However, neonatal jaundice and retinal hemorrhage are found more frequently with the ventouse.[35] Brachial plexus palsy related to shoulder dystocia and facial nerve palsies are slightly more common after AVD than after spontaneous deliveries.[37,39] Opinions vary on the risk of long-term neurologic damage related to AVD. The subject is under continuing investigation.[10] Some studies show a relationship between cerebral palsy and difficult forceps procedures, whereas others fail to confirm such a relationship.[28] It is generally believed that most neurologic deficit is unrelated to incidents occurring at delivery or to substandard intrapartum obstetric care.[40]

RISK MANAGEMENT

In the vast majority of AVDs the normal outcome gives no reason for complaint. However, in our litigious society a bad outcome increases the risk of litigation against the operator or hospital, regardless of the cause.

In lawsuits against physicians who chose the option of AVD, the common allegations[41] are inadequate indica-tion, failure to rule out cephalopelvic disproportion, and faulty performance causing fetal injury (this may include incorrect diagnosis of station or position, improper use of instruments, or the use of excessive force). The lack of informed consent is frequently cited. Although strongly urged by attorneys, obtaining fully informed consent is often not feasible in an emergency situation. In such circumstances, the best defense is to be able to demonstrate the need for and appropriateness of the procedure and its performance (in other words, the indications for intervention should be absolute and not relative, and execution of the intervention must be competent). As an absolute minimum, if prior informed signed consent is not obtained, the chart should note a discussion of the procedure with the woman, her partner, and even (if appropriate and there is time) with her family. Physicians in training may be particularly vulnerable to lawsuits unless adequate supervision is present. The "learning curve" excuse is invalid because all patients are entitled to the same standard of care.

In any suit following a bad outcome, regardless of the delivery mode, the operator is forced into a defensive position, attempting to prove that the outcome was due to factors other than the alleged misdeeds. After the fact verbal explanations of usually poorly remembered events may appear to be merely an effort to escape responsibility. Careful documentation is the keystone in the operator's defense. Notes that outline the clinical circumstances, the cognitive steps in choice of options of delivery, and a detailed operative note of maneuvers used are mandatory. Consideration of a cesarean section option, possibly with simultaneous preparations, should be noted, particularly with a midpelvic procedure. Many institutions routinely measure cord gases in all assisted vaginal deliveries in order to document the infant's condition at birth. Finally, the fear of litigation should not dictate medical practice; AVD remains good medical practice in appropriate circumstances and with appropriate safeguards. Despite this exhortation, however, a survey showed that by 1996 over half of ACOG fellows had already abandoned midcavity AVDs in favor of cesarean section.[42]

INSTRUMENTS AND CHOICE OF PROCEDURE

Ventouse/Vacuum

The principal idea of the vacuum extractor is to use a cup device attached by tubing to a pump to create enough negative pressure to allow traction on the cup. In this way, traction is transferred to the fetal head (scalp) which is thereby pulled along the birth canal axis. Traction is applied during a uterine contraction, resulting in descent of the fetal head by a push-pull effect. Positioning of the cup on the fetal head and the development of a caput succedaneum are important considerations.

Malström devised a metal cup with rounded edges and an outside diameter of 60 mm, with the vacuum tubing and traction chain coming off the center of the back of the cup dome. By gradual increments of negative pressure, the fetal scalp is sucked into the hollow of the shallow cup to create a caput succedaneum called a "chignon." Placement of the chignon is very important and a major determinant of outcome. If properly placed at the "flexing point" of the fetal head, a point located on the sagittal suture 3 cm in front of the posterior fontanel, traction will result in maximal flexion of a synclitic head.[43,44] Incorrect placement may result in deflexed and asynclitic fetal head attitudes and consequent failure of the vacuum extractor technique (Fig. 74–2). Assuming that the length of the sagittal suture is approximately 9 cm at term, when the cup is properly placed on the flexion point, the leading edge of the cup will be about 3 cm away from the anterior fontanel.[44] Proper cup positioning is crucial to move the fetal head from a midpelvic level to the plane of the outlet of the birth canal, and thus, positioning should always be a primary concern when performing a ventouse delivery.

An important modification to the Malström vacuum extractor was designed by Bird.[43] He moved the vacuum hose and traction chain attachment from the dome to the lateral wall or rim of the cup. This modified cup was to be used specifically for posterior and lateral positions of the occiput. This alteration allowed easier placement of the cup over the flexing point, and its utility has been supported by an observational study in Portsmouth.[45]

Traction force studies have suggested that 22.7 kg (50 lb) of traction force may be the upper limit of fetal safety for assisted deliveries.[46–48] Duchon noted that with a vacuum cup having a diameter of 60 mm, a vacuum of 550 to 600 mm Hg (0.8 kg/cm^2) will allow 22 kg of traction force before detachment or "pop off" occurs.[49] This should be considered the end point of safety, and inappropriate increases in vacuum should be avoided to minimize fetal morbidity. Repeated detachments of the cup are often associated with scalp injury.

In 1973, Kobayashi introduced a single unit pliable Silastic cup with a stainless steel valve on the stem that allows for relief of a significant amount of the suction force to the scalp between contractions without loss of application of the cup to the fetal head.[50] The Silastic cup diameter is 65 mm and fits over the fetal occiput like a skull cap. The advantage of this design over the metal cup is that there is less scalp trauma because the cup has no rigid edge and can shape to the fetal head. Also, there is no need to take time to develop a chignon so that traction can be applied shortly after proper application. The disadvantage is that placement of the cup center over the flexing point of the fetal head is not easily done on a nonflexed head in the midpelvic area. Two randomized comparisons of the soft cups with rigid cups have been reported.[51,52] Both found a higher failure rate with the Silastic cup, especially with occiput posterior positions. On this basis, use of the Silastic cup should be restricted to easy or outlet procedures. Nevertheless, because of the perceived increased safety and convenience of the soft cup, this device has almost completely replaced the metal cup for use in vacuum extractor deliveries in the United States.

In 1973, a three-component plastic system vacuum extractor composed of a disposable plastic replica of the Malström cup with a flexible handle stem that can be attached to disposable plastic tubing and reusable hand pump was described by Paul and associates[53] from the University of Southern California. They reported favorably on their experience with the device. The cup was 50 mm in diameter and required the development of a chignon as with the rigid cup. The advantage over the rigid cup was the simplicity of assembly because there were fewer parts to fit together. Also, defective tubing and rough edges on the cup were avoided. In later years, the cup was modified to remove the necessity of forming a chignon before traction. The cup diameter was increased to 60 mm and the cup shaped like a teacup (i.e., the dome was deepened). This device is called a Mityvac.

A new device, called the Kiwi Complete Delivery System, has been introduced that has incorporated several important aspects of past experience and innovative new ideas. The innovative aspect of this completely disposable system is the use of a hand-pump/traction system directly attached to the vacuum cup that allows the obstetrician to develop the negative pressure via an accurate vacuum indication gauge in the traction handle. The two vacuum cups utilize past experience for design. The Kiwi Pro Cup is a soft, flexible, 65-mm diameter cup, similar

to the Kobayashi cup that expands to mold to the fetal head in the low occiput anterior position. The Kiwi Omni Cup is a rigid, flat plastic cup, 50 mm in diameter, similar to the Malström metal cup. The traction/suction line is anchored in the center of the back of the cup and can flex into a radial recession on the back side of the cup to allow lateral traction like the Bird modification of the Malström cup. This design facilitates rotational function of the device for malpositions such as occiput transverse or posterior. Because of its unique design and convenience for the operator, the Kiwi Complete Delivery System is becoming popular (Fig. 74–3).

Because maintained vacuum or negative pressure is crucial for effective use of the ventouse extractor and "pop off" can result in fetal scalp trauma, properly maintained equipment to provide an airtight seal within the pump and tubing is essential. The equipment should be regularly serviced and defective parts (including smooth-rimmed cups) replaced. The operator should test run the system for air leakage immediately before applying the cup to the fetal head.

PROCEDURE: VENTOUSE DELIVERY

GENERAL

After determining that there is a clear indication for a ventouse delivery, the operator should discuss the following issues with the patient or her partner:

- The alternative methods of delivery available
- The advantages and disadvantages of the vacuum extractor
- The expected outcome
- Any possible complications (both minor and serious)

These issues should be recorded in the notes at some time close to the procedure. Ideally, the operator should have a choice of vacuum extractor type, so that they can choose an appropriate instrument for the situation.

SILASTIC OR PLASTIC CUP

This can be used for a flexed, relatively synclitic fetal head at the pelvic outlet, whereas for a deflexed, asynclitic fetal

FIGURE 74–3
Delivery with ventouse/vacuum.

head, use of the Kiwi cup carries a higher chance of successful delivery. If fetal head malposition, such as occiput posterior or transverse, causes dystocia, then use of the Bird cup (or Kiwi Omni Cup) would be a good choice. An incorrectly chosen instrument lessens the chance of a successful outcome. Before application of the cup to the fetal head, the operator must check the pump, hose, and cup, fully assembled, for proper and maintained negative pressure when the cup is applied to the palm of a gloved hand.

After the patient has been washed with antiseptic solution and draped in the dorsal lithotomy position for delivery, the operator should empty the urinary bladder and then check the fetal head position and station. Analgesia should preferably be by regional block, placed previously. However, an alternative for deliveries expected to be straightforward is a pudendal block with perineal infiltration of local anesthetic.

The application technique of the cup will differ, depending on whether the cup is metal or soft.

MALSTRÖM METAL CUP

For the Malström metal cup, betadine or an antiseptic soap solution is applied to the rim of the cup and the cup slipped carefully into the vagina. The cup is then positioned over the flexing point of the fetal head with the rim nearest to the anterior fontanel positioned 3 cm from it (see Fig. 74–2). The negative pressure of the system is increased to 0.2 kg/cm^2, and the perimeter of the cup is checked for entrapped cervical or vaginal tissue. Negative pressure is increased by 0.2 kg/cm^2 every 2 minutes to a maximum pressure of 0.8 kg/cm^2 in order to build the chignon. At this point, traction in the axis of the birth canal can be applied during uterine contractions.

By placing a hand in the vagina with the thumb on the cup and index finger on the fetal scalp, traction force can be monitored in the following manner:

- Gradually increase the traction force until the cup begins to slip away from the fetal scalp, diminish the traction somewhat, and then hold for the remainder of the uterine contraction.
- Release traction between uterine contractions.

The expectation is that the presenting part should descend with each push-pull event and that the head will be delivered within approximately five pulls. The fetal heart rate is monitored throughout the procedure with an external fetal heart rate monitor. Once the head is delivered, the suction is disconnected and the cup is removed.

SOFT CUP (See Fig. 74–3)

For application of the soft cup, a flexed synclitic fetal head position is presumed. After application of betadine or antiseptic soap solution to the cup rim, the edges of the cup are carefully folded in to diminish its diameter and it is then inserted into the vagina. Because of the larger overall size of the Silastic cup, periurethral and labial lacerations can occur

easily unless extra care is taken. Once on the fetal head, the operator should palpate around the edges of the cup to clear any trapped tissues, move the stem of the cup as close to the flexing point near the occiput as possible, and pump the negative pressure to 0.2 kg/cm^2. A further check should be made for any tissue under the cup rim, then a uterine contraction should be awaited. With the onset of a uterine contraction, the negative pressure is increased to 0.8 kg/cm^2 and traction exerted, placing the intravaginal hand and fingers as noted previously to monitor the traction force (see Fig. 74–3). After the contraction, the partial release valve mechanism is triggered to drop the negative pressure to 0.2 kg/cm^2 between contractions. Expectations for progress are the same as noted previously. The operator using a vacuum extractor must be willing to abandon the technique if obvious progress of descent is not evident with approximately five push-pull events or after several "pop offs." An attempt at forceps delivery at this point is ill-advised.

FORCEPS

Obstetric forceps in current use may be loosely grouped in two major categories—classical and special. Classical instruments are related to those devised by Sir James Y. Simpson (1848) and by George T. Elliot (1858). Simpson type forceps are characterized by a spread shank and somewhat longer cephalic curve. Examples of the type are the long and short Simpson, Simpson-Braun, Luikart-Simpson, DeLee, Hawks-Dennen, Neville Barnes, and Wrigley, as well as the DeWees and many obsolescent axis traction instruments. They are preferred by many for their superior traction ability. The Elliot type forceps are characterized by overlapping shanks and a shorter cephalic curve. Examples of the type include the Elliot, Tucker-MacLane and its Luikart modification, Bailey-Williamson, and others.

Special instruments include the Piper forceps designed for the aftercoming head in breech delivery, the Kielland forceps for rotational delivery at any station, the Barton forceps for transverse arrest in the flat pelvis, the divergent forceps of Laufe and Zeppelin, the Moolgaoker, the Shute, and other cleverly designed instruments. A key feature of instruments such as Kielland or Moolgaoker forceps is their lack of pelvic curve, which facilitates atraumatic rotation but reduces their effectiveness for axis traction.

The choice of instrument is often influenced by regional as well as personal preferences. For example, the Wrigley and Neville Barnes instruments commonly used in the United Kingdom and Canada are almost unknown in the United States. Some operators prefer to approach most clinical situations with the same instrument, thereby losing the unique clinical advantages of the various available forceps. The larger, more molded head is more accurately contacted by the blades with the longer tapering cephalic curve of a Simpson type, whereas the unmolded head is better accommodated by the shorter, full cephalic curve of an Elliot type.[21,35,54]

With the occiput in an anterior quadrant any classical instrument with the appropriate cephalic curve may be chosen. Most commonly used for outlet or low forceps are the Wrigley, the Simpson (short or long), or an Elliot type of instrument. For low forceps with rotation greater than 45 degrees several alternatives are available. Most operators prefer a special instrument for rotation, such as the Kielland, the Moolgaoker, or Shute; however, either an Elliot or Simpson type of classical forceps may also be used. At midforceps level the same choices apply, but the need for axis traction principles becomes more important. In the United Kingdom it is traditional not to use forceps with a cephalic curve because of the supposed increased risk of spiral tears of the vagina. For forceps to the aftercoming head, Piper forceps are generally preferred, although the Kielland forceps and even classical forceps have been used effectively.

PROCEDURE: FORCEPS DELIVERY

POSITION

Numerous texts outline many of the specifics of procedure for forceps delivery. Certain principles given here have universal pertinence to the use of forceps, regardless of the type of instrument chosen. In some areas, the least complicated procedures may be performed with the patient in Sims' lateral recumbent position. For clarity, the use of the lithotomy position (with wedging under the right buttock to produce some lateral tilt and avoid caval compression and maternal hypotension) is assumed in the following discussion. Once the prerequisites for forceps use have been observed (indication explained to the mother and permission obtained, adequate analgesia ensured, maternal bladder emptied, membranes ruptured, position and station of the head determined), the aspects of application and traction must be considered.

APPLICATION (Fig. 74–4)

Application is extremely important to the safe and accurate control of the head as force is transmitted from the operator to the fetal skull via the instrument. To minimize the amount of force required and the potential of trauma, descent of the long axis of the head must be accomplished in the axis of the pelvis. If the landmarks on the head are obscured and the fetal position is unknown, the operator should not use forceps.[15]

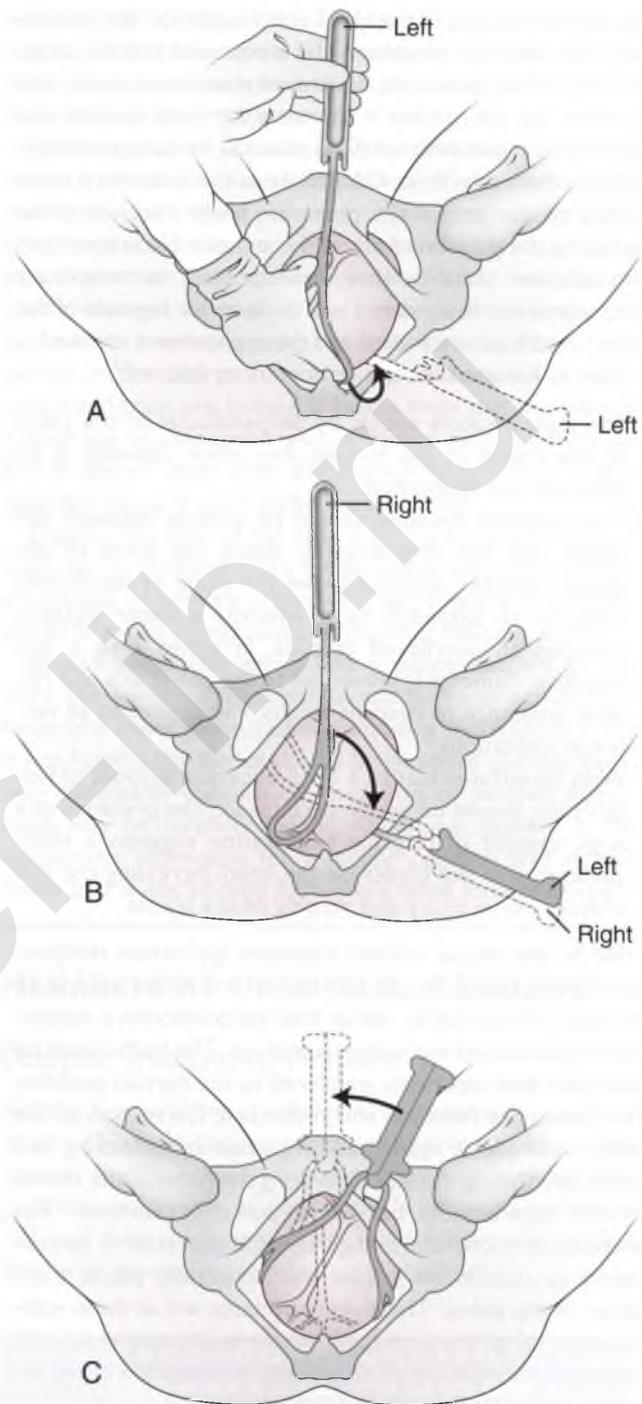
In an oblique anterior position of the occiput, the blade of a classical instrument going to the posterior segment of the pelvis should be inserted first.[4] The posterior blade then splints the head, preventing rotation to a less favorable occiput transverse as the anterior blade is wandered into place. With classical instrument applications, the left blade is held in the left hand and is applied to the left side of the mother's pelvis and to the left side of the fetal head. These four points of laterality are reversed for the right blade.


FIGURE 74–4
Forceps application left occiput anterior position.

Exceptions, when a left blade would go to the right side of the head, would include application to an OP position, to an aftercoming head, or with certain special instruments and maneuvers such as the Scanzoni rotation.

To commence insertion, the posterior blade is held vertically, perpendicular to the long axis of the patient. The cephalic curve of the instrument is approximated to the curve of the fetal skull, guided by the fingers of the opposite hand. The handle is gently moved in an arc away from the midline toward the thigh, then downward, then back toward

the midline. The toe of the blade slides higher on the head to seat over the malar eminence. This is repeated with the anterior blade. The amount of downward component in the arc traversed by the handles is the same for each blade in the case of an occiput anterior (OA) position. Increasing rotation of the occiput away from OA decreases the downward component of the arc of the posterior blade insertion while increasing the downward arc of the anterior blade insertion. The anterior blade is often more subject to temporary obstruction as it is wandered into the anterior segment of the pelvis. The blades are locked and the application is checked.

Checks for accurate application are as follows[21]:

- The sagittal suture should be perpendicular to the plane of the shanks of the forceps. Any other situation is an asymmetrical application.
- The posterior fontanel should be midway between the blades and one fingerbreadth above the plane of the shanks. Greater distance above the plane of the shanks indicates an extended head, whereas a lesser distance indicates an overflexed attitude. In either case, a less favorable diameter is presented to the pelvic axis and relative resistance to descent results. This applies to all vertex presentations.
- With fenestrated blades, a small but equal amount of fenestration should be felt on each blade. The presence of a large amount of palpable fenestration suggests a short application of the blades on the head, increasing the risk of facial nerve injury and slipping of the blades.

When the checks indicate improper application, readjustment is necessary. Should the sagittal suture be oblique to the plane of the shanks rather than perpendicular, a dangerous brow-mastoid application is present. The blades must be unlocked, then separately wandered to the correct position. The blades are relocked and rechecked. Correction of the flexion attitude is readily accomplished by unlocking and separately shifting the blades to bring the plane of the shanks to one fingerbreadth below the posterior fontanel. The presence of more than a fingertip of fenestration is an indication to unlock the blades and separately adjust them higher in the pelvis. These readjustments are all done without removal of the forceps. If proper application cannot be accomplished, removal of the forceps, reevaluation of the situation, then reapplication are indicated.

TRACTION

The ultimate and dominant function of the obstetric forceps is traction to accomplish descent of the head in the birth canal. The pelvic curve, so carefully designed into the instrument, is mechanically effective with the occiput in the anterior position. Increasing rotation of the occiput away from OA decreases the pelvic curve until it is nonexistent in occiput transverse (OT). Thus, a correctional rotation of the head to OA should be accomplished either before or with the onset of traction. The head is rotated along its long axis by rotating the handles in a wide arc ending with the occiput

at OA. The toes of the blades should describe as small an arc as possible in the upper pelvis.

Compression of the fetal head is an undesirable forceps effect and should be minimized by the use of the fingerguards rather than squeezing the handles during traction. Force applied at the fingerguards is so close to the fulcrum at the adjacent lock that negligible compressive force is applied to the head. The natural compression supplied by the pelvic walls and intervening soft tissues serves to maintain the position of the instrument on the head. Assuming that the clinical situation permits, traction should be timed to coincide with uterine contractions and voluntary expulsive effort by the mother. The operator may be seated or standing, well balanced, using principally shoulder and arm muscles. Traction force should be increased gradually rather than rapidly. Jerking the instrument increases the risk of injury to fetus and mother. A steady pull should be maintained and then gradually released as the contraction wanes. The number of pulls and the force required will vary with the case. Delivery should usually be effected by traction with no more than three contractions, employing no more than moderate force. There are two components of traction, both of which must be considered: direction and amount.

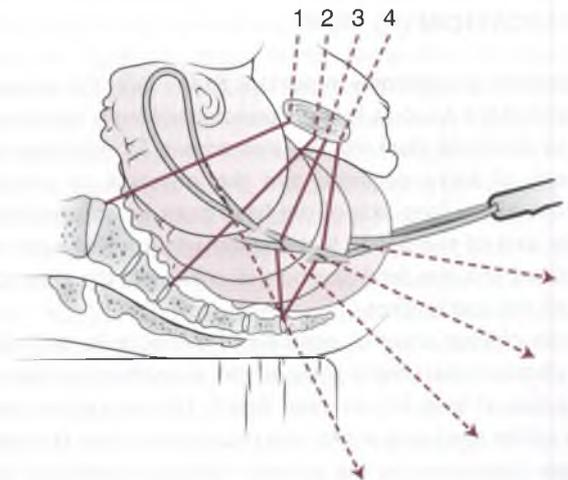
The direction of traction must be in the axis of the pelvic curvature, the curve of Carus. This direction alters with the different obstetric planes of the pelvis (see Fig. 74–1). The critical head diameter that must be moved is the biparietal diameter. Effective force must be directed as a perpendicular to the plane of the pelvis at the level of the biparietal diameter (Fig. 74–5) using an axis traction principle. This is done manually with the Pajot-Saxtorph maneuver with traction outward on the fingerguards and downward on the shanks of the instrument (Fig. 74–6). The resultant vector of force ideally is in the proper direction. This vector must be estimated by the operator and is more difficult with the biparietal diameter at higher station. The axis traction


FIGURE 74–5
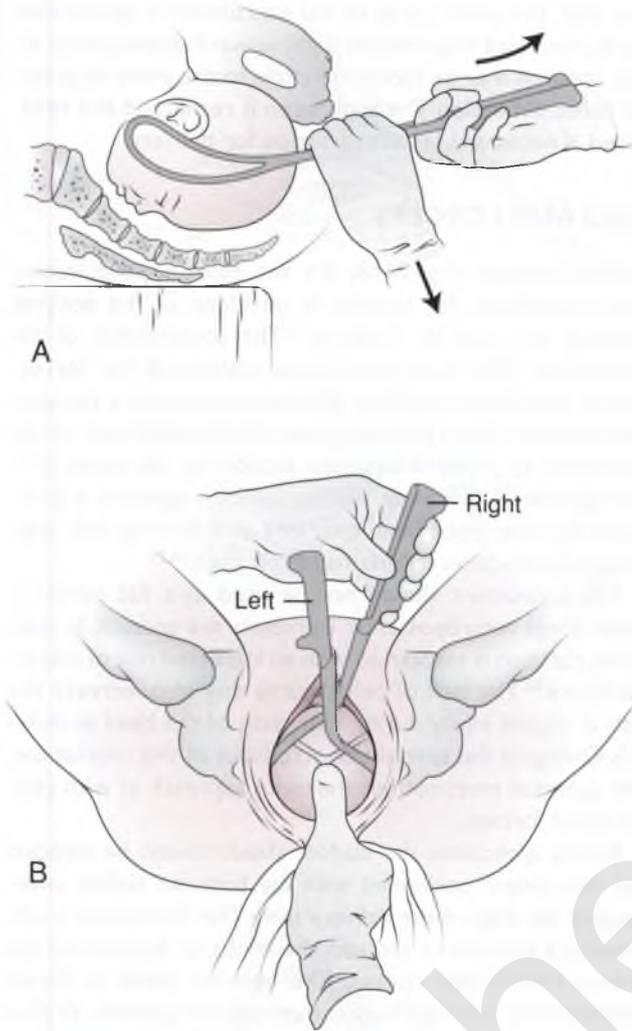
Line of axis traction (perpendicular to the plane of the pelvis at which the head is stationed) at different planes of the pelvis: 1, High. 2, Mid. 3, Low. 4, Outlet. (From Dennen PC: Forceps Deliveries, 3rd ed. Philadelphia, F.A. Davis, 1988.)


FIGURE 74–6
A, Traction. *B,* Removal of forceps; Ritgen head control.

principle is more easily accomplished instrumentally with an attachment such as the Bill handle which will fit any classical forceps, or with an axis traction instrument.

As the biparietal diameter descends, the direction of traction and the level of the handles rise. The long axis of the head tends to be held in the axis of the pelvis by maternal structure pressure. With traction and elevation of the handles, observation of the edge of the instrument in relation to the adjacent scalp can show the operator the proper direction of pull. If the instrument is elevated too soon, the scalp appears to sink in relation to the upper edge of the blade. Conversely, late elevation of the instrument results in the scalp rising as the head is forced to extend. As the occiput passes under the symphysis pubis, the handle elevation may reach 45 degrees above the horizontal. Higher elevation of the handles increases the risk of vaginal sulcus tears.

The amount of traction force should always be the least possible to accomplish reasonable descent. Maximum permissible force is 45 lb (20 kg) in the nullipara or 30 lb (13 kg) in the multipara.[13] Most deliveries are accomplished

with considerably less force. The amount of vectored force may be difficult to estimate when using manual axis traction. With a traction attachment, the vectored force is equal to the total traction force exerted.

Episiotomy, quite popular in North America, is less so in other areas of the world. Regardless of the controversy over routine use of the procedure, episiotomy results in the need for less tractive force. There is continuing controversy about whether the episiotomy should be mediolateral (posterolateral) or midline; this author prefers the median approach as more cosmetic, easier to repair, and much less painful in the puerperium. However, although data from controlled trials are lacking, it seems likely that the median episiotomy is associated with a higher rate of third- or fourth-degree tears than the mediolateral.[15] Thus, either approach appears valid at the present time.

During extension of the head over the perineum, the forceps may be removed and a Ritgen maneuver performed for completion of delivery of the head. The fetus should be monitored between contractions throughout the procedure.

Should reasonable effort not produce descent of the head, the initial management should be to direct traction force to a lower plane, rather than using more force. If this is not helpful, the blades should be removed and the situation completely reevaluated. The same, or another, instrument may be carefully applied. Abdominal delivery is the appropriate alternative for a second negative trial. A ventouse trial is not advised following a failed forceps delivery.

MANAGEMENT OF SPECIAL SITUATIONS

Occiput Transverse Position

Although possible with a flat pelvis, spontaneous delivery as an OT rarely occurs; most will rotate to OA or OP. Should timely delivery become necessary with an OT position, or in cases of the relatively common persistent OT and deep transverse arrest, several options are available, with equivalent results for all methods.[55]

> ### PROCEDURE: OCCIPUT TRANSVERSE POSITION

MANUAL ROTATION

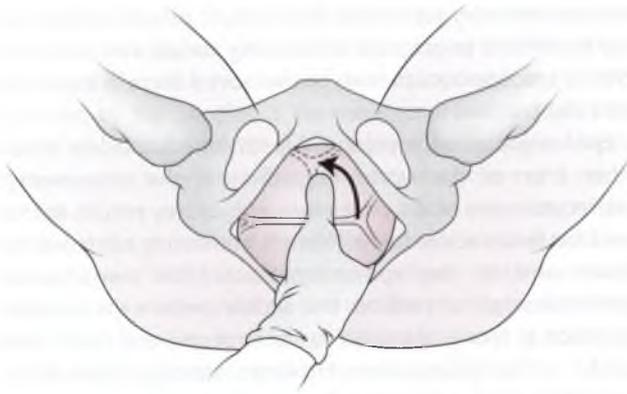
Manual rotation (Fig. 74–7) is a method used successfully by some operators. Used alone and followed by spontaneous delivery there is a significant decrease in the danger of sulcus and vaginal tears.[54] Assuming planned subsequent forceps use, the hand used for rotation depends upon the location of the occiput. Because the left hand would be used to guide the toe of the right forceps blade after manual rotation from an ROT OT to OA, the left hand is used for rotation from ROT. Conversely, the right hand rotates from LOT. The fingers are introduced into the vagina behind the posterior parietal bone with the palm upward and the thumb over the anterior


FIGURE 74–7
Manual rotation of the head.

parietal bone. The head is then flexed, if possible, and rotated toward OA. Fundal pressure fixes the head, and the posterior blade of the forceps is applied as the fingers splint the head in its new position. Rotation is usually easiest with the biparietal diameter at the plane of greatest pelvic dimension. Higher displacement of the head, even disengagement, is considered potentially hazardous. Some operators feel that resorting to this alternative is an acceptable risk, with fundal pressure reengaging the rotated head in OA, provided that immediate recourse to abdominal delivery is available.

CLASSICAL FORCEPS

Classical forceps rotation is commonly used, although accurate application to the head in OT is more difficult to accomplish than in anterior positions. More points of obstruction may be met in wandering the anterior blade. Midforceps rotations are particularly difficult because the pelvic curve of the instrument is not available in the transverse position, and in application the perineum may obstruct adequate depression of the handle of the anterior blade. The Simpson type instrument may be used, but the Elliot type overlapping shanks offer less resistance to rotation and application may be slightly easier.[56]

Initial application of the anterior blade has been advocated.[15] Most prefer application of the posterior blade first. The blade (left blade in an LOT) is introduced directly posterior to the head following the plane of least resistance until the handle is below the horizontal. The handle is lower with increasing height of the head. To compensate for the pelvic curve of the instrument, the handle must deviate laterally away from the midline during insertion so that the toe stays in the midline. The anterior blade (the right blade in the case of an LOT) is introduced as high as possible under the pubic ramus with the handle initially almost vertical. The handle descends through an arc of nearly 180 degrees. The heel of the blade is simultaneously wandered upward with pressure from the fingers of the vaginal hand. The blades are locked with the shanks as close as possible to one finger-breadth medial to the posterior fontanel. Standard checks of application apply. Rotation is then accomplished with rotation of the handles upward through a wide arc consis-

tent with the pelvic curve of the instrument. If obstruction is met, the head may require slight upward displacement so that rotation may be facilitated close to the plane of greatest pelvic dimension. The application is rechecked and readjusted, if necessary, prior to traction for delivery.

KIELLAND FORCEPS

Kielland forceps (Fig. 74–8) are the most popular instrument worldwide for transverse positions of the occiput, although this may be changing.[57] The construction of the instrument offers a single accurate application for correction of asynclitism, rotation, and extraction, with a semiaxis traction pull. Use of the instrument should yield fetal results equivalent to those of cesarean section for the same clinical situation.[28–30,58] Early studies, which suggested a poor outcome, have since been criticized as indicating that inappropriate selection criteria had been used.[58,59]

The instrument should not be used in a flat pelvis or when short anteroposterior diameters are present. In such cases, rotation is associated with an increased risk of maternal injury.[56] The lack of pelvic curve may also increase the risk of vaginal injury during extension of the head at delivery. Owing to the special characteristics of this instrument, the operator must not use the same approach as with conventional forceps.

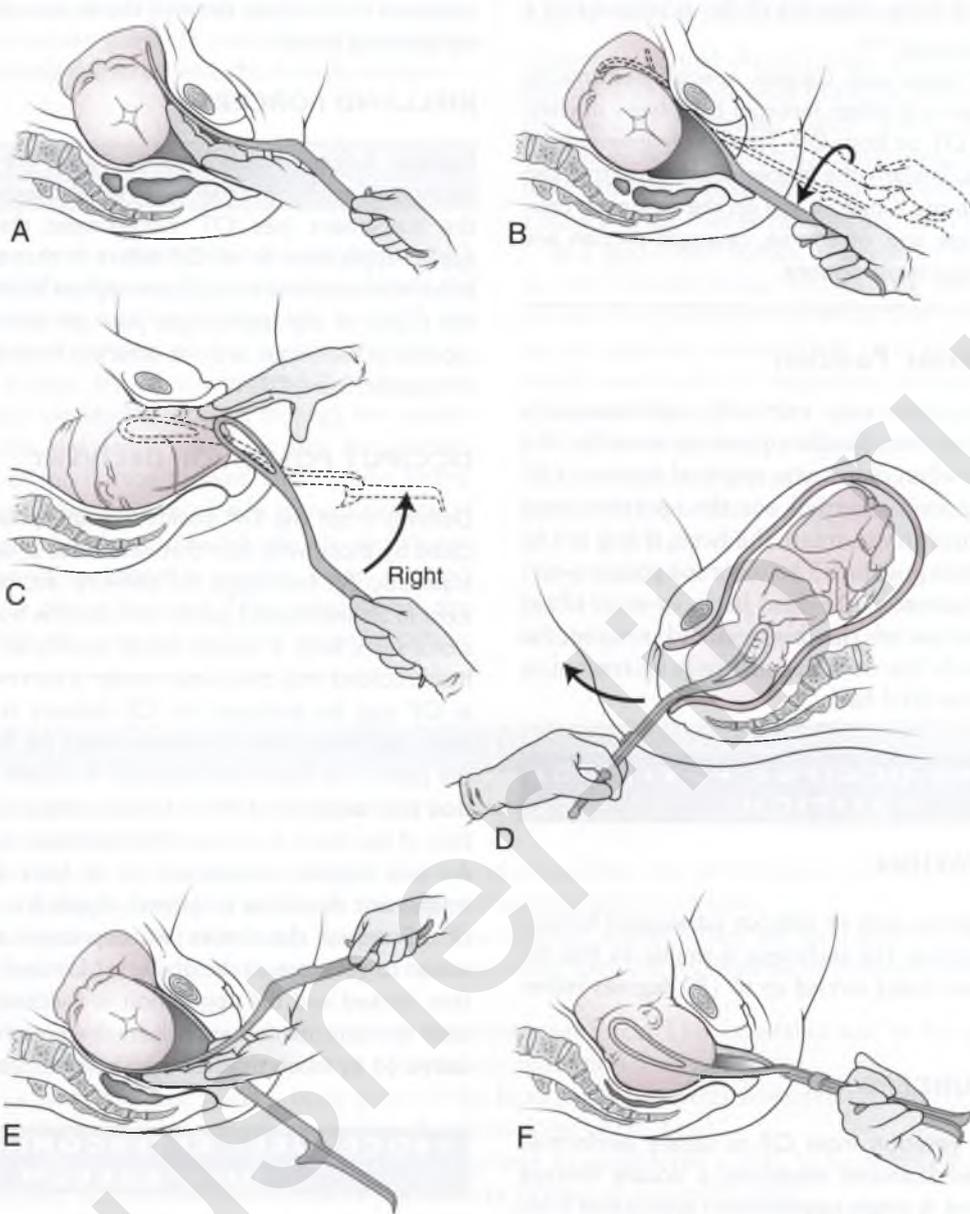
Before application, the bladder should always be emptied and the patient positioned with the buttocks slightly overhanging the edge of the delivery table. The instrument is oriented in a position of use with the knobs, or buttons, on the shanks toward the occiput. The anterior blade is always inserted first. Four application methods are possible. With a very low station, the blade may be applied directly from below upward. In Kielland's original inversion application (sometimes called the classical application) the blade is inserted in an inverted manner, concavity of the cephalic curve upward, beneath the symphysis and anterior to the head. The toe is carried into the uterus until the "elbow" of the leading edge of the shank is close to the pubis. At this point the blade is rotated 180 degrees on its own axis in the direction of the button. The blade will then drop onto the head with the cephalic curve applied to the anterior parietal bone. If difficulty is encountered, the anterior blade is removed in favor of a wandering application. The third and fourth methods involve wandering over the occiput in case of a flexed head or over the face in case of an extended head. Some operators mistakenly fear the inversion method will tear the lower segment, and routinely use the wandering method. With the anterior blade in place, the posterior blade is introduced posterior to the head, with the cephalic curve upward, following the plane of least resistance. Obstruction is frequently met at the sacral promontory. This is overcome with a lateral shift to avoid the obstruction. When in place, the instrument's sliding lock is engaged with the handles at approximately 45 below the horizontal in a midforceps procedure. The level of the handles depends on the level of the biparietal diameter, being higher with a lower head.


FIGURE 74–8
The use of Kielland's forceps with a left occiput transverse position. *A* and *B*, Classical (inversion) method of application of anterior blade. *C*, Direct application of anterior blade to low head. *D*, Wandering application of anterior blade. *E*, Direct application of posterior blade (anterior blade in place). *F*, Traction after rotation to occiput anterior position.

Any asynclitism is corrected by equalizing the level of the fingerguards. Correction of inadequate flexion is facilitated if the blades are unlocked and separately wandered to one fingerbreadth medial to the posterior fontanel. They are then relocked and moved back toward the midline.

Rotation toward OA position is accomplished, usually with remarkably little effort, by rotating the instrument along its own axis. If resistance is met, lowering the plane of the handles should be tried. Continued resistance may be due to a relative obstruction at that level. The head should first be drawn downward in transverse position for 1 cm and rotation attempted. If unsuccesful, the head should be displaced to 1 cm above the original station and rotated. Following rotation to OA, the application should be rechecked.

Extraction may be performed with the Kielland forceps. The operator must remember that the nearly straight instrument must be pulled in a lower plane below the horizontal and should not be raised above the horizontal at delivery. Some operators change to another instrument for better traction.

OTHER FORCEPS

Barton forceps, with its hinged anterior blade, is another alternative for managing transverse arrest. Its main indication is a flat maternal pelvis, which is a contraindication for the Kielland forceps.[21,54,60] With Barton forceps, the head is brought down in the transverse position, then rotated to OA as it traverses the plane of the outlet. The need for this

instrument is so infrequent that the reader is referred to a standard text for its use.[13,15]

In the United States and Canada, special instruments (Mann, Laufe, Shute, and other forceps) have been devised for rotation from OT or from OP. These instruments have regional advocates. Similarly, the Moolgaoker[61] has attracted followers in the United Kingdom and on the European continent. The ventouse and, of course, cesarean section are also alternate management options.

Occiput Posterior Position

Heads in OP position may eventually spontaneously rotate to OA and deliver. Similar options to those for the OT are available when delivery is required from an OP. Before any procedure is carried out the operator must know in which direction to rotate the head, if it is not in an oblique posterior position. The recorded position earlier in labor, palpation of the fetal back, or even ultrasonographic location of the back should resolve the question. Obviously the occiput must only be rotated in the direction of the fetal back.

PROCEDURE: OCCIPUT POSTERIOR POSITION

MANUAL ROTATION

Manual rotation either with or without subsequent forceps extraction is an option. The technique is similar to that for an OT with rotation being carried up to 180 degrees rather than 90 degrees.

CLASSICAL FORCEPS

Classical forceps rotation from OP is usually performed with the modified Scanzoni maneuver, a double forceps application method. A single upside-down application from below followed by a 180-degree rotation has been described but is not popular.[54] In the Scanzoni technique an Elliot-type instrument is preferred.[56] It is applied to the OP head as if it were an OA. In an ROP position the blades would be applied as if the position were LOA. When the application is checked, the plane of the shanks should be just above the posterior fontanel. The rotation to OA is accomplished with rotation of the handles through a wide arc, ending with the handles pointing downward. The blades are now upside-down with toes pointing posteriorly. One blade should be left as a splint against backward rotation while the other is removed downward, then inverted and reinserted between the splinting blade and the head. The splinting blade is then removed downward prior to reapplication in standard manner to the vertex, which is now in OA position. An ordinary forceps technique is then used for delivery. Some operators prefer to substitute a better tractor at the reapplication. The use of a solid blade or indented fenestration instrument for rotation prevents

insertion of the blade through the fenestration of the vaginal splinting blade.

KIELLAND FORCEPS

Kielland forceps rotation is probably the most popular method of rotation of an OP. The previous comments on the instrument (see OT management, discussed earlier) apply. Application to an OP differs in that the blades, with buttons toward the occiput, are applied directly from below the thighs to the appropriate position on the head. Other aspects of technique are not different from those discussed in rotation from OT.

OCCIPUT POSTERIOR DELIVERY

Delivery from the OP position is an option that is advocated by those who fear that rotational procedures may be traumatic. An indication for delivery without rotation can exist in an anthropoid pelvis with narrow transverse dimensions. Also, with a funnel pelvis, usually android, with the head molded into the outlet under a narrow arch, delivery in OP may be indicated. An OP delivery is relatively traumatic as unfavorable diameters must be brought through the pelvis. The biparietal diameter is usually at a higher station than anticipated. More force is required and the direction of the force is critical. More perineal space is required. An axis traction instrument or at least a Simpson type instrument should be employed. Applied as in the first step of a Scanzoni, the shanks are depressed against the perineum to get close to the posterior fontanel. The blades are then locked and the application is checked. With traction, after the anterior fontanel clears the symphysis, the head is delivered by flexion rather than by extension.

PROCEDURE: 'AFTERCOMING' HEAD OF A BREECH

Following delivery of the arms and body of the infant, the body is wrapped in a towel, care of which is placed in the hands of the necessary assistant. This serves to keep fetal extremities out of the field, and when excessive elevation of the body is avoided, there is less chance of cervical hyperextension injury.[14] In the controlled breech delivery, the back is upward and the head enters the pelvis within a few degrees of mentum posterior. The position is determined by palpation. The Piper forceps are applied upward from a kneeling position. The left blade is applied first, guided by two fingers of the right hand. The handle is started beneath the patient's right thigh, then swept downward and medially as the toe passes upward to the right parietal area of the infant. The handle then rests 45 to 50 degrees below the horizontal. The right blade is similarly applied upward from beneath the left thigh. The application is checked by palpation of the chin between the shanks of the instrument. The infant is then allowed to straddle the instrument, and traction is applied in a direction and manner similar to routine forceps

use. Vectoring is not needed because the reverse pelvic curve of the instrument gives the instrument axis traction. The head is routinely delivered with the forceps in place.

Although cesarean section is not within the purview of AVD, it should be noted that the use of instruments to deliver the head from the uterine incision at cesarean section[54] can decrease traumatic extension of that incision. Wrigley or short Simpson forceps are often employed. A single vectis blade, to turn and elevate the occiput through the uterine incision, can have the same effect, as can the curved, unhinged blade of the Barton forceps. The Murless instrument, with a single, hinged, locking blade, is more popular in the United Kingdom. It is introduced laterally and slipped beneath the head. When locked in position, it acts as a vectis and elevator to deliver the head.[54] The ventouse has also been advocated for this purpose, and is an excellent option.

Comparison of Ventouse and Forceps

Operative vaginal delivery trials comparing the obstetric forceps with the vacuum extractor have documented that the vacuum technique offers lower rates of maternal trauma such as genital tract lacerations, but higher rates of newborn scalp trauma and cephalhematoma than forceps. Efficacy of the two techniques are fairly equivalent.[62–77]

In a mid-1990s survey of residency training programs in the United States, 210 of 291 identified programs answered a questionnaire about their practice.[69] Forceps are the primary instrument in most programs (68%), but nearly one third of responding centers prefer vacuum extraction. Nearly all the responding programs (199 of 209, 95%) teach AVD using vaccum, mainly the soft cup vacuum extractor (metallic cups are used in only 14% of centers). Instruction in midpelvic operative vaginal delivery is currently offered in only 64% of the programs. Deep transverse arrest is handled initially by forceps in half the responding centers, whereas 28% and 22% would proceed with cesarean section or attempt a vacuum extraction, respectively.

CONCLUSIONS

- Appropriate use of the ventouse or the obstetric forceps as options in management of the second stage of labor is good medical practice.
- Careful attention to indications, contraindications, prerequisites, and performance should lead to a positive outcome. Mounting evidence attests to the safety of appropriate procedures.
- The instruments are not inherently dangerous. The manner in which they are used may be. In addition to a working knowledge of the instruments, the operator must have the willingness to abandon an unsuccessful procedure.
- Injury is the result of force applied to tissues that resist that force. That resistance can be felt and is obvious. The operator who refuses to apply force of injurious dimension does not injure.
- More important than the leading bony point of the head is the biparietal diameter, the widest and critical diameter, which must be moved. It contains the pivot point of the head.
- All operative procedures in assisted vaginal delivery may be considered a trial, to be performed with care and with adequate facilities for timely abdominal delivery in case of a negative trial.
- Protection is afforded to the operator by recording of the cognitive processes of decision for and execution of the operative procedure. A specific detailed documentation in the patient's record is always indicated.

SUMMARY OF MANAGEMENT OPTIONS
Assisted Vaginal Delivery

Management Options	Quality of Evidence	Strength of Recommendation	References
Indications			
Maternal indications include distress, exhaustion, and certain maternal medical disorders (see text).	IV	C	4, 72, 73
Fetal indications include presumed fetal jeopardy and breech delivery (forceps to aftercoming head).	IV	C	4, 72, 73
Process indications include malposition (OP, OT, asynclitism) and unsuccessful ventouse procedure (forceps trial with caution and facilities for cesarean section standing by).	IV	C	4, 72, 73

Continued

SUMMARY OF MANAGEMENT OPTIONS
Assisted Vaginal Delivery *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Indications—Continued			
Practitioners should be aware that no indication is absolute and must be able to distinguish "standard" from "special" indications.	IV	C	72
Contraindications			
Unengaged head (two fifths or more palpable abdominally or at or above ischial spines vaginally)	IV	C	72
	Ia	A	74
	IIa	B	68
Inability to define position	IV	C	75, 76
Malposition (face, brow)			
Suspected or actual cephalopelvic disproportion (pelvic anatomy or macrosomia related)			
Certain fetal anomalies			
Prematurity (? <34 weeks for ventouse) or <1500 g			
Repeated scalp pH estimations (ventouse)			
Operator inexperience or lack of training with instrument			
Prerequisites			
Engaged head (but one fifth palpable abdominally or above +2 station is potentially hazardous)	IV	C	72, 73
Fully dilated (some argue for 9+ cm with ventouse), membranes ruptured			
Empty bladder (? not for outlet delivery)			
Known presentation, position, and station			
Adequate analgesia/anesthesia			
Experienced operator and adequate support facilities			
Willingness to abandon procedure if difficult			
Informed and consenting patient			
Working, serviced equipment for ventouse and matching blades for forceps			
OT or OP Options			
Manual rotation/ventouse/rotational forceps	–	GPP	–
Possible delivery as OP position	–	GPP	–
Selection by circumstances, individual experience, and preferences rather than scientific guidelines	IV	C	72
Requires experience and skill	IV	C	72
Choice of Instrument			
Practitioners should use the most acceptable intrument for individual circumstances.	IV	C	72
Deficient knowledge and incorrect technique contribute to increased complications. Practitioners should be aware of the potential risks and necessary safety measures.	IV	C	72
Vacuum versus forceps:	Ia	A	74
Vacuum has higher rates of delivery failure, cephalhematomas, retinal hemorrhages, and jaundice.			

SUMMARY OF MANAGEMENT OPTIONS
Assisted Vaginal Delivery *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Choice of Instrument—Continued			
Forceps has higher rates of regional/general anesthesia and maternal trauma.			
No differences in rates of cesarean section, Apgar scores, long-term (5 y) maternal and baby follow-up.			
Soft versus metal vacuum cups:	Ia	A	77
Soft cup has higher rates of delivery failure (especially with OP, OT, and difficult OA positions).			
Metal cup has higher rates of neonatal scalp trauma.

Delivery After Previous Cesarean Section

Gordon C. S. Smith

INTRODUCTION

Rates of primary cesarean section have increased over the last 20 years. Consequently, increasing numbers of women present with second pregnancies and face the issue of mode of delivery. The dictum of "once a cesarean always a cesarean" largely applied in the United States until the 1980s (although not in the United Kingdom or Europe). However, a series of studies in the 1980s reported the relative safety of attempting vaginal birth following cesarean delivery (VBAC). Rates of VBAC increased in the United States until 1996[1] and then declined following reports of the risks of uterine rupture.[2] Further studies over the last 2 to 3 years have described risks of VBAC which may well increase the trend toward planned repeat cesarean delivery (PRCD). The choice between PRCD and VBAC, like virtually every other medical choice, involves the balancing of risks and benefits.

Estimating these risks and benefits requires the interpretation of large numbers of studies which are almost exclusively observational in nature. The risks of mode of delivery in women with a previous cesarean delivery can be classified at several different levels. First, risks can be divided into maternal risks and risks to the infant. Each can be further divided into short term and long term. Frequently, the different risks favor different modes of delivery. Furthermore, the research question of how to assess the risks and benefits of VBAC versus PRCD is complex due to an absolute reliance on observational data. Virtually all studies are open to some form of criticism. However, even studies with obvious weaknesses can still yield useful information if assessed in an unbiased manner. Many parties involved in the debate about VBAC start with strongly held prior beliefs about whether it is a "good" or "bad" thing. Consequently, there is a tendency in much of the literature for reviews of VBAC to fall into camps of believers and nonbelievers. The reliance of analyses on frequently flawed but partially informative research studies means that biased parties can interpret the literature in a way that confirms their prior belief. The aim of this chapter is to attempt an unbiased summary of the risks and benefits associated with delivery of pregnant women who have previously been delivered by cesarean section.

METHODOLOGIC ISSUES WHEN COMPARING RATES OF ADVERSE OUTCOMES BETWEEN VAGINAL BIRTH AFTER CESAREAN AND PLANNED REPEAT CESAREAN DELIVERY

Selection Bias and Randomized Controlled Trials

Theoretically, the ideal method for comparing the relative risk of VBAC and PRCD would be a randomized controlled trial (RCT). In practice this is unlikely to occur since most women would not accept the choice being made in a random fashion. Moreover, many of the events of interest are relatively uncommon, such as uterine rupture, hysterectomy, perinatal or maternal death. Consequently, it is unlikely that even if a trial was organized that it would be statistically powered to address the questions of central clinical interest. Although RCTs are clearly the gold standard in evidence-based medicine, it would be wrong to overstate their importance. The main utility of an RCT is to produce a bias-free estimate of relative risk. Two of the major questions relating to VBAC are:

- Does PRCD protect the fetus from severe adverse events in the short term?
- Is PRCD harmful to the mother in the long term?

Because severe adverse events are rare, it would be extremely difficult to organize an adequately powered trial to address the first question. Regarding the second, even if the long-term effects were confined to the outcome of the next pregnancy, follow-up would be required for years after initial recruitment, which is unlikely to be a practical proposition.

The major weakness of observational studies is the issue of selection bias, namely differences might be observed that are not due to the grouping but to factors that determined the grouping. However, observational data have some strengths when comparing outcomes following VBAC and PRCD. The issue of selection bias is less problematic in the context of assessing potentially beneficial effects of PRCD. Women who have PRCD are systematically more likely to have complications such as pre-existing maternal disease or gestational diabetes, and they are also older and shorter.[3,4] Selection of women for VBAC is likely to identify a healthy cohort. It follows that if better outcomes are observed in observational studies among women having PRCD, it is very likely that the differences were observed despite rather than because of selection bias. Moreover, it follows that where the outcomes are equivalent between PRCD and VBAC or are better for VBAC, selection bias is likely to have given the VBAC group an advantage. Observational data can allow identification of different pregnancies in the same woman. Analysis of such data may allow assessment of some of the absolute risks of rare adverse events in future pregnancies.

Definition of Vaginal Birth After Cesarean

Another methodologic issue is the question of whether a trial of labor was truly attempted. A proportion of women who elect to have a PRCD will present prior to their scheduled date of cesarean delivery in early labor. Often, these women will be delivered in early labor by emergency cesarean section. Many of the databases that contain sufficient numbers of cases to make adequately powered comparisons of key outcomes will lack the detailed information required to distinguish between these women and women who were genuinely attempting VBAC but required emergency cesarean delivery. This problem can be overcome by comparing the outcomes of apparent VBAC before and at or after 40 weeks' gestation. In the latter group, the majority of women scheduled for PRCD will have been delivered. If similar absolute risks are observed before and after the start of the 40th week, results are likely to be robust. However, even in the most detailed databases, there is likely to be some ambiguity about whether a trial of labor was truly attempted. This uncertainty might sometimes reflect a flexible clinical plan. For example, a woman presenting in early labor might elect for planned repeat cesarean delivery if vaginal examination demonstrated minimal cervical dilation, whereas VBAC would have been attempted if cervical findings were more promising. It is important for the comparison of studies that the definition of VBAC is explicit in all published work.

Ascertainment Bias

The issue of ascertainment bias has also not been properly addressed. Many studies of uterine rupture include both symptomatic uterine rupture and asymptomatic dehiscence. Diagnosis of the latter is most likely to be made at the time of cesarean section since the practice of confirming the integrity of the scar following vaginal birth is no longer recommended. It follows, therefore, that ascertainment of uterine rupture will be increased for any exposure associated with an increased risk of cesarean delivery. Ascertainment bias cannot explain the increased rates of uterine rupture observed among women attempting VBAC following one previous cesarean delivery[3] since the comparison group, PRCD, would have 100% ascertainment of uterine rupture. However, among those attempting VBAC, any factor associated with an increased risk of emergency cesarean section will necessarily be associated with an apparent increased risk of uterine rupture due to ascertainment bias. For example, a study of women who had two previous cesarean deliveries demonstrated an increased risk of uterine rupture among women delivered by planned cesarean section.[5] This finding was almost certainly due to the combined effects of selection bias and ascertainment bias. Ascertainment bias could be overcome by confining analysis to those women who have a symptomatic rupture. However, the data required to discriminate this group are lacking from many of the administrative databases that contain sufficient numbers of women who experience uterine rupture.

Influence of Risk of Emergency Cesarean Delivery

Many of the risks described for PRCD, such as infection and hemorrhage, are more common among women who attempt VBAC but then require emergency cesarean delivery than among women who are delivered by PRCD.[2] It follows, therefore, that among groups who have a high risk of emergency cesarean section, comparison of outcomes of VBAC and PRCD are likely to favor the latter. The greater risk of adverse events following emergency rather than planned cesarean delivery[6] indicate that at certain levels of risk of emergency cesarean delivery, a strategy of delivering all women by a planned procedure may actually carry a lower risk of adverse events directly attributable to surgery. The full-term breech trial, the largest RCT of planned cesarean section, confirmed this proposition, demonstrating similar rates of maternal morbidity comparing those delivered by planned cesarean section with those for whom vaginal birth was attempted.[7] This paradoxical neutral rate of surgical complications despite close to 100% cesarean delivery in the intervention group reflects the 36% emergency

cesarean section rate among those attempting vaginal breech birth. It follows, therefore, that comparisons of outcomes between women attempting VBAC and women having PRCD will differ according to the emergency cesarean delivery rate in the former group.

Relative and Absolute Risks

Medical research tends to follow an analytical paradigm inherited from the basic experimental sciences. The approach is to determine a measurable variable, to make a comparison between two groups, and to determine whether the dependent variable differs in a way that exceeds what is consistent with chance. RCTs are the clearest manifestation of the experimental scientific approach in medicine. However, this focus is sometimes inappropriate in medicine, and its shortcomings can be appreciated in the case of VBAC. First, there may be many outcomes that differ between the two groups. By their nature, RCTs tend to concentrate on short-term outcomes due to the expense and practical difficulties of long-term follow-up. For instance, in the case of the full-term breech trial, the analysis was confined to short-term neonatal and maternal outcomes. If the women were followed up to the end of their reproductive careers, detrimental effects of a first cesarean delivery may become evident. However, by the nature of the question, this could never be addressed by an RCT, and inferences can only be drawn from observational data. The focus on the experimental paradigm also leads to emphasis being placed on the relative rather than the absolute risk. This can lead to bizarre misinterpretation of the data. For instance, a meta-analysis of observational studies quoted absolute risks of perinatal death of 5.8 per 1000 for VBAC and 3.4 per 1000 for PRCD with an odds ratio of 1.7 for perinatal death in the VBAC group.[8] However, many of these deaths were not truly related to the chosen mode of delivery. A large scale retrospective cohort study then described more accurate estimates of absolute risks related to the mode of delivery of 1.2 per 1000 and 0.1 per 1000 respectively with an odds ratio of approximately 12 for VBAC.[4] Despite the fact that the true absolute risk of VBAC described in that study was five times lower than previously described, the greater relative risk when compared with PRCD led to it being interpreted by some observers as justification of PRCD because of a much greater true relative risk.

COMPARISON OF OUTCOMES OF VBAC AND PRCD

Maternal Risks

Short Term

Vaginal birth carries some direct risks, such as vaginal and perineal laceration, including trauma to the anal sphincter and mucosa. However, the major sources of significant short-term maternal morbidity in the context of attempted VBAC are emergency cesarean delivery and uterine rupture. The balance of risks comparing VBAC and PRCD depends on the extent to which the excess of cesarean deliveries in the PRCD group is compensated by more severe complications in the VBAC group. The greater severity of complications in the VBAC group is because the cesarean delivery is performed as an emergency[6] and because there is more likely to be a uterine rupture.[3] Since the comparison depends on the excess of cesarean deliveries in the PRCD group, VBAC will compare more favorably when the rate of successful vaginal birth is higher.

A large-scale, population-based study in 2001 demonstrated a significantly increased risk of uterine rupture among women attempting VBAC following spontaneous onset of labor (5.2 per 1000) compared with those having PRCD (1.6 per 1000),[3] which was consistent with an earlier meta-analysis of approximately 40,000 women.[8] The meta-analysis was dominated by a single large-scale study in which uterine rupture was not defined.[9] However, the population-based cohort defined rupture on the basis of International Classification of Diseases (ICD)9 codes, which include antepartum and intrapartum rupture.[3] Since the former is likely to include cases of asymptomatic dehiscence in the PRCD group, the true excess of clinically significant uterine rupture may be higher in the VBAC group.

The net effect on maternal morbidity can be inferred from analysis of outcomes that indicate surgical problems. Overall, women attempting VBAC have decreased rates of febrile morbidity (odds ratio = 0:7), blood transfusion (odds ratio = 0:6), hysterectomy (odds ratio = 0:4), and venous thromboembolism (odds ratio = 0:4) compared with PRCD.[8,9] However, the lower rates of complications in the VBAC group could reflect selection bias. For instance, over 30% of women having PRCD wish to have a tubal ligation.[9] Systematic variation in plans for further pregnancies could lead to a bias toward hysterectomy to manage intraoperative bleeding in women having PRCD. Attempted VBAC has been associated with an increased risk of serious intraoperative injury (vascular, bowel, or urinary tract) affecting 1.3% compared with 0.6% of women having PRCD, which presumably reflects difficulties that arise due to uterine rupture and the greater risk of emergency versus planned cesarean delivery.[2] Current studies are too small to determine the relationship among VBAC, PRCD, and maternal death. There is a nonsignificant trend toward greater maternal mortality in the meta-analysis among women attempting VBAC, with three deaths among 27,504 attempting VBAC and no deaths among 17,740 women having PRCD.[8] Two of the maternal deaths in the VBAC group were due to venous thromboembolism. If any difference is confirmed in this regard with further observational studies, it is unlikely to be explained by selection bias due

to the greater likelihood of pre-existing maternal disease and older age of the PRCD mothers.

Long Term

Long-term maternal consequences of the choice between VBAC and PRCD are numerous. If attempted VBAC results in vaginal birth, particularly operative vaginal delivery, recent observational studies suggest that a woman may be at increased risk of urinary incontinence (overall prevalence 15.9% among those delivered by cesarean section versus 21% delivered vaginally).[10] If VBAC is attempted and results in catastrophic uterine rupture, the uterus will be vulnerable to antepartum uterine rupture in future pregnancies. Due to the rarity of these events and the lack of detail in most administrative databases, the absolute risk is difficult to quantify.

Observational studies have suggested that women delivered by cesarean section are more likely to experience difficulty in conceiving (odds ratio = 1.5).[11] The implications of this for the decision between VBAC and PRCD are difficult to define. First, these women have already had a cesarean delivery and it is unclear whether there is a "dose-response" relationship between number of cesarean deliveries and lowered fertility. Second, lowered fertility prior to the first birth is a risk factor for cesarean delivery,[11] and it is questionable, therefore, whether the relationship between cesarean delivery and lowered fertility is causal. This question may be resolved by examining the association according to the indication for the first cesarean delivery.

The major long-term effect of PRCD is on the outcome of future pregnancies. Previous cesarean delivery is associated with an increased risk of placental abruption in future pregnancies (odds ratio = 1.3).[12] Moreover, multiple previous cesarean deliveries are also associated with an increased risk of placenta previa and, in particular, placenta previa associated with morbid adherence of the placenta. The overall incidence of placenta previa is 0.3%.[13] Compared with women who had no previous cesarean deliveries, the odds ratio for placenta previa in relation to number of previous cesarean deliveries is 1.2 for one procedure, 2.6 for two procedures, and 3.6 for three or more previous cesarean deliveries.[14] Combining these data, there appears to be an absolute risk of placenta previa of 0.5% to 1% among women with repeated cesarean deliveries. Morbid adherence of the placenta, placenta accreta, or percreta, is a rarer and still more serious complication of placentation associated with anterior placenta previa among women with a previous cesarean delivery. The overall incidence of severe placenta accreta (defined as resulting in death, hysterectomy, blood transfusion, coagulopathy, or being associated with placenta percreta) was estimated as 0.05%, and the odds ratio for women with repeated cesarean deliveries is 3.3.[15] Although the absolute risk of this event in future pregnancies is low, in the region of 1 in 1000, clearly the consequences can be severe.

Multiple cesarean deliveries could, theoretically, also affect surgical procedures outside pregnancy, for example, by increasing the likelihood of bladder trauma at the time of hysterectomy. A history of multiple previous cesarean deliveries is quoted as a relative contraindication to vaginal hysterectomy. However, recent studies do not suggest either increased rates of complications overall or a trend of increasing risk of complications with the number of previous cesarean deliveries.[16,17]

Fetal/Neonatal Risks

Short Term

Both PRCD and VBAC carry risks for the offspring. The major risk of PRCD for the neonate is the possibility of neonatal respiratory morbidity, specifically, respiratory distress syndrome, transient tachypnea of the newborn, and primary pulmonary hypertension.[18] The incidence of composite respiratory morbidity at term following vaginal delivery is 0.5%, for emergency cesarean delivery 1.2%, and for planned cesarean delivery before labor 3.5%.[19] Persistent pulmonary hypertension is the most serious of these problems. It is estimated to affect 0.4% of neonates delivered by planned cesarean section, an incidence four to five times greater than among infants delivered vaginally.[18]

The potential adverse effects of VBAC on the neonate relate both to specific issues of uterine rupture and emergency cesarean delivery but also to general adverse associations of vaginal birth. An analysis of a cohort of infants born at term to women with a previous cesarean delivery described increased rates of suspected and proven sepsis among infants delivered following attempted VBAC compared with PRCD (1% vs. 0.1%, respectively for proven sepsis), primarily due to increased rates among those who ended up having an emergency cesarean delivery.[20] The net effect of reduced respiratory morbidity and increased sepsis following VBAC compared with PRCD may favor the former since the risk of admission to special care is lower among infants delivered following attempted VBAC than PRCD (4.6% vs. 7%, respectively).[9] However, the caveat must be applied, as in all cases where VBAC is associated with lower risks, that women attempting VBAC are likely to be a "healthy cohort" due to selection bias. For instance, macrosomic offspring of diabetic women with a previous cesarean delivery will almost inevitably have PRCD, and these infants are at very high risk of neonatal complications.

Planned cesarean delivery clearly has some protective effect on the fetus by avoiding the stress of labor and the potential for trauma during vaginal delivery. Planned cesarean delivery is associated with the lowest rates in the offspring of intracranial hemorrhage[21] and hypoxic ischemic encephalopathy (HIE).[22] The overall net effect on serious but rare complications in the offspring is difficult to assess since relatively detailed information is

required. Generally, the studies that are large and robust enough to detect differences in rare outcomes lack detailed information for adequate analysis. Death in the neonatal period can be used as a composite measure of severe neonatal complications. A meta-analysis of observational studies demonstrated an increased risk of perinatal death among the offspring of women attempting VBAC compared with PRCD. The absolute risks quoted were 0.6% and 0.3%, respectively, and the odds ratio for death in the VBAC group was 1.7 (1.3–2.3).[8] However, the meta-analysis was dominated by a single study from Switzerland that made up 75% of the patients analyzed. The Swiss study included deaths from 28 weeks onward, and the vast majority of the deaths included in this study would not be causally related to the mode of delivery.[9] A population-based retrospective cohort study in Scotland addressed this issue by linking national databases of perinatal death data and maternity data. Using this approach, it was possible to identify perinatal deaths occurring at term among women with previous cesarean births and compare the absolute and relative risks of these events in relation to mode of delivery. Among women attempting VBAC, the rate of intrapartum stillbirth was 0.05%, and the rate of neonatal death was 0.08%. In comparison, women delivered by PRCD had no risk of intrapartum stillbirth, and the rate of neonatal death was 0.01%, which was significantly lower than among women attempting VBAC.[4] The absolute risks of death were similar when the analysis was confined to births at or after 40 weeks' gestation. The relative risk of perinatal death unrelated to congenital abnormality for attempted VBAC with reference to PRCD was approximately 12. However, the absolute risk of perinatal death among women attempting VBAC was very similar to nulliparous women. The overall rate of delivery-related perinatal death associated with VBAC at term was 0.13%: one third were due to uterine rupture, one third were due to other causes of intrapartum asphyxia, and one third were due to nonasphyxial causes. The single death among over 9000 PRCDs at term was attributed to maternal disease.[4] This analysis suggests that the balance of serious but rare complications favors planned repeat cesarean section. It might be argued that PRCD may have carried additional serious neonatal respiratory morbidity. However, it seems reasonable to speculate that sublethal serious morbidity might also favor PRCD. Although there may have been an excess of severe respiratory problems among the PRCD group that did not result in death, it is equally likely that, as in previous studies,[21,22] serious morbidity such as intracranial hemorrhage and HIE were less common in the PRCD group.

Whereas the analysis of the risks and benefits of cesarean delivery has tended to focus on delivery-related events, the major cause of perinatal death overall is stillbirth prior to the onset of labor. The risk of this event increases with advancing gestational age, and the cumulative risk of unexplained stillbirth is the major determinant of perinatal loss associated with continuing pregnancy beyond the 39th week.[23] Among 15,000 women delivered at term by a means other than PRCD, there were 20 delivery-related perinatal deaths. Among the same group there were 35 stillbirths in which death of the fetus occurred before the onset of labor, and 20 of these occurred at or after the 39th week and could potentially have been prevented by PRCD.[4] Recent analyses indicate that among all women having a second birth, a previous cesarean delivery is associated with a two- to threefold increased risk of unexplained stillbirth compared with women whose first birth was vaginal and that this is independent of the indication for the first cesarean delivery or maternal characteristics.[24] This demonstrates that an additional potential benefit of PRCD may be to reduce the risk of antepartum stillbirth. The absolute risk of this event is, however, relatively low at approximately 1 per 1000.

Long Term

There is some evidence that obstetric complications can affect a number of aspects of health in later life. Recent studies have demonstrated that children delivered by cesarean section have an increased risk of hospital admission for asthma in childhood, with odds ratios in the region of 1.2 to 1.3 compared with vaginal birth.[25,26] It has been hypothesized that this may be explained by effects of mode of delivery on the gut and susceptibility to atopy. However, cesarean delivery is a well-recognized cause of neonatal respiratory morbidity at term, specifically, transient tachypnea of the newborn and respiratory distress syndrome.[19,27] A number of previous studies have demonstrated that neonatal respiratory morbidity secondary to preterm delivery is associated with an increased risk of later asthma.[28–31] It is likely that the association with later asthma is a long-term consequence of neonatal respiratory morbidity.[32]

The reduced risk of HIE among infants delivered by planned cesarean delivery suggests that these children may be at reduced risk of developing cerebral palsy in later life. However, an adequate analysis of this issue has not been published. A meta-analysis of observational studies has demonstrated that "complicated" cesarean delivery is associated with a 10-fold excess risk of early-onset schizophrenia in later life.[33] Although this issue is still unclear and is likely to remain unclear for many years, the possible lifelong effects of both cesarean delivery and traumatic birth should be considered and should be an area of active research.

FACTORS AFFECTING THE BALANCE OF RISKS AND BENEFITS

Likelihood of Success of VBAC

One of the key features in deciding between PRCD and attempted VBAC is the background risk of emergency

cesarean section associated with VBAC. The choice is not between PRCD and certain vaginal delivery. Rather, it is the choice between planned cesarean delivery and attempting vaginal birth with the possibility of emergency cesarean delivery.

Large-scale European population-based studies have demonstrated successful VBAC rates of approximately 75%.[4,9] A number of factors associated with increased or decreased chance of success have been identified. The indication for the first cesarean delivery gives some predictive information regarding the probability of successful VBAC. Women whose first cesarean section was for failure to progress had an increased proportion of emergency cesarean deliveries (37%) during attempted VBAC, whereas those delivered for breech presentation in their first pregnancy had a lower rate of emergency cesarean delivery (14%), which was comparable to nulliparous women.[34] Women with no previous successful vaginal birth are at five to seven times greater risk of requiring emergency cesarean delivery compared with those who have had a previous vaginal birth.[35] A history of gestational diabetes is also associated with a significantly higher risk of emergency cesarean section during VBAC compared with controls (36% vs. 23%, respectively).[36]

A number of factors during labor and delivery are also predictive of the risk of emergency cesarean delivery. The risk of cesarean delivery increases with increasing birth weight of the neonate.[37,38] This post hoc knowledge has little practical use at present due to the inherent inaccuracy of ultrasonic prediction of birth weight.[39] Further studies are required that relate the ultrasound estimated fetal weight to the risk of cesarean delivery to determine whether this association might have some clinical application in risk assessment in the future. Slow progress during labor is also associated with increased rates of cesarean delivery as demonstrated by associations with limited cervical dilation on admission (odds ratio 1.9)[35] and the need for augmentation of labor (odds ratio 2.2).[35]

As the previous discussion indicates, a number of factors are associated with an increased risk of emergency cesarean delivery during VBAC. However, counseling about the risk of VBAC is, at best, semiquantitative. An effective statistical method is required to give women individual assessments of risk. Risk scoring is widely used elsewhere in medicine, such as in the intensive care unit and for cardiac surgery. The relevance of this to VBAC would be at several levels. First, PRCD and VBAC are thought to be economically equivalent when the rate of emergency cesarean delivery is 25% to 30%.[40] Second, the benefits of VBAC are related to avoiding cesarean delivery. For women at high risk of emergency cesarean delivery, the main advantage is lost. Moreover, due to the higher directly attributable adverse effects of emergency cesarean delivery, PRCD is likely to be associated with lower rates of maternal complications, such as febrile morbidity and blood transfusion, when the background risk of emergency cesarean delivery is high.

Factors Determining Risk of Uterine Rupture

Clearly one of the major issues when considering VBAC is the probability of uterine rupture. This outcome is significant as it can affect the health of the child and mother and may determine complications in future pregnancies. This has led to a number of studies that have attempted to address the factors predicting uterine rupture.

Previous classical cesarean section is associated with a much greater risk of antepartum and intrapartum uterine rupture and is an indication for planned cesarean delivery at 36 to 37 weeks' gestation. In contrast, previous vertical lower uterine segment cesarean delivery does not appear to be associated with an increased risk of uterine rupture compared with a low transverse incision,[41] although this analysis is based on reported data for fewer than 400 women with such incisions. Single-layer closure of a low transverse incision was associated with a four- to fivefold risk of uterine rupture after adjustment in multivariate analysis for a number of maternal and demographic factors.[42]

A number of studies have demonstrated that the risk of rupture varies inversely with the interval between the previous cesarean delivery and the next pregnancy.[42-45] Increased birth weight is also associated with an increased risk of rupture,[37] but again the clinical utility of this association in risk scoring is limited due to the inaccuracy of antenatal estimation of fetal weight.

Reports of increased risk of uterine rupture associated with prostaglandins (rate 2.4% compared with 0.5–0.7% for other women in labor)[3,46] has led the ACOG (American College of Obstetrics and Gynecology) to discourage the use of prostaglandin when inducing labor among women attempting VBAC.[47] In contrast, the risk of uterine rupture is not increased when labor is induced with oxytocin when compared with women in spontaneous labor.[3] The overall absolute risk of uterine rupture was 0.2% among women with a previous vaginal birth, which was fivefold lower than among women with no previous vaginal birth. The apparent protective effect was observed whether the vaginal births were before or after the cesarean delivery.[48]

Influence of Future Reproductive Intentions

Perhaps one of the key issues when deciding about mode of delivery in women with one previous cesarean section is the individual's intentions regarding further pregnancies. The natural focus when making decisions regarding VBAC and PRCD is the possibility of serious adverse consequences in the current pregnancy. Although VBAC is associated with lower rates of non-life-threatening complications, the potential for catastrophic uterine rupture raises the possibility that PRCD may be associated with lower risks of severe maternal morbidity and mortality. Consistent with this, there is a trend toward lower mater-

nal mortality in the PRCD group, as discussed earlier. This argument would not hold, however, when the mother is planning many future births. Logically, one could not support a decision to have a PRCD after a first cesarean and then attempt vaginal birth after a second cesarean. Women who elect for PRCD and are planning future pregnancies must consider the additional future risks associated with multiple previous cesarean deliveries. In the context of complications likely to lead to severe maternal morbidity or death, the major factor is placenta previa with accreta or percreta. It is currently very difficult to assess the balance of the risk of severe morbidity and mortality of uterine rupture during VBAC and of complications of abnormal placentation in future pregnancies. These questions will only be addressed by high-quality observational studies using detailed and large-scale databases, probably involving record linkage to maternal death inquiry data and obstetric data. However, it seems currently plausible that the balance of risks and benefits of VBAC favors attempted vaginal birth among women who desire to have many future pregnancies. [Editor's note: Although it should also be borne in mind that the techniques for cesarean section have improved steadily in recent years and will presumably continue to improve. In particular, imaging techniques for the detection of placenta accreta are improving rapidly, and surgical techniques are being devised to improve the safety of dealing with such cases (including approaches such as selective embolization and leaving the placenta in situ with the subsequent use of methotrexate—see Chapter 77)].

SUMMARY OF MANGEMENT OPTIONS
Delivery After Cesarean Section
Decisions Regarding Mode of Delivery

Management Options	Quality of Evidence	Strength of Recommendation	References
The evidence that forms the basis of informed discussion of VBAC vs PRCD is based on observational studies only with the potential for bias			
Overall, women attempting VBAC have 50% greater morbidity although this depends on the background risk of failure	III	B	58
Absolute risk of maternal morbidity:	III	B	58
Highest with failed VBAC—14.1%			
Intermediate with PRCD—3.6%			
Lowest with successful VBAC—2.4%			
No validated predictive tool for assessing risk of failed VBAC	III	B	59
The major risks of VBAC are:			
Uterine rupture risk is 5.2 per 1000 VBAC compared with 1.6 per 1000 PRCD; can be catastrophic, leading to perinatal death (1 per 2000) and very rarely maternal death (<1 in 10,000)	III	B	3,8,9,60
General risks associated with vaginal birth, such as intrapartum asphyxia and perineal trauma			
Likelihood of perinatal death higher in low throughput obstetric units	III	B	57
Other risks of VBAC are:			
Urinary incontinence in later life (approximately 5% higher incidence)	III	B	10
Neonatal sepsis, intracerebral hemorrhage, HIE	III	B	20–22
The major risks of PRCD are:			
Short-term maternal complications (febrile, blood transfusion, hysterectomy, thromboembolism)	III	B	8,9
Neonatal respiratory morbidity, which can be severe (respiratory distress OR = 7.0; pulmonary hypertension OR = 4–5)	III	B	18
Rare but serious complications in future pregnancies relating to morbid placental implantation (placental abruption OR = 1.3; placenta previa OR ~3.0; morbid adherence OR = 3.3)	III	B	12,14,15
Other risks of PRCD are:			
Childhood asthma (OR = 1.3)	III	B	25

Continued

Delivery After Cesarean Section
Decisions Regarding Mode of Delivery *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Successful VBAC more likely with:			
Breech or fetal distress as indication for original CS (rather than poor progress)	III	B	34
Previous vaginal delivery (5–7 times more successful)	III	B	35
No diabetes	III	B	36
Lower birth weight	III	B	37,38
Normal progress in labor	III	B	35
Uterine rupture more likely with:			
Previous classical CS	III	B	41
No previous vaginal birth	III	B	48
Single layer closure	III	B	42
Shorter interpregnancy interval	III	B	42–45
Higher birth weight	III	B	37
Induction of labor with prostaglandin, relative risk = 4.7	III	B	3,55
Cost effectiveness of VBAC vs. PRCD is equivalent if emergency CS rate = 25–30%	III	B	40
The decision to attempt VBAC is complex, requires careful counseling and should take into consideration:	—	GPP	—
Maternal preferences and priorities including motivation to achieve a vaginal birth			
Importance placed on rare but serious adverse outcomes (see above)			
Presence of factors that influence likelihood of successful VBAC vs uterine rupture (see above)			
Plans for future pregnancies			

CS, cesarean section; HIE, hypoxic ischemic encephalopathy; OR, odds ratio; PRCD, planned repeat cesarean delivery; VBAC, vaginal birth after cesarean.

MANAGEMENT OF WOMEN ATTEMPTING VBAC

The management of labor in a woman attempting VBAC cannot be based on RCT evidence, since the trials have not been conducted (and almost certainly never will be) that are sufficiently robust to determine the effects of management on the risk of rare events, such as perinatal death at term. Management must be guided, therefore, on the basis of understanding the risks of VBAC. Given the small but finite risks involved, a conservative approach is justified. Rejection of caution in this context on the basis that "there is no evidence that demonstrates X is useful" is not justified when the issue is lack of evidence rather than convincing data that indicate no benefit.

Given that the absolute risk of uterine rupture is in the region of 1 in 100 to 1 in 200 and that it can result in rapid fetal demise and life-threatening maternal hemorrhage, it seems self-evident that VBAC should be attempted only in units with immediate access to facili-

ties for the management of uterine rupture. This will usually require resident obstetric, anesthetic, and neonatology services with access to hematology and other support services. Uterine rupture is classically diagnosed by pain, vaginal bleeding, maternal hypotension, or collapse. However, the earliest warning sign may be an abnormal fetal heart rate pattern. Given this, and the risk of intrapartum asphyxia due both to the rupture and other events, a recommendation for continuous electronic fetal monitoring is mandatory. A small proportion of women will be requesting VBAC because they want "natural childbirth," and they may refuse continuous electronic fetal monitoring. In such cases, it is essential on both ethical and medicolegal grounds that appropriate attempts are made to persuade the woman to accept continuous monitoring, and these attempts should be fully documented, together with the names of witnesses to the discussion. It is quite often possible to persuade many of these women to accept almost continuous fetal monitoring using a handheld Doppler ultrasound

fetal heart detector, and if fetal heart rate decelerations are clearly audible, most women will then accept continuous monitoring. Concerns that the symptoms of uterine rupture might be masked by epidural anesthesia have not been sustained and use of epidural analgesia is appropriate when attempting VBAC.[49] The use of intrauterine pressure catheters was previously widespread, but this is no longer the case as they do not appear to indicate reliably the event of a uterine rupture and may, therefore, be falsely reassuring.[50] Oxytocin as a means of inducing labor does not appear to be associated with an increased risk of uterine rupture compared with women in spontaneous labor.[3] However, oxytocin should be used extremely cautiously to augment the progress of women in labor. It should only be used when uterine activity is clearly inadequate, and great care should be taken to avoid uterine hyperstimulation. In women who are obese, or very restless, it is often difficult to assess uterine contractions adequately by external palpation and there may be a specific case for the use of intrauterine pressure catheters to measure uterine activity in these circumstances. Regular cervical examinations should be performed in all cases and there should be a low threshold for emergency cesarean delivery when cervical dilation is inadequate in the presence of normal uterine activity. Postpartum examination of the uterine scar at the time of vaginal examination is no longer recommended since cases where surgical repair is required are almost invariably symptomatic.[51]

VBAC in "Special" Situations

The classic determinants of eligibility for VBAC are that a woman has had a single previous cesarean section through a low transverse uterine incision for a nonrecurrent indication and that she has a singleton infant in a longitudinal lie and cephalic presentation in her present pregnancy with no other contraindication for vaginal birth. A number of studies have examined the risks and benefits of VBAC in other situations. For instance, a number of studies have reported that no excess risks are associated with VBAC among women with twins.[52-54] However, none of these included more than 100 pregnancies. In order to exclude a 1% incidence of an adverse event with conventionally accepted levels of statistical certainty, a trial would have to examine the outcome of approximately 350 cases and see no events. Clearly, if a single event was observed, the finding would be consistent with a true incidence of less than 1%, but then even greater numbers would be required to define the limits of the estimated risk.

Other examples of special situations include suspected fetal macrosomia, multiple previous cesarean deliveries, and induction of labor with an unfavorable cervix. These and other indications regarded as "special" are usually referred to in these terms due to an increased risk of uterine rupture and, often, an increased risk of emergency cesarean section. As discussed earlier, there are multiple risk factors for uterine rupture, such as single-layer closure, a short interval between the previous cesarean delivery and the next pregnancy, macrosomia, prostaglandin induction, and no previous vaginal birth. Some combinations of these events have been shown to be associated with high absolute risks of uterine rupture. For example, a short interpregnancy interval and a previous single-layer closure is associated with a 5% to 6% risk of uterine rupture during a future VBAC attempt.[42] This is much higher than the absolute risk associated with prostaglandin induction.[3] Nevertheless, prostaglandin induction is now discouraged by the ACOG.[47] However, statements that VBAC is or is not recommended in the presence of a single risk factor are potentially misleading. For instance, if the fivefold reduction in risk associated with a previous vaginal birth is correct[48] and there is no interaction between parity and use of prostaglandin, then women with a previous vaginal birth being induced with prostaglandin would have a risk of uterine rupture of less than 1%.

It is, therefore, currently impossible to address fully the risks of VBAC in association with different maternal characteristics to provide women with an individualized risk of uterine rupture and probability of successful vaginal birth. Ideally, one could take the prior odds of such outcomes and obtain a best estimate of these risks on the basis of the key maternal and obstetric characteristics. At present the best approach is to assess the presence of single or multiple risk factors for uterine rupture and emergency cesarean delivery and discuss these with each individual woman. When assessing evidence, a clear distinction must be made between lack of adequate evidence and adequately powered studies that find no increase in risk. Attempting VBAC in twin pregnancy falls into the former category.

RECENT STUDIES

A number of areas discussed above have recently been addressed. First, a study has been reported where the outcome studied was uterine rupture leading to death of the infant.[57] This confirmed that prostaglandin induction and no previous vaginal birth were associated with an increased risk of catastrophic rupture and that the previously described associations could not be explained by ascertainment bias. This study did not demonstrate an association between the use of oxytocin to induce labor and the risk of uterine rupture. The study also demonstrated that if a uterine rupture occurred, it was approximately three times more likely to result in death of the infant in a low throughput hospital. This was thought to reflect the fact that high throughput hospitals are more likely to have the facilities available for immediate delivery and resuscitation of the infant (resident experienced obstetric, anaesthetic, and pediatric staff; a dedicated obstetric operating room; and a neonatal intensive care unit). This study provides empirical data to support the

proposition that attempted VBAC should only take place in units with these facilities.

Second, a large scale, multi-center prospective cohort study of approximately 18,000 VBAC attempts and 16,000 PRCD was reported at the end of 2004.[58] This is the only large scale prospective study of VBAC to be reported. Significant maternal morbidity was, overall, approximately 50% more common among women attempting VBAC. However, the best outcomes, as previously described, were to women who attempted VBAC and were successful. The absolute risk of one or more serious maternal complications was 14.1% among women attempting VBAC and failing, 3.6% among women having a planned repeat cesarean delivery and 2.4% among women who had a successful attempt at VBAC. There were only two perinatal deaths (both neonatal) attributed to uterine rupture among the offspring of women attempting VBAC and this likely reflects the fact the study was confined to high throughput centers. There was a 1 in 2000 risk of hypoxic ischemic encephalopathy among women attempting VBAC and no such events among women having a PRCD.

The foregoing underlines the importance of the background risk of cesarean delivery on the risks and benefits of attempting VBAC. A meta-analysis of observational studies of scoring systems for predicting the risk of cesarean section demonstrated that there were only two validated methods for predicting the risk of cesarean section and both utilized data that would only be available during the intrapartum period.[59] They stated that "conducting high-quality research on the factors that delin-eate women who are at higher likelihood of vaginal delivery without complications and developing accurate user-friendly screening tools to integrate these data should be a national research priority."

Finally, a recent large scale retrospective analysis of Canadian data allowed some estimates of the absolute risk of maternal death.[60] They estimated a 1–2 per 100,000 risk of death associated with an attempt at VBAC. The risk of death was 5–6 per 100,000 among women having a PRCD, after excluding complex cases such as placenta previa. However, they did not have information on the number of previous cesarean deliveries and were unable to adjust for key maternal characteristics other than age. Therefore, the apparent increased risk of death among women having PRCD needs to be interpreted with caution.

FUTURE PRIORITIES FOR RESEARCH

A simple and pragmatic method for quantifying the risk of emergency cesarean delivery and uterine rupture during attempted VBAC in relation to combinations of maternal characteristics would help decision-making considerably. Currently, there is no practical method for giving a woman an individualized risk of adverse events during attempted VBAC. Ideally, some of the key issues discussed above would be resolved by a large scale randomized controlled trial. The problems with this ideal are that it would have to be very large and allow long term follow-up and a truly informative trial is unlikely to be a practical proposition.

SUMMARY OF MANAGEMENT OPTIONS			
Conduct of Trial of Labor			
Management Options	Quality of Evidence	Strength of Recommendation	References
Attempt at VBAC should only be conducted in a setting with resident obstetric/anesthetic/neonatal staff and access to full laboratory support.	III	B	57
The issue of intravenous access and crossmatching of blood are controversial.	–	GPP	–
Conduct critical review of progress of labor.	–	GPP	–
Judicious use of oxytocin is acceptable but should be discontinued if response to uterine stimulation does not occur promptly, and vigilance for uterine hyperstimulation should be maintained.	III	B	57
Continuously monitor fetal heart rate.	III	B	56
Routine insertion of intrauterine pressure catheter is of no proven benefit and may be falsely reassuring.	III	B	50
Regional anesthesia is not contraindicated.	IV	C	49
Digital palpation/examination of scar is not indicated.	III	B	51

VBAC, vaginal birth after cesarean.

CONCLUSIONS

The evidence informing decisions between PRCD and VBAC is based entirely on observational data and, therefore, open to biased interpretation.

The major risks of VBAC are:

- uterine rupture (overall approximately 0.4–0.5%), which can be catastrophic, leading to perinatal death in about 1 per 2000 and very rarely leading to maternal death (<1 in 10,000)
- general risks associated with vaginal birth, such as intrapartum asphyxia and birth trauma
- an increased risk of perioperative morbidity among those women requiring emergency cesarean delivery

The major risks of PRCD are:

- an increased risk of mild to moderate short-term complications in the mother
- an increased risk of respiratory morbidity in the neonate, which can be severe
- an increased risk of rare but serious complications in future pregnancies relating to morbid placental implantation

The balance of risks and benefits depends on the background risk of emergency cesarean delivery if VBAC is attempted, which itself depends on:

- whether the mother has had previous vaginal births
- the indication for the first cesarean delivery
- whether the onset of labor in the current pregnancy will be induced or spontaneous
- progress in early labor

The decision to attempt VBAC is complex, requires careful counseling, and will depend on:

- the mother's motivation to achieve a vaginal birth
- plans for future pregnancies
- the importance placed on rare but serious adverse outcomes

Cesarean Section

Jan E. Dickinson

INTRODUCTION

Of the profound alterations in the practice of obstetrics over the past century, one of the most apparent has been the progressive increase in the frequency of cesarean delivery. Sporadically reported throughout medical history, cesarean birth has only during the last century been technically refined and rendered safe for both mother and fetus. The safety of the lower uterine segment technique, the evolution of anesthetic proficiency, the availability of blood products and antibiotics, the broadening of indications for the operation, the recognition of the fetus as a patient, the feasibility of vaginal delivery following cesarean section, and the acceptance of this procedure by women have characterized the evolution of cesarean birth in the twentieth century. These factors have all contributed to the rise in the incidence of cesarean birth over the past 50 years. The past decade has seen further evolution of cesarean birth as an issue of choice for women as a preferred mode of delivery, producing intense polarization of both medical and lay opinion.[1–7] Additionally, the secondary rise in repeat cesarean delivery has been associated with an increase in severe complications of cesarean birth, particularly complications of placentation.[8,9] Placenta accreta and its subtypes have been reported with increasing frequency in association with repeat cesarean birth.[10,11] Such abnormalities of placentation clearly have great potential to increase maternal morbidity for repeat cesarean birth.

INCIDENCE OF CESAREAN SECTION

During the 1970s and early 1980s, the cesarean delivery rate progressively increased throughout the world, more dramatically in some countries than in others (Fig. 76–1). By the 1990s and beyond, most countries observed a progressive increase in cesarean birth. Women are now four times more likely to have a cesarean birth than 30 years ago.[12] The reasons for this increase in cesarean birth are multifactorial and include the increasing number of women with a prior cesarean delivery, the increase in multifetal gestations, the use of intrapartum electronic fetal monitoring, changes in obstetric training, medicolegal concerns, alterations in parental and societal expectations of pregnancy outcome, and maternal autonomy in decision-making regarding delivery mode.

In 1984, cesarean delivery became the number one in-hospital operative procedure in the United States[13] and accounted for 21% of all live births. By 1988, this figure climbed to 24.7%.[14] Advocacy for vaginal birth after cesarean (VBAC) in the late 1980s and 1990s was probably associated with a lessening of the incidence in the United States; in 1999 the incidence declined to 22%.[15] However increasing concerns for the potential complications of VBAC[16,17] have reduced some of the early enthusiasm for this technique, and the observed decline has been short lived, with the resumption of a progressive increase in the cesarean birth rate. In 2001 the US cesarean delivery rate was 24.4%, the fifth consecutive annual rise, and the VBAC rate fell 20%.[18]

In Europe and the United Kingdom, an increase in cesarean birth has also been evident, but with wide national variation. A recent review of cesarean birth in Norway showed a sharp increase in the cesarean delivery rate, from 2.5% in 1972 to 12.8% in 1987 with a slight rise to 13.6% in 1999.[19] This relatively low rate of cesarean delivery in Nordic countries has not been manifest in other areas of Europe. In 1980 the cesarean delivery rate in England was 9%, increasing to 13% in 1992[20]; a recent audit of rates demonstrated an abrupt rise to 21.3% in 2000.[21] Similar rates have been reported in Italy (22.5% in 1995),[22] with France midway at 17.5% in 1995.[23]

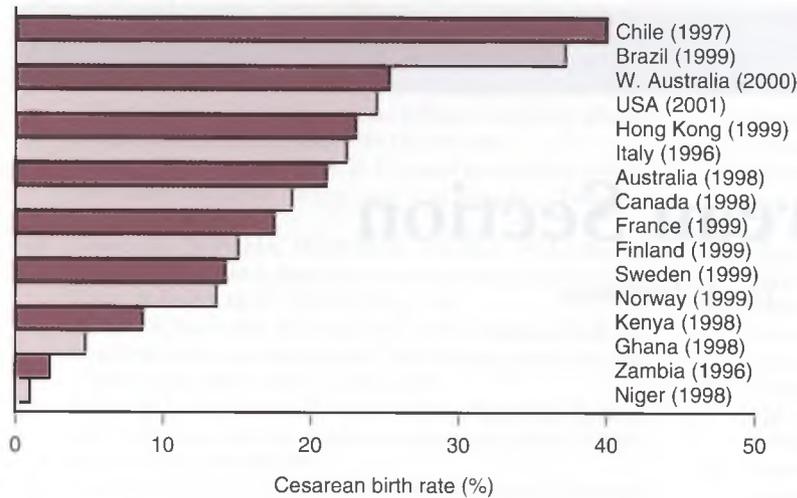
In Australia, there has been a continual increase in the incidence of cesarean birth. In the author's state of Western Australia, rates of cesarean birth have steadily increased, from 15.7% in 1986, to 20.3% in 1995, and to


FIGURE 76–1
Contemporary international cesarean delivery rates

25.3% in 2000,[24] with no suggestion of a decline or plateau in the incidence.

Data from South America have consistently demonstrated some of the highest cesarean birth rates internationally.[25] In Chile the incidence of cesarean birth increased from 27.7% in 1986 to 37.2% in 1994.[25] In Brazil a high incidence of cesarean delivery has been present for many years, reaching 50% in some areas.[26] The contrary situation exists in sub-Saharan Africa, where very low cesarean birth rates, generally less than 5%, have been reported for many years. This phenomenon most likely represents inadequate access to medical services in economically depressed countries. High maternal and perinatal mortality rates are typical in many areas of sub-Saharan Africa. In Zambia the cesarean delivery rate was 1.6% in 1996; other countries' rates were similarly low: Ghana, 4.1% (1996); Tanzania, 2.2% (1998); and Kenya, 6.7% (1998).[27]

INDICATIONS FOR CESAREAN SECTION

There are four principal indications for cesarean delivery:

- dystocia (inadequate labor progress)
- suspected fetal compromise
- malpresentation
- prior cesarean birth.

These indications account for more than 70% of cesarean deliveries and are therefore the major determining factors of the cesarean birth rate[28] (Table 76–1). Programs designed to alter cesarean delivery rates have tended to focus on modifying these four primary operative indications (e.g., active management of labor protocols, increasing VBAC rates). Several other issues have been correlated with cesarean birth rates, including hospital type and facilities, individual medical practices, health insurance status, women's childbirth attitudes, and medicolegal influences.

Recently, much attention has been given to maternal requests for cesarean birth in the absence of a traditional obstetric indication. Although there are bipartisan views on this contentious issue, several points need to be addressed. First, it is recognized that women must be involved in the management decisions regarding their pregnancy and birth. Women vary greatly in their birth experience desires, and individualization is central to any delivery mode policy. Second, it is now appreciated that much of the increased mortality previously ascribed to cesarean birth did not discriminate between elective procedures and nonelective procedures. In a low risk woman an elective cesarean section with appropriate perioperative care has an extremely low mortality risk. Third, there is an increasing amount of knowledge and discussion of the long-term effects of vaginal birth on the female pelvic floor and sexual function. Fourth, although the first cesarean delivery may be uncomplicated, subsequent pregnancies are clearly associated with an increased risk of placenta previa and accreta. Finally, within the specialty of obstetrics are several practitioners who believe cesarean birth to be the most appropriate delivery mode and have published their

TABLE 76–1

views widely, whereas others believe it is a major surgical procedure with attendant risks.[29] The debate will continue; however, it is clear that obstetric paternalism is giving way to patient autonomy. Education and discussion remain the keystones in obstetric care, and continuing audit of outcomes is essential.

ISSUES IN THE OPERATIVE TECHNIQUE OF CESAREAN BIRTH

Cesarean delivery is the most frequent major surgical procedure performed in obstetrics and gynecology. There is, however, wide variation in the surgical techniques used in cesarean birth and the quality of evidence to support the techniques used.[30] Randomized controlled clinical trials are not widely used in the evaluation of surgical procedures, with such therapies usually characterized by observational evidence. The lack of randomized controlled trials of surgical interventions has not gone unnoticed.[31] History, personal prestige, commercial competition, surgical equipoise, inadequate funding and infrastructure, inadequate surgeon education in epidemiology, and the presence of emergency or rare conditions are cited as obstacles to the conduct of randomized clinical trials in surgery.[31] The particular issue of the "learning curve" is problematic in the conduct of the surgical randomized clinical trial, because there will inevitably be a bias in favor of the familiar technique and errors are more likely to occur during the acquisition of skills with a new procedure.

A recent survey of British obstetricians observed a wide range in the techniques for procedures in cesarean delivery.[30] Relative concordance of technique was observed in only a few aspects of cesarean delivery (e.g., double-layer closure of the uterine incision, prophylactic antibiotic use, and Pfannenstiel abdominal entry).[30] There were large variations in the technique of uterine entry, abdominal packing, uterine closure techniques, peritoneal closure, used of subrectus sheath wound drainage, and superficial fat closure. Despite evidence from randomized clinical trials, many obstetricians continued to use practices that have been demonstrated to increase morbidity (e.g., 27.6% performed manual removal of the placenta).

SURGICAL TECHNIQUES IN CESAREAN DELIVERY

The Abdominal Incision for Cesarean Birth

Preparation of the Patient

Preoperative positioning with left lateral tilt will minimize maternal inferior vena caval compression, reducing the risk of hypotension and reductions in placental perfusion. A urinary catheter usually remains in situ perioperatively, draining continuously to a closed system.

Suprapubic and abdominal hair should be removed as short a time before the procedure as possible. Skin infections may occur if shaving is performed remote from the surgery, due to the occurrence of grazes during shaving, and may increase the incidence of wound infections. An antiseptic solution, usually povidone-iodine, is applied to the skin. Iodophor-impregnated adhesive films have been assessed in a small clinical trial,[32] and although they did not appear to alter postoperative wound infection rates, they did reduce the skin preparation time, a consideration in emergency situations. Standard plastic adhesive drapes are no more effective than linen drapes in preventing wound infections and may adversely affect healing if dislodged.[33] They have become popular when coupled with integral gutters to collect the blood and amniotic fluid shed during the operation, reducing contamination, a consideration of particular importance in areas of high hepatitis B and HIV prevalence.

The Choice of Skin Incision

The choice of the abdominal incision and its closure should be individualized to the characteristics of the woman and the circumstances demanding operative intervention. The massively obese multigravida will require a different operative technique than that used on the unscarred abdomen of a thin primigravida. The ideal incision provides prompt surgical access, adequate exposure, and a secure wound closure.

The transverse suprapubic skin incision is the most common technique used for cesarean delivery in the developed world. The Joel-Cohen incision has been proposed as the quickest method of delivering the fetus compared, with the Pfannenstiel, or midline vertical abdominal incision.[34-36] The Pfannenstiel incision is a straight horizontal incision about 2 cm above the pubic symphysis with its mid-portion within the shaved area of the pubis. A Joel-Cohen incision is also a straight horizontal incision, but higher, being about 3 cm below the line joining the anterior and superior iliac spines. It can therefore be rather longer than the Pfannenstiel incision, and it is easier to pull aside the rectus muscles at this level. Three randomized controlled trials have examined abdominal entry techniques.[37-39] The first, published in 1987, used a quasi-randomized study design and compared the Maylard transverse muscle-splitting incision with the Pfannenstiel incision in 97 women.[37] In this small study the time to achieve delivery was longer in the Maylard group (10.4 ± 3.1 minutes vs. 7.6 ± 4.1 minutes, Maylard vs. Pfannenstiel, respectively, $P < 0.05$). There was no significant difference in febrile morbidity (OR, 0.72; 95% CI, 0.22–2.39) or blood loss as estimated by hemoglobin alteration (3.1 ± 0.6 g/L vs. 3.0 ± 0.8 g/L). The Maylard incision was significantly larger than the Pfannenstiel (18.3 ± 4.5 cm vs. 14 ± 2.1 cm), which, although providing an increased surgical field, may have

some cosmetic disadvantages in contemporary elective cesarean birth. The size of the abdominal incision was a critical factor in the degree of difficulty of delivery, with a significant negative correlation between perceived delivery difficulty and incision size reported. An abdominal incision size of 15 cm or greater was associated with significantly less difficulty in cesarean delivery.

The second study, available only in abstract form,[38] compared the Pfannenstiel and Joel-Cohen incisions in 268 women. A reduction in operating time (35 vs. 26 minutes) and maternal composite morbidity (16.3% vs. 7%, P <0.05) was reported with the Joel-Cohen technique.

The most recent trial also compared the Pfannenstiel and Joel-Cohen incisions in 310 women with pregnancies beyond 32 weeks' gestation.[39] The total operative time was similar (Pfannenstiel 33 minutes (range, 18–70 minutes) vs. Joel-Cohen 32 minutes (range, 12–60 minutes), although the time taken to deliver the fetus was more rapid with the Joel-Cohen incision (Pfannenstiel, 240 seconds [range, 50–600 sec] vs. Joel-Cohen, 90 seconds [range, 60–600 sec] P = 0.05). There was no significant difference in the incidence of perioperative complications nor infant neurodevelopmental outcome at 6 months. The reduction in fetal extraction time did not appear to have a clear maternal-fetal benefit. Additionally, the authors of this study commented that the cosmesis of the Joel-Cohen incision (a component of the technique known in toto as the Misgav Ladach method) was inferior to that for the Pfannenstiel incision.

A vertical skin incision was the original approach to enter the peritoneal cavity, although it now has been usurped by the more cosmetic low transverse incision. The main indications for its use are a previous midline vertical incision, obesity, or uncertain operative diagnosis for example, in trauma to the pregnant abdomen or an intra-abdominal tumor mass. In an observational study in 1976, Haeri[40] reported no significant difference between the two incisions in terms of operating time (53 minutes vs. 45 minutes, transverse vs. vertical incision, respectively), postoperative febrile morbidity (30% vs. 48%), and postcesarean hemoglobin <10 g/dL (28% vs. 36%). There was, however, an increase in the incidence of complete wound breakdown in the vertical skin incision group (0% vs. 7%) and total maternal morbidity (OR, 0.46; 95% CI, 0.25–0.86).

In the massively obese patient, a vertical skin incision with avoidance of the subpanniculus fold may be indicated. The higher wound infection rate in this subpopulation requires modifications of perioperative procedures. Gallup[41] reduced the wound infection rate from 42% to 3% by careful perioperative techniques. If a transverse incision is chosen for the obese patient, it should be away from the subpanniculus fold, and a subcutaneous closure should be used to reduce dead space and subsequent seroma formation.

The Uterine Incision for Cesarean Birth

The clinical situation prompting the need for abdominal delivery determines the uterine incision to deliver the fetus. The low transverse uterine incision is used in over 90% of cesarean deliveries. This high prevalence is due to its ease of repair, reduced adhesion formation, decreased blood loss, and low incidence of dehiscence or rupture in subsequent pregnancies.[42] A previous low transverse uterine incision may render the woman eligible for a trial of labor in a subsequent pregnancy. The disadvantages of the low transverse incision are primarily restricted to situations in which the lower uterine segment is undeveloped. In this circumstance there is a greater chance of lateral extension into the major uterine vessels, resulting in maternal morbidity from hemorrhage. If the initial incision is inadequate to deliver the fetus, extension of the uterine incision to a J or a U or an inverted T incision will be required, creating a more vulnerable scar.

The low vertical incision, also a lower-segment incision, may be used in situations in which the transverse incision is inappropriate, predominantly in patients with an underdeveloped lower uterine segment. When used in these circumstances, there is a lower risk of lateral extension into the uterine vessels. The incision may be extended upward into the body of the uterus if more room is needed. An upper uterine segment extension renders closure more difficult and precludes a subsequent trial of labor. More extensive dissection of the bladder is necessary to keep the vertical incision within the lower uterine segment. If the incision extends downward, it may tear through the cervix into the vagina and possibly the bladder. The low vertical incision may be used if a contraction ring needs to be cut in order to deliver the infant. If the vertical incision is confined to the lower uterine segment there is a lower probability of dehiscence and/or rupture in a subsequent pregnancy.[42]

Infrequently performed in modern obstetrics, the classical uterine incision is a vertical incision into the upper uterine segment. It is required in circumstances where exposure of the lower uterine segment is inadequate, in elective cesarean hysterectomy, or in cases of a noncorrectable back-down transverse lie. The incision permits rapid delivery and reduces the risk of bladder injury, because the bladder is not dissected. When an anterior placenta previa is present, an upper segment incision may be used to avoid incising the placenta. However, dissection around the placenta following a lower-segment incision can eliminate the need for a classical uterine incision. The many disadvantages of the classical uterine incision result in its limited use in obstetrics today. The incision is more complicated and time-consuming to repair, the incidence of infection is higher, and adhesion formation is common. There is a greater risk of incision rupture during subsequent pregnancies[42,43]; if rupture occurs, the resultant bleeding is much greater

than with the relatively avascular lower segment. The fetus is also more likely to be expelled from the uterus into the peritoneal cavity. For these reasons, most obstetricians consider a vertical upper uterine incision to be a contraindication to a trial of vaginal delivery, committing women to elective repeat cesarean deliveries.

In a recent review of 19,726 consecutive cesarean deliveries between 1980 and 1998, Patterson and colleagues[44] observed a distribution of uterine incisions of 98.5% low transverse, 1.1% classical, and 0.4% inverted T. Over the period of the study there was an increase in the incidence of inverted T incisions, from 0.2% to 0.9%. Maternal morbidity, expressed as puerperal infection, blood transfusion, hysterectomy, intensive care unit admission, and maternal death, was significantly higher in classical cesarean delivery compared with the low transverse incision. Perinatal morbidity was also increased in classical and inverted T incisions compared with low transverse cesarean, reflecting the preterm birth preponderance with the former incisions.

Considerable variation exists among obstetricians in the surgical technique used in the conduct of a low transverse uterine incision for cesarean birth. In the survey by Tully and colleagues,[30] 54.7% of surgeons used predominantly blunt dissection and 45.7% predominantly sharp dissection to enter the uterine cavity. Manual removal of the placenta was utilized by 24.7%, and 33.7% routinely closed the parietal peritoneum.

Formal investigation of the creation of the uterine incision consists of four randomized controlled trials involving 526 women[45–48] assessing the use of absorbable staples compared with extending the incision manually or with scissors in low transverse uterine cesarean delivery. Stapling techniques have been introduced to decrease blood loss from the incision margins. In a meta-analysis of these trials by the Cochrane Collaboration,[49] the stapling technique did not offer any reduction in total operation time (weighted mean difference = −1.17 minutes; 95% CI, −3.57, 1.22), although there was a significant increase in the incision to fetal delivery time (0.85 minutes; 95% CI, 0.48–1.23). There was a reduction in intraoperative blood loss with stapling techniques (weighted mean difference = − 41.22 mL; 95% CI, −50.63 to −31.8). The evidence currently available does not warrant the routine use of stapling techniques in the creation of the lower uterine segment incision, and the incision-to-delivery interval delay could have adverse consequences in some situations. In addition, the cost of the guns and staples is considerable; this will probably limit their wider use.

The comparison of blunt and sharp extension of the uterine incision has been compared in a small randomized trial involving 286 women.[50] There was no reported difference in the incidence of unintended uterine incision extension, intraoperative duration, or estimated blood loss between the two techniques. The primary correlate of incision extension was the stage of labor, being significantly greater when cesarean section was performed in the second stage of labor regardless of the uterine incision technique employed. The small sample size of this trial does render the conclusion of the study that the techniques are equivalent open to some debate.

Techniques for the delivery of the placenta at cesarean birth have been the subject of three randomized controlled clinical trials[51–53] involving 224 women; these studies were also assessed by the Cochrane Collaboration.[54] Manual removal of the placenta was associated with a significant increase in maternal blood loss and postoperative infectious morbidity. Lasley and coworkers[55] randomized 333 women to manual or spontaneous placental delivery and observed an increase in wound infection rates (OR, 2.33; 95% CI, 0.72–8.73) and a strong trend to an increase in endometritis with manual removal (OR, 1.85; 95% CI, 0.97–3.53). Manual placental removal at cesarean section should therefore be performed only when clinically indicated and not as a routine practice. Disappointingly, in the survey by Tully and colleagues,[30] 25.1% of obstetricians routinely employed manual removal of the placenta at cesarean delivery.

Maternal antibiotics to decrease the incidence of postoperative endomyometritis are administered prophylactically in many centers, although there remain a surprising number who do not use the technique[56] despite compelling evidence of its efficacy in trials involving over 10,000 women.[57] Commonly a single dose of a first- or second-generation cephalosporin is given, although either the addition of metronidazole or the use of ampicillin plus clavulanic acid or sulbactam to cover gram-negative anaerobes is increasing and has been shown to be more effective than ampicillin alone.[58] The Cochrane Collaboration meta-analysis of 47 published randomized controlled trials of antibiotic prophylaxis regimens[59] demonstrated ampicillin and first-generation cephalosporins have a similar efficacy in reducing endometritis (OR, 1.27; 95% CI, 0.84–1.93), with no benefit in using more broad-spectrum agents (ampicillin versus second- or third-generation cephalosporin OR, 0.83; 95% CI, 0.54–1.26; first-generation cephalosporin versus second- or third-generation cephalosporin OR, 1.21; 95% CI, 0.97–1.51). A multiple-dose regimen for prophylaxis was not more effective than a single-dose regimen (OR, 0.92; 95% CI, 0.70–1.23). Antibiotic administration is sometimes on a selective rather than comprehensive basis (e.g., in cases of nonelective cesarean section with prior rupture of the membranes), although the evidence suggests it is of value in all cases.[60]

The uterus may be exteriorized for repair. This procedure is not a necessary routine but does assist visualization and technically facilitates repair of the uterine incision, especially if there have been lateral extensions. The relaxing uterus can be promptly recognized and massage applied, potentially decreasing intraoperative blood loss. Hershey and Quilligan[61] reported lower blood loss in women undergoing exteriorization repair (mean reduction in hematocrit, 6.2 ± 0.35 vs. 7.0 ± 0.43,

exteriorization vs. intraperitoneal, respectively, $P < 0.01$), although Magann and coworkers[51] did not confirm this significant reduction in their trial. No increase in febrile morbidity has been reported with uterine exteriorization.[51,61] The main adverse effect is pain and vagal-induced vomiting with traction when the woman is awake and the cesarean is being performed under regional analgesia. The incidence of venous air embolism is increased when uterine exteriorization and manual removal of the placenta are performed at cesarean section.[62]

The Cochrane Collaboration has provided a review including two of the five randomized controlled trials of uterine exteriorization versus intraperitoneal repair at cesarean delivery.[63] These two trials involved 486 women, but neither was felt to be methodologically strong. Uterine exteriorization was associated with a reduction in the duration of postcesarean fever (OR, 0.40; 95% CI, 0.17–0.94), and a nonsignificant trend to less infections and gastrointestinal disturbance. No difference in blood loss was found. This review concluded there was insufficient information to make a recommendation on the routine use of uterine exteriorization. Since that Cochrane review was published a further three trials have been published.[64–67] These three trials have not reported results markedly different from those in the Cochrane review.

Surgical Closure Techniques

The uterine incision can be closed with one or two layers. Use of a single-layer closure technique reduces operating time without any obvious short-term detrimental effects.[67–69] A small follow-up study from Tucker and colleagues[70] involving 292 women did not demonstrate an increase in uterine scar dehiscence in the single-layer closure compared with the conventional two-layer closure group. Jelsema and coworkers,[69] in an observational study of 200 women, compared continuous, nonlocking, single-layer closure with the standard two-layer uterine closure. No differences in the febrile morbidity rates were observed, although there was an increased need for additional hemostatic sutures. The Cochrane review of single-versus two-layer uterine closure concludes, on the basis of two randomized trials involving 1006 women available at the time of review,[67,68] that the only advantage to single-layer closure is a reduction in operating time.[71] In that review, based only on one study, there were fewer uterine scar deformities as assessed by hysterosalpingogram, 3 months after delivery. In the United Kingdom, the vast majority of surgeons (96.3%) use a two-layer uterine closure technique.[30] The number of published trials is small; further information is required before single-layer closure can be recommended as a routine.

It has been traditional surgical procedure to close the peritoneum. The reasons for peritoneal closure have never been scientifically validated, however, they include restoration of surgical anatomy and a potential reduction in infection, wound dehiscence, and adhesion formation. Animal experimentation has suggested that adhesion formation may in fact be greater with peritoneal closure due to foreign body reaction to the suture material.[72,73] No significant short-term differences in postoperative complications have been observed in trials of peritoneal nonclosure in general surgery[74,75] or gynecology.[76,77] The Cochrane review of peritoneal closure includes four trials involving 1194 women.[78] There was no difference in short-term postoperative morbidity in women regardless of peritoneal closure or nonclosure. Operating time was reduced if the peritoneum was not closed. The reviewers concluded that there was insufficient data to warrant a practice alteration; although there were no short-term disadvantages in peritoneal nonclosure, no long-term data were available.

Subsequent to the Cochrane review, a further three trials of peritoneal closure have been published.[79-81] A concern with most published trials is the lack of standardization of other aspects of surgical technique of cesarean delivery. A significant reduction in postoperative febrile morbidity (OR, 0.36; 95% CI, 0.17–0.72) and operating time (7.9 minutes) was reported by Grundsell and colleagues[79] in a trial involving 361 women. Assessment of postoperative pain with peritoneal closure has been assessed. In a small study of 40 women, Højberg and colleagues[80] reported no significant difference in postoperative pain scores based on peritoneal closure, although the nonclosure group required less oral analgesia. Rafique and coworkers[81] observed lower narcotic analgesic requirements and greater patient satisfaction (possibly due to a reduction in the narcotic side effects in addition to a reduction in pain) in women randomized to peritoneal nonclosure. Again, a significant reduction in operating time was reported, and a consistent reduction of 5 to 8 minutes has been observed in all the studies. The available clinical and nonclinical data appear to support the concept of peritoneal nonclosure at cesarean birth. These data have been reflected in clinical practice, with the majority of obstetricians favoring nonclosure of both the pelvic (71.1%) and parietal (66.2%) peritoneum in the survey by Tully and colleagues.[30]

Closure of the subcutaneous tissue has been the subject of two trials.[82,83] Del Valle and colleagues[82] investigated the efficacy of subcutaneous closure in 438 women and concluded that a running closure with absorbable suture such as plain catgut was associated with a lower incidence of superficial wound disruption. A similar randomized controlled trial conducted in women with more than 2 cm of subcutaneous fat also demonstrated a lower incidence of wound disruption (14.5% vs. 26.6%, $P = 0.02$), a lower seroma formation rate (6% vs. 19%, $P = 0.003$), and a trend to lower overt wound infection rate (6.0% vs. 7.8%, NS) in the women allocated to the subcutaneous closure group.[83]

Closure of the skin following a cesarean birth may be achieved with interrupted sutures, staples, or a subcutic-

ular suture, the technique and suture material usually being related predominantly to personal preference. Skin closure with staples is more rapid than other techniques[84] but has been associated with increased wound pain and reduced cosmesis. Skin closure techniques have been the subject of three clinical studies.[85-87] Frishman and coworkers[85] conducted a randomized trial comparing skin closure with subcuticular suture or staples for Pfannenstiel incisions in 66 women. The operating time was less in those women randomized to skin closure with staples. Analgesic use was less in women randomized to the suture group and there was also a suggestion of improved cosmesis; however, this is a small trial with methodologic problems, limiting the validity of the results. The use of blunt and sharp-tipped needles produced no difference in wound infections.[86] The overall incidence of wound infection in this study of 204 women was low and the study underpowered for the conclusion. In a small trial of the cosmesis of intracuticular and subcuticular sutures, satisfaction scores were higher for the intracuticular suturing technique at greater than 4 months' postprocedure.[87] The Cochrane review of skin closure techniques at cesarean delivery reported on the only available randomized controlled trial[88] and commented on the lack of available evidence in this aspect of cesarean delivery. Despite the lack of data, the majority of British obstetricians reported subcuticular skin closure as their routine (73.9%).[30]

Alternative Techniques for Cesarean Birth

Alternative surgical techniques to the traditional surgical approach to cesarean birth have been reported in recent years. The Misgav Ladach, Pelosi, and Stark techniques of cesarean section have been the subject of several reports.[35,36,89-92] The Misgav Ladach technique was developed in Israel and involves the Joel-Cohen abdominal incision, single-layer uterine closure, and nonclosure of the visceral and parietal peritoneum. Björklund and coworkers[89] evaluated this technique in Africa in a randomized controlled trial of 339 women and reported a 20% reduction in blood loss, a 50% reduction in the use of suture material, and a reduction in operating time of 7.3 minutes. There was no difference in overall postoperative infection rates. Similarly, Darj and Nordström[36] observed a reduction in operating time (mean, 13.4 minutes) and blood loss (mean, 160 mL) with the Misgav Ladach compared with the Pfannenstiel technique. The Stark technique, which also involves omission of peritoneal closure and single-layer uterine closure, was associated with a lower febrile morbidity rate (7.7% vs. 19.8%), reduced antibiotic use (33.3% vs. 81.3%), and a lower adhesion incidence in subsequent surgery (6.3% vs. 28.8%) compared with the Pfannenstiel incision, double-layer uterine closure, and peritoneal closure in an observational study of 125 women.[92] The Pelosi technique, in which the formation of the bladder flap is

eliminated, has been associated with decreased operating time, postoperative febrile morbidity, and hospital costs when compared with traditional techniques.[90,91]

It is clear that eliminating operative steps in cesarean delivery reduces the total operating time. It is not clear whether this reduction is translated into other benefits or if the infectious morbidity, pain, and blood loss alterations are real or the effect of small trials with inadequate methodology. It is also clear that large, rigorously designed and conducted clinical trials with assessment of both short- and long-term outcomes are required to adequately address the surgical technique issues in cesarean delivery. In the United Kingdom this issue is being addressed by the conduct of the CAESAR Study, a randomized controlled trial to evaluate three alternative cesarean section operative techniques.

COMPLICATIONS OF CESAREAN SECTION

Cesarean delivery is a major abdominal surgical procedure and is thus subject to the standard complications—medical, anesthetic, and surgical—associated with a laparotomy (Table 76–2). It is beyond the scope of this chapter to deal with all the potential complications that may surround a cesarean birth. However, maternal morbidity and mortality associated with cesarean delivery are increased in women with preexisting medical disorders.

Hemorrhage

Hemorrhage at the time of cesarean delivery may be related to the operative procedure, such as damage to the uterine vessels, or be incidental, such as occurs due to uterine atony, placenta previa, or placenta accreta. The origin of the excess blood loss is generally apparent at the time of surgery and is dealt with as is appropriate to the etiology. Management is covered in detail in Chapter 77.

TABLE 76–2

Complications of Cesarean Section

Anesthesia-related
   aspiration syndrome
   hypotension
   spinal headache
Hemorrhage
   uterine atony
   placenta previa/accreta
   lacerations
Urinary tract and gastrointestinal injuries
General postoperative complications
   respiratory: atelectasis/pneumonia
   gastrointestinal: ileus
   urinary tract infections
   thromboembolism
Endomyometritis
Wound infection

The incidence of placenta accreta appears to be increasing[10,11] and is second only to uterine atony as an indication for emergency hysterectomy for obstetric hemorrhage. There is an association of placenta accreta with placenta previa and previous cesarean delivery, incidence of which have both increased with the recent trend toward more liberal indications for cesarean delivery. Clark and colleagues[10] reported that 25% of women undergoing cesarean delivery for placenta previa in the presence of one or more uterine scars subsequently underwent cesarean hysterectomy for placenta accreta. This risk appears to increase directly with the number of previous uterine incisions. If the placenta is accreta, effective management usually requires total abdominal hysterectomy, although additional options, including the use of uterine compression sutures or leaving the placenta in situ, have been reported. The uterus, vagina, or broad ligament may be lacerated during a cesarean delivery. Traumatic deliveries or poor delivery technique are associated with an increased frequency of operative lacerations. Lacerations involving uterine tissue are usually sutured without difficulty. Vertical lacerations into the vagina or lateral extensions into the broad ligament may be associated with substantial blood loss and the potential for ureteric damage during their repair. Before beginning repair of lacerations into the broad ligament, identification of the ureter is frequently necessary. The initial suture must be inserted just distal to the apex of the laceration.

Urinary Tract Injuries

Injuries to the urinary bladder occur with variable incidence during the course of cesarean delivery.[93,94] The Pfannenstiel incision, with lower entry into the peritoneal cavity, increases the risk of inadvertent cystotomy, especially after prolonged labor in which the bladder is pulled cephalad. Scarring and secondary obliteration of the vesicouterine space following previous cesarean section increase the incidence of trauma secondary to attempts at dissection. The bladder may also be damaged secondary to a uterine laceration, particularly in association with a low vertical uterine incision.

Various techniques are employed to reduce the incidence of intraoperative bladder injury. Preoperative catheterization of the bladder and peritoneal entry as far cephalad as possible are important. Injuries to the base of the bladder are most frequent during a repeat procedure, in which clear tissue planes do not always exist. Careful sharp rather than blunt dissection of the bladder will reduce the occurrence of inadvertent cystotomy as well as reducing blood loss. If there is concern as to possible bladder injury, the abdomen must not be closed until the issue is resolved by transurethral instillation of methylene blue-colored saline with leakage of fluid identifying the cystotomy site.

Full-thickness bladder lacerations should be repaired with a two-layer closure with continuous or interrupted

2-0 or 3-0 chromic catgut. The site of the bladder laceration is important, because repair of a laceration of the bladder dome is usually straightforward. The bladder base is thinner, receives less blood flow, and appears to heal more slowly, and occlusion of the ureteric orifice is also a possibility. Fistula formation is not usually a problem if accidental cystotomy is promptly recognized and repaired.

Ureteric injury is one of the most dreaded complications of any pelvic operation. It is, however, an uncommon occurrence at cesarean section. Eisenkop and colleagues[94] reported 7 ureteric injuries in 7527 women undergoing cesarean delivery. In 5, the ureteric injury occurred during an attempt to control hemorrhage from extension of the uterine incision. When controlling hemorrhage, it is useful to apply direct pressure while identifying the course of the ureter to permit accurate suture placement and reduce the potential for ureteral injury.

Postoperative Complications

Respiratory complications remain a primary cause of postoperative morbidity following major surgical procedures. Deep breathing exercises, incentive spirometry, chest percussion, and postural drainage all have merit, depending on the clinical circumstance.

Gastrointestinal dysfunction is not uncommon after a cesarean delivery; it is usually restricted to a transient ileus. The Cochrane Review of postoperative feeding assessed six trials to evaluate the effect of early and delayed oral intake after cesarean birth.[95] Although the studies were of variable quality, on the available data the review concluded there was no justification to withholding early oral intake after cesarean birth. Early oral intake was associated with a reduced time to return of bowel sounds, a reduced postoperative stay, and a trend to a reduction in abdominal distension.

Urinary tract infections are a common complication of cesarean section and occur with a variable frequency of 2% to 16%, the rate depending on the duration of catheterization and the preoperative health of the woman.[93,96]

Thromboembolic disease during pregnancy is an uncommon event but remains a major cause of maternal morbidity and mortality. Indeed, pulmonary thromboembolism is a leading cause of maternal death in the United Kingdom.[97] The greatest incidence in the puerperium is among cesarean patients, particularly if the surgery is performed as an emergency procedure during labor. Other factors increasing the risk of venous thromboembolism include advanced maternal age, obesity, and inherited thrombophilia disorders. The risk of a deep venous thrombosis after cesarean delivery is 3 to 5 times greater than after vaginal delivery.[98] The reactive thrombocytosis after cesarean birth, the impact of which is compounded by anemia, infection, and postpartum hemorrhage, further increases the risk. In 1995 the Royal College of

Obstetricians and Gynaecologists[99] published a Working Party Report on prophylaxis against thromboembolism in the United Kingdom. This document has drawn attention to the risks of thromboembolic disorders after cesarean birth and the need to consider prophylaxis for high risk women. Routine prophylaxis against postoperative deep vein thrombosis now includes the use of mechanical calf compression intraoperatively (e.g., Flowtron boots), the use of calf compression stockings (e.g., TED), and subcutaneous heparin, either unfractionated or high-molecular weight heparin.[100] Low-molecular weight heparin is now commonly used peripartum, because it can be administered on a once-daily dosage regimen.[101] These heparins are not secreted in breast milk and therefore can be used in lactating women.

Endomyometritis

In the absence of prophylactic antibiotics, postcesarean endomyometritis occurs with an incidence of 20% to 40%.[102,103] Postoperative infections may be reduced by 50% to 60% with the use of prophylactic antibiotics at the time of cesarean delivery.[104,105] In approximately 10% of cases, concurrent bacteremia will accompany postcesarean endomyometritis.[102,104] Uncommonly, postcesarean endomyometritis may be complicated by pelvic abscess, septic shock, and septic pelvic thrombophlebitis. The major risk factors for the development of postcesarean infection are young age, low socioeconomic status, prolonged labor, prolonged rupture of membranes, and multiple vaginal examinations.

Postcesarean section endomyometritis is a polymicrobial infection with bacteria normally present in the lower genital tract: aerobic streptococci (group B and D streptococci), anaerobic gram-positive cocci (peptococcus and peptostreptococcus), aerobic (*E. coli*, *Klebsiella pneumoniae*, *Proteus* spp.) and anaerobic gram-negative bacilli (*Bacteroides* spp. and *Gardnerella vaginalis*).[102] The symptoms and signs of endomyometritis usually develop 24 to 48 hours after surgery. The main clinical manifestations are fever, tachycardia, lower abdominal pain, uterine and adnexal tenderness, and peritoneal irritation. After appropriate laboratory investigation, including complete blood count, aerobic and anaerobic blood cultures, and aerobic and anaerobic endometrial cultures, antibiotic therapy is instituted. Several effective regimens are available: clindamycin plus an aminoglycoside or aztreonam, penicillin plus aminoglycoside and metronidazole or one of the extended-spectrum penicillins such as ticarcillin/clavulanic acid or ampicillin/sulbactam. If a cephalosporin has been administered for prophylaxis, a penicillin should be used due to the possibility of *Enterococcus*.

Most patients show a clear response to treatment within 72 hours. The two most common causes of apparent treatment failure are concurrent wound infection and

resistant microorganisms. If a wound infection develops, incision and drainage is indicated, but a change in antibiotics is not usually necessary. The principal microorganisms likely to be resistant to initial treatment regimens are aerobic gram-negative bacilli, enterococci, and *Bacteroides* spp. If a resistant organism is thought to be present, antibiotic therapy should be modified. Parenteral therapy should be continued for a minimum of 24 hours after the patient becomes afebrile and asymptomatic. At this point, therapy may be discontinued. Patients do not need to be maintained on oral antibiotics after discharge from hospital.[104] Extended therapy of this nature is expensive and increases the risk of side effects without providing any measurable therapeutic benefit.

In patients who fail to improve after a change in antibiotic therapy, another detailed examination should be performed to detect a wound infection or pelvic abscess. Other possible causes of poor treatment response include viral infections, venous thrombophlebitis, and drug fever.

Wound Infection

Adverse outcomes associated with abdominal wounds in the obstetric patient occur more frequently in the presence of anemia, premature rupture of the membranes, prolapsed cord, and meconium staining. Reported wound infection rates associated with cesarean section range from 2.5% to 16.1%.[106–108] Nielson and Hokegard[109] found rates of 4.7% for elective cases and 24.2% for emergency cases. A mixture of anaerobic and aerobic bacteria (*E. coli*, *Proteus mirabilis*, *Bacteroides* spp., beta-hemolytic streptococci) are isolated from postcesarean wound infections, similar to those found in postpartum endomyometritis. *Staphylococcus aureus* is isolated from postcesarean wound infections in 25% of cases and appears to originate from the skin rather than the endometrium.[110] Early diagnosis is important, and frequent inspection of the cesarean wound and temperature review is paramount.

Prevention of wound infections involves careful preoperative preparation. Preoperative hexachlorophene showers,[111] clipping of abdominal hair rather than shaving,[111,112] liberal application of skin antiseptic agents in the operating room, and use of wound drapes are simple but effective measures to decrease the incidence of wound infection. Sterile technique, attention to hemostasis, obliteration of tissue dead space and removal of devitalized tissues are important surgical factors that promote appropriate wound healing and prevent wound infection. The use of closed drainage systems is preferable to Penrose-type drains, because the former remain sterile as long as flow continues.

As with any infective process, prompt recognition and treatment are essential. An infected wound is usually characterized by localized pain, tenderness, erythema, and

purulent discharge, typically becoming clinically evident 4 to 7 days after surgery. Systemic evidence may also be present, with fever and leukocytosis. The early development of a wound infection, usually in association with cellulitis and high spiking fever, is characteristic of group A and group B beta-hemolytic streptococci. Initial treatment involves opening the wound along the affected area to the fascia and culturing the exudate (anaerobic and aerobic). Incision and drainage with debridement of necrotic tissue is vital. Applications of hydrogen peroxide to chemically debride the area should follow initial local surgical efforts. Because antiseptic solutions are cytotoxic, saline lavage must follow their application, then wet-to-dry dressings. When all necrotic tissue is removed and granulation tissue forms, cessation of debriding agents and the use of wet-to-wet dressings is important. The wound may be reapproximated once granulation tissue appears or be left to close by secondary intention. Drainage is usually sufficient, and systemic antibiotics are not indicated for simple wound infections. A serious complication of wound infection is necrotizing fasciitis, a synergistic infection that destroys subcutaneous tissues. Repeated, aggressive debridement in association with broad-spectrum antibiotics and hyperbaric oxygen therapy is vital to achieve cure.

CONCLUSIONS

- Obstetric practice has altered markedly over the past 50 years. With a progressive reduction in maternal and perinatal mortality rates, the focus of care centers now on continuing improvements in morbidity.
- Cesarean delivery has emerged as a centerpoint of obstetric care with liberalization of the indications for such delivery.
- It is clear that ongoing research is required into the surgical techniques for cesarean delivery to promote improved outcomes for women, not just in the first cesarean birth, but also in subsequent procedures.

SUMMARY OF MANAGEMENT OPTIONS
Cesarean Section

Management Options	Quality of Evidence	Strength of Recommendation	References
Preparation			
Vaginal preparation with povidone-iodine does not reduce postcesarean infectious morbidity.	Ib	A	113
Left lateral tilt for cesarean section reduces the incidence of low Apgar scores.	Ia	A	114
No evidence that adhesive drapes confer benefit over conventional linen drapes.	Ib / III	A / B	32 / 33
Cross-match blood with anticipated above-average blood loss (e.g., placenta previa, multiple cesarean sections).	–	GPP	–
Experienced surgeon for anticipated complicated cases (e.g., fibroid uterus, extreme prematurity, placenta previa, multiple cesarean sections).	–	GPP	–
Skin Incision			
Transverse incisions are associated with lower maternal morbidity, including dehiscence, compared to vertical incisions.	Ib	A	40
Pfannenstiel incisions result in faster operations than Maylard incisions.	IIa	B	37
Joel-Cohen incision is faster than Pfannenstiel incision but cosmetically less acceptable. No other differences.	Ib	A	38,39
Uterine Incision			
Transverse lower uterine incision is associated with less maternal morbidity.	III	B	42,43,115,116
Absorbable staples for uterine wound cannot at present be recommended for routine practice.	Ia	A	49
There is no evidence of benefit of blunt versus sharp dissection/ extension of uterine incision.	Ib	A	50

Cesarean Section *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Delivery of the Placenta			
Manual removal is associated with increased maternal blood loss and infection.	Ia	A	54
Oxytocic Agents			
Active management using oxytocic agent is better than expectant management in vaginal deliveries and one would expect the same with cesarean section.	Ia	A	117
Ergometrine-oxytocin is statistically better in preventing postpartum hemorrhage than oxytocin alone but has more side effects.	Ia	A	118
Bolus oxytocin is as effective as intramyometrial prostaglandin and misoprostol in preventing postpartum hemorrhage, but the latter two were more often associated with retained placenta.	Ib	A	119,120
Carbetocin may be associated with less intraoperative blood loss compared to oxytocin.	Ib	A	121
Exteriorization of Uterus			
No evidence of increased morbidity associated with exteriorization of the uterus.	Ia	A	63
Closure			
Uterus: A single-layer uterine incision closure is not associated with increased maternal morbidity; but trials are small and no justification for changing practice exists.	Ia	A	71
Peritoneum: Closure is not necessary in routine practice.	Ia	A	78
Subcutaneous layer: Closure is associated with less superficial wound dehiscence, especially in obese women.	Ib	A	82,83
Subrectus suction drainage: This reduces the rate of wound infection.	Ib	A	122
Skin closure: No data to guide optimum method.	Ia	A	88
Perioperative Measures			
Prophylactic antibiotics are associated with reduced maternal morbidity in emergency cesarean section and with reduced incidence of endometritis in elective cesarean section.	Ia	A	59
Antibiotic regimens: Ampicillin and first-generation cephalosporins are equally effective in reducing postoperative endometritis. Single-dose regimens are as effective as repeat doses, with the exception of urinary tract infection.	Ia	A	123
Thromboprophylaxis is recommended for all women undergoing cesarean section.	IV	C	99
Oral intake: No justification in withholding early oral intake.	Ia	A	95

Postnatal

Postpartum Hemorrhage and Other Problems of the Third Stage

Michael S. Rogers / Alan M. Z. Chang

INTRODUCTION

The major cause of maternal death worldwide is hemorrhage. The World Health Organization (WHO) estimated that 25% of 585,000 maternal deaths in 1990 worldwide were due to severe peripartum hemorrhage,[1] with a further 20 million mothers per year suffering significant morbidity from this cause. In developed countries hemorrhage still figures in the top four obstetric causes of maternal mortality, ranking third or fourth after thromboembolism, hypertensive diseases, and amniotic fluid embolism (AFE).

This chapter deals primarily with methods of managing the third stage of labor and the various severe complications that the obstetrician may be faced with, including primary postpartum hemorrhage (PPH), uterine inversion, lower genital tract trauma, uterine rupture, and AFE.

Many complications associated with maternal mortality are preventable and avoidable if rational scientific approaches are taken to management. The 1997–1999 UK Confidential Enquiry[2] concluded that the routine use of national guidelines, developed in part as a result of findings and recommendations from previous reports, had resulted in significant decreases in deaths, and that guidelines had not been followed in the cases in which deaths occurred from these causes. Because most deliveries are rightfully under the control of midwives, it is essential that obstetricians and midwives reach a consensus on the implementation of appropriate management techniques if maternal morbidity and mortality are to be minimized.

THE NORMAL THIRD STAGE OF LABOR

Recognizing the sequence of events in the third stage of labor and understanding the mechanism of placental separation may aid the detection of cases at risk of third-stage complications and the management of pathology.

Prostaglandin F (PGF), $PGF_{2\alpha}$, and oxytocin are the biochemical agents primarily involved in the third stage of labor. During the first and second stages of labor only $PGF_{2\alpha}$ and oxytocin are significantly raised in maternal plasma compared to prelabor concentrations. At 5 minutes after birth, maternal PGF and $PGF_{2\alpha}$ concentrations peak at about twice the levels found at the commencement of the second stage. A rapid increase in prostaglandin concentrations is also found in umbilical cord venous blood, suggesting that this postpartum prostaglandin surge originates in the placenta.[3] After placental separation the concentrations decrease but at rates slower than the metabolic clearance of prostaglandin, indicating that its production continues in the decidua and myometrium. Plasma oxytocin also drops to prelabor levels within 30 minutes of delivery, unless sustained by exogenous infusion.

Continuous real-time ultrasound, performed during the third stage of labor, has revealed that the process of placental separation can be divided into four phases:[4]

1. **Latent**—uterine wall at the placental site remains thin; placenta-free wall contracts
2. **Contraction**—thickening of uterine wall at the placental site
3. **Detachment**—actual separation of the placenta from the adjacent uterine wall
4. **Expulsion**—sliding of the placenta out of the uterine cavity.

Forceful uterine contractions in the latent phase induce shearing forces between the uterine wall and the unyielding placental tissue, initiating the separation of the placenta. A wave of separation begins at one of the placental poles, usually at a point near to the lower segment, and propagates toward the fundus during the

contraction and detachment phases.[5] Separation of the fundal placenta begins at more than one of the placental poles, and the central part is last to separate. (This is the reverse of the Schultze and Mathews Duncan mechanisms described in most texts.) In almost half of the cases with a previous cesarean section the separation pattern was reversed, commencing at the fundus, suggesting that myometrial strength in the region of the uterine scar may have been compromised.[5]

Although spontaneous delivery of the placenta usually occurs within 10 minutes of the baby's birth, the third stage is not considered prolonged unless it lasts more than 30 minutes. Combs and Laros,[6] in an 11-year study of 12,979 consecutive, singleton vaginal deliveries, demonstrated that the duration of the third stage followed a log-normal distribution, with a median of 6 minutes (interquartile range, 4 to 10 minutes). The prevalence of a third stage in excess of 30 minutes was 3.3%. Although stating that prophylactic oxytocic agents were not used routinely, their figures for duration are remarkably similar to those from the much larger series (45,869 singleton vaginal deliveries) reported by Dombrowski and colleagues,[7] who estimated that using active management of the third stage, 90% of term placentas will deliver spontaneously by 15 minutes and only 2.2% will be undelivered at 30 minutes. A series of reports from our unit have also confirmed similar third-stage duration, and rates of prolonged third stage associated with different uterotonic agents (oxytocin [Pitocin, Syntocinon]: 1.4% to 1.8%; oxytocin/ergometrine [Syntometrine]: 1.6% to 2.8%; misoprostol [Cytotec]: 1.4%).[8,9,10]

Management Options

There are markedly polarized views between those who believe in active management and those who believe in expectant (natural) management of the third stage.

Active management of the third stage includes:

- Administration of a prophylactic oxytocic agent or prostaglandin within 2 minutes of the baby's birth to induce uterine contraction
- Immediate cutting and clamping of the cord to enhance placental separation
- Placental delivery by controlled cord traction.

In expectant management there is:

- No prophylactic oxytocic
- No cord clamping until pulsations cease
- Delivery of placenta is by maternal effort and gravity rather than cord traction.

Use of Prophylactic Uterotonic Agents

There no longer appears to be any valid argument in favor of the physiologic approach, because two substantive studies comparing active management with expectant management have clearly indicated the advantages of active management. The Bristol trial,[11] where active management had been the norm, and the Hinchingbrooke trial,[12] where expectant management had been the norm, both demonstrated significant reductions in the incidence of PPH with active management compared with expectant management (5.9% versus 17.9% and 6.8% versus 16.5%, respectively). Both studies were terminated after interim analysis because the difference in PPH rate was so great.

Which Uterotonic Agent?

In recent years, considerable attention has been paid to the choice of a uterotonic agent, in particular comparing the cheap and orally administered prostaglandin misoprostol with the combination agent Syntometrine (oxytocin/ergonovine). The findings seem to indicate that rectal misoprostol is a viable alternative to oxytocin in areas where storage and parenteral administration of drugs are problems (oxytocin has to be stored at 4°C to retain its efficacy, whereas tablets of misoprostol kept dry retain their efficacy even at tropical temperatures for several years or more),[13] but its side effects (shivering, nausea, and diarrhea) and slightly lower efficacy make it unsuitable for routine prophylaxis against PPH. Oxytocin (Pitocin) or oxytocin combined with ergometrine (Syntometrine) therefore remain the preferred drugs for routine use in developed countries. Some trials have suggested that oxytocin alone is as efficacious as Syntometrine, whereas others have reported that it is not as effective. Intravenous ergometrine is associated with an increase in the incidence of retained placenta, possibly as a result of myometrial spasm distal to a fundally placed placenta leading to its forced retention, and should not be the agent of choice for routine administration.[14] Ergometrine also causes peripheral vasoconstriction and a rise in blood pressure and should only be given with caution, if at all, to women with hypertension. Oxytocin, on the other hand, when given as an acute bolus, can cause a marked drop in blood pressure. Caution should therefore be exercised when giving oxytocin to women with cardiovascular problems, and a continuous low-dose infusion is probably preferable to bolus injection.

The active and passive management approaches represent the two extremes of the spectrum of common practice. Although the randomized controlled trials performed to date have only compared these two approaches, the benefits of early cord clamping and controlled cord traction in the prevention of PPH have not been established separately from the use of prophylactic uterotonic agents. It is from these two aspects that most criticisms of active management arise.

Timing of Cord Clamping

The umbilical cord can be clamped immediately after birth, clamped after pulsations cease, or left unclamped.

The cord may need to be clamped before birth if there is tight nuchal entanglement. Although early clamping of the cord has been reported to be associated with significant shortening of the third stage, this has only been demonstrated in trials where no prophylactic oxytocin was given.[15,16] The difference in the effects of early versus late cord clamping on the neonate are relatively minor, and opinions differ as to their relative risks and benefits. The deferral of cord clamping until 3 minutes after birth results in a neonatal transfusion of about 80 mL of blood from the placenta.[17] This contributes about 50 mg of iron, which may reduce the frequency of iron-deficiency anemia later in childhood.[18] The theoretical downsides of this blood transfusion are hypervolemia, polycythemia, hyperviscosity, and hyperbilirubinemia. In practice however, these have not been found to produce a clinically relevant increase in neonatal morbidity.[19]

The WHO review of evidence on management of the third stage concludes

> there is no clear evidence to favor one practice over the other. Delaying cord clamping until the pulsations stop is the physiological way of treating the cord and is not associated with adverse effects, at least in normal deliveries. Early cord clamping conflicts with traditional beliefs and is an intervention that needs justification.[20]

In preterm infants, delay in cord clamping has demonstrable benefits and has been shown to decrease the need for blood ($P < 0.001$) and albumin ($P < 0.03$) transfusions during the first 24 hours of life.[21]

Controlled Cord Traction

The use of cord traction has a long history, with the earliest records dating back to Aristotle. Simple cord traction was displaced in the 1800s by the introduction of the Credé maneuver.[22] In this maneuver, the placenta is expelled by downward pressure on the fundus of the uterus in the direction of the birth canal, with the thumb placed on the posterior surface and the flat of the hand on the anterior surface of the fundus. This was proposed as an alternative means to manual removal for expelling the retained placenta and was found to avoid the uterine inversion that was occasionally associated with cord traction. Brandt in 1933 and Andrews in 1940 independently introduced similar methods to improve the use of cord traction to deliver the retained placenta. These involved traction on the cord with countertraction applied to the uterus abdominally. It was not until the 1960s, however, that the modern technique known as *controlled cord traction* was introduced by Spencer,[23] accompanied by the routine administration of ergonovine.

The current consensus is that, when traction is applied to the umbilical cord, it should be done only during a uterine contraction while controlling the uterus by Brandt-Andrews maneuver to prevent uterine inversion. However, it should be noted that the benefits of both early cord clamping and the use of routine controlled cord traction to prevent PPH have not as yet been supported by evidence from randomized controlled trials.

SUMMARY OF MANAGEMENT OPTIONS
Normal Third Stage of Labor

Management Options	Quality of Evidence	Strength of Recommendation	References
Active management of third stage is advised for all women, and includes all the following:	Ia	A	11–13,45
• Administer oxytocic agent (Pitocin (oxytocin) or Syntometrine (oxytocin and ergometrine) more commonly used than misoprostol).	Ib	A	8,13
• Clamp and cut cord.	—	GPP	—
• Use controlled cord traction (no randomized controlled data to show it reduces PPH rates of itself).	III	B	23
Timing of cord clamping			
• No evidence to indicate optimum timing in term delivery.	Ia	A	20
• In preterm infants, delay in clamping may be of benefit.	III	B	21
Ensure intravenous access for women at risk.	—	GPP	—
Save serum for rapid cross-match if needed, or actually cross-match 2 units, for women at risk.	—	GPP	—

RETAINED PLACENTA

Diagnosis and Definition

Using a diagnostic cutoff of 30 minutes for a prolonged third stage, 42% of retained placentas deliver spontaneously within the next 30 minutes,[24] with very few delivering spontaneously after 1 hour.[25] Because the incidence of significant PPH rises after 30 minutes in the third stage,[6] it therefore seems logical to institute some form of active intervention in an attempt to deliver the placenta between 30 and 60 minutes into the third stage. Dombrowski and colleagues[7] noted that, compared with term pregnancies, the frequency of retained placenta (2.0% overall) was markedly increased among very preterm (gestation <27 weeks) and preterm pregnancies (gestation <37 weeks), with odds ratios of 20.8 and 3.0, respectively.

Management Options

Manual removal appears to be the management of choice for retained placenta. However, it is associated with a risk of infection (endometritis) and trauma (perforation of the uterine wall involved with the procedure). Ely and colleagues,[26] in a retrospective study of 1052 manual removals, found that clinical endometritis developed in 6.7% of cases compared with only 1.8% following spontaneous placental delivery.

In some studies, manual removal appears to be aggressively pursued, with rates exceeding 3% and often performed only 15 to 20 minutes into the third stage. The rate generally quoted internationally is 1% to 2%.

In the absence of hemorrhage there is no urgency to resort to manual removal when less invasive alternatives are available.

Patients with a prolonged third stage are often treated as a homogeneous group, although they have different clinical conditions. These include the retention of an already detached placenta (trapped placenta), an adherent placenta, and placenta accreta. Each condition should be distinguished from the others, and each requires a specific clinical approach. Herman[27] notes that each of these conditions is associated with a different sonographic appearance, and concludes that "proper utilization of ultrasound may be crucial for optimal management."

Trapped Placenta

Trapped placenta often follows the intravenous administration of ergometrine when the onset of uterine contraction is very rapid. This tends to close the cervix at the same time as the placental detachment occurs, trapping the placenta. Intramuscular injection of ergometrine results in the onset of uterine contraction in 10 minutes, which is likely to follow rather than precede placental separation, so trapped placenta is less likely to occur. The clinical findings of a trapped placenta include a small, contracted fundus, with some vaginal bleeding and cord lengthening indicative of placental separation, and the placental margin may be palpable through the closed cervical os. On ultrasound examination the entire myometrium is thickened and a clear demarcation may be seen between it and the placenta.[4]

Delivery of a trapped placenta can usually be achieved using controlled cord traction, which encourages cervical dilation. Intravenous glyceryl trinitrate (100 to 200 μg) is useful as a short-term tocolytic agent, appears efficacious and safe, and may obviate the need for general anesthesia for uterine relaxation.[28] Releasing the cord clamp, to allow blood trapped in the placenta to drain, may also help.

Adherent Placenta

With an adherent placenta, the uterine fundus remains broad and high and myometrial contractions may be weak or absent, but there is no bleeding while the placenta remains wholly attached. Adherent placenta is caused by a deficiency in the contractile force exerted by the myometrium underlying the placental site despite normal anatomy (i.e., it is not caused by pathologic invasion of the placenta into the uterine muscle, known as *placenta accreta*). On ultrasound the myometrium appears thick and contracted in all areas, except where the placenta remains attached, and the uterine wall remains less than 2 cm in thickness.[4] If the placenta becomes partly separated the myometrium over the detached area appears thicker, but that underlying the adherent part remains thin (<2 cm).[4] Detachment usually starts in the lower part of the uterus and is associated with bleeding from the placental bed.[5] Treatment options depend on the amount of bleeding:

- In the absence of bleeding, a conservative approach can be adopted and manual removal of the placenta can be postponed while the problem is investigated (by ultrasound).
- Where there is active bleeding, immediate active management is necessary.

Effective treatment of the adherent placenta is based on stimulating a contraction of the underlying myometrium that has sufficient strength to induce separation of the placenta. Oxytocin, ergonovine, and misoprostol are all capable of inducing sustained myometrial contractions. However, there is no evidence that systemic and repeated administration of either oxytocics or prostaglandins is able to assist in the delivery of the adherent placenta.

Recent studies have shown that uterotonic agents administered via umbilical vein injection may be effective in causing the adherent placenta to separate, and this method is currently recommended as the first line of treatment by the WHO.[29]

The Pipingas technique has been shown effective in delivering drugs to the placental bed.[30] A size 10 nasogastric tube is passed along the umbilical vein until resistance is felt, then retracted about 5 cm, and prostaglandin $F_{2\alpha}$ (20 mg diluted in 20 mL of normal saline) or oxytocin (30 IU diluted in 20 mL of normal saline) is injected through the catheter.[31]

SUMMARY OF MANAGEMENT OPTIONS
Retained Placenta

Management Options	Quality of Evidence	Strength of Recommendation	References

Adherent Placenta			
• If there is active bleeding, manual removal is necessary.	–	GPP	–
• If there is no active bleeding, consider intraumbilical uterotonic agents before resorting to manual removal.	III	B	29–31

ADHERENT PLACENTA (PLACENTA ACCRETA, INCRETA, PERCRETA)

Placenta accreta is a condition in which all or part of the placenta is adherent to the uterine wall because of myometrial invasion by chorionic villi. It may occur when there is either a primary deficiency of, or secondary damage to, the decidua basalis.

Three grades are defined according to the depth of myometrial invasion:

- Accreta—chorionic villi are in contact with the myometrium, rather than being contained within the decidua (80% of cases)
- Increta—extensive villous invasion into the myometrium (15% of cases)
- Percreta—villous invasion extends to (or through) the serosal covering of the uterus (5% of cases).

Placenta accreta was previously reported to be rare (1 in 30,000 deliveries between 1930 and 1950), but the prevalence has risen considerably (1 in 2500 deliveries),[25] a rise attributed to the rise in cesarean section rates. All three grades of placenta accreta are most commonly found in patients with a history of uterine surgery, principally cesarean section, with the probability of placenta previa being accreta rising as high as 67% after four cesarean sections.[32] Placenta accreta is associated both with placenta previa and advanced maternal age. This close association with both previous cesarean section and placenta previa means that placenta accreta rarely complicates vaginal delivery. In fact, in the series reported by Miller and colleagues,[33] 55 of the 62 cases were associated with placenta previa and all were delivered by cesarean section. The rate of placenta accreta was therefore only 1 in 22,000 in the absence of placenta previa. Rarely, abnormal attachment is seen in the absence of prior surgery (e.g., associated with Ascherman syndrome and submucous fibroids). Interestingly, the adherence is not necessarily over the site of the previous scar.

All three grades of placenta accreta can result in profuse postpartum hemorrhage due to incomplete separation of the placenta. Being alert to this possibility is essential in patients who have a combination of placenta previa and a history of previous uterine surgery. If the diagnosis of placenta accreta can be confirmed, plans for delivery by cesarean section by a surgeon experienced in dealing with such cases, and in a facility where resuscitation and intensive care are available, should be made.

Diagnosis

The diagnosis of placenta accreta can be made using color flow Doppler ultrasound as early as the second trimester. Typical features of a placenta accreta include the following:[27]

- The normal hypo-echoic boundary between the placenta and the urinary bladder or serosa is lost.
- The placenta appears to be contiguous with the bladder wall.
- Sonolucent spaces are visible within the placenta, adjacent to the uterine wall.
- Color Doppler reveals persistent blood flow between the basal placenta and the myometrium.[34]

A thickness of myometrial involvement greater than 1 mm, accompanied by the presence of large placental lakes, can predict myometrial invasion with a sensitivity of 100% and specificity of 72%.[35] Magnetic resonance imaging may be useful in the presence of a posterior placenta and for assessing deep myometrial, parametrial, and bladder involvement, or when the ultrasound findings are equivocal.[36]

Management Options

Attempts to physically remove an accretic placenta may lead to severe and uncontrollable hemorrhage. If the diagnosis can be made before delivery, the following options can be considered:

- Scan the uterus intraoperatively using an ultrasound transducer in a sterile sleeve, placing the transducer directly onto the uterus to obtain a detailed view. This enables delineation of the placental attachment. The baby can then be delivered through an incision designed to avoid the placenta (this may need to be fundal or deviated to one side or the other, avoiding the vessels in the broad ligament). The placenta can then be left in situ and its degeneration followed by weekly serum β-human chorionic gonadotropin (β-hCG) measurements and ultrasound evaluation of placental bed vascularity. Remnants can be removed manually or by curettage when β-hCG levels become undetectable and placental blood flow is no longer seen on ultrasound.[37] This is usually successful in avoiding the need for further intervention, but major secondary postpartum hemorrhage can still occur, and occasionally hysterectomy is required.
- If the placenta is left in situ, treatment with methotrexate (50 mg IV on alternate days with folinic acid rescue) may speed degeneration of the placenta and resorption of persisting chorionic villi.[38]
- Elective cesarean hysterectomy may be required as a definitive therapy, and it can be the management of choice if the woman has completed her family.

If a placenta accreta is diagnosed before delivery, the following issues should be considered:

- General anesthesia is probably wise, because it can be difficult to cope with major blood loss while the patient is awake. However, placement of an epidural catheter preoperatively is useful to achieve postoperative pain control.

- It may be useful to pass a nasogastric tube.
- An arterial line for detailed intrapartum blood pressure monitoring should be inserted.
- Insertion of a central venous pressure monitoring line is also wise, and the use of a Swan-Ganz catheter can be considered if facilities are available.
- Calf compressors can be used to minimize the risk of deep vein thrombosis during prolonged surgery, and subcutaneous heparin postsurgery should also be considered.
- Involvement of urologists and vascular surgeons may be necessary. Cystoscopy prelaparotomy can be useful to check for any bladder invasion by the placenta.
- Preparations for major blood transfusion should be made in conjunction with the hematology department.

There are occasions when conservation of the uterus is desired by the patient; in such cases an attempt to avoid hysterectomy can be made. However, only a few cases using this more conservative management have been reported, and hemorrhage and infection are common complications. The cesarean hysterectomy rate is much higher for placenta accreta (>50%) than for placenta previa alone (2%). Although mortality for placenta accreta is now uncommon,[25] morbidity remains high; consequently peripartum hysterectomy remains the current treatment of choice in most cases.

The more usual presentation is discovery of a partially accretic placenta during cesarean section. Hemostasis may be achieved if the accretic area is not too extensive, by placing sutures deep into the myometrial bed using a multiple 3-cm square suturing pattern over the area of maximal bleeding: Cho and colleagues[39] reported successful use of this technique in 23 cases of refractory bleeding with apparently normal uterine cavities on follow-up evaluation.

Other methods have been attempted but hysterectomy is often required, particularly when the bleeding site is from the lower uterine segment.[40]

Treat any associated uterine atony as described under Primary Postpartum Hemorrhage.	–	GPP	–

CONCLUSIONS

- Prophylactic uterotonics reduce the incidence and severity of PPH, but have limited effects on the actual duration of the third stage of labor; thus, a prophylactic uterotonic agent should be administered to all mothers, with the choice of the agent depending on the clinical situation and on its availability.
- If delivery can be achieved without clamping and cutting of the umbilical cord, this can be delayed until cord pulsation ceases (this will usually occur within 1 to 3 minutes of birth). In the meantime, resuscitation of the newborn can be attended to.
- When clinical signs of separation are present (uterine fundus contracted and palpable above the umbilicus, a show of blood seen vaginally and the umbilical cord lengthens), the placenta is either in the lower uterine segment or in the vagina. Placental expulsion can be achieved by maternal effort or by gentle controlled cord traction, after ensuring the uterus is contracted. In the absence of bleeding, there is no immediate need for active measures, and it is appropriate to wait for up to 30 minutes for the placenta to separate.
- If spontaneous placental separation does not occur within 30 minutes and there is no bleeding, there is no need for immediate active management. However, the uterus should be examined frequently to ensure there is no undetected bleeding, and an ultrasound examination of the placental site may be beneficial in distinguishing the stage of separation and the possible cause of delay, providing a rational basis for further management (Table 77–1). Sublingual glyceryl trinitrate can be given for the "trapped" placenta. In both preterm and term pregnancies with adherent placenta, separation may be achieved by the injection of 20 to 30 mL of oxytocin or prostaglandin solution into the placental bed via an infant nasogastric tube threaded down the umbilical vein. Failure of this technique should alert the clinician that placenta accreta may be present.[41]
- If bleeding is suspected or seen, a systemic uterotonic (oxytocin 10 IU intravenously, Hemabate 250 μg intramuscularly, or misoprostol 1000 μg per rectum) should be given while arrangements are made for manual removal of the placenta (Fig. 77–1) or for transfer of the patient to another facility if appropriate.

PRIMARY POSTPARTUM HEMORRHAGE

Definition

Primary (early) PPH refers to excessive blood loss (>500 mL) during the third stage of labor or in the first 24 hours after delivery; thereafter, significant bleeding is referred to as secondary (late) PPH. Secondary PPH is discussed in detail in Chapter 78.

Significance

In the absence of anemia, blood loss up to 500 mL can be considered physiologic (i.e., within normal limits) and is unlikely to lead to cardiovascular compromise. For those who already have severe anemia (<5 g/dL), this amount of blood loss may induce heart failure or cardiovascular collapse.[42]

Maternal deaths due to obstetric hemorrhage are often associated with substandard care.[2,43] Accurate estimation of blood loss, prompt recognition and treatment of clotting disorders, early involvement of experienced clinicians, availability of anesthetic support, appropriate fluid replacement, and adequate physiologic monitoring are factors that govern maternal survival.

Etiology

Approximately 80% to 90% of cases of primary PPH are associated with uterine atony. However, a combination of

TABLE 77–1

Summary of Clinical and Ultrasound Findings at Different Stages of Placental Separation and Recommendations for Management

	STAGE OF PLACENTAL SEPARATION			
	FULLY ADHERENT	**PARTIALLY SEPARATED**	**FULLY SEPARATED: TRAPPED**	**FULLY SEPARATED: NORMAL**
Clinical Signs				
Duration third stage		>30 minutes		< 30 minutes
Uterine fundus	Above umbilicus			Below umbilicus
Uterus	Broad	Broad	Small, contracted	Small, contracted
Cord lengthening	No	No	Sometimes	Yes
Bleeding	No	Yes	Yes	Yes
Ultrasound Appearance				
Myometrium (placental site)	<2 cm thick across entire placental site	<2 cm thick at fundus >2 cm at lower pole	<2 cm thick at all levels; surrounding placenta	>2 cm thick at all levels; above placenta
Placental position	Upper segment	Upper segment	Upper segment	Lower segment or vagina
Doppler flow (myometrium-placenta)	Present	Absent	Absent	
Management				
Initial: 30–60 minutes	Expectant	Hemabate 250 μg IM; misoprostol 1000 μg PR	Controlled cord traction; glyceryl trinitrate	Maternal effort; gentle controlled cord traction
>60 minutes	Umbilical vein uterotonic	Manual removal	Manual removal	
Failed	Methotrexate/ hysterectomy	Hysterectomy		

improvements in drug therapy for uterine atony and increased cesarean section rates in developed countries have resulted in uterine atony often taking second place to placenta accreta as a cause of morbidity.[44] Less common causes of PPH are upper (uterus, cervix) and lower (vagina, perineum) genital tract trauma, uterine inversion, retained placental tissue, and disseminated intravascular coagulation (DIC).

Management Options

Prevention

Major reductions in the frequency and severity of PPH have followed the adoption of routine prophylactic administration of oxytocics in the management of the third stage.[45] This consists of injections of synthetic oxytocin, methylergometrine, or a combination of the two (Syntometrine) with crowning of the head, delivery of the baby's anterior shoulder, or immediately after delivery.

In high risk situations (multiple pregnancy, obstructed labor, or manual removal of the placenta), prophylaxis may be extended by the infusion of 40 units oxytocin in 500 mL Hartmann's solution over 4 hours. However, the effectiveness of this has not yet been proven by randomized controlled trial, and many of those delivered by emergency cesarean section show evidence of loss of myometrial oxytocin receptors, reflected by a decrease in binding sites and very low mRNA concentrations.[46]

Treatment

The management of primary PPH will depend on the presence of risk factors and the probable cause. For example (Table 77–2), uterine atony may follow

FIGURE 77–1
Manual removal of placenta. The fingers are moved from side to side until the placenta is completely detached. Reproduced with permission from Cunningham FG, MacDonald PC, Gant NF: Williams Obstetrics, 18th ed. Norwalk, Conn, Appleton & Lange, 1989.

TABLE 77–2

Summary of Risk Factors, Clinical Findings, and Recommendations for Management for the Major Causes of Primary PPH

RISK FACTORS	CLINICAL FINDINGS	DIAGNOSIS	INITIAL ACTION	SECOND-LINE
Obstructed labor Multiple pregnancy, polyhdramnios Tocolytics	Soft, relaxed uterus	Uterine atony	Massage/compression Repeat oxytocin, either systemic or intramyometrial	Hemabate 250 μg, either systemic or intramyometrial
Obstructed labor Fetal distress Difficult or rotational forceps delivery PROM	Contracted uterus	Uterine rupture	Repair rupture if possible	Hysterectomy
Delayed second stage Ventouse/forceps delivery Precipitate labor	Contracted uterus	Cervical/vaginal tear	Repair tears	Vaginal tamponade
Retained placenta	Fundus not palpable abdominally	Uterine inversion	Reduce inversion by manual or hydrostatic pressure; tocolysis if necessary	Hysterectomy
Retained placenta	Fundus palpable	Retained products	Uterine exploration/curettage	Hysterectomy
Amniotic fluid embolism	Contracted uterus	Disseminated intravascular coagulation	Fresh frozen plasma, fresh whole blood transfusion	Heparin
Placental abruption Fulminating preeclampsia	Bleeding from IV site or sutures			

obstructed labor, multiple pregnancy, or polyhydramnios, in which the myometrium is overexerted or overstretched.

Where primary PPH is caused by failure of the uterus to contract, the condition is easily recognized by the soft relaxed uterus. Bimanual compression and abdominal massage will usually stimulate a contraction and stop the bleeding, although bleeding may resume as soon as such stimulation is stopped (Fig. 77–2). For this reason utero-

FIGURE 77–2
Bimanual compression of the uterus and massage with abdominal hand will usually effectively control hemorrhage from uterine atony. Reproduced with permission from Cunningham FG, MacDonald PC, Gant NF: Williams Obstetrics, 18th ed. Norwalk, Conn, Appleton & Lange, 1989.

tonic agents such as oxytocin or Syntometrine and prostaglandins such as Hemabate or misoprostol should also be administered to achieve a longer period of myometrial contraction, allowing clotting mechanisms to become fully activated. Because the immediate administration of these agents is essential, it is important that front-line staff, such as midwives or traditional birth attendants, are empowered to do so on their own initiative.

If bleeding continues despite adequate uterine contraction, exploration of the genital tract is necessary to detect other causes such as trauma (uterine, cervical, or vaginal tears) or retained placental tissue, particularly in cases where risk factors were present (i.e., obstructed labor, fetal distress, difficult operative delivery, manual removal of placenta).

In the event that these measures fail to control bleeding, hysterectomy may be resorted to as a life-saving procedure. However, as with placenta accreta, there will be occasions when conservation of the uterus is important to the patient, and alternative therapies may be attempted.

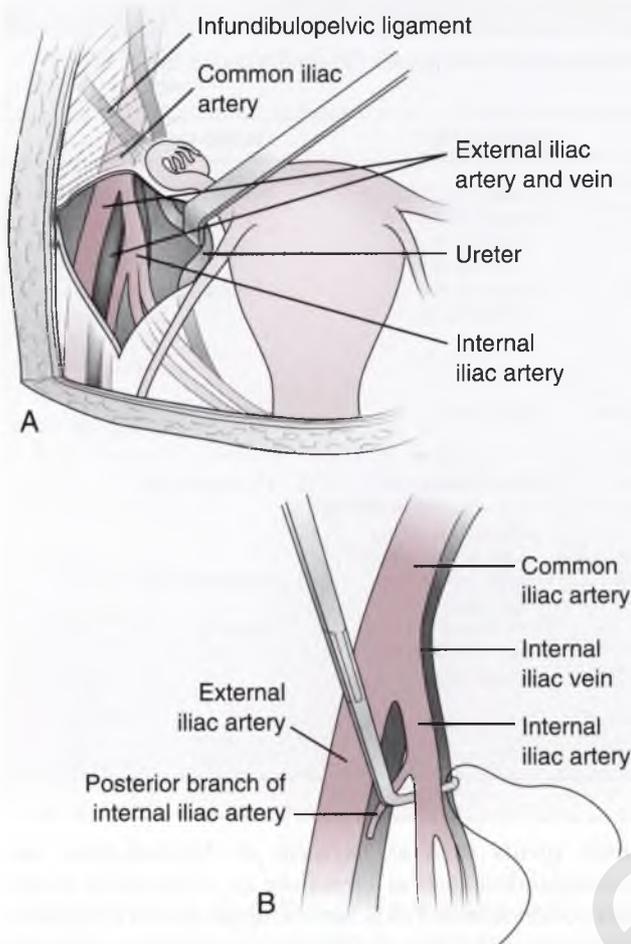
Bilateral internal iliac artery ligation (Fig. 77–3) may reduce the pulse pressure and allow the normal coagulation mechanism to engage,[47] but the procedure is technically difficult during pregnancy and has a poor success rate (less than 50% success).[48] Waters[49] proposed the alternative of bilateral uterine artery ligation (Fig.77–4); reported success rates for this procedure vary between 80% and 96%.[50] AbdRabbo[51] subsequently reported a 100% success rate by also ligating the ovarian vessels where uterine artery ligation alone was unsuccessful (Fig. 77–5).


FIGURE 77–3
Operative technique of internal iliac artery ligation. *A*, The retroperitoneal space over the right internal and external iliac vessels has been opened and the ureter retracted medially. *B*, A right-angled clamp is passed between the iliac artery and vein to receive a ligature of number 0 silk. The vessel should be doubly ligated. Reproduced with permission from Pauerstein C: Clinical Obstetrics. New York, Wiley, 1987.

Arterial embolization is highly effective (>95% success)[52] but requires time and specialized facilities to carry out. When the situation is urgent, uterine tamponade can be achieved either by packing the uterine cavity[53] or applying uterine compression sutures such as those described by B-Lynch.[54] In their simplest form, compression sutures are the insertion of absorbable sutures (e.g., Dexon) from the front to the back of the uterus through the lower segment about 1 cm above the cervix and about 2 cm medial to the uterine artery on each side.[55] These are then tied over the top of the uterus, compressing the uterine body (the loose ends can be tied together at the top to prevent the sutures slipping down the side) (Figs. 77–6 to 77–9). Lower segment bleeding from placenta previa or accreta may respond to sutures placed deep into the myometrial bed.

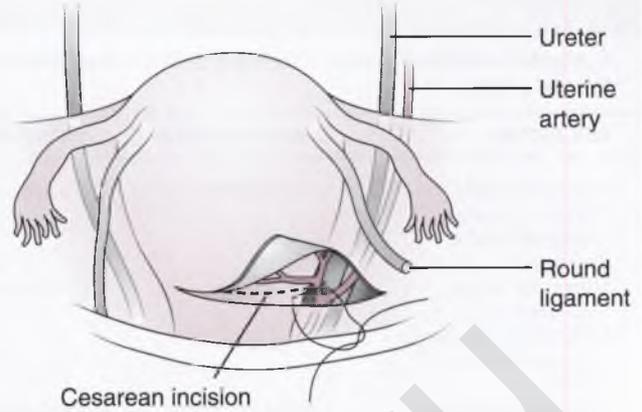
If compression sutures on their own are insufficient or a laparotomy has not yet been performed, another useful technique is to inflate a sterile saline-filled balloon inside the uterine cavity[56-58] (e.g., the Rusch balloon or Cook's


FIGURE 77–4
Operative technique for uterine artery ligation. The vesicouterine fold of peritoneum has been incised transversely and the bladder mobilized inferiorly. A number 1 chromic catgut suture on a large smooth needle has been placed through the avascular space of the broad ligament and through the uterus. The suture includes the uterine vessels and several centimeters of myometrium. Reproduced with permission from Pauerstein C: Clinical Obstetrics. New York, Wiley, 1987.

balloon; see Fig. 77–10). Some types can be inflated with up to 500 mL of sterile saline. This type of tamponade can also be used to arrest bleeding from extensive vaginal lacerations and can even be used to stem bleeding in the pelvis following hysterectomy (the tube used to inflate the balloon is passed through the vagina, and then traction toward the feet is applied to maintain pressure within the pelvic cavity[59]; see Fig. 77–11).

Finally, DIC may complicate any situation in which coagulation factors are exhausted, such as in severe preeclampsia, placental abruption, AFE, or protracted hemorrhage.

While measures are being taken to control obstetric hemorrhage, the patient will require transfusion with adequate volumes of whole blood and/or blood substitutes to maintain blood volume and tissue perfusion. In facilities where cross-matched blood is not readily avail-

able, autologous autotransfusion may be considered. The Cell Saver is an autotransfusion device that collects blood from the operative site using an anticoagulated suction device, separates red blood cells from contaminants by filtration and differential centrifugation, and re-infuses them into the patient. The process appears to be effective in removing fetal and amniotic debris and has not been reported to be complicated by infection, AFE, or DIC.[60]

SUMMARY OF MANAGEMENT OPTIONS
Primary Postpartum Hemorrhage

Management Options	Quality of Evidence	Strength of Recommendation	References
Prevention			
Active management of third stage advised for all women, comprising all the following:	Ia	A	11–13,45
• Administer oxytocic agent (Oxytocin or Syntometrine more commonly used than misoprostol).	Ib	A	8,13
• Clamp and cut cord.	--	GPP	--
• Use controlled cord traction (no randomized controlled data to show that it reduces PPH rates).	III	B	23
No evidence that oxytocin infusion in high risk settings improves outcome.	III	B	104

SUMMARY OF MANAGEMENT OPTIONS
Primary Postpartum Hemorrhage *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Treatment			
Initial emergency measures:	–	GPP	–
• Rub-up contraction.			
• Administer intravenous oxytocin (5–10 units) (ergometrine 0.25–0.5 mg i.m. an alternative but should be avoided in hypertensive patients).			
• Establish intravenous access.			
• Cross-match blood.			
General management options for major obstetric hemorrhage	See Chapter 79		
Specific measures:			
• Examine uterus to confirm atony is cause.	–	GPP	–
• Confirm placenta appears intact or perform uterine exploration and removal of placental fragments if suspicion of incomplete third stage.	–	GPP	–
• Bimanual compression is a temporary measure.	–	GPP	–
• Commence i.v. oxytocin infusion.	III	B	104
• Give further i.v. bolus of oxytocin.	III	B	104
• Rule out trauma to vagina, cervix, or uterus.	–	GPP	–
• Use uterine packing or balloon tamponade.	III	B	53,56–58
• Prostaglandin options include:			
• 15-methyl-PGFa (0.25 mg) i.m. or PGF$_{2\alpha}$ (0.5–1.0 mg) into uterine muscle	III	B	105
• Rectal misoprostol 1000µg	III, Ib	B, A	106
• Use B-Lynch sutures or simpler alternatives.	III	B	54,55
• Perform arterial embolization if units have resources and experience.	III	B	52
• Perform bilateral uterine artery ligation.	III	B	50
• Perform bilateral internal iliac artery ligation.	III	B	47
• Perform bilateral ovarian artery ligation.	III	B	51
• Perform hysterectomy.	III	B	107
• Consider Cell Saver.	III	B	60

UTERINE INVERSION

Definition

The uterus is partially (first-degree) or completely (second- and third-degree) turned inside out. Second-degree inversion refers to cases in which the fundus has passed through the cervix but not outside the vagina.

Etiology

Inversion of the uterus is principally a complication of the third stage of labor, and the most common cause is traction applied to the umbilical cord while the uterus is relaxed. The institution of active management of the third stage of labor is associated with a fourfold decrease in the incidence of acute uterine inversion following vaginal delivery.[61] In a case in which the placenta is adherent or accretic, the thin and relaxed myometrium is prone to inversion when traction is applied.[62] This is particularly so if the placenta is fundally situated, because there is direct traction on the central portion of the noncontracted muscle.[50]

Diagnosis

Uterine inversion is often associated with acute lower abdominal pain and profound shock of neurogenic and hemorrhagic origin. The shock is often out of proportion to the degree of blood loss, although if the placenta remains attached following inversion shock is less likely to occur. Bimanual examination will confirm the diagnosis and also reveal the degree of inversion.

Management Options

Once inversion is recognized, oxytocin should be withheld until correction has been established. If puerperal inversion of the uterus is recognized immediately, the uterine corpus can usually be pushed back through the cervical ring, by pressure directed toward the umbilicus, either manually (Johnson maneuver)[63] or by hydrostatic pressure[64] (Fig. 77-12). Tocolysis with beta-mimetics or magnesium sulfate may facilitate the procedure, although glyceryl trinitrate is unlikely to prove effective unless the placenta is still in situ.[65] When reduction under tocolysis fails, general anesthesia with halothane may be induced to provide uterine relaxation and reduction attempted again, although hysterectomy will frequently be indicated. Tews and colleagues have recently reported a new abdominal, uterus-preserving approach for such cases.[66] At laparotomy, the bladder is dissected off the cervix and the vagina entered by a longitudinal incision. Two fingers are advanced through this incision, above the invaginated uterine body and, exerting counterpressure with the other hand, the inversion can be reversed. Uterotonic drugs are then given immediately to maintain uterine contraction and to prevent reinversion.

UTERINE RUPTURE

Definition

Uterine rupture (full-thickness tear through myometrium and serosa) is an uncommon obstetric complication, which may occur in a previously intact uterus or in one with a previous cesarean or myomectomy scar. Different terms are sometimes used to describe partial separation (dehiscence) or healing defects (windows) of uterine scars.

Etiology

The approximate incidence of uterine rupture is 0.05%[67] to 0.086%[68] of all pregnancies. Changes in obstetric practice have variable effects on the prevalence. The increasing rates of cesarean section make subsequent rupture more likely, and dehiscence of a cesarean section scar is the most common cause of uterine rupture reported in recent series.[69] However, the tendency to do fewer classical cesarean sections, the more frequent performance of elective repeat cesarean section,[53] and lower

overall parity[70] have reduced the overall rate of uterine rupture.

Uterine rupture is rarely encountered in developed countries in the absence of previous surgery, but is more commonly seen when iatrogenically caused by the excessive and prolonged use of oxytocics in the presence of a uterine scar.[54,71] Taylor and colleagues, in a recent multicenter study, showed that the risk of uterine rupture in patients undergoing a trial of labor after previous cesarean section was significantly higher when vaginal PGE_2 was used (6/58 [10.3%] vs. 8/732 [1.1%]).[72]

Uterine rupture is more frequent when women are left for prolonged periods in obstructed labor. This is more likely to occur in developing countries, although the situation has improved greatly in recent years following improvements in medical facilities, transport systems, organization of medical care, and levels of patient education.[73,74] However, unrelieved obstructed labor remains the major cause of uterine rupture, usually occurring in grand multiparous patients when the fetus is macrosomic or abnormal, or when malpresentation occurs.

Uterine rupture can occur in nulliparous patients, but the risk is relatively low, accounting for less than 10% of cases, despite the higher incidence of obstructed labor in nulliparous patients compared with multiparae. Maternal and fetal outcomes are usually worse in women with an unscarred uterus than in those with a previous uterine scar whose delivery is planned.[75] If patients with a uterine scar fail to seek medical attention and labor at home, their outcome tends to be worse.[76]

Diagnosis

A nonreassuring fetal heart rate with recurrent variable decelerations may be indicative of imminent uterine rupture. On abdominal palpation a retraction (Bandl's) ring may be palpable at the junction between the upper segment and a grossly distended lower segment. Severe pain is usually elicited by palpation over the rupture site. Vaginal bleeding in a case of obstructed labor is diagnostic but may be hidden above an impacted presenting part.[77] Catheterization of the bladder will almost always reveal blood-stained urine, but fresh arterial blood indicates that the rupture actually involves the bladder.[78]

Once uterine rupture has occurred, the fetus extrudes through the defect and placental separation will begin. Immediate maternal cardiovascular collapse is a rare event unless the tear extends into the broad ligament vessels. Usually maternal condition deteriorates progressively as bleeding continues and eventually leads to collapse only if the situation is left unattended. Examination of the abdomen will reveal generalized tenderness, easily palpable fetal parts, and absent fetal heart activity.[72]

Occasionally the rupture occurs during vaginal delivery of the infant (usually an operative procedure for delay and fetal distress) and presents as a primary PPH.[73] Thus uterine rupture remains a differential diagnosis in PPH, particularly among those with a previous uterine scar.

Management Options

Emergency laparotomy is indicated whenever the diagnosis is suspected:

> It is much better to diagnose rupture of the uterus too readily than to miss it, as any delay gravely impairs the patient's chances of survival.[67]

When confronted with uterine rupture, the clinician should repair the uterus if this is possible. However, in many cases the damage will be too extensive for repair, particularly if spontaneous rupture occurs in an unscarred uterus; for these, hysterectomy may be necessary.

The presence of a repaired ruptured uterus imposes difficult decisions in the management of future pregnancies. If the defect is confined to the lower segment the risk of rupture in a subsequent pregnancy will be similar to that of someone with a previous cesarean section. Extensive tears involving the upper segment will carry a greater risk, and future pregnancy may be contraindicated, particularly in developing countries where access to an adequately staffed and equipped health care facility is absent. In this situation, sterilization may be safer for the woman.

When future pregnancy occurs, the planning of the delivery is essential, and the treatment of choice is an elective cesarean section at term (37 to 38 weeks' gestation).

AMNIOTIC FLUID EMBOLISM (See also Chapter 80)

Definition

Amniotic fluid embolism is a rare event occurring during labor usually after spontaneous or artificial rupture of membranes (70%), at cesarean section (19%), or during the 48 hours after delivery (11%), although others have also reported it occurring following first-trimester termination of pregnancy[79] and after amniocentesis.[80]

Epidemiology

The reported incidence of AFE ranges from 1 in 8000 births[81] to 1 in 80,000 births.[82] Twenty-five percent of patients die within 1 hour of the onset of symptoms; overall, the reported mortality is 61% to 86%, and the interval from onset of symptoms to death varies between 10 minutes and 32 hours.[83] Even in those that survive, the initial hypoxemia is often so profound that irreversible neurologic injury occurs despite appropriate resuscitation. In Clark's analysis of the American national registry, less than 3 out of 20 survivors had no residual neurologic damage.[82] Because mortality for this condition is so high and the incidence so uncommon, the proportion of maternal deaths attributed to AFE is largely dependent on the prevalence of other causes of maternal death and the efficacy of treatments for these conditions. In the United Kingdom, for example, AFE rates fifth as a cause of direct maternal deaths with thromboembolic disease rated first,[84] whereas in Hong Kong the situation is reversed because of the rarity of deep vein thrombosis among the predominantly Chinese population. In mainland China AFE accounts for 15% of maternal deaths and as a cause rates second after hemorrhage.[85] Similarly, AFE is the most common cause of maternal death in Singapore, accounting for over 30% of all maternal deaths, with thromboembolic disease rated second (20%) due to the more mixed Asian population.[86] In developing countries maternal deaths due to other causes may be so common that AFE is not even considered as a separate category. Preliminary data from the United Kingdom National Register of cases suggest that mortality may not be as high as described above, with only 16% mortality reported to date, although maternal and neonatal morbidity rates are high.[84]

Clinical Manifestations

The onset of symptoms in AFE is sudden and catastrophic: 27% to 51% present with acute respiratory distress (tachypnea, shortness of breath, cyanosis), 13% to 27% with acute hypotension, 17% with fetal distress, 10% to 30% with convulsions,[82,87] and up to 12% with DIC alone (PPH, bleeding from abdominal or perineal sutures or IV sites).[88] Other symptoms include nausea and vomiting, anxiety, shivering, and sweating. These are followed within 1 to 4 hours by evidence of DIC in virtually all cases.[82]

There are no consistent identifiable predisposing factors for AFE apart from the timing of the event.[83]

Etiology

There is no evidence to support the misconception that amniotic fluid enters the maternal circulation at delivery in most women.[89] The presence of squamous cells in the pulmonary circulation is no longer considered diagnostic of AFE, because squamous cells can also be found in nonpregnant patients in blood samples taken from the lungs at pulmonary artery catheterization.[90] In patients with clinical evidence of AFE, blood aspirated from the pulmonary artery contains mucin, vernix, and lanugo and occasionally meconium, as well as squamous cells, which are frequently coated with leukocytes, suggesting a maternal reaction to this fetal debris.[91] The mechanism by which amniotic fluid suddenly enters the maternal circulation is unknown but most likely involves tears in the veins of the lower uterine segment or endocervix.[92]

Pathophysiology

Once AFE has occurred, it induces two potentially fatal processes: cardiopulmonary collapse and DIC. Clark and colleagues noted the similarity between AFE and other shock states, and proposed that the condition resulted from an anaphylactoid response to the presence of amniotic fluid constituents such as meconium or lanugo.[82] In the presence of meconium or a dead fetus, the time from initial presentation to cardiac arrest and death is shorter than following embolization with clear amniotic fluid.[82] Various mediators such as endothelin[93] are released from the maternal tissues in response to AFE, causing myocardial depression, increases in systemic and pulmonary vascular resistance, decreased cardiac output, and DIC.

It is also possible that bioactive chemicals already present in amniotic fluid cause these events directly. Experimental models of AFE using pregnant animals injected with autologous amniotic fluid[94] produce changes consistent with the presence of a potent vasoconstrictor in amniotic fluid. El Maradny and colleagues have shown that the vasoconstrictor is likely to be endothelin, although their study was performed in rabbits using human rather than autologous amniotic fluid.[95] In humans the major haemodynamic abnormality is left ventricular failure, possibly with transient pulmonary hypertension;[96] endothelin causes increases in both systemic and pulmonary vascular resistance. Other factors, including proteolytic enzymes, histamine, serotonin, platelet-activating factor, prostaglandins, and other potent vasoconstrictive arachidonic acid metabolites such as leukotrienes and isoprostanes, have been implicated in the hemodynamic changes and the development of DIC.[83]

Diagnosis

Early diagnosis may be the best way to improve outcome of AFE. At present the diagnosis is made clinically on the basis of the sudden onset of signs and symptoms after excluding the differential diagnoses (Table 77-3).

The diagnosis can be confirmed by retrieval of fetal debris from the pulmonary artery via a Swan-Ganz catheter. Samples may occasionally be contaminated by maternal cells, but large numbers of squamous cells are strongly supportive of the diagnosis, particularly if they are coated with neutrophils.[97] Many patients do not survive long enough for the diagnosis to be confirmed by this method, but postmortem diagnosis can be made by detection of such debris in the pulmonary vessels.

Kobayashi and colleagues have developed a rapid blood test for AFE that shows promise but still requires clinical evaluation. It is based on an immunoassay for Sialyl, a mucin-type glycoprotein originating from the intestinal and respiratory tracts that is present in both meconium and in clear amniotic fluid.[98]

Management Options

Amniotic fluid embolism is managed symptomatically by maintenance of oxygenation, circulatory support, and correction of DIC. If the fetus is undelivered, cesarean section should be performed as soon as possible, because perinatal mortality and morbidity from hypoxia-ischemia is very high in such instances.[99] Oxygen should be given in all cases, with the concentration and mode of delivery adjusted according to the patient's oxygen saturation, which should be maintained as close to 100% as possible.[100] Initial treatment of shock includes rapid blood volume expansion and direct-acting vasopressors such as phenylephrine to optimize perfusion pressure; dopamine can be used later to improve myocardial function.[101] Pulmonary artery wedge pressure should be monitored

via a Swan-Ganz catheter to assist in adjusting therapy, and blood aspirated via the catheter can be examined to confirm the diagnosis.[96] Diuretics or systemic vasodilators may be indicated in some cases.

Disseminated intravascular coagulation should be managed initially by transfusion of packed red cells or fresh whole blood to maintain tissue oxygenation, because significant hemorrhage will usually have occurred. Therapy should be guided by the clinical condition of the patient and laboratory evidence of continuing coagulopathy. Fresh frozen plasma and platelet transfusion should also be given to replace clotting factors consumed by the process. Case reports suggest that plasma exchange techniques may be helpful in clearing fibrin degradation products from the circulation. Use of cryoprecipitate, FOY (a serine proteinase inhibitor), cardiopulmonary bypass and pulmonary thromboembolectomy, nitric oxide, and inhaled aerosolized prostacyclin have also been reported.[83] Clark[82] has also suggested the use of corticosteroids and epinephrine, but these have yet to be evaluated in clinical trials.

• Treat any DIC	–	GPP	–

PREECLAMPSIA/ECLAMPSIA (See also Chapters 36 and 80)

A frequently forgotten risk in the third stage of labor is that of preeclampsia or eclampsia. The onset of preeclampsia is extremely variable, and in the Chinese population in Hong Kong up to 50% of cases develop proteinuria and hypertension for the first time during labor or in the immediate puerperium. A similar phenomenon is seen in the black African population, in whom eclamptic convulsions are commonly seen up to 48 hours after delivery. Eclamptic convulsions can occur at any time, before or after the development of proteinuria. Douglas and Redman[102] surveyed 383 cases of eclampsia that were reported in the United Kingdom in 1992 (incidence 4.9/10,000 maternities) and found that 85% of these cases had attended for antenatal care within 1 week prior to the convulsion. Of these cases 11% had no evidence of proteinuria or hypertension, 10% exhibited proteinuria only, and 22% hypertension only, leaving only 57% with the classical picture of proteinuric PPH with both hypertension and proteinuria.

CONCLUSIONS

- Mothers are at their highest risk of death during the third stage of labor, and yet this is the least studied part of obstetric practice.
- Recent ultrasound studies during the third stage have helped define the process of placental separation and development of a more rational approach to management where separation is delayed.
- Prevention of PPH remains a primary concern, and despite the clear-cut advantages of routine oxytocin administration, the practice is not yet ubiquitous.
- Scientific evaluation of both established and new management protocols is also required to minimize morbidity associated with excessive intervention.
- All of the complications considered in this chapter can lead to rapid deterioration of the mother, and how decisions are made is therefore critical to their survival.
- Key to successful outcome is appropriate emergency resuscitation and transfer to a properly equipped facility, with early involvement of experienced obstetricians and anesthetists.

Puerperal Problems

Anthony Ambrose / John Repke

INTRODUCTION AND GENERAL APPROACH

The puerperium has been referred to as the "fourth trimester" of pregnancy, encompassing the period between delivery and complete physiologic involution and psychological adjustment.[1] Although this component of the human reproductive process does not get the same attention as many other aspects of pregnancy (there is no specific current American College of Obstetrics and Gynecology (ACOG) recommendation or board standard; there is no specific UpToDate* article), its importance remains indisputable. In both developing countries and the United States, more than 60% of maternal deaths occur in the postpartum period. The first 24 hours postpartum and the first postpartum week are both critical periods, with 45% of postpartum deaths occurring within 1 day of delivery, more than 65% within 1 week, and in excess of 80% within 2 weeks.[2] It is a period of cataclysmic change in which the mother returns to her usual physiology after the dramatic but more gradual adaptations of the previous 266 days.

The role of the obstetrician is to conduct the parturient through this period, gradually passing the management of any chronic or lingering problems to her primary care provider.

As patient populations become more ethnically diverse, it is important to realize that postpartum health beliefs and practices, while often similar among cultures, may also differ drastically. Practitioners should make efforts to develop their knowledge regarding the beliefs and traditions of all their patients.[3]

Maternal obesity contributes to postpartum complications, as reported after a retrospective analysis of data from a validated maternity database system in the United Kingdom. Compared with women with a normal body mass index (BMI), women with a BMI greater than 25 were at increased risk for postpartum hemorrhage (odds ratio, OR = 1:1.6), genital tract infection (OR = 1:2.4), urinary tract infection (OR = 1:1.7), and wound infection (OR = 1:2.7).[4]

Bereavement

Unfortunately, not all pregnancy outcomes are happy. As many as one woman in five will suffer a perinatal loss through neonatal death, stillbirth, elective abortion, or miscarriage, and as many as one in five of these will suffer some form of prolonged psychological abnormality.[5,6] The birth of an anomalous[7] or severely ill infant can be almost as difficult to bear. Mothers experiencing an emergency hysterectomy for hemorrhage, or even a planned surgical sterilization, can manifest grief.[8] Postpartum depression may be more common and more severe when a perinatal loss has occurred.[9]

Interestingly, a recent review of the literature for evidence concerning programs of support aimed at encouraging acceptance of loss, specific bereavement counseling, or specialized psychological support or counseling, to include psychotherapy for women and families experiencing perinatal loss, was unable to locate any randomized trials.[5] On the other hand, a number of reports of personal and institutional experiences in providing such services exist and arguably provide reasonable support for such programs.[10–12] Tasteful and good-quality photographs of the deceased child, especially, would seem to be valued by parents and families.[13,14]

It is incumbent for the staff of the birthing facility to recognize patients who are in need of bereavement services, and then to provide what is generally a multidisciplinary approach to assisting the family through the immediate and long-term dilemmas such a loss causes. Many coordinated and formalized programs do this very well. The perceptions of healthcare professionals about

---

*UpToDate is a medical information resource provider that can be found at www.uptodate.com.

the emotional care needs of families experiencing perinatal loss were significantly increased after attending a formal educational program about bereavement.[15]

In the late 1970s, individuals at Gundersen Lutheran Medical Center in La Crosse, Wisconsin, providing emotional support for families whose babies died during pregnancy or shortly after birth, became increasingly aware of the pain and grief that families experience when a baby dies. This emotional support effort served as the prototype for *Resolve Through Sharing* (RTS), a perinatal bereavement program formally launched there in 1981, which has subsequently spread nationally and even internationally.

Families experiencing the loss of a baby grieve for their baby and the loss of an entire lifetime with that child. RTS recognizes that the support, acceptance, and gentle guidance given by professionals upon learning of a loss are important first steps in the journey of grief. The caregiver's knowledge and guidance validate that grief is a normal response to loss, allowing bereaved families to grieve in their own way, in their own time. Families are involved in the decision-making process. Education, consultation, and evaluation are integral parts of the program. The RTS support person remains in touch with the family for a year or more, referring to other healthcare professionals when additional management support is necessary.[16]

Examination of Placenta

Examination of the placenta in the delivery or operating room should be a standard, especially in the case of a less than optimal outcome. The placenta can provide the clinician with much information regarding the roots of various problems of the mother and newborn. After gross examination, the decision can be made whether to enlist the assistance of the pathologist for careful gross and microscopic examination.[17] Pathology reports may be particularly helpful during preconception counseling. Indeed, any patient experiencing a less than optimal outcome should be offered the opportunity for counseling before considering another conception.

Pain Relief

The advent of patient-controlled analgesia/anesthesia utilizing indwelling epidural catheters has revolutionized pain management in the immediate puerperium. For patients not having epidurals, evidence about various methods remains somewhat murky. Prostaglandin synthetase inhibitors, while affording effective control of uterine contractions, may produce excessive bleeding as a side effect. The broad spectrum of perceived pain among women experiencing delivery remains unexplained.

Calvert and Fleming in Glasgow, Scotland, have reviewed the literature concerning approaches to dealing with perineal pain following vaginal delivery. They note the dearth of data to support many traditional and apparently efficacious practices and emphasize the need for careful evaluation of damage, use of nontraumatic suture when repair is necessary, and listening carefully to the patient as she describes her pain.[18]

Education: Assuming the Role of the Mother

Many normal psychological changes take place to prepare the mother for her new responsibilities. Any impediment to these changes may result in a lack of emotional response to the infant at delivery. During the immediate newborn period, prenatal preparation needs to be recalled and developed, in addition to many new and often unanticipated tasks as the maternal role is taken on.[19]

Medications

The administration of appropriate medications such as Rh-immune globulin, vaccinations, and others must not be overlooked prior to discharge. It should be remembered that dosages of many medications for chronic disease states (e.g., thyroid disease, hypertension, seizure disorders) likely were changed (generally increased) during pregnancy because of maternal physiologic adaptations (e.g., the increase in plasma volume, or changes in the rate of drug metabolism). During the puerperium these drug dosages usually need to be restored to prepregnancy levels. The blood levels of antiseizure medications may rise dramatically in the early puerperium if dosages are not adjusted. Coordination with the patient's primary care provider is vital.

General Health Considerations

The puerperium also offers an opportunity for the caregiver to reinforce the healthy lifestyle that many women adopt during pregnancy. This is the time to intervene to prevent recidivism into unhealthy habits, such as the use of tobacco, alcohol, and other unhealthy substances. The nutrition counseling many women undergo during pregnancy, whether or not they have been diagnosed with gestational diabetes, will serve them well in the nonpregnant state and should be reinforced. Even pregestational diabetics often embrace long-overlooked advice for the sake of the babies they carry; this is an opportunity to bolster that resolve.

Length of Stay

At least eight trials have attempted to compare early discharge (with substantial variation in the definition thereof) of healthy mothers with term infants, with standard care in the settings in which the trials were conducted. Investigational problems included high postrandomization exclusions, protocol violations, and failure to use a well-validated standardized instrument to assess postpar-

tum depression. So, although there seems to be no evidence of adverse outcomes associated with policies of early postnatal discharge, methodologic limitations of included studies mean that such complications cannot be ruled out.[20] Indeed, such difficult-to-measure outcomes such as fatigue due to sleep deprivation may be affected by length of stay.

Returning to Exercise

As morphologic and physiologic adaptations to pregnancy recede gradually over many weeks, it seems prudent that mothers return progressively to prepregnancy levels of exercise and physical conditioning. Complications associated with the resumption of physical training, even among elite athletes, seem to be rare.[21] Modest weight reduction during lactation appears to be safe and does not seem to compromise infant weight gain in most cases.[22,23] As a general rule, feeding their babies before exercise helps mothers avoid problems associated with breast engorgement and lactic acid accumulation in breast milk.[24,25]

Returning to Work

This remains a topic replete with opinion but generally unencumbered by data. Although published in the past,

ACOG has withdrawn written guidelines. A survey was done by Contemporary OB/GYN in 1983, in which 803 questionnaires were mailed to readers; 392 responses were received (49%). When asked "How many days should patients wait before returning to work after undergoing, [Page no. 5] . . . scheduled repeat caesarean section, . . .?", responses were, on average, 34.7 days (sedentary job), 39.5 days (job that requires standing or walking), and 47.6 days (job that requires heavy physical exertion).[26] Provisions of legislation such as the Family and Medical Leave Act produce a dilemma for the obstetrician, who generally is in no position objectively to assess the capabilities of the patient and has little or no medical evidence on which to rely. The facts that every patient is different and every employment situation is different would seem to demand individualization from the advising provider, but the dearth of evidence-based data to support one's recommendation invites criticism and inappropriate intrusion into the contractual arrangements between employers and employees. In our own practice we tend to deal with this by informing patient and employer that there is little or no data to support a firm recommendation, and advise the patient to return to work, and to do work, according to her comfort level. This allows the patient and her employer to negotiate, compromise, and come to a mutually acceptable arrangement.

SUMMARY OF MANAGEMENT OPTIONS
Overall Care in the Puerperium

SECONDARY POSTPARTUM HEMORRHAGE
(See also Chapter 77)

Excessive vaginal bleeding between 24 hours and 6 weeks following delivery is the traditional definition of secondary or late postpartum hemorrhage (PPH).[27,28] It is a major cause of maternal morbidity and potential maternal mortality.[29,30] Calculating its precise incidence is challenging, as the definition varies; however, it is undoubtedly uncommon, having been reported to complicate fewer than 1% of deliveries.[31]

Secondary PPH is a clinical diagnosis of exclusion, generally presenting as abrupt onset of heavy, sometimes massive (>10% of total blood volume) bleeding 7 to 14 days after delivery.[29] Such bleeding may sometimes represent the initial menstrual period after childbirth, which is often the result of an anovulatory cycle and thus may be heavy, painful, and prolonged.[30]

Differential Diagnosis

The most common causes of late hemorrhage (Table 78–1) include subinvolution of the placental site, retained products of conception, and infection; previously undiagnosed tumors may rarely present in this fashion.[32] It is often attributed to sloughing of the placental eschar.[29] Subinvolution would seem to be the consequence of failure of obliteration of the vessels underlying the placental site; its mechanism is poorly understood.[33]

Women suffering delayed postpartum hemorrhage frequently have retained placental fragments, especially if the bleeding is heavy. This group was noted to have had an increased incidence, in prior pregnancies, of complications, which might reflect aberrant maternal-trophoblastic interaction, such as preeclampsia, intrauterine growth restriction, spontaneous abortion, or retained placenta.[34]

Another possible cause is endometritis, which should be suspected if the history includes uterine tenderness, fever, or foul lochia. This is effectively treated by antibi-

otics without dilation and curettage (to avoid Asherman's syndrome). If curettage is undertaken, it is probably wise to give antibiotics for at least 6 to 12 hours before the procedure, to guard against bacteremia, unless the bleeding mandates urgent intervention. In such a case, intravenous antibiotics should be given at the time of the procedure. The combination of estrogens and progesterone may allow adequate regeneration of the endometrium and may help prevent formation of synechiae.[28] Therefore, in women with secondary postpartum hemorrhage, prescribing a progesterone-only contraceptive pill would be a mistake, as this would have neither a beneficial effect on the endometrium, nor would it accelerate placental site involution.[30]

Occasionally, relatively earlier secondary PPH (later in the first week) may be related to coagulopathy, especially von Willebrand's disease. As von Willebrand's factor is physiologically increased in pregnancy, a patient may be well during pregnancy, but develop a problem as she returns to the nonpregnant state; unexpected severe bleeding may occur despite only mildly reduced levels of factor VIII. All of these women are at risk for both intrapartum and postpartum bleeding. Mild disease usually requires no therapy, especially if factor VIII levels remain

TABLE 78–1
Causes of Secondary Postpartum Hemorrhage

Abnormalities of placentation
   Idiopathic subinvolution of uteroplacental vessels
   Retained placental tissue
   Placenta accreta
Infection
   Endometritis, myometritis, parametritis
   Infection/dehiscence of cesarean scar
Preexisting uterine disease

   Cervical neoplasm
Trauma: rupture of vulvar or vaginal hematoma
Coagulopathy

Modified from Neill A, Thornton S: Secondary postpartum hemorrhage. J Obstet Gynaecol 2002;22:119–122.

within normal limits. In the case of severe disease, (factor VIII levels < 5%), the risk of bleeding is substantial.

Management Options

Management of suspected secondary postpartum hemorrhage consists of stabilization, investigation to establish a cause for the bleeding, and appropriate treatment. Invasive examination in the office setting (e.g., using endometrial sampling devices) may result in a dramatic increase in the volume of bleeding, and uterine perforation is possible, especially if the uterus or its contents are infected. For this reason, investigation should be performed in a more controlled setting.

Crystalloid and blood products should be given as necessary to maintain intravascular volume and coagulability. The initial treatment of late postpartum hemorrhage consists of oxytocic agents plus antibiotics. Pelvic ultrasonography can be helpful in investigating whether there is clot or other debris within the endometrial cavity. However, bear in mind that ultrasound cannot reliably differentiate retained placental fragments from retracted blood clots. Thus, diagnoses of retained placental fragments are not always reliable. If significant bleeding persists despite medical therapy, suction or sharp curettage (or both) should be considered, especially if retained

products of conception are suspected after ultrasound examination. The use of sharp curettage probably increases the risk of both uterine perforation and Asherman's syndrome. Ultrasonography may be helpful during curettage, allowing visualization of the location of instruments. Although it is probably wise to send evacuated tissue for histologic examination to rule out trophoblastic disease, degenerating chorionic villi and decidua will be also obtained from all postpartum uteri if samples are taken and do not therefore necessarily warrant a diagnosis of "significant retained products."

Authors in Belgium evaluated color Doppler and the gray-scale sonographic appearance of the uterus after pregnancy. Areas of enhanced vascularity of the uterus, ranging from a focal vascular pedicle to a larger area of the myometrium, were relatively common, predominantly seen in the presence of placental remnants, in the early postpartum period, and after instrumental or manual delivery of the placenta. These investigators felt their results may prove to be of practical value in the management of abnormal uterine bleeding in the puerperium.[35]

In cases of exceptionally heavy bleeding, before hysterectomy or surgical exploration is undertaken, angiographic embolization by skilled interventional radiologists can be considered.[36,37] Hysterectomy is only indicated in the rare patient in whom conservative therapy fails.

SUMMARY OF MANAGEMENT OPTIONS
Secondary Postpartum Hemorrhage

Management Options	Quality of Evidence	Strength of Recommendation	References
Clinical features important in making diagnosis.	III	B	241
Ultrasonography of uterine contents does not distinguish blood clot from placenta; echogenic masses are found in asymptomatic women. Empty uterus on scan may allow a conservative approach.	III	B	241
IV fluids and blood for hemodynamic stabilisation may be necessary in some patients; correct coagulation defects	–	GPP	–
Antibiotics for 12–24 h prior to surgical evacuation	–	GPP	–
Uterotonics and antibiotics may reduce need for curettage	III	B	241
Surgical/suction evacuation of uterus	III	B	242
Embolization may be tried in persistent bleeding after evacuation before resorting to hysterectomy	IIb	B	36, 37
Send surgical products for histologic examination	–	GPP	–

PUERPERAL PYREXIA/INFECTION

Uterine Infection

Approximately 1% to 3% of women having vaginal delivery will develop what is frequently referred to as puerperal endometritis, although these infections may more validly be described as endoparamyometritis, as they often involve more than the innermost tissue lay-

ers of the uterus and sometimes surrounding structures as well (Table 78–2). Cesarean deliveries performed prior to the onset of labor and rupture of membranes may be associated with an incidence of 5% to 15% of such infections, and when a cesarean section is performed after lengthy labor or ruptured membranes, the incidence may be in excess of 30%. Rates will vary widely among populations and depending on definitions used.[38]

TABLE 78-2

Differential Diagnosis of Persistent Puerperal Fever

DIAGNOSIS	DIAGNOSTIC TESTS	TREATMENT
Resistant microorganisms	Endometrial and blood culture	Modify antibiotic therapy
Wound infection	Physical examination	Incision, drainage
	Needle aspiration Ultrasound	Antibiotics
Pelvic abscess	Physical examination Ultrasound, CT, MRI	Drainage Antibiotics
Septic pelvic vein thrombophlebitis	Ultrasound, CT, MRI	Anticoagulation Antibiotics
Recrudescence of autoimmune disease	Serology	Corticosteroids
Drug fever	Inspect temperature graph, identify eosinophilia	Discontinue antibiotics
Mastitis	Physical examination	Modify antibiotic coverage to cover staphylococci

CT, computed tomography; MRI, magnetic resonance imaging.
Modified from Duff: Maternal and perinatal infection. In Gable SG, Nielge JR, Simpson JL (eds). *Obstetrics: Normal & Problem Pregnancies*, 4th ed. New York, Churchill Livingstone, 2002.

These infections are generally polymicrobial, caused by organisms present in the normal vaginal flora, now granted access to the upper genital tract, peritoneal cavity, and circulation. The more common pathogenic bacteria include group B, β-hemolytic streptococcus (GBS), anaerobic streptococci, aerobic gram-negative bacilli (usually *E. coli*, *Klebsiella pneumoniae*, and *Proteus*), and anaerobic gram-negative bacilli (generally *Bacteroides* and *Prevotella*).[38] These too may vary among populations.

Although familiar mostly to students of medical history who read the 1843 paper of Oliver Wendell Holmes "The Contagiousness of Puerperal Fever,"[39] or readers of Morton Thompson's historical fiction about Ignaz Semmelweis, "The Cry and the Covenant,"[40] group A streptococci (GAS) are not just of historical interest but can still be an important source of postpartum metritis and sepsis. GAS carrier status may occasionally be identified during routine screening for GBS, and this finding may presage serious postpartum infection.[41] A recently reported 7-month outbreak of 15 cases of postpartum sepsis due to group A hemolytic streptococci was traced to a nurse with atopic dermatitis who carried the organism,[42] raising a chilling memory of similar outbreaks that occurred in Budapest and other locales in the mid-nineteenth century.[43] The Centers for Disease Control and Prevention recently hosted a workshop to formulate recommendations for control of GAS disease among household contacts of persons with invasive GAS infections and for responding to postpartum and postsurgical invasive GAS infections.[44]

Risk factors for metritis include young maternal age, cesarean delivery, low socioeconomic status, extended duration of labor, prolonged rupture of membranes, and multiple vaginal examinations.[38] Puerperal pyrexia due to metritis typically presents with fever and temperatures in excess of 38°C, between 24 and 36 hours of delivery. Controversy exists as to whether temperature elevations within 24 hours of delivery are pathologic because they can be due to overheating of the mother secondary to the efforts of labor, especially if she had an epidural. "Milk fever" can also be a benign cause (see later discussion). Careful evaluation of intrapartum events and observations is necessary to distinguish benign from infectious pyrexia. Other findings and complaints may include tachycardia, pelvic and lower abdominal pain, uterine tenderness, foul lochia, and general malaise.[38]

Patients with such findings or complaints deserve a thorough evaluation, because the differential diagnosis is broad, and metritis should not be assumed. Differential diagnosis includes mastitis, urinary tract infection, atelectasis (especially following cesarean delivery), and bacterial or viral infections virtually anywhere within the respiratory, genitourinary, and gastrointestinal tracts. Examination of the breasts, percussion of the sinuses, inspection of the pharynx, auscultation of the lungs and heart, and other diagnostic techniques may discover a process not related to the uterus. Laboratory tests, with the exception of evaluation of the urine, are not generally helpful initially. Controversy exists as to whether endometrial cultures, white blood counts, chest radiograph, and other diagnostic modalities are helpful prior to starting therapy. If endometrial cultures are attempted, some data support the use of multiple-lumen catheters in order to avoid vaginal contamination.[45] Manual examination, plus or minus visual inspection of the vagina and cervix, should always be done, even thought this may be uncomfortable for the patient. Discovering a hematoma or abscess is important as it directs appropriate therapy; finding and removing an overlooked vaginal sponge benefits the patient and, at the very least, prevents further embarrassment for the provider who left it behind!

Management Options

Once a thorough examination has been done, and the provider has concluded the uterus is the source of the infection, treatment generally consists of broad-spectrum parenteral antibiotics, to include coverage for β-lactamase-producing anaerobes.[46] In most cases the combination of clindamycin (900 mg IV every 8 hr) plus gentamicin (1.5 mg/kg IV every 8 hr), with gentamicin levels followed, will be safe and effective, with cure rates of 90% to 97% reported in several studies.[47-56] Parenteral therapy should continue until the patient is afebrile for 24 to 48 hours, and oral antibiotic therapy thereafter is generally not necessary, barring staphylococcal bacteremia.[57]

If the patient does not respond to the initial antibiotic regimen after 48 to 72 hours, modification in therapy may be necessary. In this case, cultures may prove valuable. Resistant organisms such as enterococci are responsible for many treatment failures. Adding ampicillin (2 g IV every 4 hr) may improve the rate of response.[58]

Should the patient still not improve, evaluation should be repeated and extended. Wound infection, pelvic abscess, septic pelvic thrombophlebitis, and drug fever should be added to the differential diagnosis.[46]

A standardized protocol similar to the aforementioned was evaluated with respect to its efficacy against postcesarean endometritis in Alabama. Twenty percent (322) of 1643 patients delivered by cesarean were diagnosed with endometritis and treated with clindamycin-gentamicin; 129 of these women also received either ampicillin or vancomycin; only 19 of 322 (6%) had persistent fever. Six of these had a wound complication, 1 an infected hematoma, and 12 were suspected as having antimicrobial resistance. Their standardized protocol resulted in a 94% initial cure rate.[59]

A recent prospective, placebo-controlled, double-blinded study in Tennessee investigated whether once-daily dosing of gentamicin and clindamycin (gentamicin 5 mg/kg and clindamycin phosphate 2700 mg) would be as efficacious as administration every 8 hours. There was no difference in the mean time from starting therapy until becoming afebrile between the groups, and success rates were similar (82% in the daily-dose group, and 69% in the thrice-daily dose group).[60]

Septic Pelvic Vein Thrombophlebitis

Septic pelvic vein thrombophlebitis (SPT) is probably a rather infrequent postpartum complication, occurring in only 1:2000 pregnancies. Intrauterine infection may cause seeding of pathogens into the venous circulation, leading to endothelial damage and thrombosis.[61]

Duff[62] has reported that SPT may occur in two rather distinct forms:

- Ovarian vein syndrome/thrombosis
- "Enigmatic fever"

More common is ovarian vein syndrome, which is acute thrombosis of one (usually the right) or both ovarian veins.[63] Common findings are moderate fever, pain, gastrointestinal symptoms, and tachycardia. The abdomen is often tender, and the patient may have guarding and decreased bowel sounds. Differential diagnoses include pyelonephritis, renal stone, appendicitis, broad ligament hematoma, adnexal torsion, and pelvic abscess.[61] Ultrasound, computed tomography, and other imaging modalities have been reported to demonstrate extensive thrombosis of an ovarian vein. Medical treatment consists of thrombolytic agents, heparin, and antibiotics.[64]

Less common is so-called enigmatic fever.[65] Patients initially seem to have metritis and receive systemic antibiotics. Initially, there may be some improvement, but patients frequently have temperature instability. Fever and tachycardia may persist. Differential diagnoses include drug fever, viral syndrome, autoimmune disease, and pelvic abscess.[61]

Management Options

Diagnostic imaging (CT, MRI) may help to detect large thrombi. A group in Winnipeg reported the result of an CT scan of the abdomen and pelvis with infused IV contrast, which demonstrated a massive thrombosis extending from the superior vena cava to the femoral vein, and which responded to a regimen of clindamycin, gentamicin, and unfractionated heparin (Figure 78–1).[66]

Diagnostic imaging may miss thrombi in smaller vessels. In this case, a favorable response to therapeutic-dose heparin supports the diagnosis.[67,68] Patients generally respond within 2 to 3 days. If there is no response and the patient worsens, consultation with a vascular surgeon may be prudent.[62,67]

Although most would recommend the use of heparin in the treatment of SPT, this is not entirely uncontroversial. A study in Dallas used abdominopelvic CT imaging to search for evidence of puerperal SPT in women diagnosed with pelvic infection and fever that persisted after 5 days of adequate antimicrobial therapy with clindamycin, gentamicin, and ampicillin. Sixty-nine women met the criteria for prolonged infection, and 15 (22%) of these were found to have SPT. Four of these women had delivered vaginally; 11 by cesarean section. Of the 15, all

FIGURE 78–1
Infused CT of the abdomen, with the arrow demonstrating left ileofemoral thrombosis. The associated low-density area surrounding the vein represents perivascular inflammation.

were treated with continued antimicrobial therapy, 6 with the addition of heparin and 9 without. There was no significant difference between the responses of women who were and those who were not given heparin. This study, using their criteria for diagnosis of SPT, reported a 1:9000 incidence of SPT after vaginal delivery, and a 1:800 incidence following cesarean section.[69]

Urinary Tract Infections

Factors such as vaginal examinations, urethral catheterization, and the 5% to 10% incidence of asymptomatic bacteruria[61] during pregnancy place the just-delivered mother at risk for infection in any part of her urinary tract. Other risk factors appearing in the literature include being black, native-American, or Hispanic American, unmarried status, cesarean delivery, tocolysis, renal disease, preeclampsia-eclampsia, and abruptio placentae.[70] Urinary tract infections in pregnancy are caused primarily by *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus* species. Pyelonephritis is a particularly serious infection in pregnancy because it may be complicated by preterm labor, bacteremia, and acute respiratory distress syndrome (ARDS).[61]

SUMMARY OF MANAGEMENT OPTIONS
Puerperal Pyrexia

Management Options	Quality of Evidence	Strength of Recommendation	References
Uterine Infection			
Prevention:			
Limit vaginal examinations, intrauterine monitoring, exteriorizing the uterus at CS and manual removal of placenta at CS	–	GPP	–
Prophylactic antibiotics at the time of CS	Ia	A	243
Management:			
Gentamycin and clindamycin or extended spectrum β-lactam (e.g., imipenem-cilastatin)	Ia	A	244
Continue until afebrile for at least 24 h	–	GPP	–
If patient not responding after 48–72 h seek other causes (e.g. retained products of conception, abscess, hematoma, ovarian vein thrombosis etc), review microbiology and antibiotic regimen	–	GPP	–
Septic Pelvic Vein Thrombophlebitis			
Diagnosis of exclusion; no localizing symptoms	IV	C	62
At least 7 days of therapeutic heparin	Ib	A	70
Broad-spectrum antibiotics	Ib	A	70
Ovarian Vein Thrombosis			
CT/MRI for diagnosis	IV	C	66,68
Heparin and long-term anticoagulation as for thromboembolic disease elsewhere	IV	C	63
Broad-spectrum antibiotics	IV	C	63
Vascular surgery if failed response to medical treatment	–	GPP	–
Urinary Infection			
Culture urine; appropriate antibiotics (oral or parenteral depending on clinical severity)	–	GPP	–
Puerperal Hematomas			
Expectant management and compression if less than 5 cm and not expanding	IV	C	247
Large hematomas require evacuation, hemostasis, restoration of anatomy, closed drainage	IV / III	C / B	245 / 246
Large hemotomas above the levators require imaging for detection and surgical correction	IV	C	247

CS, cesarean section; CT, computed tomography; MRI, magnetic resonance imaging.

DISORDERS OF THE BREASTS

For various reasons, approximately half of U.S. women do not breast feed their newborns.[71] Although it is well known that women may experience great discomfort before lactation ceases, precise data about this annoyance is lacking.

Lactation: Suppression and Stimulation

Over the years a number of nonpharmacologic means have been used to suppress lactation and relieve symptoms of engorgement. These include, but are not limited to, strapping or binding the breasts, forcing fluids, restricting fluids and diet, applying various ointments and other products (e.g., cabbage leaves, ice packs) to the breasts and nipples, narcotics, wearing a tightly fitting brassiere, emptying the breasts by massage or pump, and avoiding expression of milk.[72-76] It is evident that a number of these approaches are contradictory.

In the United States, various pharmacologic methods for lactation suppression were used during most of the 20th century.[77] The natural suppression of prolactin secretion results in breast involution; this was approximated pharmacologically with medicines such as bromocriptine. However, since 1988 the U.S. Food and Drug Administration has recommended against the routine use of pharmacologic methods (save analgesics) for lactation suppression and relief of associated symptoms because evidence from randomized controlled studies on the safety and efficacy of those drugs for that purpose is lacking.[78,79] Reports linked bromocriptine with cerebrovascular accident, myocardial infarction, seizure, and other problems in puerperal women. Because of associations with such serious complications, this drug is no longer approved for lactation suppression.[80–85]

Peterson and colleagues at the Centers for Disease Control and Prevention searched the world literature in 1998 to locate data about the postpartum symptoms experienced by women who do not breast feed, and to review data on the efficacy of nonpharmacologic methods of lactation suppression. Their findings were disappointing: extant data suggested that, in spite of current nonpharmacologic treatment for lactation suppression, as many as one woman in three may experience severe breast pain postpartum. Moreover, they found no studies focusing primarily on the symptoms of such women. They did offer directions for future research, suggesting studies that included treatment groups for wearing a breast binder, wearing a tightly fitting brassiere, pumping breast milk mechanically or manually, applying ice packs to the breasts, applying topical analgesics or other substances to the breasts, and taking only oral analgesics. Between 30% and 50% of nonnursing patients will have engorgement and pain that may persist for up to a week.[79]

Unwanted lactation failure is a rare complication that has been associated with retained placenta, via suppression of prolactin.[86] Prolactin may also be suppressed by ergot, pyridoxine, and some diuretics.

It has been reported that metoclopramide[87] and sulpiride[88] may enhance lactation. Use of oxytocin (which has to be taken as snuff, to avoid first-pass inactivation in the liver) has been demonstrated to improve milk let-down and may help with the successful establishment of breast-feeding in some women, especially those with preterm babies.

Mastitis and Abscess

It is not unusual for the breasts to become distended and firm during the first day or two after delivery; this may be accompanied by a transient temperature elevation.[89] It has been reported that 13% of all postpartum women may demonstrate such "breast fever," which seldom lasts more than 24 hours.[90] When fever develops during the puerperium, however, breast fever should be a diagnosis of exclusion, as it is important not to miss more dangerous pathology.

Puerperal mastitis or breast abscess is the most frequent significant complication of nursing. Fever, localized pain, and erythema, often confined to one or more quadrants, are common findings. Onset is generally in the first or second postpartum week, but it may also develop later. It may be related to an obstruction in the milk ducts. When initiating lactation, the nipple and areolar skin often undergo local inflammation and swelling until the nipple is conditioned to frequent suckling. This swelling causes a relative obstruction to milk flow and can be seeded by skin bacteria especially staphylococci or streptococci, leading to bacterial mastitis. There is some evidence that the immediate source of these organisms is the infant's nose and throat. The breast (generally unilaterally and in one quadrant) becomes painful, swollen, warm, and red. An abscess develops in approximately 10% of such women; there may be local fluctuance and pointing.[91,92]

Cultures of the milk are usually unhelpful; infection is almost always with a maternal skin organism. Treatment with antibiotics generally results in prompt resolution of symptoms, and following prompt treatment, the development of abscesses is rare. Dicloxacillin (500 mg PO every 6 hr) may be started empirically.[93] When they do develop, abscesses require surgical incision and drainage[94,95] or aspiration with ultrasound guidance.[96] Continuing to breast feed may be extremely important: the only women who developed abscesses in a series of 65 woman with puerperal mastitis were among the small group who chose to cease nursing.[97] This is probably because continuing to breast feed allows the flow of milk to flush infection from the duct system.

A prospective study done in Turkey assessed contributing factors in puerperal breast abscess. Mastitis patients who were treated with antibiotics did not develop breast abscess. Ultrasonography was helpful, allowing needle aspiration; healing times were similar to those in abscess patients treated with incision and drainage. Needle aspiration patients were reported to have excellent cosmetic results.[98]

SUMMARY OF MANAGEMENT OPTIONS
Breast Problems

Management Options	Quality of Evidence	Strength of Recommendation	References
Lactation Suppression			
Physical support; evidence for value of other topical measures is poor	III	B	72–76
Analgesia should be the only pharmacologic agent used	Ia	A	78,79
Bromocriptine should not be used	IV	C	80–85

Culture milk with complicated mastitis or abscess	–	GPP	–
Continued pumping/expressing and feeding	IIa	B	97

MEDICAL COMPLAINTS IN THE PUERPERIUM

During the "fourth trimester," the recently delivered woman must negotiate the dramatic changes from late pregnancy and delivery and return to her normal non-pregnant physiology.

Cardiovascular Complications

Maternal cardiac output remains elevated for at least 2 days postpartum, primarily because of increased stroke volume from increased venous return. Cardiac output and blood volume drop rapidly thereafter and are almost back to normal by 2 weeks after delivery. Women with stenotic lesions, real or potential left-to-right shunts, or low cardiac output are at particularly high risk for cardiac failure in the immediate postpartum period because of both high stroke volume and cardiac output, and the sudden fluid shifts that occur during the return to nonpregnant physiology. Such women are at higher risk for cardiovascular collapse during the first 10 to 14 days postpartum than they are even during pregnancy.[99]

ARDS may occur during pregnancy or the puerperium. A group in San Diego reported that ARDS occurred approximately 10 times more frequently in or following pregnancy (1 per 6277 deliveries) than the 1.5 cases per 100,000 per year reported for the general population. Leading causes were infection, preeclampsia/eclampsia, and aspiration.[100]

Hypertension

Between 1% and 5% of pregnancies are complicated by chronic hypertension. These women are at risk for superimposition of preeclampsia. Many will have entered pregnancy having been taking antihypertensive medication; some will have had changes made to those regimens because of concerns about possible fetal effects. For example, angiotensin-converting enzyme (ACE) inhibitors, a mainstay of many chronic hypertension treatment regimens, are generally contraindicated during pregnancy because of concerns about harmful fetal effects in the 2nd and 3rd trimester.[101,102] Once the patient has delivered, however, she can usually reinstate them. It is important to coordinate such a change with the baby's pediatrician, however; although the American Academy of Pediatrics considers ACE inhibitors to be compatible with breast-feeding,[103] the ultimate responsibility for the baby's health falls to the pediatrician. It is also prudent to coordinate management of hypertension with the patient's primary care provider upon discharge from hospital.

Cardiomyopathy

Approximately 1000 women in the United States annually suffer from peripartum cardiomyopathy, and some will not survive. Human peripartum cardiomyopathy remains a difficult problem, whose cause and mechanisms of pathogenesis remain a mystery. Recent evidence suggests that this is an autoimmune disease with many contributing factors and effector mechanisms. Investigators from

Emory University have found that sera from these patients contain high titers of autoantibodies against some human cardiac tissue proteins, which were not present in the sera of patients with idiopathic cardiomyopathy. Advances in medical therapy and cardiac transplantation have significantly improved quality of life and survival, but it remains a challenging problem.[104,105]

Diabetes

Women who were diagnosed with gestational diabetes generally do not require treatment following delivery. However, they are at increased risk for developing type II diabetes (approximately 50% will do so within 10 years). Following the traditional postpartum visit at 6 to 8 weeks, they should be directed to follow-up with their primary care providers in 2 to 3 months, at which time they should discuss with their providers the possibility of having provocative testing for diabetes. This may be accomplished by an oral glucose tolerance test, in which a plasma glucose level equal to or more than 200 mg/dL (11 mmol/L) would be sufficient for a diagnosis of diabetes. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.[106]

In the case of women with pregestational diabetes, their treatment following delivery depends on their glucose levels as they return to their usual diet and activity levels. Upon discharge from the hospital, they can generally return to a management program similar to the one they observed prior to conception. Coordination with the providers furnishing that management is prudent.

Thromboembolic Disease

Due largely to the physiologic changes of pregnancy, as well as relative immobilization during the latter parts of pregnancy, venous thromboembolism is much more common in the puerperium than during a similar period in women who have not recently been pregnant. Maternal deep vein thromboses (DVTs) are more common (80%–90%) in the left leg, occur usually in the iliofemoral veins, and are often associated with pulmonary embolism. Those with prior DVT and with hereditary thrombophilias are at highest risk.[107]

Women with inherited thrombophilias have an increased risk for venous thromboembolism, particularly during the puerperium. The overall prevalence of thrombophilic traits in the general population may be 10% or more; the probability of carrying multiple defects is therefore not that rare. Screening for these traits should be done liberally.[108]

In an ACOG high risk pregnancy monograph, Lockwood recommended that, no matter their past history, asymptomatic pregnant women with antithrombin deficiency and women who are homozygotes or compound heterozygotes for factor V Leiden or prothrombin (G20210A) mutations are at very high risk for thromboembolic episodes and should have anticoagulant therapy

throughout pregnancy and in the puerperium.[109,110] Following delivery (6–12 hr), heparin therapy should be resumed and warfarin (Coumadin) therapy begun. Until the internationalized ratio (INR) has been in the therapeutic range for two consecutive days, heparin should be continued. Coumadin should be continued for at least 6 weeks, and longer if there have been prior thromboembolic events.

If a woman developed a venous thromboembolism (VTE) during pregnancy, whether or not she was found to have an inherited or acquired thrombophilia, Lockwood recommends full anticoagulation during pregnancy, resumption of heparin after delivery, and establishment and maintenance of therapeutic levels of oral anticoagulation for 6 to 18 weeks thereafter. He is careful to note that, as there are no randomized clinical trials to assess the efficacy of anticoagulation therapy in preventing maternal or fetal complications, recommendations must rely on expert opinion.[110]

Similar recommendations were published by a group in Australia and New Zealand, recommending 6 months of therapy and treatment for at least 6 weeks postpartum for women who experienced VTE either during pregnancy or postpartum.[72]

For women who had a previous thromboembolism, they recommend therapy postpartum, with the decision whether to treat during pregnancy based upon whether the index event was spontaneous or provoked, the presence or absence of a family history of VTE, the presence of a known thrombophilia, and whether there have been multiple episodes of VTE.[72,111]

Women with a past history of a single provoked thrombotic event with an underlying thrombophilia may be treated by careful observation before delivery and 6 weeks of postpartum prophylaxis.[72,111]

Women with recurrent VTE, previous idiopathic VTE, or a previous VTE and strong family history, but no demonstrated thrombophilia are advised to use thrombophylaxis throughout pregnancy and for 6 weeks thereafter.[72,111]

In our own practice, we liberally solicit input from hematologists on a case-by-case basis, as clinical knowledge about the thrombophilias and their role in VTE during and after pregnancy is increasing rapidly.

Finally, the puerperium offers an opportunity to perform or complete a thrombophilia workup, which may have either been delayed or done only partially during pregnancy, because of physiologic changes elevating a number of clotting factors, including factor VIII, protein S, and protein C.

Postpartum Alopecia

An uncommon complication of pregnancy is a diffuse shedding of scalp hair, often beginning 2 to 5 months after delivery. It is not well described in the medical literature, nor is its cause clearly elucidated. Treatment approaches have severally included topical estrogens and progesterone, as well as thyroid supplementation, all with inconsistent results. It remains a puzzling problem.[112]

CHANGES IN COGNITION AND MOOD: PUERPERAL PSYCHOLOGICAL REACTIONS

Several authors have suggested that women may show specific areas of cognitive changes during and after pregnancy, notably deficits in verbal learning and memory (See also Chapter 56). Mood appears to be affected as well. Steroidal hormones are increasingly recognized as highly relevant in multiple aspects of brain functioning.[113] Although steroid hormones show a pattern of associations with mood during and after pregnancy, no such pattern is evident for cognition.

The postpartum period may represent a time of increased vulnerability to depression for some women.[114] Postpartum "blues" is a transient condition characterized by mild, and often rapid, mood swings, from elation to sadness, irritability, anxiety, decreased concentration, insomnia, tearfulness, and crying spells.[115] Due largely to inconsistencies in diagnostic criteria, the data regarding incidence conflict. Major depressive disorders are thought to afflict 5% to 9% of women at any time, with a lifetime risk of 10% to 25%.[116] New episodes of depression in the first 4 to 6 weeks after delivery occur three times more frequently than in nonpregnant controls.[117] Depression has been described in up to 30% of women in the first postpartum year.[118–120] Other studies have not confirmed this relation, observing rates of postpartum depression similar to depression diagnosed without relation to pregnancy.[121–123]

Hormonal changes following delivery are often presumed to play a role in the development of PPD; however, the relationship between postpartum changes and the development of depression is not well understood.[114] Women may complain of depressive symptoms shortly after delivery, at any time during the following few months, and at cessation of lactation, although it is unclear whether stopping nursing child is cause or effect.[124] Moreover, there is good evidence that, in many cases, PPD may begin well before delivery. One study reported that the prevalence of depression at 32 weeks (13.5%) was higher than postpartum (9.1%).[125] In another study, half of all women diagnosed with PPD had onset of symptoms during or even before their pregnancies.[126]

Wickberg and Hwang investigated the use of the Edinburgh Postnatal Depression Scale (EPDS) on a population-based sample of 1655 women who completed the scale at 2 and 3 months postpartum. They also interviewed 128 using the Montgomery Asberg Depression Rating Scale (MADRS) and assessed them according to DSM-III-R criteria for major depression. A cut-off score

of 11.5 on the EPDS identified all but two women with major depression (sensitivity = 96%, specificity 49%, positive predictive value 59%).[127]

Thoppil and others presented at the 2002 Armed Forces District ACOG meeting a report of their institution's multidisciplinary approach to identifying women at risk for depression during pregnancy and postpartum (Table 78–3). Called ISIS (identify, screen, intervene, and support), it was developed and supported by their psychiatry, obstetrics, and social work groups. Social workers educate patients about signs and symptoms of depression at the obstetrics orientation visit. Risk factors for depression are screened for at the first visit with midwife or obstetrician. The EPDS is applied at the 32-week visit. Patients with elevated scores are further evaluated, and consultation and treatment may be initiated by the psychiatry department. Although outcomes data are not yet available, the authors have found that this program thus far has worked smoothly.[128]

Management Options

Psychotherapy is the first-line treatment for depression during pregnancy or after the birth of a child. In some cases, antidepressant treatment may be warranted. The decision to prescribe an antidepressant drug during pregnancy or the postpartum period must be made on an individual basis.[129] Use of pharmacologic therapy in postpartum lactating women must balance the risk of possible deleterious drug effects on the infant via the mother's milk versus the risk of not treating a serious psychiatric condition. All medicines used for this purpose appear in breast milk in varying amounts. The provider must consider such risks to the baby as drug toxicity and the possibility of long-term effects on behavior and neu-

rologic development, which have not as yet been elucidated.[130] Coordination with the baby's pediatrician is essential. Another consideration that must be dealt with before prescribing an antidepressant drug during pregnancy or the postpartum period concerns the matter of who will assume the responsibility for the patient's treatment once the puerperium has passed.

In one study, 25 women met standard diagnostic criteria for postpartum depression. They took 10, 20, or 40 mg/day of paroxetine for at least 4 weeks, and no other mood-altering drugs. Researchers studied fresh breast milk, collected within 6 hours of taking the drug, along with maternal and infant blood samples. Even the lowest dosage of paroxetine improved depression in some of the women. There were no differences among groups in the milk/plasma ratio, no matter what dosage the women took. Only very small amounts were found in breast milk and the infants' serum. These findings imply that one may treat a nursing woman safely with paroxetine,[131,132] as has been shown in similar studies of fluoxetine and sertraline. Prudence may be important, however; Stowe has found that in studying infants exposed to paroxetine via mother's milk, the drug was not found in their blood, similar to studies of sertraline and fluoxetine. However, he warns that one cannot assume it was not in the baby's brain, and it may be premature to base safety conclusions on undetectable concentrations in infant serum.[132]

The reader is referred to Chapter 56 for a more detailed discussion of the management options for postpartum blues, depression, and psychosis.

SEPARATED SYMPHYSIS PUBIS

Separated symphysis pubis (SSP) is a rare condition involving separation of the symphysis pubis in late pregnancy or during delivery. It usually occurs in otherwise healthy pregnancies and is likely to be the result of hormonal or biomechanical factors (or both). It is also referred to severally as subluxation (an incomplete or partial dislocation[133] of the symphysis pubis), diastasis of the symphysis pubis (probably erroneously),[133] and pelvic girdle relaxation.[134] This entity appears to be more common in the Scandinavian countries, raising the question of a genetic link. Symptoms may range from mild discomfort to total debilitation. Differential diagnosis is broad (osteitis pubis; sports injury; osteomyelitis; postsurgical injury; neoplasm; pubic osteolysis; idiopathic lower back pain; posttraumatic back pain; herniated nucleus pulposus; and various orthopedic, urologic, gynecologic problems) and requires exclusion of more serious medical and orthopedic conditions.

Separation of the symphysis pubis associated with pregnancy has striking clinical similarities to osteitis pubis. However, radiographic findings associated with SSP lack the typical rarefaction and sclerosis seen with osteitis pubis. Often, all that is seen is symphyseal

---

TABLE 78–3

DSM-IV Criteria for a Major Depressive Episode

A. Five or more of the following symptoms must be present daily or almost daily for at least 2 consecutive weeks:
  1. Depressed mood*
  2. Loss of interest or pleasure*
  3. Significant increase or decrease in appetite
  4. Insomnia or hypersomnia
  5. Psychomotor agitation or retardation
  6. Fatigue or loss of energy
  7. Feelings of worthlessness or guilt
  8. Diminished concentration
  9. Recurrent thoughts of suicide or death
B. The symptoms do not meet the criteria for other psychiatric conditions.
C. The symptoms cause significant impairment in functioning at work, school, and social activities.
D. The symptoms are not caused directly by a substance or general medical condition.
E. The symptoms are not caused by bereavement after the loss of a loved one.

*At least one of the five symptoms must be item 1 or 2.

separation, usually of more than 10 mm.[135] Kubitz and Goodlin cited seven cases of symptomatic subluxation in pregnancy or parturition with a prevalence of 1 in 300 births, which is more common than pregnancy complicated by osteitis pubis.[136]

SSP is thought to be caused by hormonal (relaxin and progesterone)[137,138] or biomechanical factors, relaxation, and weakening of the pelvic joints during pregnancy, because the joints of the pelvic girdle are forced to carry the additional weight of the uterus and its contents.[137,139] It is believed the symphysis pubis itself has limited movement, limited to a 3° rotation and a maximum vertical movement of 2 mm.[134] As the movement of the sacroiliac joints is also limited, this would tend to put more pressure on the symphysis.[140] Mechanical precipitating factors include tumultuous labor, difficult assisted vaginal delivery, large baby, excessive abduction of the thighs at the time of delivery, and sudden pressure on the symphysis pubis. In a group of 14 women evaluated by CT scan of the pelvis within 24 hours of delivery, 42% of these asymptomatic women had, on average, a 6.5 mm widening of the symphysis relative to age-matched nonpregnant controls, implying that some degree of asymptomatic separation of the symphysis is normal postpartum.[134,141]

SSP symptoms may present at any time intrapartum or postpartum, with a broad range of symptoms, including pain in the back or pelvic area, difficulty with ambulation, and local manifestation over the symphysis such as tenderness, induration, ecchymoses, and a palpable joint defect.[142]

Management Options

Successful treatment approaches include analgesia, bedrest, binders, limitation of ambulation, walking in a shuffling style when ambulating, avoiding both adduction and abduction of the hips, injections of local anesthetics, steroids, and other medications. Because of ambulation limitations, DVT becomes a risk, and thromboprophylaxis should be considered. Patient education and emotional support is critical, and follow-up with rehabilitative services, orthopedics, home nursing, and social work may be appropriate.[137,142,143]

Apparent paralysis of the lower limbs can sometimes be due to separation of the symphysis pubis or one of the synchondroses of the sacroiliac joint during labor. This may be followed by pain and continuing significant interference with locomotion as recovery occurs.[99]

OBSTETRIC PARALYSIS

The earliest well-documented report of maternal obstetric paralysis, albeit partial, in the English language literature comes from Dublin, around 1838,[145] describing how a young primigravida suffered foot-drop and loss of sensation in the right leg after a normal delivery.

In most cases of maternal obstetric paralysis, symptoms are unilateral, consisting of leg weakness, or, in more severe cases, foot drop. Prognosis for recovery from mild injuries is excellent with physical therapy; however, if fatty degeneration of nerve fibers has occurred, in which the nerves have been functionally severed from their nutritive centers (wallerian degeneration), recovery may take much longer and may never be complete.[133,147]

The incidence of obstetric paralysis is difficult to estimate due to the rapid evolution of obstetric practice during the past several decades. Data from series gathered from the 1930s to the 1970s suggest estimates of intrinsic obstetric maternal paralysis and adverse neurologic outcomes of between 1:2100 and 1:3000.[146,148,149] More contemporary estimates suggest this to be a much more rare complication, probably between 1:7000 and 1:14,000 in patients who do not receive regional anaesthesia/analgesia.[150]

In the industrialized world, obstetric paralysis is an entity seldom reported unless regional anesthesia/analgesia is involved; neurologic complications that follow childbirth are frequently blamed on epidurals and spinals, even when this is not the case.[151] The mechanisms whereby regional/conduction anesthesia/analgesia may be associated with neurologic damage have been well-documented and include neurotoxicity, ischemia, trauma, and compression that may be due to hematomata or abscesses.[151]

Bademasi and colleagues[152] in 1980 presented the results of a prospective study of 34 Nigerian women with puerperal paresis of the lower limbs. These patients tended to be shorter than average. Lumbosacral plexus injury with foot-drop was the most frequent presenting feature (88%); 38% had bilateral involvement; 26% had femoral neuropathy; and 35% absent ankle tendon jerks. Fifteen percent had spastic paraparesis. Electromyographic examination and conduction velocity examination were consistent with proximal neuropraxia of the lumbosacral trunk in 88%. The major predisposing factor was prolonged labor. Further associations with paralysis were hydroureter, vesicovaginal fistula, and rectovaginal fistula (possibly due to pressure necrosis). Recovery was complete in 76%. The authors concluded that direct pressure on the lumbosacral plexus and nerve trunks by the presenting fetal part is the major factor in the pathogenesis of obstetric neuropraxia.

A later paper by Feasby and associates[144] used comprehensive electrophysiologic testing to document two cases of lumbosacral plexus injury, which localized the site of this obstetric paralysis to the lumbosacral trunk (L4-5) and S1 root where they join and pass over the pelvic rim. They noted that paralysis may be mild or severe. Small maternal size, large fetus, midforceps rotation, and fetal malposition were noted to be conditions that might place the mother at risk for nerve injury.

These findings are consistent with earlier reports that the roots of the sciatic nerve may be compressed in the

pelvis by the fetal head or obstetric forceps, and the brunt of the resulting motor deficit is then borne by muscles supplied by the common perineal fibers because of their relationship to the bony pelvis. This type of lumbosacral plexus injury seems to be more likely when a short patient with a small pelvis carries a rather large baby, so that labor is complicated by minor disproportion, or when midforceps are used during delivery because of malpresentation.[149] Mothers with a straight sacrum, a flat wide posterior pelvis, posterior displacement of the transverse diameter of the inlet, wide sacroiliac notches, and prominent ischial spines have been thought to have a predisposition to this complication.

Neurotoxicity within the epidural space has been reported to cause paraplegia following the injection of various substances, including a relatively large dose of hypertonic potassium chloride.[153] Several years ago, several cases of neurologic deficit were attributed to the use of 2-chloroprocaine containing the antioxidant 0.2% sodium bisulfite. It would seem that the problem was not the medication but the preservative.[154] In general, however, injections into the epidural space would be expected to be well tolerated[155] as opposed to subarachnoid injections; nerve roots are extremely vulnerable to neurolytic substances.[156] Disastrous consequences of spinal anesthesia/analgesia, albeit rare, have been reported.[157,158]

Ischemia may lead to spinal cord damage; reports have associated this with arterial constriction,[159] vascular malformation,[160] disc herniation,[161,162] vertebral canal stenosis,[163] abscess,[164,165] and hematoma.[166,167] The last condition is of particular concern in this era of prophylactic use of anticoagulants in a growing number of patients. Anesthesiologists especially have expressed a concern about needle or catheter placement in patients who have been using low-molecular-weight heparins. However, to date reports of catastrophic hematoma formation have been lacking.

Management Options

When neurologic damage follows childbirth, it is important to elucidate the mechanism of its occurrence; it is generally advisable to seek the opinion of a neurologist early in the course of the problem.

URINARY RETENTION

Although there would seem to be no universally accepted definition of postpartum urinary retention, this has frequently been classified as either clinically overt postpartum urinary retention, that is, the inability to void spontaneously after delivery, or covert urinary retention, identified through measurements of postvoid bladder residual volumes, measured or calculated by either catheterization or bladder imaging.[168–170]

The cause of postpartum urinary retention has not been clearly elucidated: in normal micturition, afferent input arises from stretch receptors in the bladder that travel through myelinated fibers in the pelvic nerve to the spinal cord and pontine micturition center. Efferent signals mediate relaxation of the urethral and periurethral striated muscles and pelvic floor through the pudendal and sacral nerves; detrusor muscle contraction and relaxation of urethral smooth muscle are mediated by the pelvic nerve and parasympathetic outflow.[171,172]

The capacity of the puerperal bladder is increased over that of the nonpregnant state; it is relatively insensitive to intravesical fluid pressure. Overdistention, incomplete emptying, and excessive residual urine are not unusual. This may be contributed to by anesthetic effects, especially after spinal or epidural analgesia/anesthesia. Conditions are ripe for the development of urinary tract infection because of bladder trauma and dilated renal pelves and ureters, which will not return to their prepregnant state until 2 to 8 weeks after delivery.[88]

The physiologic changes of pregnancy, regional anesthesia, instrumental delivery, cesarean delivery, perineal trauma, protracted labor,[173] and primiparity have variously been associated with postpartum urinary retention, as have rare instances of lumbar disk disease,[174] spinal subdural hematoma,[175] postpartum uterine retroversion,[176] and impacted pelvic masses.[177]

Impaired function of the detrusor can result from overdistention and might account for some cases in which prolonged urinary retention is seen. Postpartum urinary retention observed after regional analgesia/anesthesia may be due to temporary disruption of afferent input. It may be that urinary retention because of instrument-assisted vaginal delivery is related to impaired reflex and voluntary relaxation of the urethral sphincter, periurethral muscles, and pelvic floor. Instrument-assisted vaginal delivery may also result in mechanical outlet obstruction because of the perineal edema that often accompanies such procedures.[178]

Kerr-Wilson and colleagues studied the effect of labor on postpartum bladder function. Urodynamic investigations were performed on 20 patients at 48 hours and at 4 weeks after delivery to assess the effect of modern obstetric practice on the postpartum bladder. Their idea was to assess this by comparing function within 48 hours of delivery with findings at 4 weeks postpartum.

Water cystometry and uroflowmetry were performed. Studies demonstrated a slight but significant decrease in bladder capacity (from 395.5 to 331 mL) and volume at first void (from 277 to 224 mL) in the study interval. All urodynamic values studied were within normal limits on both occasions. Results were not affected by the weight of the infant or by an episiotomy. However, prolonged labor and the use of epidural anesthesia appeared to diminish postpartum bladder function transiently.[179]

In this study, the bladder was not found to be hypotonic postpartum as had been noted by other investigators previously.[180,181] This difference in more contemporary patients was attributed to active management of labor with oxytocin and more frequent cesarean delivery, which

allowed for avoidance of prolonged labor, as well as earlier catheterization if the patient was unable to void.

The effects of analgesia and anesthesia are less clear. A study from Geneva suggested that the use of epidural pain relief was associated with postpartum bladder hypotonia and urinary retention, although the cause for this may actually be the fact that their labors were significantly longer.[182] These authors concluded that, as long as prolonged labors were avoided and catheterization done promptly for bladder distention, there was no evidence for any increased risk for bladder hypotonia.

Andolf and coinvestigators[169] used ultrasonography to measure residual bladder volumes 3 days after vaginal delivery in 539 unselected consecutive women. Only 1.5% had abnormal volumes, and only 0.5% needed urinary catheters. Urinary retention was more common after instrumental delivery or epidural analgesia. Despite these reassuring findings, the same women were rescanned 4 years later and by this time one in three was experiencing voiding difficulties. This suggests that such difficulties are not due primarily to postpartum retention.

Viktrup and colleagues[183] followed 305 nulliparous women during pregnancy and the puerperium; 7% developed stress incontinence after delivery. Obstetric factors such as the length of the second stage, infant head circumference, birth weight, and episiotomy were associated with the development of stress incontinence after delivery. Impaired muscle function in or around the urethra during vaginal delivery was proposed as the pathophysiology underlying puerperal incontinence. Most women returned to normal micturition by 3 months postpartum.

A retrospective, case-control study in Minnesota identified 51 cases of clinically overt urinary retention occurring after 11,332 vaginal deliveries (incidence = 0.45%). Individually, statistically significant associations with primiparity, forceps/vacuum use, epidural/spinal anesthesia, and mediolateral episiotomy were identified, but by multivariate analysis, only instrument-assisted vaginal delivery and regional anesthesia were identified as independent risk factors.[178]

A study in Hong Kong based upon telephone interviews of 394 women, 73 of whom had been diagnosed with postpartum urinary retention, concluded that the retention cohort did not suffer statistically significantly higher subsequent rates of stress urinary incontinence, urinary frequency, nocturia, or urgency.[184] This same group reported that covert postpartum urinary retention, while documented in 9.7% of women delivering vaginally, seemed to be self-limited, with postvoid residuals returning to normal within 4 days without specific treatment.[173]

Vasovagal collapse is a dramatic but uncommon sequel to postpartum urinary retention. This can occur especially with lumbar epidural or spinal anesthesia. Even if the patient becomes aware of pain, this might signify return of the sympathetic afferents, while the sacral parasympathetics remain paralyzed. As the sacral parasympathetic supply remains insensate, the patient perceives no subjective sensation of bladder stretching. If untreated (with catheterization), bladder distention can lead to excessive supraspinal parasympathetic outflow resulting in vasovagal syncope.[185]

Evidence to date would suggest that careful attention to all postpartum women, with prompt catheterization for those who cannot void, will prevent most problems related to urinary retention.

SUMMARY OF MANAGEMENT OPTIONS
Other Puerperal Problems

Management Options	Quality of Evidence	Strength of Recommendation	References
Pubic Symphysis Separation			
Most resolve with rest, trochanter belts, analgesics, weight bearing assistance and time	III	B	143
Consider injection of symphysis with mixture of hydrocortisone and lidocaine (chymotrypsin)	III	B	143
Consider thromboprophylaxis with prolonged bedrest	—	GPP	—
Orthopedic treatment reserved for severe cases	—	GPP	—
Obstetric Paralysis—Prevention:			
Avoid prolonged, obstructed labor	—	GPP	—
Proper lithotomy and pushing positions			
Avoid regional anesthesia when coagulopathy or infection is present (systemic or local)			

CONTRACEPTION

It has been demonstrated that ovulation may occur as early as 27 days after delivery (mean: 70–75 days in the absence of lactation).[186,187] Among nursing mothers, the mean time to ovulation is about 6 months.[8] Variables affecting this include frequency of suckling, duration of each suckling period, and amount of supplementation.[188]

Persistently elevated serum prolactin levels appear to be responsible for the suppression of ovulation among lactating women.[189] Levels of prolactin decrease to the normal range by the third week postpartum in nonlactating women, but remain elevated for several more weeks in lactating patients. Immediately after delivery, levels of estrogen fall in all women and remain low in lactating patients. In women not lactating, estrogen levels begin to rise 2 weeks after delivery and are significantly higher than in lactating women by day 17 postpartum. Follicle-stimulating hormone (FSH) levels are identical in women regardless of whether they are lactating. It is therefore assumed that the ovary does not respond to FSH stimulation in the presence of increased prolactin levels.[8]

It is generally advised that vaginal coitus may be resumed when the perineum is comfortable and lochia has slowed. Desire and willingness to resume vaginal coitus after delivery varies greatly among women—this may depend on several factors, including return of libido, presence of vaginal atrophy because of lactation, and presence and state of healing of incisions and lacerations.[190] Most women have resumed intercourse by 3 months, some much earlier.[191] On the other hand, Ryding[192] reported that 20% of women had little desire for sexual activity 3 months after delivery, and an additional 21% had complete loss of desire or aversion to sexual activity.

Abstinence, or, more properly, the intention to abstain from vaginal coitus, is not an effective means of postpartum contraception. Even though it is traditional for obstetricians to advise postponing coitus, sometimes until after the traditional 6- to 8-week postpartum examination, and in spite of lochia, which may persist for 3 to 8 weeks, coitus is likely to occur, and it is prudent to have a contraception plan in effect beforehand.

Management Options

Choice of Contraceptive Method

BARRIER METHODS

In general, barrier methods of contraception have fewer side effects than hormonal methods, and, with the exception of cervical caps and diaphragms, are available without prescription. In addition, under some circumstances they have been shown to provide protection against sexually transmitted diseases. A meta-analysis has shown that regular use of latex condoms decreased the coital transmission of HIV infection by 69%. Epidemiologic studies have shown a decreased risk of genital herpes simplex, gonorrhea, and nongonococcal urethritis in women whose partners faithfully use condoms.[193–195] Unfortunately, the efficacy of barrier methods in preventing both conception and infection depends heavily on the users adhering to manufacturer's recommendations. Most studies have demonstrated a significant difference between method effectiveness and use-effectiveness.

HORMONAL CONTRACEPTION

ACOG has recommended that progestin-only methods are the hormonal method of choice in breastfeeding women and may slightly increase the volume of breast

milk (Table 78–4).[196] Manufacturers have recommended that their use be postponed until 6 weeks postpartum in breastfeeding women, because very small amounts of progestin are passed into breast milk, although no adverse effects on infants have been noted when these medications have been started earlier.[197]

The World Health Organization (WHO) has recommended that the breastfeeding woman wait at least 6 months after childbirth to start using estrogen-progestin contraceptives.[198] ACOG has called this and a similar FDA recommendation "a conservative approach" resulting for the most part from experience of earlier combination oral contraceptive studies using higher doses of estrogens. They note "low-dose tablets (35 µg or lower) probably have a lesser effect on quality and quantity of breast milk." If combination oral contraceptives are prescribed, they should not be started before 6 weeks postpartum, and the physician should continue to evaluate the woman's individual breastfeeding experience.[8,193,199]

INTRAUTERINE CONTRACEPTIVE DEVICES

Copper-containing and hormone-releasing intrauterine devices (IUCDs) have been shown to be effective in preventing conception, with failure rates on the order of 2 to 3 pregnancies per 100 women-years.[200,201] Objections that the principal mode of action of IUCDs was, in essence, the abortion of a viable conceptus have been effectively laid to rest.[202] This concept has been supported by both the ACOG and the WHO.[8,203] It is important to inform women that, unlike barrier contraceptives, IUCDs do not provide protection against HIV or other sexually transmitted diseases.

NATURAL FAMILY PLANNING

Natural family planning (NFP) remains a controversial topic. On the basis of mailing a questionnaire to 840 Missouri physicians (obstetrician/gynecologists, family practice physicians, general practice physicians, internal medicine specialists) (65% response rate), authors concluded that most physicians underestimate the effective-

ness of NFP and do not give information of modern methods to women.[204] NFP methods are based on the prediction of ovulation using temperature, cervical mucus assessment, and timing. They are not reliable in the absence of relatively regular menstrual cycles, which may take some time to reestablish following delivery.[205] Success rates similar to barrier methods have been reported.[206]

NFP methods vary greatly, but all utilize to some extent selective timing of coitus according to some or all of a variety of methods, to include periodic abstinence, use of menstrual calendars, ovulation prediction, withdrawal, and lactational amenorrhea.

LACTATIONAL AMENORRHEA METHOD

Exclusive breastfeeding helps prevent pregnancy for the first 6 months after delivery but should be relied on only temporarily and when it meets carefully observed criteria of the lactational amenorrhea method (LAM) of contraception.[199] The suckling stimulus provides the only truly physiologic signal that suppresses fertility in normally nourished, healthy women. The variability in the duration of lactational amenorrhea between women is related to the variation in the strength of the suckling stimulus, a unique situation between each mother and baby. Full breastfeeding can provide a reliable contraceptive effect in the first 6 to 9 months. In women, suckling seems to increase the sensitivity of the hypothalamus to the negative feedback effect of estradiol on suppressing the gonadotropin-releasing hormone/luteinizing hormone (GnRH/LH) pulse generator. Practical guidelines for using breast-feeding as a natural contraceptive have been developed, which allows mothers to utilize the only natural suppressor of fertility in women as an effective means of spacing births.[206]

Table 78–5 lists the comparative effectiveness of the different methods of contraception.

STERILIZATION

Female Sterilization

Tubal sterilization is the most frequently used method of contraception in the United States.[207] More than 600,000 female sterilization procedures, and more than 500,000 male sterilization procedures are performed each year in the United States.[208,209] Preoperative counseling should include a clear discussion about risks of, alternatives to, possibility of failure, and planned irreversibility of permanent surgical sterilization.

Complication rates are low, with an overall mortality rate of 1 to 2 deaths per 100,000 sterilization procedures.[210] Long-term effects of tubal sterilization on pelvic pain, menstrual patterns, and the need for subsequent pelvic surgery are controversial and inconsistent.[211]

The findings of the U.S. Collaborative Review of Sterilization (CREST) were published by the Centers for

*Typical use refers to failure rates for women and men whose use is not consistent or always correct.
†Perfect use refers to failure rates for those whose use is consistent and always correct.
‡N/A:Effectiveness rates not available.
Modified from Facts about Birth Control. www.plannedparenthood.org.

Disease Control and Prevention in 1996;[212] these present the only available long-term failure rate data in a very large[10] group of women, with 58% still providing follow-up data at 8 to 14 years after their procedures. CREST showed a 10-year cumulative failure rate of 18.5 per 1000 for all sterilization methods combined. During that interval, postpartum tubal ligation and interval laparoscopic unipolar coagulation were the most effective methods (7.5 failures per 1000).[212] Sterilization failures are frequently manifested as ectopic pregnancies; CREST showed a 10-year cumulative probability of ectopic pregnancy of 7.3 per 1000. The specific ectopic rate following postpartum partial salpingectomy was the lowest among all methods (1.5 per 1000).[213]

In the United States, the strongest indicator of future regret is young age at the time of sterilization, regardless of parity or marital status.[211,214] Women 20 to 24 years of age at sterilization are twice as likely to experience regret as women 10 years older.[215] Approximately 6% of steril-ized women report regret or request information about sterilization reversal within 5 years of the procedure;[211] approximately 1% to 2% of men having vas ligation seek information on reversal.[215,216]

The success of surgical reversal of tubal sterilization would seem to be mainly related to the amount of undam-aged fallopian tube remaining for reanastomosis.[217] It is dif-ficult to compare studies concerning the success of sterilization, as they generally have small numbers, and because investigators use different preoperative exclusion criteria; length of follow-up also varies significantly.[218] After a Pomeroy-type procedure was reversed, studies report subsequent term pregnancy rates of 41% to 74% in a total of 198 patients, with ectopic rates of 6% to 9%.[219–221] Following bipolar cautery, reversal success as measured by term pregnancy was 42% to 52% in a total of 137 patients, with ectopic pregnancy rates of 3% to 17%.[217,219,220]

Intrapartum or early puerperium procedures are convenient as the patient is already hospitalized. Cesarean

delivery gives excellent access to the fallopian tubes. Following vaginal delivery, an epidural catheter may be left in place and then used to provide anesthesia and analgesia for a procedure later in the day or on the following day. On the other hand, waiting another couple of months for an interval procedure allows time to gain confidence in the health of the baby and dispassionately discuss all implications of permanent surgical sterilization.[8]

For years there have been concerns about a syndrome of poststerilization pain and menstrual disturbances. A large review comparing women who had tubal sterilization with controls showed no consistent differences in outcomes such as levels of hormones, and little difference in the characteristics of menses, although there is, understandably, an increase in menstrual flow in women who had been using oral contraceptives.[222] On the other hand, a cohort study with 6 years of follow-up reported that sterilized women were more likely to be hospitalized because of menstrual disorders, usually to have curettage (RR = 2.4).[223] The subgroup of women under 30 years of age studied in CREST who had menstrual dysfunction predating their sterilization procedures had more menstrual changes and, ultimately, were more likely to undergo hysterectomy than controls.[218,223,224]

Transcervical, intrauterine instillation of quinacrine may be a simple, inexpensive, effective, acceptable, and safe method of nonsurgical permanent female sterilization. A study in Bangladesh reported a 1.9% failure rate using 252 mg of quinacrine with or without adjuvant ampicillin or ibuprofen (or both). No serious complications were reported.[225] A larger study in Vietnam, however, reported higher failure rates (13% in women younger than 35, 6.8% in women older than 35). Moreover, these authors noted that toxicology studies of locally applied quinacrine were thought by WHO to be inadequate.[226] It would seem that more study is needed before this method can be recommended in the United States.

Some years ago there was in the United States enthusiasm for scheduled cesarean hysterectomy as a sterilization procedure.[227] It was thought by some that this might prove to be a life-saving measure in some cases, for example, for women with cervical dysplasia who were either noncompliant with follow-up, or had limited access to care. Most studies, however, reported worrisome complication rates, especially regarding the need for blood product replacement. Even though a group in Israel reported an improvement in the need for transfusion from 64% to 17% as their experience increased,[228] the prevailing feeling would seem to be that cesarean hysterectomy without other indications likely has, in most cases, an unfavorable benefit/risk ratio.

Although there is some confidence that tubal ligation protects from recurrent pelvic inflammatory disease, more than 70 cases of salpingitis and almost 40 cases of tubo-ovarian abscess in women who had undergone tubal occlusion have been published. Most cases of salpingitis developed more than a year after either laparoscopic or laparotomy procedures. Tubo-ovarian abscesses developed over a broad interval of time following operation, ranging from weeks to decades.[229]

Male Sterilization

Surgical ligation of the vas deferens is a safe and highly effective means of permanent surgical sterilization. Outpatient ligation of the vas deferens has been a popular procedure since the mid-1960s. As of 1988, at least 5,000,000 U.S. men had undergone this procedure.[230] Most series report subsequent pregnancy rates of less than 1%.[231] In one study, only 20 of 1000 men had a positive semen analysis during a 3-year follow-up period,[232] and the sperm count was less than 10,000/mL in 17 of these men, none of whom reported an unwanted pregnancy.

As with any such procedure, men should be counseled about the risks of, and alternatives to, the procedure, the possibility of failure, and the planned irreversibility of vas ligation. Alternative contraception should be used until at least 90 days have elapsed since the procedure, and semen analyses show either no sperm at all or, at least, no motile sperm. As life circumstances change, however, some men will decide to consider reversal of the procedure, and 50% to 70% of men in whom a reversal operation is undertaken are fertile.[233,234] The reversal success rate depends upon the duration between vasectomy and the reversal procedure; in general, the longer after vasectomy, the less the likelihood of success.[193,235]

Concern that the risk of testicular and prostate cancer may be increased in men after vasectomy would seem to be unfounded. Earlier population-based series showed no increase in risk of testicular cancer among vasectomized men,[236,237] nor any increased risk of prostate cancer.[231,238] However, a recent quantitative review of prostate cancer studies suggested that men with a prior vasectomy may be at an increased risk. However, this increase may not be causal since potential bias cannot be discounted. The overall association was small and therefore could be explained by bias. Interestingly, the relative risk increased over time.[239] Finally, a study of 22,071 U.S. physicians showed that vasectomy did not increase the risk of subsequent cardiovascular disease, even 15 or more years after the procedure.[240]

Failure rates (varies with method and timing with respect to delivery)	III	B	210
Complications (e.g., regret, ectopics, menstrual disturbance, death)	III	B	211
Cesarean hysterectomy–Should only be considered in a few selected cases	III	B	227,228
Chemical methods—Not currently advocated; further research needed	IIb	B	225,226
Vasectomy:			
Same counseling as with female sterilization:	III	B	231,236–238,240
The procedure			
The irreversibility			
Failure rates			
Complications (generally safe, with no evidence of prostate or testicular cancer or cardiovascular disease)			

CONCLUSIONS

- The puerperium is a neglected phase of pregnancy.
- Surveillance for normal recovery following pregnancy and dealing with minor complaints is all the majority of women require.
- It is an opportunity for health promotion (e.g., smoking cessation, elimination of alcohol, vaccinations, and family planning).
- A few women will develop significant problems that must be recognized and managed promptly especially those with:
  - Puerperal pyrexia
  - Breast infection
  - Medical problems

Major Obstetric Hemorrhage and Disseminated Intravascular Coagulation

John Anthony

INTRODUCTION

Maternal death from obstetric hemorrhage remains a global problem. In developing countries it ranks among the leading three causes of maternal death, and industrialized nations continue to report mortality rates in cases in which problems could have been anticipated and prevented.[1,2] In developing countries, postpartum hemorrhage accounts for a higher percentage of deaths due to hemorrhage. The combination of uterine atony with retained products of conception leading to hypovolemic shock and coagulopathy are the most common complications giving rise to death from obstetric hemorrhage.

The U.K. Confidential Enquiries into Maternal Mortality have emphasized the need to recognize the antenatal woman at risk of obstetric hemorrhage and to ensure that a multidisciplinary consultant-led team including hematologists, anesthetists, and obstetricians are available to provide adequate care. The unpredictability of obstetric hemorrhage is also acknowledged in this report and the importance of having protocols to deal with massive hemorrhage is stressed.

MAJOR OBSTETRIC HEMORRHAGE

Definition

"Major obstetric hemorrhage" is an imprecise term, more often applied to the consequences of hemorrhage than arising from any clinical appreciation of excessive blood loss that is notoriously underestimated. This chapter deals with the risks and management of severe or major obstetric hemorrhage in which there is a risk of hypovolemic shock. Inevitably, there will be some overlap with other chapters, which are cross referenced.

Incidence

The incidence is difficult to estimate because the definition includes all severe episodes of antepartum, intrapartum, primary, and secondary postpartum hemorrhage, and these figures are not recorded collectively or statutorily. The incidence is likely to be about 0.5%, with the largest number of cases being due to primary postpartum hemorrhage.

Etiology

Major obstetric hemorrhage is generally caused by the following:

- Placental abruption (see also Chapter 59)
- Placenta previa (see also Chapter 59)
- Causes of primary postpartum hemorrhage (see also Chapter 77)
- Ruptured uterus (see also Chapter 77).

However, underlying disease may contribute to the bleeding, including the following:

- Bleeding disorders (e.g., von Willebrand disease)
- Acquired hemostatic disorders due to liver failure (e.g., fulminant hepatitis, acute fatty liver of pregnancy)
- Severe disseminated intravascular coagulation (discussed in this chapter)
- Platelet dysfunction (e.g., severe preeclampsia, thrombotic thrombocytopenic purpura).

Antepartum hemorrhage accounts for fewer deaths than postpartum hemorrhage in developing countries, although this pattern is reversed in industrialized countries.

Maternal Risks

Death

Deaths due to major antepartum hemorrhage are usually due to placental abruption. Maternal death from placental abruption is attributable to the effects of hypovolemia (see following discussion) combined with the complications that may arise from underlying predisposing conditions such as preeclampsia. The resting uterine tone may be increased (up to 25 mm Hg) and labor may be triggered by placental separation with the sudden onset of frequent contractions.[3,4] Although hypovolemic shock and its sequelae may develop as a result of acute blood loss, hypertension may precede or follow abruptio placentae.[5] The coincident occurrence of hypertension due to preeclampsia together with hypovolemia as a result of abruptio placentae increases the risk of renal failure due to tubular necrosis.[6] Up to one third of pregnancy-related cases of acute renal failure are due to abruptio placentae.[6] Proteinuria is usually found in cases of abruptio placentae and the pattern of glomerular protein loss is similar to that seen in acute ischemic renal failure.[7]

The mother is at risk of severe hypovolemia from placenta previa also, especially as a result of morbidly adherent implantation over a previous cesarean section scar. Placenta previa is also associated with recurrent antepartum hemorrhage and operative delivery.

Severe primary postpartum hemorrhage can lead to hypovolemic shock. Other complications are those associated with the treatment of the underlying condition such as from transfusion-related injury and surgical complications of hysterectomy.

The reported risk of maternal death following uterine rupture varies widely, being very low in industrialized countries but up to 38% in developing countries with limited resources.[8–10] Maternal morbidity rates associated with uterine rupture includes all the complications that may follow severe hypovolemic shock, postoperative complications, and reproductive sequelae that include loss of fertility and the need for future operative delivery.

Hypovolemic Shock

Shock is a clinical condition characterized by inadequate tissue perfusion due to any one of the following:

- Impaired peripheral circulation because of diminished intravascular blood volume (hypovolemic shock)—only this form of shock is covered in this chapter
- Left ventricular failure (cardiogenic shock)
- Disruption of vasoregulatory homeostasis as a result of inappropriate peripheral vasodilation (distributive shock).

Hypovolemia leads to a reduction in peripheral blood flow through the splanchnic and cutaneous circulation as a result of selective vasoconstriction mediated by the central nervous system and a baroreceptor sympathetic response. These differential changes in vascular tone allow selective preservation of blood flow to the brain, heart, and adrenal glands. Venous return to the heart is augmented by a reduction in venous capacitance mediated by catecholamine-induced venoconstriction. This sustains cardiac filling pressures, stroke volume, cardiac output, and critical organ oxygenation. Intravascular volume is also replenished by renal conservation of sodium and water triggered by increased formation of angiotensin. The secretion of antidiuretic hormone further contributes to the renal adaptation.

Sympathetic stimulation and an increase in circulating catecholamines both lead to a rising heart rate and increased myocardial contractility that further increase myocardial oxygen demand. Ongoing hemorrhage and the development of anaerobic metabolism with acidosis may lead to left ventricular failure and the development of irreversible shock.

The immunologic and metabolic response to injury is characterized by the development of the systemic inflammatory response syndrome (SIRS). This process, triggered by hypovolemia and hypoxia, gives rise to diffuse effects as a result of damage to the vascular endothelium.[11] The initial endothelial response to hypoxia includes the expression of adhesion molecules that bind lymphocytes and leukocytes as well as platelets. The activated white blood cells produce and release a range of proinflammatory cytokines and oxygen free radicals.[12] The latter species augment oxidative stress and promote lipid peroxidation once antioxidant mechanisms are saturated. Lipid peroxidation of cell membranes is presumed to result in the loss of vascular integrity with increased vascular permeability. This mechanism is the basis for the development of adult respiratory distress syndrome (ARDS) in the lung and also contributes to the development of multiorgan failure.

Reperfusion injury is also implicated in the development of multiorgan failure. When hypoxic cells can no longer sustain anaerobic metabolism because of glycogen depletion, ATP (adenosine triphosphate) levels fall and homeostatic regulation of ionic flux across the cell membrane fails with rising intracellular sodium and calcium levels. Changes in intracellular calcium concentration adversely affect various enzymes, including xanthine dehydrogenase, converting the enzyme to xanthine oxidase. This switch allows the metabolism of accumulating hypoxanthine (derived from purine catabolism) to superoxide anion and hydrogen peroxide once perfusion and oxygenation are restored.[13] The subsequent release of reactive oxygen species and peroxide augments oxidative stress giving rise to further endothelial damage. Reperfusion injury often arises from delayed restoration of flow through the splanchnic circulation even after adequate

resuscitation. The ischemic gut contains xanthine oxidase and is able to generate oxygen free radicals that on reperfusion may overwhelm the hepatic antioxidant defense mechanisms trigerring systemic endothelial damage and contributing to the onset of multiorgan failure. In addition, reduced splanchnic flow alters gut mucosal permeability, allowing the absorption of intestinal bacteria and toxins into the portal circulation.

Disseminated Intravascular Coagulation

Changes in the coagulation system accompany acute blood loss and will vary according to the extent of the blood loss and the underlying pathology associated with bleeding. The acute-phase response elicited by any form of trauma is characterized by increased hepatic synthesis of clotting factors and hyperhomocysteinemia. The resultant hypercoagulability is seldom clinically evident because these effects are usually overwhelmed in women with acute obstetric blood loss by consumptive coagulopathy.

The clotting defect seen in women after obstetric hemorrhage usually develops because of consumption of clotting factors, leading to a bleeding tendency. Disseminated intravascular coagulation (DIC) is frequently also present and develops whenever procoagulant mechanisms promote fibrin formation in the circulation. The hematologic consequences of DIC are often clinically insignificant but are sometimes associated with a profound coagulopathy (typically seen in the anaphylactoid syndrome of pregnancy but also seen in severe sepsis in which liver dysfunction and thrombocytopenia add to the risk of coagulopathy). DIC contributes to the development of organ failure as a result of SIRS, although the management of this complication is the management of the underlying condition rather than the DIC itself. The numerous mechanisms that trigger DIC do so by endothelial or platelet activation and via the release of thromboplastin into the circulation. Hence, procoagulant changes accompany the development of SIRS and are induced by leukocyte activation and endothelial dysfunction.[14] The presence of placental tissue or amniotic fluid in the maternal circulation initiates intravascular coagulation, and thromboplastin release into the circulation is known to occur in cases of abruptio placentae.

Fibrin formation initiates fibrinolysis, leading to the formation of plasmin and the elaboration of fibrin degradation products that are readily measurable in the peripheral circulation (for example, quantitative D-dimer levels). Although these breakdown products of fibrin are used to diagnose intravascular coagulation, the protection of vascular integrity during normal pregnancy includes sufficient intravascular coagulation to increase D-dimer levels with an increase in circulating thrombin-antithrombin complexes. Accelerated formation of fibrin stimulates fibrinolysis. Plasmin may stimulate the complement cascade, which further contributes to the development of increased capillary permeability.

The physiologic adaptations of pregnancy protect the mother from the hemodynamic and hemostatic effects of hemorrhage at the time of delivery. These changes include a 30% increase in blood volume as a result of plasma volume expansion combined with an increase in red blood cell mass. These changes are accompanied by physiologic peripheral vasodilation to accommodate the increased blood volume and cardiac output. The combined effects of these changes allow more extensive hemorrhage prior to the development of shock and the net gain of 1 to 2 L of intravascular volume exceeds the estimated blood loss of 500 to 600 mL at the time of normal delivery. Hemostasis is augmented by increased hepatic production of clotting factors, especially fibrinogen, while the anticlotting mechanism is impeded by a reduction in the level of free protein S. Fibrinolysis also diminishes in response to placental production of plasminogen activator inhibitor II.

Clinical Presentation

The development of hypovolemic shock is recognized by a progressive fall in blood pressure and a rising pulse rate. The severity of the blood loss can be classified on the basis of clinical signs alone (Table 79–1).

Hemodynamic monitoring will confirm low ventricular filling pressures (central venous pressure or pulmonary capillary wedge pressure) and a low cardiac output. In addition, measurement of central venous oxygen saturation will confirm increased rates of oxygen extraction (<65%) as cardiac output and peripheral perfusion diminish. In determining the diagnosis of acute hypovolemia, investigations are of limited utility. This is especially true of hemoglobin concentration estimation because the hematocrit will only fall as transcapillary rehydration from interstitial fluid takes place slowly over several hours.

TABLE 79–1				
Clinical Classification of the Severity of Blood Loss				
CLINICAL SIGN	**BLOOD LOSS <15%**	**BLOOD LOSS 15–30%**	**BLOOD LOSS 30–40%**	**BLOOD LOSS >40%**
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Urinary output (mL/h)	>30	20–30	5–15	<5
Neurologic status	Anxiety	Anxiety	Confusion	Lethargy

From Marino PL: The ICU Book. New York, Williams & Wilkins, 1998, p 209.

Coagulopathy may be very obvious in the woman who presents with bleeding gums and oozing from all venipuncture sites. In many cases of coagulopathy, however, these signs will not be evident and the diagnosis will depend upon measurement of the international normalized ratio (INR), activated partial thromboplastin time (aPTT), and platelet count.

Renal Failure

Acute oliguric renal failure will develop as a consequence of hypovolemic shock. The loss of 15% to 30% of the intravascular blood volume will result in reduced renovascular perfusion and readily reversible changes in urinary output and blood urea and creatinine levels. Ongoing blood loss leads to the development of acute tubular necrosis in which ischemic injury to the tubules results in tubular epithelial cells becoming detached and blocking the tubules. This adds an obstructive component to the renal ischemia that will further reduce glomerular filtration. The development of SIRS may also add an immunologic component to the pathogenesis of renal tubular dysfunction.

Adult Respiratory Distress Syndrome

ARDS develops as part of the systemic inflammatory response syndrome but may also arise as a consequence of multiple blood transfusions. In the latter case, human leukocyte antibodies present in transfused plasma may be responsible for activation of the complement cascade with subsequent pulmonary vascular injury. ARDS is characterized clinically as a form of noncardiogenic pulmonary edema. The underlying pathophysiology is based upon inflammatory changes rather than an accumulation of interstitial edema fluid (usually associated with high pulmonary capillary wedge pressures).

Complications of Blood Transfusion

The immediate complications include incompatible transfusion, hyperkalemia, and citrate intoxication. Hyperkalemia arises because of the leakage of potassium from stored red blood cells and is a potential problem in those who require transfusion despite renal failure. The development of hyperkalemia may be suspected if the electrocardiogram shows peaked T waves with wide PR and QRS intervals. Citrate intoxication develops because calcium ions are chelated, leading to hypocalcemia (manifest as irritability, hypotension, and a prolonged QT interval on the electrocardiogram). Conversely, the U.K. Confidential Enquiries into Maternal Mortality has demonstrated that some maternal deaths from major obstetric hemorrhage have resulted from a failure to give sufficient blood replacement.

Transfusion-related lung injury presents as noncardiogenic pulmonary edema within several hours of transfusion and requires mechanical ventilation for up to 48 hours. Longer-term risks are those related to infection with hepatitis viruses, HIV, and bacterial infection.

Endocrinopathy

During pregnancy the pituitary gland increases in size several-fold. The blood supply to the anterior pituitary gland is dependent on flow through the superior hypophyseal artery and is susceptible to avascular necrosis. The likely clinical presentation includes failure of lactation, amenorrhea, and loss of secondary sexual characteristics, followed by the evolution of hypothyroidism and adrenocortical insufficiency (Sheehan's syndrome). Sheehan's syndrome may evolve over a lengthy period of time after the precipitating event. The diagnosis should be suspected in the woman who fails to lactate, and confirmatory tests of hypothalamic and pituitary function are carried out. Neuroradiologic investigation will usually reveal an abnormal or empty sella turcica.

Anemia

Anemia may be a late complication of massive hemorrhage. Replenishment of the red blood cell mass will require hematopoiesis dependent on adequate iron stores associated with a normal dietary intake of folic acid.

Fetal Risks
Death

Fetal loss in association with placental abruption is due to hypoxia and prematurity with perinatal mortality rates as high as 12%.[15] Placental abruption is the leading cause of perinatal death in many countries.[16,17] Fetomaternal hemorrhage is a common occurrence following abruptio placentae.[18]

Major obstetric hemorrhage due to placenta previa less commonly causes perinatal death, but again, this is due to prematurity or fetal hypoxia.[19–21]

The fetal risks following uterine rupture depend on the nature of the rupture and vary from no adverse effects to severe asphyxia and death.

Cerebral Hypoxia

Antepartum or intrapartum hypoxia may result in an infant in poor condition at delivery, with subsequent development of convulsions, intracerebral edema, and hemorrhage. This may lead to conditions such as periventricular leukomalacia and porencephalic cysts and long-term neurologic handicap. Pulmonary hemorrhage and necrotizing enterocolitis may also occur after an hypoxic episode.

Consequences of Prematurity

These complications account for most of the cases of neonatal death if the infant has survived the initial insult,

and include respiratory distress syndrome and persistent fetal circulation with patent ductus arteriosus. Complications associated with prolonged neonatal intensive care such as sepsis and bronchopulmonary dysplasia are relatively common.

Management Options

(See also Chapters 59 and 77)

Prenatal: Identification of "At-Risk" Patients

ANY BLEEDING

Massive blood loss cannot always be anticipated or prevented. Some high risk patients can be identified more easily, such as those with placenta previa. However, the prediction of such an event in the general obstetric population is poor. If a woman is anemic prior to labor, or states that she will refuse blood products on religious grounds, she is at increased risk should she bleed excessively in association with delivery. It is good practice in such cases for delivery to occur in a large unit with appropriate staff and facilities.

Patients who have had a previous hemorrhage in pregnancy are at risk of recurrence and should be counseled about such risk and delivered in larger obstetric units with full resuscitative measures available. They should be aware of the procedures for urgent admission to the unit and the need to attend with any degree of bleeding. Iron prophylaxis is advisable in this group (although the risk of major hemorrhage is not generally seen as an indication for routine iron therapy).

PLACENTA PREVIA

Advancing age and parity are associated with the development of placenta previa, although the relative importance of these two factors is disputed.[22,23] Uterine scars, previous miscarriages, terminations, and dilation and curettage are reported as predisposing factors, possibly due to endometrial damage.[24] Placenta previa is more common in multiple pregnancy, owing to increased placental size. Maternal age is an important factor in recurrent placenta previa, and the risk of recurrence is quoted as between 10% and 15%.[25] There is an association between a previous cesarean section and the subsequent development of placenta previa (3%–10%); the risk increases with the number of previous cesarean sections.[22,26] This group of patients is also at risk of placenta accreta (reported as 10%–67%), again increasing with the number of previous cesarean sections. Any patient with a placenta previa and previous cesarean section should be informed of the possible necessity of a hysterectomy. The repeat cesarean section should be booked in an appropriate unit and performed by a senior obstetrician with blood crossmatched and immediately available.

However, only 15% to 20% of cases of placenta previa have major bleeding episodes.[27,28] It should be stressed to the woman with a placenta previa that she is much more likely not to have a severe hemorrhage than she is to have one, especially as ultrasonographic diagnosis has led to increased detection of asymptomatic placenta previa that may prove to be of uncertain clinical significance.

Although bleeding with a placental previa is assumed to be of maternal origin, it has been suggested that a proportion of the blood loss may be fetal in origin.[23] A denaturation test to detect the presence of fetal cells should be carried out in the presence of hemorrhage if delivery is not planned.[28]

PLACENTAL ABRUPTION

The causative factors are known in only a minority of cases of placental abruption but an association with increasing parity, smoking, low socioeconomic status, intrauterine growth restriction, and preeclampsia is reported.[29–31]

The importance of maternal factors is shown by the recurrence rate of 6% to 16% after one placental abruption and 20% to 25% after two previous placental abruptions.[29] Interventions in women at risk have not been shown unequivocally to reduce the occurrence or consequences of placental abruption. Thus, maintenance of a normal blood pressure and cessation of smoking may reduce the risk, although this has not been proved in controlled trials. Similarly, both folic acid supplementation and low-dose aspirin therapy, though advocated by some, have not been shown to reduce the risk of recurrent abruption.

RISK OF POSTPARTUM HEMORRHAGE

Any woman having a baby is at some risk of postpartum hemorrhage (3%–5% of deliveries) and women contemplating a home delivery should be informed of this, as many cases occur unexpectedly. If there has been a previous postpartum hemorrhage, the risks of recurrence are increased to approximately 8% to 10%. Women with a history of retained placenta and those with multiple pregnancy are also at risk. Active management of the third stage of labor should be advised.[32]

Active Bleeding: General Management

The essential management of major bleeding is the same, whatever the underlying cause of hemorrhage, and involves the following steps:

- Stop the bleeding
- Restore the circulating blood volume and oxygen-carrying capacity
- Correct any coagulation defect
- Maintaining vigilance for and dealing with the consequences of hypovolemia.

MANAGEMENT PROTOCOL

Every obstetric unit should have its own protocol for management of massive hemorrhage available on the

delivery unit for all nursing and medical staff. This enables the appropriate clinical and laboratory staff to be summoned early and a clear management strategy to be adopted. An example of a general management protocol for major hemorrhage is given in Table 79–2, and these guidelines should be followed without delay as soon as a major bleeding episode is recognized. This protocol clearly outlines the necessary steps to be taken. Similar guidelines could be drawn up for any obstetric unit customized to local circumstances.

SITE OF MANAGEMENT

The setting will vary with local resources and established practices. Many units have a high dependency area where such patients can be managed. However, there will be a stage in the management of these patients at which admission to an intensive care unit is indicated. These indications will also vary with local resources and practices but an arbitrary list of possible indicators is given in Table 79–3.

MONITORING

The woman bleeding as a result of obstetric hemorrhage may require increasingly invasive monitoring, depending on the extent of the hemorrhage.

- Clinical monitoring should include measurement of blood pressure, pulse rate, urinary output combined with an estimation of the extent of the blood loss on a half-hourly to hourly basis.
- Hypovolemic patients should all have invasive hemodynamic monitoring to assess intravascular volume and ventricular filling pressures (either a central venous pressure line or, in the case of preeclampsia, a pulmonary artery catheter)—see later discussion.
- The extent of the coagulation defect and the hemoglobin concentration must also be assessed, the frequency of which will be determined by the severity and duration of the hemorrhage.
- Organ function may be compromised by massive blood loss and the sequelae associated with resuscitation and massive transfusion. Hence, organ-specific complications such as renal failure and acute lung injury should be considered and laboratory monitoring of renal function, peripheral oxygenation (Astrup), and chest x-rays may all be required on a daily basis. In high dependency units, peripheral oxygen saturation is commonly monitored continuously during resuscitation.

FLUID, BLOOD, AND BLOOD PRODUCT REPLACEMENT

Restoration of the circulating blood volume and reperfusion of ischemic organs is an essential priority and needs

---

TABLE 79–2

Sample Major Hemorrhage Protocol

Organization

1. Switchboard operator sends urgently for the following:
   a. Obstetric resident if not present
   b. Duty obstetric anesthetist
   c. Obstetric nursing officer to arrange extra staff
   d. Blood bank technician
   e. Porter to maternity unit (for transfer of samples)
2. Consultant hematologist and obstetrician are informed of the clinical situation.
3. One nurse to be solely assigned to record keeping:
   a. Patient vital signs, central venous pressure, and urine output
   b. Amount and type of all fluids the patient receives
   c. Dosage and types of drugs given
4. Prepare for theater as soon as possible—most diagnoses require surgical intervention.

Clinical Management

1. Insert two large-bore (preferably 14-gauge) cannulas. Take 20 mL of blood for complete blood count, baseline clotting studies, and cross-matching and order at least 6 units of blood together with 3 units of fresh frozen plasma.
2. Give oxygen via face mask.
3. Commence fluid replacement quickly. (All fluids and blood should be given through a warming device.)
   a. Initially crystalloid and colloid. Hartmann's solution to a maximum of 1.5–2 L.
   b. Uncrossed blood. Rh-negative, matched with the patient's ABO blood group should be given next if cross-matched blood not ready.
   c. Cross-matched blood given as soon as possible.
   d. Give O-negative blood only if none of the above are available (but it may be lifesaving).
4. Insert central venous line and urinary catheter.
5. Stop the bleeding
   a. If ante partum, deliver the fetus (see text).
   b. If postpartum, deliver the placenta if still in utero, commence bimanual compression of the uterus, and give ergometrine 0.5 mg IV. Commence syntocinon infusion of 40 units in 500 mL of Hartmann's solution to run over 4 hours.
   c. If bleeding because of genital tract trauma or retained products, take the patient to theater promptly to explore the uterine cavity and repair damage.
   d. If bleeding continues, consider coagulation failure. Temporary direct aortic compression may give valuable time.
   e. Other surgical measures:
      Direct intramyometrial injection of prostaglandin E$_2$ 0.5 mg, or prostaglandin F$_{2\alpha}$ 0.25 mg
      Insertion of Lynch suture
      Ligation of uterine arteries on both sides
      Ligation of internal iliac arteries
      Hysterectomy

TABLE 79–3

Indications for Intensive Care

1. All patients requiring mechanical ventilation
2. All patients with ongoing hemorrhage
3. All patients requiring inotropic support
4. All patients with organ failure
   a. Renal failure (urine output <30 mL/h, creatinine >150 mmol/L)
   b. Respiratory distress
5. All patients with underlying complicating disorders
   a. Preeclampsia/eclampsia/HELLP syndrome
   b. Acute fatty liver of pregnancy
   c. Other causes of acute liver failure
   d. Anaphylactoid syndrome
6. All patients with invasive monitoring

to be accomplished within 6 hours of developing hypovolemia if inflammatory sequelae are to be avoided.[33] Intravenous fluids must be infused as rapidly as possible until the pulse rate begins to decline. Thereafter, the volume infused should be titrated against a number of clinical parameters, including blood pressure (mean arterial pressure >60 mm Hg), peripheral capillary filling, urinary output, and central venous pressure. In the intensive care setting, other indices of tissue oxygenation (oxygen delivery and consumption indices) as well as mixed venous oxygen saturation levels may be used to optimize fluid management.[33,34]

The rapid administration of fluids depends upon the viscosity of the fluid chosen and the physical properties of the cannula used to establish the infusion. Acellular fluids (rather than blood or packed red blood cells) can be infused rapidly and should be used to initiate resuscitation. Randomized studies have shown no benefit associated with the use of colloidal solutions; consequently, they should only be used as an adjunct to crystalloids in specific situations in which low oncotic pressure may complicate the presentation (e.g., severe preeclampsia with abruptio placentae). Crystalloids commonly used for resuscitation include lactated Ringer's solution or normal saline. The choice of the cystalloid is probably less important than the volume and the rate at which the solution is given. The rate of fluid infusion is determined by the bore and length of the infusion cannula with short large-bore peripheral cannulas (ideally, two 14-gauge cannulae) being preferable to long central lines. The initial goal of fluid therapy is a fall in pulse rate with a rise in mean blood pressure to above 60 mm Hg. As a rule of thumb, the amount of crystalloid required will be three times the volume of blood lost. Central venous pressure measurement after resuscitation should rise to between 10 and 12 mm Hg and fluid should be administered as a bolus challenge against the CVP until a sustained rise in pressure beyond these values can be demonstrated. If central venous oxygen saturation monitoring is utilized, values of less than 65% are associated with abnormally high rates of oxygen extraction from blood perfusing the peripheral tissues as a result of ongoing hypovolemia and indicate the need for ongoing resuscitation.

Occasionally, severe persistent hypotension despite fluid resuscitation indicates the need for inotropic support to maintain sufficient cardiac output. This can be attained using adrenaline, dopamine, or dobutamine. Vasopressor doses of adrenaline range from 0.01 to 0.1 µg/kg/minute and should be titrated against the blood pressure. Dopamine in a dose of 4 to 7 µg/kg/minute stimulates β-receptors and increases cardiac output. Dobutamine is primarily a β_1-receptor stimulant and is mostly used for treating left ventricular failure in a dose of 5 to 15 µg/kg/minute. Control of hemorrhage and adequate fluid replacement should allow rapid weaning from inotropic support.

Correction of the coagulation defect usually requires the administration of fresh frozen plasma (FFP) in a ratio of 1 unit to every unit of packed red blood cells considered necessary to restore the oxygen-carrying capacity.[35] Each unit of FFP will restore procoagulant activity by about 10% and will also raise the fibrinogen level by 40 mg/dL. Cryoprecipitate contains factor VIII, fibrinogen, and von Willebrand factor and should be given when the fibrinogen levels fall below 100 mg/dL. Each unit of cryoprecipitate will raise the fibrinogen level by 100 mg/dL. The advice of a hematologist should be sought when correcting the coagulation defect that develops after massive hemorrhage. Platelets do not need to be infused to restore hemostasis until the count falls below 50×10^9 cells/L providing the platelets are functionally normal (women with preeclampsia may have qualitative platelet defects as well as thrombocytopenia). Each unit of platelet concentrate will raise the platelet count by 5×10^9/L. Administration of FFP should be continued until the aPTT and INR are measurably normal.

For the patient with uncontrollable hemorrhage where all other measures have failed, evidence is accumulating that recombinant factor VIIa is proving successful.[36-38]

Correction of the red blood cell mass deficit is guided by the rule that each unit of packed cells will restore hemoglobin concentration by 1 g/dL. There is no consensus regarding what would be generally considered a desirable hemoglobin concentration. Hemoglobin concentrations equal to or less than 6 g/dL probably merit transfusion and in obstetric patients with ongoing blood loss a more liberal transfusion policy is necessary. Full cross-match is preferred prior to transfusion, although with massive hemorrhage, type-specific partially cross-matched blood can be used (5 minute cross-match). Most labor units will also have a limited supply of type O negative blood available for obstetric emergencies. Because of the risks associated with transfusion of donated blood, in circumstances in which the need for transfusion may be foreseeable, autologous blood transfusion should be offered and can be accomplished either by predonation or preoperative normovolemic hemodilution.

During resuscitation, supplemental oxygen delivery should be provided by means of a 40% facemask and the patient should be kept warm with space blankets or commercially available pneumatic blanket warming device. Additional intensive care monitoring of blood pressure via a radial artery line is also helpful both to allow continuous monitoring of the systemic pressure and to facilitate repeated hematologic investigation.

Specific Management

PLACENTAL ABRUPTION

In severe abruption, the woman is usually in severe pain and may be in shock due to hypovolemia. The amount of

vaginal bleeding will vary. Coagulopathy occurs in about one third of cases when the fetus is dead, but is comparatively rare with a live fetus. Labor occurs spontaneously in approximately 50% of patients.

Maternal resuscitation, as described in the previous section, is the immediate priority. Adequate analgesia should be given if required, usually by intravenous narcotics supplemented by nitrous oxide/oxygen mixtures self-administered by mask. Epidural analgesia is contraindicated in any woman who is actively bleeding because of the peripheral vasodilation associated with lumbar sympathetic blockade.

The only treatment for severe placental abruption is to empty the uterus as soon as feasible. If the fetus is dead, then normal management is to aim for a vaginal delivery, except where there is an obvious obstetric indication for cesarean section such as transverse lie. In rare situations uterine contractions cannot be stimulated or maternal shock is uncorrectable. Cesarean section may have to be undertaken in such cases, although there is a significant maternal risk from blood loss, especially if there is also a coagulopathy. If there is no response to oxytocin, prostaglandins may be administered with appropriate surveillance in an attempt to stimulate uterine contractions. The management of labor in patients with abruptio placentae is uninformed by any randomized evidence, and no clear guidelines are thus available. There is an increased risk of uterine rupture with a large abruption, particularly if there is a Couvelaire uterus.

Determining if the fetus is alive by auscultation may be difficult because of a tender, hypertonic uterus, especially if there is a retroplacental clot and anterior placenta. Accordingly, visualization of the heart using ultrasound is usually the quickest method if a machine is available. If not, it may be necessary to rupture the membranes and attach a fetal ECG electrode providing the patient is known to have been screened for HIV infection. Exclusion of placenta previa may be difficult on clinical grounds if the presenting part cannot be palpated, and the two conditions may coexist. Ideally, location of the placental site is checked by ultrasonography before any vaginal examination.

If the fetus is alive, then consideration should be given to early delivery by cesarean section for fetal reasons. This will depend on the gestation, as it is extremely improbable that a fetus under 26 weeks will survive such an asphyxial episode. The mode of delivery will also depend on the fetal condition as judged by cardiotocography. If the fetal heart rate pattern is totally normal (which is unlikely), induction of labor with continuous monitoring can be considered. An abnormal cardiotocograph tracing is usually an indication for cesarean delivery providing that the fetal heart beat is confirmed to be present immediately prior to the cesarean section.

The clinical diagnosis of abruptio placentae in the woman who has had a previous cesarean delivery must lead to consideration of whether the clinical presentation could be due to uterine rupture. Signs of generalized peritonitis, cessation of labor, hematuria, and malpresentation may all indicate uterine rupture; abdominal paracentesis may also reveal hemoperitoneum. A high index of clinical suspicion necessitates laparotomy to exclude the diagnosis.

PLACENTA PREVIA

Massive hemorrhage from placenta previa follows smaller "warning" bleeds in the majority of cases, and the placental site will often already be known. The fetal heart is usually still present, and additionally, there may be evidence of uterine contractions or premature rupture of membranes in about 20% of cases.

Initial management involves maternal resuscitation as described earlier. A patient with such a severe hemorrhage due to placenta previa will require delivery by cesarean section irrespective of whether the fetus is dead or alive. The cesarean section may need to be performed as resuscitative efforts are under way if the mother's condition cannot be stabilized. Occasionally, vaginal delivery may be contemplated if the fetus is dead or extremely premature. Where there is any possibility of placenta previa, a digital examination should only occur in theater after the decision has been made to deliver and the diagnosis of placenta previa is in doubt. Cesarean section for placenta previa is often a difficult procedure associated with fetal malpresentation, a poorly developed lower uterine segment, and excessive blood loss that further compromises the condition of the patient. The operation should be performed by a senior obstetrician in association with a senior anesthetist and with extra blood immediately available.

Several aspects of cesarean delivery present additional unresolved dilemmas. These include the choice of anesthesia, the technique by which the amniotic cavity is reached, and the method of delivery of the baby. Regional anesthesia, which is the generally preferred technique of obstetric anesthesia, is associated with peripheral vasodilation that could be deleterious in women who experience massive intraoperative hemorrhage. Reaching the amniotic cavity in women with an anterior placenta previa presents the surgeon with a choice of dissecting the placenta free from the decidua in order to open the amniotic cavity at the edge of the placenta or the alternative choice of transecting the placenta to open the amniotic cavity directly beneath the uterine incision. These techniques have not been subject to randomized comparison and most practice is informed only by prevailing surgical habit. Delivery of the baby may similarly challenge the surgeon to attempt a potentially difficult cephalic delivery compared to internal podalic version and breech extraction.

Placenta previa accreta may be encountered in about 5% of cases with no previous scar in the uterus, and in up to 67% of cases with multiple cesarean sections. Early recourse to hysterectomy may be necessary but conserva-

tive management has been attempted, including oxytocics, uterine devascularization procedures, brace sutures, and catheter compression techniques (see later discussion). Postpartum hemorrhage is also more common because of the inability of the lower uterine segment to contract efficiently and should be anticipated and similar prophylactic measures taken (see later discussion).

PRIMARY POSTPARTUM HEMORRHAGE

Initial Management. Most cases of massive postpartum hemorrhage are primary and occur within the first hour after delivery. It is relatively uncommon for secondary hemorrhage to present with blood loss of more than 1000 mL.

The principles of management are as follows:

- Arrest the hemorrhage
- Resuscitation (see earlier discussion)
- Definitive management of the underlying problem.

In the labor ward initial treatment should include rubbing up the fundus to expel clots and to provoke a uterine contraction. Massive hemorrhage in excess of the attainable rate of fluid replacement may lead to rapidly progressive hypovolemia and cardiac arrest. This situation should be recognized when it develops and temporizing measures are necessary to allow resuscitative measures time to restore circulating blood volume. The temporizing measures employed are those of controlling blood loss by direct pressure on the bleeding vessels. In the case of uterine hemorrhage, this is achieved by bimanual compression of the uterine fundus. The fundus of the uterus is sandwiched between the fist of the obstetrician placed in the anterior vaginal fornix and the abdominal hand that compresses the body of the uterus against the vaginal hand. In desperate circumstances, aortic compression should also be considered. This can be executed by placing the palm of the hand on the abdomen above the umbilicus and applying firm pressure to occlude the aorta.

The cause of the bleeding should be identified early in the management. The main causes are uterine atony (including retained placental tissue), trauma, and coagulation defects.

Management of the Underlying Cause. Few of the necessary interventions can be sustained on the basis of randomized studies. However, the role of oxytocic drugs has been reviewed and their utility in active management of the third stage of labor is well established.[39]

More than one etiologic factor may be present. The commonest cause is uterine atony. Pharmacologic intervention must include a range of oxytocic drugs. First-line treatment requires the use of oxytocin and ergometrine. Oxytocin is administered as a bolus of 5 units intravenously followed by an infusion of 20 units in a liter of Ringer's lactate or normal saline. Ergometrine is given, either in combination with oxytocin (syntometrine) or on its own in a dose of 0.5 mg IM or IV. This dose may be repeated. Ergometrine may be of limited utility in developing countries with poor facilities for refrigeration and storage away from light.[40,41] There is some evidence that rectal misoprostol may be an effective agent for controlling severe hemorrhage and should be used in combination with oxytocin and ergometrine.[39,42,43] Other pharmacologic options include the use of methylated prostaglandin $F_{2\alpha}$ preparations (Hemabate), although the side effect profile of the prostaglandin $F_{2\alpha}$ analogues include hypertension, bronchospasm, and diarrhea that limit the utility of these agents even if they are effective in controlling uterine hemorrhage.[44]

Persistent uterine hemorrhage unresponsive to pharmacologic manipulation may need to be dealt with surgically in a series of increasingly radical procedures. The choice of procedure will be influenced by the specific individual circumstances that may include bleeding due to retained products, hemorrhage as a result of persistent uterine atony, bleeding at the time of cesarean section, bleeding from the lower segment following delivery of a placenta previa, and bleeding as a result of trauma. The surgical options include evacuation of the uterus, devascularization of the uterus, compression techniques, and definitive management in the form of hysterectomy.[42,45,46]

Evacuation of the uterine cavity should be preceded by careful examination under anesthesia to exclude uterine rupture. Removal of placental tissue may be achieved by a combination of digital evacuation, the use of Desjardin forceps, and curettage with a large curette (Baum's curette).

Stepwise devascularization of the uterus commences with ligation of the uterine arteries adjacent to the lower segment. This may necessitate opening the leaves of the broad ligament by dividing the round ligaments.[42] The supposition upon which this intervention is based is that a reduction in the perfusing pressures within the uterine circulation may allow the hemostatic mechanism to reassert itself. Failure to control hemorrhage in this way should lead to ligation of the infundibulopelvic vessels, taking care to avoid damage to the fallopian tubes. Devascularization may also be achieved by occluding the internal iliac artery either by ligation or embolization.[42] Ligation of the internal iliac artery requires careful dissection of the retroperitoneal space and identification of the ureter. This technique should not be attempted without adequate surgical experience in pelvic dissection, and the reported success rates vary from a 42% to 65% chance of avoiding hysterectomy.[47]

Various compression techniques are described. The B-Lynch brace is transfixed through the lower segment with two loops of chromic catgut over the fundus, applying pressure to the body of the uterus in the same way that a pair of braces would be worn.[48] Simpler techniques include sutures that traverse both anterior and posterior walls of the uterus in the form of two parallel sutures inserted into the upper uterine segment.[49]

Bleeding from the lower segment of the uterus after delivery of a placenta previa may be difficult to control

because the lower segment does not retract to the same extent as the upper segment. Transcervical catheters with a large bulb (Sengstaken-Blakemore tube) may be used to compress these vessels and have even been advocated as an alternative to uterine packing as a way of controlling postpartum hemorrhage.[50] Uterine packing using gauze packs, previously advocated, as a mechanism for controlling blood loss is no longer practiced because of the difficulty of packing the distensible postpartum uterus and because of concerns about infection.

Hysterectomy remains the final resort in controlling intractable uterine bleeding and may be indicated a priori in cases of uterine rupture. Concern about loss of fertility should not deter the surgeon faced with life-threatening hemorrhage from taking this, sometimes unavoidable, step.

SECONDARY POSTPARTUM HEMORRHAGE

Massive blood loss occurring after the first 24 hours following delivery is less common than primary postpartum hemorrhage and is usually due to subinvolution of the uterus caused by retained pieces of placenta or membrane and superimposed infection. About 1% of secondary postpartum hemorrhage patients will require hysterectomy.

Severe hemorrhage will require maternal resuscitation (see earlier discussion). Definitive treatment comprises exclusion of retained products of conception, treatment for possible sepsis, and the exclusion of underlying trophoblastic disease. None of these interventions have been tested in randomized studies.[51] Antibiotic therapy will generally include a combination of penicillin with an aminoglycoside and anaerobic cover using metronidazole. Alternatives may include the use of cephalosporins or quinolones. Uterine evacuation should be performed if there is any question of retained products or trophoblastic disease.

Pelvic hematoma formation from vulval or vaginal trauma is dealt with conservatively in cases of supraleva-

tor retroperitoneal hemorrhage, although this remains a life-threatening source of hemorrhage. Ongoing resuscitation may be required until the bleeding tamponades spontaneously. If this fails to occur, either surgery or radiologic embolization of the traumatized vessel(s) should be considered. The surgical approach may necessitate both hysterectomy and internal iliac ligation. Infralevator hematomas are usually evacuated and either packed for 24 hours or repaired with mattress sutures to obliterate the cavity.

RUPTURED UTERUS AND OTHER GENITAL TRACT TRAUMA

The immediate pre- and postoperative management will include all the previously described principles of dealing with acute hypovolemia and coagulopathy. Experienced anesthetic support is essential.

The suspected diagnosis of uterine rupture necessitates a laparotomy at which time the decision to repair or remove the uterus will need to be made. These decisions need to be individualized, and few generalizations are possible.

Scar dehiscence can be dealt with by simple repair, but more catastrophic rupture (especially of the unscarred uterus) will require hysterectomy. If contiguous injury to the bladder is identified, urologic assistance will usually be required.

Significant bleeding from other genital tract trauma will require surgical repair. The important principles of management are as follows:

- Prompt and effective resuscitation (see previous discussion)
- Prompt surgical exploration and repair to identify and repair the injury
- Effective anesthesia
- Input from other specialists (colorectal, urologic) as indicated.

SUMMARY OF MANAGEMENT OPTIONS
Massive Obstetric Hemorrhage

Management Options (See also Chapters 41, 59, and 77)	Quality of Evidence	Strength of Recommendation	References
Prenatal—Identification of the At-Risk Patient			
Criteria for risk (though no evidence of measures to prevent/ameliorate bleeding) are as follows:	—	GPP	—
Anemia			
Refusal of blood products			
Previous antepartum hemorrhage, postpartum hemorrhage (PPH), cesarean section, placenta previa			
Value of prophylactic iron therapy is uncertain.	—	GPP	—
Perform delivery in adequately resourced unit.	—	GPP	—

DISSEMINATED INTRAVASCULAR COAGULATION

Definition

Disseminated intravascular coagulation is the widespread activation of intravascular coagulation leading to the deposition of fibrin within the circulation. Consumption of clotting factors usually leads to a bleeding diathesis, although a small percentage of affected individuals may go on to develop widespread thrombosis with peripheral organ ischemia. Some degree of DIC accompanies most forms of obstetric hemorrhage; however, the greater risk of coagulopathy usually arises from consumption of clotting factors and platelets as a result of massive hemorrhage. The combination of massive hemorrhage and coagulation failure is recognized as one of the most serious complications in pregnancy. DIC may arise from a wide variety of clinical situations in obstetrics but is always a secondary phenomenon following a "trigger" of generalized coagulation activity. The clinical manifestations of coagulation failure can vary from mild disorders detected on laboratory tests only, to massive uncontrol-lable hemorrhage with very low fibrinogen and platelet levels. A failure to anticipate or detect the early stages of DIC is cited as a major deficiency in the care of women who die from obstetric hemorrhage, and despite advances in obstetric care and hematologic services, hemorrhage with associated DIC remains a major cause of maternal death and morbidity.

Mechanisms

DIC is triggered by various mechanisms (summarized in Table 79–4):

- Blood loss itself with transfusion and volume replacement
- Release of thromboplastic agents into the circulation
- Endothelial damage to small vessels
- Procoagulant phospholipids produced in response to intravascular hemolysis.

With obstetric complications associated with coagulation failure, there may be interaction of several mechanisms. Once DIC has occurred, there is a potential for a vicious circle, with further consumption of clotting fac-

TABLE 79-4

Mechanism of Disseminated Intravascular Coagulation Occurring During Pregnancy

A. Injury to vascular endothelium:
   Preeclampsia
   Hypovolemic shock
   Septicemic shock
B. Release of thromboplastic tissue factors:
   Placental abruption
   Amniotic fluid embolism
   Retained dead fetus
   Chorioamnionitis
   Hydatidiform mole
   Placenta accreta
   Hypertonic saline used to induce abortion
   Acute fatty liver
C. Production of procoagulant:
   Fetomaternal hemorrhage
   Phospholipids
   Incompativile blood transfusion
   Septicemia
   Intravascular hemolysis
D. In many obstetric complications, there may be interaction between several mechanisms and more than one trigger factor present.

FIGURE 79-1

Once disseminated intravascular coagulation has occurred, there is a potential for a vicious circle, with further consumption of clotting factors and platelets and bleeding until the underlying cause is corrected.

tors and platelets and bleeding until the underlying cause is corrected (Fig. 79–1).

Risks

The risks to both the mother and fetus from coagulation failure in terms of death and morbidity are the same as those discussed earlier under major obstetric hemorrhage. The specific situations in which DIC and coagulation failure may occur and the risks of each underlying condition are considered here.

Placental Abruption

Placental abruption remains the most common cause of coagulation failure in obstetrics and is related to the degree of placental separation and hypovolemic shock. In severe placental abruption with a dead fetus, profound hypofibrinogenemia has been reported in about one third of cases but is much less common if the fetus is alive.[28,52] Earlier stages of DIC are common with mild to moderate abruption but can usually be corrected early if delivery is not delayed.[53] The initial mechanism is due to the release of thromboplastins, but in severe abruption hypovolemic shock, large volume transfusion, and high levels of fibrin degradation products (FDPs) that act as anticoagulants themselves will exacerbate the situation.

Amniotic Fluid Embolism

Amniotic fluid embolism occurs during labor, during cesarean section, or within a short time after delivery. This condition may lead to maternal death as a result of severe pulmonary hypertension following embolization of the pulmonary vessels by fetal squames. If the mother survives this acute event, there may be an anaphylactoid reaction to the presence of the fetal tissues in the maternal circulation associated with cardiovascular collapse, pulmonary edema, seizure activity, and the development of an intractable bleeding diathesis due to severe DIC. The diagnosis is suggested by the detection of fetal squames within the maternal lungs at the time of postmortem, and therefore, the incidence of successfully treated cases is difficult to determine as the diagnosis is only suggestive and cannot be proved. The incidence of death from amniotic fluid embolism between 1970 and 1987 in England and Wales was 7.1 per million maternities. In most cases, the maternal death is unpredictable and unavoidable, and as obstetric care improves, amniotic fluid embolism has been responsible for an increasing proportion of maternal deaths and is now the fifth most common cause of death in the United Kingdom.

Retention of a Dead Fetus

A gradual reduction in clotting factors occurs following intrauterine fetal death, but these changes are not detectable on laboratory testing for 3 to 4 weeks. Approximately 80% of patients with a retained dead fetus

will go into spontaneous labor within 3 weeks, but 30% of patients who remain undelivered for more than 4 weeks will develop DIC, usually of a mild degree.[54] Release of thromboplastic substances from the dead fetus into the maternal circulation is thought to be the trigger mechanism.

Preeclampsia

Preeclampsia is associated with endothelial perturbation currently thought to be due to oxidative stress and the release of reactive oxygen species by the ischemic placenta. The changes in endothelial function predispose to multiorgan systems involvement, including the clotting system.[55]

All preeclamptic patients have an increased rate of platelet turnover, and some develop overt thrombocytopenia. Activation of the coagulation cascade leads to a low-grade DIC that only rarely results in a clinically significant hemorrhage in the occasional patient with severe liver necrosis due to the HELLP syndrome.[56] Excessive bleeding, which is often observed at the time of cesarean delivery, is more likely to be due to a qualitative platelet defect in thrombocytopenic individuals than any deficit in clotting factors.

Sepsis

Endotoxic shock can be associated with chorioamnionitis, septic abortion, or postpartum intrauterine infection. Gram-negative organisms are the most common isolated, although *Clostridium welchi* and *Bacteroides* species may be encountered, particularly in septic abortion. The bacterial endotoxin produces severe endothelial damage leading to fibrin deposition and DIC. Secondary intravascular hemolysis, which produces hematuria and oliguria characteristic of the condition, then occurs, and microangiopathic hemolysis can also cause purpuric skin lesions. Hypotension and coagulation failure are poor prognostic features in the presence of sepsis.[57,58]

Other Risk Factors

Other rarer conditions of pregnancy that have been associated with DIC and coagulation failure include induced abortion with hypertonic saline, acute fatty liver of pregnancy, and other hepatic disorders.[59,60] Hydatidiform mole and placenta accreta are associated with DIC because of loss of the intact decidua basalis, and passage of amniotic fluid and other thromboplastic substances into the maternal circulation is more likely.[61,62] Incompatible blood transfusions, large fetomaternal hemorrhage, and other causes of intravascular hemolysis, including drug reactions and the use of other replacement fluids, can also precipitate or exacerbate existing DIC.[63]

Management Options

General

There is a wide spectrum in the manifestation of the process of DIC, but the aims of management are as follows:[64,65]

- To manage the underlying disorder in order to remove the initiating stimulus
- To maintain circulating blood volume
- To replace clotting factors and red blood cells

Management of the underlying disorder will depend upon the specific condition. In the case of placental abruption, delivery will usually lead to rapid recovery once the mother is adequately resuscitated. Amniotic fluid embolism and acute fatty liver of pregnancy will typically result in more resistant coagulopathy that may not be readily corrected despite vigorous attempts at resuscitation.[66]

Laboratory Investigation

If DIC is suspected, blood should be taken and sent for cross-matching and appropriate laboratory tests before commencing definitive treatment (Table 79–5). Blood can be observed for evidence of clotting, but there is little point in performing whole blood clotting tests at the bedside as they are unreliable and time-consuming.[67] Generally, the laboratory assessment of coagulation requires measurement of the aPTT, the INR, the platelet count, and fibrinogen concentrations together with some estimation of FDPs or D-dimers as an index of intravascular fibrinolysis.

Fluid Replacement in Coagulation Failure

The management of coagulation failure is often subsidiary to management of massive hypovolemia. The urgent necessity in the initial stages is to maintain circulatory volume and tissue perfusion, and resuscitation with

---

TABLE 79–5

Laboratory Investigations

1. Complete blood count including platelet estimation (2.5 mL in EDTA bottle)
2. Coagulation screen:
   Prothrombin time (extrinsic system)
   Partial thromboplastin time (intrinsic system)
   Thrombin time
   Fibrinogen titer (4.5 mL with 0.5 mL citrate anticoagulant)
3. Fibrin degradation products/D-dimers (2.0 mL in special bottle with antifibrinolytic agent)
4. Cross-matching, at least 6 units (10 mL in plain tube) Ideally, 20 mL of blood should be sent, but 10 mL is sufficient for essential tests. The sample should be collected as atraumatically and quickly as possible, and any heparinized IV lines avoided.

crystalloid and colloid solutions should be undertaken as soon as possible, as outlined in the previous section. Dextran solutions should not be used because they interfere with platelet function and can aggravate bleeding and DIC, as well as invalidate the laboratory investigations.[68] Prompt and adequate fluid replacement will also prevent renal failure and help in the clearance of elevated levels of FDPs from the circulation via the liver, aiding the restoration of normal hemostasis.

Replacement of Blood Products

Blood products should be given as soon as available. Fresh frozen plasma (FFP) and stored red blood cells provide all the necessary components in fresh whole blood apart from platelets, and the clotting factors in FFP are well preserved for at least 12 months provided the sample is stored correctly.[35] The use of fresh whole blood should not be encouraged, as it cannot be screened for possible infections. Furthermore, it is not easily obtained in an emergency. It is occasionally necessary to give extra fibrinogen in the form of cryoprecipitate, although sufficient amounts are usually provided in FFP, which also contains factors V, VIII, and antithrombin III in higher concentrations. Platelets are not found in FFP, and their functional activity rapidly deteriorates in stored blood. The platelet count reflects both the degree of DIC and the amount of transfused blood given. If there is persistent bleeding and the platelet count is very low (definitions vary but $<50 \times 10^9$ is often used), the patient may be given concentrated platelets, but these are not usually necessary to gain hemostasis.[67]

Other Treatment Options

Heparin therapy has been used to treat DIC from many different underlying causes, but there is no evidence to suggest that its use confers any benefit over supportive therapy. Heparin is contraindicated if there is hypovolemia and obviously this would include that secondary to placental abruption.[69] Heparin therapy has been suggested in the management of amniotic fluid embolism, but in the face of massive coagulation failure and clinical hemorrhage, it is difficult to justify.[66] It has likewise been suggested in the management of sepsis, although the most recent literature suggests that recombinant protein C may have advantages in terms of preventing fibrin deposition and stimulating the immune response.[69-73] Antifibrinolytic drugs have also been used, but there is the risk that their use would prevent the removal of microvascular thrombi from organs such as kidney or brain as the DIC resolves, leading to long-term sequelae.

SUMMARY OF MANAGEMENT OPTIONS
Disseminated Intravascular Coagulation

Management Options	Quality of Evidence	Strength of Recommendation	References
Remove Insult/"Trigger"			
Empty uterus with major antepartum hemorrhage, retained dead fetus, molar pregnancy	See Major Obstetric Hemorrhage Box (above) and Chapters 4 and 26		
Treat uterine atony/repair trauma with postpartum hemorrhage (PPH)	See Chapter 77		
End pregnancy with preeclampsia	See Preeclampsia, Chapter 36		
Antibiotics with sepsis	–	GPP	–
General			
Involve hematologist and support services (blood transfusion, etc.) early	IV	C	64
Investigations			
See Table 72–5	–	GPP	–
Maintain Circulation			
See Major Obstetric Hemorrhage Box (above)	IV	C	64
Colloids (rather than crystalloid) initially but blood ideally	IV	C	64
Avoid dextran	III	B	68

SUMMARY OF MANAGEMENT OPTIONS
Disseminated Intravascular Coagulation *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Replacement of Blood Products			
Hematologic priorities are to replace blood constituents and coagulation factors (fresh frozen plasma and cryoprecipitate first-line rather than platelets)	III	B	35,70
Other Treatment			
Heparin and antithrombolytic therapy have both been used in DIC to break the cycle of consumptive coagulopathy. Neither has been subjected to controlled trials.	IV III	C B	64,66 65
Concentrates of anticoagulant proteins such as antithrombin, protein C, and activated protein C are possibly useful in DIC due to severe sepsis.	III	B	70,71
Recombinant activated protein C is very effective in severe DIC due to sepsis outside pregnancy; limited experience in pregnancy.	III IV	B C	72 73

CONCLUSIONS

- Hemorrhage and its consequences remain an unpredictable and potentially lethal complication of pregnancy.
- A clear understanding is required of the causes as well as the principles of managing obstetric hemorrhage.
- Much of what we practice and teach remains uninformed by high-quality studies, although there is much accumulated experience from which we can learn.
- Although we should continue to strive for better evidence of effective care, indecision in the management of individual patients is not an option when faced with major obstetric hemorrhage.
- The skills required to care for these women include those of the obstetrician, anesthetists, intensivists, hematologists, renal physicians, and radiologists.
- The obstetrician will usually be the physician most involved with the care of these patients and should have regular "fire-drills" in all aspects of resuscitation and the management of major hemorrhage.

Critical Care of the Obstetric Patient

John Anthony

INTRODUCTION

Maternal mortality accounts for half a million deaths annually.[1] The risk of obstetric mortality varies according to the socioeconomic development of different countries, and many deaths could be avoided with better access to medical care. Industrialized countries, however, continue to focus on maternal deaths because many are associated with substandard care, some of which could be avoided by greater attention to critical care management.[2]

The admission of obstetric patients to critical care facilities is low (published intensive care unit [ICU] admission rates are 0.29% to 1.5% of deliveries in industrialized countries).[1,3] No standardized criteria define the requirement for critical care among pregnant women. The reasons for ICU admission range from obstetric complications (usually due to preeclampsia, hemorrhage, and sepsis) through medical disorders exacerbated by pregnancy (e.g., cardiac disease and thromboembolism) to conditions incidental to pregnancy (e.g., respiratory disease, complications of HIV infection). Only one dedicated obstetric ICU published its experience several years ago, and the pattern of admissions may be changing in developing countries due to the evolving HIV pandemic, with a far greater burden of sick patients being admitted as a result of infection and postoperative sepsis.[3]

Provision of critical care to the pregnant woman requires knowledge of intensive care principles as well as relevant aspects of maternal and fetal physiology.

RELEVANT PHYSIOLOGY OF PREGNANCY

Cardiovascular Changes

The dominant cardiovascular change in pregnancy is the increase in cardiac output leading to accelerated delivery of oxygenated blood to the peripheral tissues including the uterus and choriodecidual space. Stroke volume and cardiac output rise by 40%, and blood pressure falls due to peripheral vasodilation and because the placental circulation functions as an arteriovenous fistula. These changes precede and exceed the fetal and maternal metabolic requirements of pregnancy to such an extent that the difference in arteriovenous oxygen declines in normal pregnancy.[4] Increased cardiac output is achieved largely by a rise in circulating blood volume due to physiologic hyperreninism that increases aldosterone levels 10-fold.[5] This adaptation leads to water and electrolyte retention and a 50% increase in plasma volume.[6,7] Doppler ultrasound has been used to redefine the cardiac changes that accompany the increase in cardiac output. Both filling phases of the left ventricle show increased filling velocities. The peak mitral flow velocity in early diastole (E wave) and the peak velocity during atrial systole (A wave) both increase. The increase in early wave velocity occurs by the end of the first trimester, whereas the peak A-wave velocity changes occur in the third trimester. The E/A ratio increases in the first trimester but falls again as the A-wave velocity increases and is accompanied by decreasing left ventricular isovolumetric relaxation time.[8,9] Left ventricular mass increases significantly while fractional shortening and velocity of shortening diminish throughout pregnancy.[10] Systolic function is preserved by falling systemic (including uterine artery) resistance.[8,9] Peak left ventricular wall stress, an indicator of afterload, has been demonstrated in early pregnancy and normalizes as ventricular mass increases in the midtrimester.[10] Giva and colleagues report a 45% increase in cardiac output in normal pregnancy accompanied by an increase in left ventricular end-diastolic volume and increased end-systolic wall stress accompanied by transient left ventricular

hypertrophy.[11] These authors also report a reversible decline in left ventricular function during the second and third trimesters.

The pulmonary circulation shows increased flow during pregnancy with some reduction in vascular resistance without any significant alteration in blood pressure. These changes are evident by 8 weeks' gestation without any subsequent alteration and return to prepregnancy values by 6 months postpartum.[12] Systemic arterial vascular compliance is thought to diminish because of reduced vascular tone.[13]

Plasma volume expansion is matched by enhanced oxygen-carrying capacity brought about by a 14% to 28% increase in red cell mass.[14] Fetal respiration depends on maternal hyperventilation that creates a partially compensated respiratory alkalosis. The partial pressure of carbon dioxide ($PaCO_2$) in a pregnant woman will fall approximately 15% with a reduction in plasma bicarbonate, although arterial pH remains unaltered.[15]

Effective renal plasma flow rises with increasing cardiac output and blood volume, leading to a 50% increase in glomerular filtration.[16] This results in increased fractional excretion of glucose as well as other metabolites and drugs.

Coagulation

The mother is protected against the effects of hemorrhage at the time of delivery by her increased blood volume and also by enhanced coagulation. Coagulation changes include increased estrogen-dependent hepatic synthesis of fibrinogen and factors VII, VIII, X, and XIII.[17] The anticlotting mechanism is physiologically impaired by reduced levels of protein S. Pregnancy is therefore a state of physiologic resistance to the action of activated protein C because free protein S is a necessary cofactor in this reaction. The fibrinolytic system is also impeded by increased levels of both plasminogen activator inhibitor-I (PAI-I, derived from endothelial cells) and PAI-II, derived from the placenta. Expression of procoagulant activity takes place normally during pregnancy and may be detected by measuring levels of circulating thrombin-antithrombin III complexes.[17]

Effect of Delivery

These physiologic changes in pregnancy are progressive during pregnancy and revert to normal at varying rates during the puerperium. Hence, labor stimulates a further increase in cardiac output, peaking out at 10 L/min as a result of autotransfusion of blood from the choriodecidual circulation during the third stage of labor.[18] Blood pressure fluctuates during pregnancy, falling by 10% to 15% in the midtrimester but rises again toward prepregnancy levels by the end of the third trimester, with a further rise occurring in some patients during labor.

Uteroplacental Effects

Blood flow to the choriodecidual space is determined by both the cardiac output and dilation of the spiral arteries prior to the 20th week of pregnancy. These dilated vessels cannot vasoregulate blood flow to the placenta, which remains directly proportional to changes in maternal cardiac output and blood pressure. Vasoconstriction in the uterine circulation can develop in response to catecholamines, while uterine contractions restrict flow through these vessels by compression of the vessel wall. Transplacental gas exchange takes place by simple diffusion, and even at low partial pressures, fetal hemoglobin binds oxygen avidly because the oxyhemoglobin dissociation curve is shifted to the left. Even minor changes in the partial pressure of oxygen (PaO_2) in the maternal circulation may significantly improve fetal hemoglobin saturation operating on the steep part of the oxyhemoglobin dissociation curve. Fetal well-being is therefore critically dependent on maternal cardiac output, uterine blood flow, and maternal PaO_2.

Anatomic Changes

The enlarged uterus compresses the inferior vena cava and aorta. This may lead to supine hypotension as a result of diminished venous return, although the adrenergic response to aortocaval compression tends to maintain or increase blood pressure. Diminished cardiac output can nevertheless critically impair uterine perfusion, especially during labor.

The diaphragm is displaced by the enlarging uterus resulting in a 10% to 20% reduction in residual volume and functional residual capacity. Under the influence of progesterone, the respiratory center increases chest wall movement, leading to an increase in tidal volume. This leads to respiratory alkalosis and hypocapnia.

METHODS OF MONITORING

Oxygen Saturation Monitoring

Spectrophotometry is the detection of specific light frequencies reflected by a range of molecules. Specific molecules reflect specific frequencies, and their reflective properties differ with changes in molecular conformation. Oximetry is the detection of oxygenated and deoxygenated blood. The oxygenated hemoglobin reflects more light at 660 nm, whereas at 940 nm deoxyhemoglobin reflects infrared light more strongly. This allows the simultaneous acquisition of peripheral signals from which the ratio of oxyhemoglobin to deoxyhemoglobin can be calculated and expressed as a percentage of oxyhemoglobin saturation.

Oximetry may be based on transcutaneous measurements or can be derived from mixed venous blood via a probe located in a pulmonary artery catheter. The peripheral pulse

oximetry devices rely on detection of pulsed alterations in light transmitted between a transmitter and a photodetector.

Although oximetry is regarded as an effective method of monitoring oxygenation, some limitations are recognized. They include the assumptions that methemoglobin and carboxyhemoglobin are not present in significant concentrations. Invasive mixed venous oxygen saturation monitoring is less frequently used than peripheral oxygen saturation monitoring. It also shows greater spontaneous variation than peripheral monitors but has a clinical role to play in determining the balance between peripheral oxygen delivery and peripheral oxygen consumption. This is a robust measurement that will reflect changes in cardiac output, hemoglobin concentration, and arterial and venous hemoglobin oxygen saturation. This provides useful clinical information in many clinical circumstances.

Hemodynamic Monitoring of Cardiac Output

Hemodynamic monitoring is an integral part of intensive care management and is especially important in cases of severe hemorrhage, severe preeclampsia, and septic shock. An adequate cardiac output is essential in delivering oxygenated blood to the peripheral tissues. Low output will reflect either hypovolemia or ventricular failure. Knowledge of the cardiac output will determine management and will also allow calculation of other derived hemodynamic values, including vascular resistance and oxygen delivery and consumption indices.

Cardiac output was previously most commonly measured using the Fick principle. This principle states that the amount of a substance taken up by the body per unit time equals the difference between the arterial and venous levels multiplied by the blood flow. Hence, oxygen consumption by the body divided by the arteriovenous oxygen difference equals the cardiac output. This principle has been modified to use other markers, including dye dilution techniques and the thermodilution principle of the pulmonary artery catheter. In the latter case, iced water is the marker injected into the right atrium, with a probe measuring the temperature of the blood flowing through the pulmonary artery, thus allowing the derivation of the cardiac output from the area under the curve. This technique, although clinically robust, may produce results confounded by variations in catheter position and variations in injectate temperature and volume, as well as changes in the rate of saline injection. Despite these limitations, this technology remains the gold standard against which newer techniques are assessed. The need to cannulate peripheral and central vessels has been associated with some risk of injury and noninvasive techniques of measuring cardiac output have been sought.

Ultrasound in the form of echocardiography allows estimation of cardiac output by measuring changes in left ventricular dimensions during systole measured in the plane below the level of the mitral valve. By assuming that the ventricle is ellipsoid in shape and that the long axis is double the short axis, stroke volume can be calculated from the cube of the change in left ventricular dimension. This measurement is inaccurate when the assumptions on which it is based are no longer true. Hence, the dilated ventricle and the pregnant woman with an increased volume and end-diastolic dimensions violate these assumptions and may overestimate stroke volume and cardiac output. Doppler ultrasound has now added to the utility of echocardiography by allowing an estimation of blood velocity. The Doppler principle measures the frequency of a reflected ultrasound beam striking moving erythrocytes, where the change in frequency detected is proportional to the velocity of the red cells moving in the axis of the beam. The velocity of a column of red cells multiplied by the period of ejection provides a measure of the distance traveled by a column of blood during systole. The use of ultrasound to measure the diameter of the vessels containing the blood will allow calculation of cross-sectional area with subsequent derivation of stroke volume and cardiac output. The velocity of blood flow can also be related to the pressure gradient down which the blood is moving, providing a way of calculating intracardiac pressure gradients and pulmonary artery pressures.

Doppler probes may be range-gated (pulsed) to allow the measurement of a signal from a given depth of tissue. The pulsed Doppler signal usually allows simultaneous ultrasound imaging and estimation of the angle of insonation between the Doppler probe and the vessel. This latter measurement is important because the calculation of velocity from the reflected Doppler signal requires a knowledge of the angle between the ultrasound beam and the column of blood from which the signal is being reflected. Where the signal is perpendicular to the moving column of blood, no movement will be detected, and the closer the beam moves to being parallel to the vessel, the more completely the reflected vector represents the velocity of the cells in the path of the beam.

The combination of cross-sectional echocardiography and Doppler measurement of flow velocity at specific points in the heart and great vessels allows the determination of volumetric flow. The mitral and aortic valve orifices and the root or arch of the aorta have all been studied using both suprasternal and intraesophageal Doppler probes. Potential for error exists in these techniques, both in the calculation of the insonation angle and the measurement of the cross-sectional area of the vessel. Of the different sites studied, the best correlation between the Doppler technique and thermodilution studies was documented in the aortic valve orifice measurements. Although transthoracic Doppler studies are the most widely accessible tool, transesophageal Doppler allows the posterior structures of the heart to be more

clearly imaged with more accurate diagnosis of cardiac pathology and precise alignment to the aortic valve in both the long and short axis as well as providing long axis views of the ascending aorta.[19] The use of multiplanar transesophageal echocardiography allows precise measurements of asymmetrical ventricles that cannot be reliably imaged using a transthoracic probe.[20] The probe has particular utility in the diagnosis of aortic dissection and thromboembolism, although the need for esophageal endoscopy limits the application of this technology to specific situations including intraoperative and postoperative care.[21]

Doppler echocardiography has provided a ready means of studying women at risk of developing hypertensive complications during pregnancy. The most detailed study, to date, by Borghi and associates described detailed cardiac findings among 40 women with mild preeclampsia compared with a control cohort of pregnant women and nonpregnant controls.[22] This study showed a progressive rise in left ventricular mass between nonpregnant women and women with a normal pregnancy, with a further increase in mass among women with preeclampsia. Ejection fraction and fractional shortening decreased in normal pregnancy though this did not reach statistical significance. However, women with preeclampsia had a significant reduction in both these parameters compared with nonpregnant women. In addition, left ventricular end-diastolic volume rose significantly in preeclampsia. Together with a fall in cardiac output in the preeclamptic group, these findings suggest a compensatory increase in ventricular size to maintain cardiac output against an elevated systemic vascular resistance.

The latter study also showed changes in the peak filling velocities of the left ventricle during diastole. The E/A ratio fell significantly during pregnancy, partly reflecting increased preload. In preeclampsia further augmentation of the A-wave peak velocity resulted in further significant reduction in the ratio. Collectively these data support the notion of changes in both cardiac systolic and diastolic function. The authors also measured atrial natriuretic peptide (ANP) levels. In keeping with previous studies, elevated levels of ANP were found in pregnancy, with further increments occurring in preeclampsia. These could not be accounted for by differences in atrial size although a significant correlation was found between left ventricular mass and volume in women with preeclampsia.[22]

Transesophageal Doppler monitoring of hemodynamic data has been carried out in adult ICUs and found to be equivalent to data derived from pulmonary artery catheter measurements.[23] Pregnancy data are few, and only one study has reported the use of transesophageal Doppler monitoring in pregnancy compared with pulmonary artery catheters. That study showed that the Doppler consistently underestimated cardiac output by 40% in women under the age of 35 years.[24] This error may be due to the assumptions implicit in the algorithm used to calculate output. These assumptions include a fixed aortic diameter during systole and a fixed percentage of blood perfusing upper and lower parts of the body. Pregnancy physiologic changes probably invalidate these assumptions. The authors nevertheless conclude that esophageal Doppler may contribute to the estimation of trends over time.

Other techniques of measuring cardiac output include impedance cardiography based on changes in transthoracic electrical resistance associated with the ejection of blood into the pulmonary circulation. This technique has been shown to overestimate low cardiac output, with the opposite error in high cardiac output states.

Invasive Pressure Monitoring

Invasive pressure monitoring includes the insertion of lines used for the measurement of intra-arterial pressure and central venous and pulmonary artery pressure.

Intra-arterial lines allow for continuous assessment of systemic blood pressure and also eliminate the need for repeated venesection, often a prerequisite in the management of the critically ill patient. Various noninvasive blood pressure monitors are also available that measure pressure using an oscillometric principle. These monitors have been shown to be significantly inaccurate when measuring blood pressure from women with preeclampsia, consistently underestimating pressures measured by direct arterial line measurement and auscultation.[25]

Central venous pressure (CVP) monitoring is employed as a measure of right ventricular filling pressure and intravascular blood volume. These lines may be inserted as long lines via the antecubital fossa or can be introduced via the internal jugular or subclavian veins. The long-line technique is preferred in any patient with a bleeding diathesis and also in anyone who cannot tolerate positioning in the Trendelenburg position for internal jugular catheterization (e.g., women with pulmonary edema). CVP in the normovolemic patient should measure between 10 and 12 mm Hg. When managing hypovolemia fluid should be administered as repeated bolus dose infusions until the CVP shows a sustained rise above 10 to 12 mm Hg over a 30-minute period. Central venous lines allow the withdrawal of mixed venous blood in which estimation of the PaO_2 will indicate the extent of peripheral oxygen extraction. In normally oxygenated and perfused individuals, central venous oxygen saturation should remain above 65%. CVP monitoring should not be used to monitor fluid management in severe preeclampsia because left ventricular diastolic dysfunction in this condition results in left-sided changes in pressure that are not reflected by similar changes in right ventricular filling pressures. Hence, a bolus of intravenous fluid may lead to a rapid increase in pulmonary capillary wedge pressure without any change in CVP.

Pulmonary artery catheterization, although controversial, remains a standard intensive care monitoring technique.

Current evidence indicates that pulmonary artery catheters (PAC) do not alter ICU mortality and morbidity, although their utility is recognized in specific patients.[26] In obstetric practice, severe preeclampsia and maternal cardiac disease justify the measurement of left ventricular filling pressures, and measurement of cardiac output allows the calculation of derived hemodynamic parameters such as the systemic vascular resistance and left ventricular stroke work volume. Knowledge of these parameters is a useful guide to appropriate fluid and vasodilator therapy. In preeclampsia, rapid plasma volume expansion has been shown repeatedly to cause a sharp rise in left-sided filling pressures, often without any changes in CVP.[27-29] This occurs despite evidence of normal systolic ventricular function and is a reflection of reduced ventricular compliance during diastole.

PACs, like CVP lines, are inserted either via the internal jugular vein or as a long-line insertion through the antecubital fossa. Catheter placement may lead to a number of complications, especially in inexperienced hands, and should not be undertaken without adequate training and supervision. The incidence of complications may also be lower in pregnant patients than in other ICU populations; the Groote Schuur Obstetric ICU reported no major complications over a 3-year period.[30]

The indications for the insertion of a PAC are similar to those in nonpregnant patients. In addition, severe preeclampsia is recognized to be a condition in which changes in left ventricular diastolic function necessitate monitoring of pulmonary capillary wedge pressure after fluid loading. The Groote Schuur Obstetric ICU audit showed that most catheters were inserted for the management of preeclampsia in patients who also had renal failure (56%), pulmonary edema (32%), or eclampsia (6%).[30]

Although the Pulmonary Artery Catheter Consensus Conference concluded that PAC monitoring did not reduce complications and mortality in patients with preeclampsia, the statement recognized the utility of the catheter in specific circumstances including oliguria unresponsive to fluids, pulmonary edema, and resistant hypertension.[26]

Capnometry

Exhaled gas can be evaluated using an infrared probe and a photodetector set to detect carbon dioxide. This is usually found in the expiratory limb of a ventilator circuit. Expired gas shows a pattern of increasing carbon dioxide concentration related to the sequential expiration of air in the upper airway followed by air from the alveoli. The end-expiratory (or end-tidal) carbon dioxide concentration should approximate the $PaCO_2$ in arterial blood. The development of a gradient between these measurements reflects an increase in anatomic or physiologic dead space. In the latter event, low cardiac output and pulmonary embolism may both affect the measurement. Changes in end-tidal $PaCO_2$ have been correlated to

changes in cardiac output and may be used as a means of monitoring the efficacy of resuscitation.

INDICATIONS FOR MONITORING (CAUSES OF CRITICAL ILLNESS IN PREGNANCY)

The main causes of critical illness in pregnancy are listed in Table 80–1.

MANAGEMENT OF CRITICALLY ILL MONITORED PATIENTS

Severe Preeclampsia (See also Chapter 36)

The preeclampsia syndrome can develop into multiorgan failure (including neurologic, renal, liver, hematologic, and cardiorespiratory disease). Preeclampsia affects 2% to 6% of pregnant women and remains among the leading global causes of maternal mortality.[31-33] Eclampsia with or without evidence of intracranial hemorrhage is the single most lethal complication of preeclampsia/eclampsia. Deaths have also been associated with pulmonary edema; hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome; renal failure; and the development of hypovolemia (commonly due to concurrent abruptio placentae).

The pathogenesis involves chronic placental ischemia that predisposes to an accelerated production of lipid peroxides and oxygen free radicals. Systemic endothelial injury and altered vascular reactivity develop subsequently and are assumed to be a consequence of endothelial damage. The onset of clinical disease is marked by the development of hypertension, proteinuria, and intrauterine fetal growth restriction. Impaired prostacyclin

HELLP, hemolysis, elevated liver enzymes, low platelets.

production and increased release of vasoconstrictors (including thromboxane, endothelin, serotonin, and possibly catecholamines) lead to rising peripheral vascular resistance.[34-38] Endothelial damage leads to expression of cell adhesion molecules that interact with activated leukocytes and platelets.[39,40] Platelet turnover accelerates and may end in thrombocytopenia. Activated platelets also release cytokines that trigger intravascular coagulation.[39,41] Endothelial damage leads to interstitial edema, intravascular dehydration, intensified peripheral vasospasm, and diminished cardiac output. Low cardiac output translates into a critically low rate of oxygen delivery to the peripheral tissues, and multiorgan failure in severe preeclampsia can be attributed to multiorgan ischemia, developing because of vasospasm, low cardiac output, and intravascular coagulation.[28,42]

Management of Renal Failure

The presentation of renal impairment is commonly that of oliguria (a urine output of <30 mL/hr over 4 hr) with or without hematuria. Provided that the patient is not already in positive fluid balance, plasma volume expansion should be attempted. If two fluid challenges (300 mL of colloidal solution) fail to improve the urinary output, low-dose dopamine should be commenced at an infusion rate of 1 to 5 μg/kg/minute. Low-dose dopamine is thought to act as a selective renal artery vasodilator, and although of questionable benefit in general critical care, two randomized studies have demonstrated efficacy without adverse effects in the oliguric preeclamptic patient.[43,44] Patients who fail to respond to either of these measures require more intensive monitoring. Pulmonary artery catheters are a useful adjunct in securing optimal left ventricular preload and afterload. The volume-replete vasodilated patient who fails to pass urine over a 4-hour period should be considered to have intrinsic renal pathology, namely acute tubular necrosis. A single large dose of furosemide (0.5–1 g IV) may convert these patients to high-output renal failure. Should this measure also fail, care must be taken to avoid fluid overload by restricting IV fluid administration to output plus 500 mL/24 hours (to allow for insensible loss), and the patient should be prepared for dialysis.

Management of Respiratory Distress

Respiratory distress in the preeclamptic patient can be caused by or associated with

- Upper airway edema
- Pulmonary edema (patients with severe preeclampsia are predisposed to the development of pulmonary edema because of low oncotic pressure, leaky capillaries, and left ventricular dysfunction; diastolic dysfunction cannot be detected without invasive monitoring or access to echocardiography; iatrogenic fluid overload, even with small amounts of fluid, is also a frequent

cause of pulmonary edema; cardiomyopathy and valvular heart disease may be indistinguishable from other causes of pulmonary edema without echocardiography or invasive monitoring)
- Aspiration pneumonia (especially if the patient has had a cesarean section under general anesthetic) (see also Chapter 38)
- Postoperative atelectasis (it also occurs in some women with the HELLP syndrome from "splinting" of the right hemidiaphragm because of liver pain) (see also Chapter 38)
- Pulmonary embolism (see following discussion and also Chapter 43)
- Adult respiratory distress syndrome (ARDS) (though not a primary complication of preeclampsia, it may follow aspiration pneumonia or prolonged ventilation) (see also Chapter 38).

Clearly patients who present with respiratory distress are a diagnostic challenge. Where the diagnosis remains in doubt after clinical examination and special investigation, echocardiography or pulmonary artery catheterization are indicated.

Pulmonary edema will need to be managed according to the hemodynamic findings. Elevated pulmonary capillary wedge pressure may result from high systemic vascular resistance, left ventricular failure, or fluid overload. These complications may require vasodilation with agents such as dihydralazine, the use of diuretics, or a combination of both. Drugs that are negatively inotropic are generally avoided. In the absence of iatrogenic fluid overload, afterload reduction by vasodilation may be the most important aspect of management.

The development of localized lung signs and purulent sputum should alert the clinician to the possibility of aspiration pneumonia. Radiographic findings vary from normal lung fields to unilateral shadowing, atelectasis, and collapse. Bronchoscopy may be necessary if aspiration of particulate matter is suspected. Treatment with broad-spectrum (including anaerobic) antibiotics and physiotherapy would be indicated.

Management of other causes of respiratory distress are covered in the relevant chapters.

Management of Resistant Hypertension (See also Chapter 36)

Hypertension that fails to respond to standard vasodilator therapy has been cited as an indication for invasive hemodynamic monitoring.[45] The purpose of this is to distinguish hypertension due to high cardiac output from that arising from elevated systemic vascular resistance. Treatment aimed at reducing a high cardiac output may seem counterintuitive, but life-threatening hypertension due to this cause should be treated with drugs such as labetalol rather than the more traditionally used calcium channel blockers and direct-acting vasodilators such as dihydralazine.

Eclampsia (See also Chapter 36)

Eclampsia is the occurrence of generalized tonic-clonic seizures in a pregnant patient with proteinuric hypertension. Most seizures occur prior to delivery, although 40% occur within 24 hours of delivery. Eclampsia may be preceded by prodromal symptoms of headaches and visual disturbances (blurred vision, photopsia, scotomata, and diplopia).[46] The blood pressure at the time of seizure activity varies from levels that are mildly elevated or even normal, although they more commonly have moderate to severe hypertension.[47] Seizure activity is, however, associated with a sharp increase in blood pressure and decreased peripheral oxygen saturation levels. This is important because severe hypertension has been linked to the risk of cerebrovascular hemorrhage.

The differential diagnosis of seizure activity in pregnancy is extensive and includes epilepsy, systemic lupus erythematosus, thrombotic thrombocytopenic purpura (TTP), amniotic fluid embolus, cerebral venous thrombosis, malaria, and cocaine intoxication.[48-50] Late postpartum eclampsia (seizures first developing between 48 hours and 4 weeks after delivery) requires neuroradiologic investigation to exclude alternative diagnoses.[51-53]

The critical care management of eclampsia is centered on the prevention of recurrent seizures, control of the airway to prevent aspiration pneumonia, control of severe hypertension, management of other organ failure, and termination of the pregnancy.

Seizure Prophylaxis

Magnesium sulfate is the drug of choice for seizure prophylaxis. Randomized evidence clearly demonstrates a significantly lower risk of recurrent seizures with magnesium sulfate than for phenytoin and benzodiazepines.[54,55] Magnesium sulfate is a weak calcium channel blocker that regulates intracellular calcium flux through the N-methyl-D-aspartate receptor in neuronal tissue and may inhibit ischemic neuronal damage brought about by anion flux through this receptor.[56] Parenterally administered magnesium results in systemic vasodilation and improved cardiac output as well as cerebral vasodilation distal to the middle cerebral artery. Retinal artery vasospasm has been reversed by magnesium sulfate infusion.[57-59] The myocardial effects of parenteral magnesium include slowing of the cardiac conduction times and in high doses magnesium is significantly negatively inotropic.[60] Intravenous magnesium sulfate reduces serum calcium levels possibly as a result of increased renal magnesium and calcium excretion.[61] Falling serum calcium inhibits acetylcholine release at the motor endplate, the extent of which is directly related to the level of the serum magnesium and inversely proportional to the calcium concentration. This is the origin of magnesium sulfate toxicity leading to neuromuscular blockade and respiratory arrest.[62,63] Dosage regimens vary, but the majority of women in the Collaborative Eclampsia Trial were treated with a 4-g IV loading dose followed by a constant infusion of 1 g/hour. Magnesium sulfate is excreted by the kidney, and impaired renal function may lead to toxicity, manifested as weakness, absent tendon reflexes, and respiratory arrest. Patients with undiagnosed myasthenia gravis may have their disease unmasked by magnesium sulfate, even when the drug only reaches normal therapeutic levels.[64]

Patients who experience recurrent seizures in spite of magnesium sulfate are best treated with intubation and ventilation. Sedation using continuous high-dose benzodiazepine or pentothal infusions will be necessary and will serve to prevent further seizures. Following multiple seizures, these women are likely to have cerebral edema with raised intracranial pressure. Consequently care should be taken to maintain a mean arterial pressure in excess of 100 mm Hg in order to preserve cerebral blood flow.[65]

Control of the Airway

Clearing the airway is an important first-aid measure accomplished by suctioning and positioning the patient head-down on her side. Endotracheal intubation is indicated in women with recurrent seizures, those who are inadequately oxygenated, and when the patient remains persistently obtunded more than 30 minutes after the seizure. Ventilatory care should be maintained for a minimum of 24 hours postpartum, until the patient is fully conscious, and any upper airway edema has dissipated.

Obstetric Management

Vaginal delivery, if foreseeable within a short period may be contemplated in the woman with no complicating features other than a single seizure. Induction of labor should not be protracted, and an arbitrary time limit should be set as a goal for attaining a vaginal delivery.

HELLP Syndrome (See also Chapter 36)

This complication of preeclampsia is due to hepatic ischemia, giving rise to periportal hemorrhage and necrosis along with microangiopathic hemolytic anemia and thrombocytopenia.[66] The mnemonic, HELLP stands for: hemolysis, elevated liver enzymes and low platelets. These patients present with epigastric pain and, in severe cases, are usually obviously ill because of associated complications including renal failure (characterized by rising urea and creatinine levels and the passage of small quantities of bloodstained or "Coke"-colored urine) and eclampsia. Many women with HELLP syndrome, however, seem to have unremarkable clinical disease.

Liver failure may arise from conditions that mimic preeclampsia, such as TTP and acute fatty liver of pregnancy.[67,68] Obstetric cholestasis and viral hepatitis may also enter the differential diagnosis in milder cases of

HELLP syndrome. Distinguishing between these conditions may be difficult, but the hallmark of preeclamptic disease is that it resolves after delivery.[69]

Subcapsular liver hematoma is a rare complication of the HELLP syndrome. The surface of the liver is covered in petechial hemorrhages that may coalesce to form one large hematoma. Rupture of this lesion leads to right upper quadrant pain and sudden hypovolemia.

Coagulopathy is uncommon, but thrombocytopenia and impaired platelet function both give rise to impaired coagulation. Prolonged partial thromboplastin times and international normalized ratios (INRs) are more likely to occur in association with acute fatty liver than HELLP syndrome. Hypoglycemia may occur in some cases, but is more characteristic of acute fatty liver of pregnancy.

The management of HELLP syndrome is delivery, whereas the associated complications (renal failure, eclampsia, and respiratory distress) may require critical care on their individual merits. Thrombocytopenia should reach a nadir within 72 hours of delivery, and if it is persistent beyond this point, a search for alternative diagnoses should commence (e.g., sepsis, folate deficiency, thrombotic thrombocytopenic purpura, systemic lupus erythematosus).

Thrombotic Thrombocytopenic Purpura

TTP is one of a spectrum of microangiopathic hemolytic conditions that include preeclampsia, hemolytic uremic syndrome (HUS), acute fatty liver of pregnancy, and autoimmune conditions such as systemic lupus erythematosus. TTP is a condition in which multimers of von Willebrand's factor, derived from the endothelium, accumulate in the circulation. Von Willebrand's factor binds platelets to the endothelium, and high concentrations are associated with peripheral platelet consumption and the formation of platelet microthrombi. Von Willebrand's factor is usually broken down by a specific metalloproteinase, but may accumulate if this enzyme is deficient or if endothelial damage provokes excessive release of von Willebrand's factor. The metalloproteinase enzyme deficiency exists either as a hereditary condition or can be acquired as a consequence of autoimmune disease due to a specific IgG inhibitor of the enzyme. Many factors can precipitate both the congenital and acquired forms of TTP, including drugs, malignancy, bacterial infection, HIV, and other viral infections. Pregnancy is the precipitating factor in 10% to 25% of cases.[70,71]

TTP presents with a clinical pentad of features:

- Microangiopathic hemolytic anemia
- Fever
- Neurologic disturbance
- Renal impairment
- Thrombocytopenia

The neurologic features of the syndrome may be transitory, and mild hypertension and proteinuria may make the condition indistinguishable from HELLP syndrome. TTP does not, however, remit after delivery, whereas HELLP syndrome invariably resolves. Other diagnostic features that may help to distinguish between the two conditions include evidence of marked hemolysis on examination of the peripheral blood smear (this is more characteristic of TTP than HELLP).

Without appropriate management TTP has a high mortality rate. Treatment consists of plasmapheresis, infusion of fresh frozen plasma, and high-dose steroids.[70] Renal failure and the neurologic manifestations may require appropriate intensive care management.

Acute Fatty Liver of Pregnancy (See also Chapter 48)

Developing in the latter half of pregnancy, acute fatty liver of pregnancy (AFLP) is a condition characterized by microvesicular fatty infiltration of the liver. The incidence is approximately 1:12,000 deliveries. Clinical disease severity varies, with some patients having only mild right upper quadrant discomfort associated with prodromal nausea and vomiting. Others develop fulminant liver failure leading to coma. A depressed level of consciousness may arise from either hypoglycemia or the onset of hepatic encephalopathy. Hypoglycemia is a common feature of AFLP and should alert the clinician to the possible diagnosis. More than 50% of affected patients will have mild hypertension and proteinuria, making the distinction from HELLP syndrome difficult. Jaundice is often present at the time of diagnosis. Liver enzymes are increased, and transaminases may rise above 1000 IU/L in severe cases. Liver failure leads to severe coagulopathy and a prolonged partial thromboplastin time and INR. DIC with microangiopathic hemolytic anemia develop together a mild neutrophil leukocytosis.[72,73]

Management principles include delivery of the fetus and treatment of the acute liver failure.[74] Coagulopathy may complicate the delivery and must be corrected beforehand. Management of liver failure also includes maintenance of the blood glucose level, the use of lactulose to limit the effects of intestinal bacteria, and administration of vitamin K to mother and baby. Intubation and ventilation may be necessary in the comatose mother who cannot protect her airway. Associated complications of renal failure and pancreatitis need to be managed individually.

Obstetric Hemorrhage

This occurs as a result of bleeding from the placental site or as a consequence of trauma to the genital tract. These issues, including medical, surgical, and critical care

management of shock and coagulopathy are dealt with in Chapter 79.

Severe Sepsis

The systemic inflammatory response syndrome (SIRS) consists of markers of a systemic immune response (Table 80–2).[75] SIRS may develop from any noxious stimulus including preeclampsia and hypovolemia. When infection causes SIRS, the condition is named sepsis. Sepsis leading to multiorgan dysfunction is termed severe sepsis, and severe sepsis plus refractory hypotension is septic shock. Collectively, infection arising during pregnancy or that resulting from underlying HIV infection is by far the single largest cause of maternal mortality in developing countries. In South Africa these two entities account for 40% of the maternal deaths: double the number of the next most prevalent cause of mortality.

The sources of sepsis vary. Pelvic infection after delivery, wound sepsis, respiratory infection, and urosepsis are all common and can all lead to life-threatening illness requiring critical care.

Pelvic Sepsis

Pelvic sepsis usually results from infection with gram-negative organisms, although gram-positive organisms and fungi can be implicated. Tuberculosis can also present with abdominal sepsis. Prolonged rupture of the membranes, obstructed labor, instrumentation of the genital tract, retained products of conception, trauma, and operative delivery, together with immunosuppression all contribute to the pathogenesis of sepsis.

Recognition of pelvic sepsis is based on the presence of SIRS together with localizing signs of pelvic infection, including peritonitis, a tender subinvoluted uterus, and malodorous lochia. Coexisting organ dysfunction, such as impaired renal function, gastrointestinal signs (ileus), hyperbilirubinemia or elevated liver enzymes, DIC, ARDS, neurologic dysfunction, and cardiorespiratory disease including left ventricular failure, will define the syndrome of severe sepsis and will indicate the need for intensive care.

TABLE 80–2

The Systemic Inflammatory Response Syndrome

Any two or more of the following features:
   Temperature >38 or <36°C
   Heart rate >90 bpm
   Respiratory rate >20 breaths/min or PaCO$_2$ <32 mm Hg
      WBC >12,000 or <4,000/mm³ or >10% immature (band forms)

WBC, white blood cell count.

Intensive care principles are self-evident. Supportive therapy will be necessary to maintain organ function by ensuring adequate peripheral perfusion, and the source of sepsis will need to be managed by medical and surgical intervention. Supportive therapy consists of fluid replacement measured against the CVP. Women with distributive shock due to peripheral vasodilation may require large amounts of fluid and blood products. Persistent hypotension due to left ventricular failure may require inotropic support using adrenaline, dopamine, or dobutamine. Coagulopathy due to liver dysfunction and DIC will need to be corrected prior to any surgical intervention, and oxygen-carrying capacity of the blood should be optimized by packed cell transfusion in women who are anemic. Appropriate respiratory support may take the form of facemask oxygen or intubation and ventilation in cases of respiratory distress with inadequate peripheral oxygen saturation or respiratory failure.

Managing the sepsis will require broad-spectrum antibiotic cover tailored to the specific infecting organism if bacteriologic surveillance from blood cultures and pus swabs identify a specific pathogen. Surgical intervention may include evacuation of retained products of conception, drainage of pelvic abscesses, and hysterectomy. The last option is often delayed because of understandable concern about future fertility. However, the woman with multiorgan failure precipitated by sepsis who fails to respond to 24 hours of appropriate antibiotic treatment is at risk of developing septic shock that may progress rapidly and is associated with mortality rates of between 20% and 50%.[76] Under these circumstances, hysterectomy to remove the source of sepsis may be a lifesaving procedure.

Respiratory Infection

This may be community acquired (often gram-positive organisms like *Streptococcus pneumoniae*) or nosocomial (usually gram-negatives e.g., *Pseudomonas*, *Acinetobacter*, *Escherichia coli*, and others).

The clinical presentation is that of SIRS together with respiratory symptoms of dyspnea, pleuritic chest pain, cough, sputum production, and clinical signs of pulmonary crepitations or consolidation with bronchial breathing. Radiographic signs may take time to develop, but new pulmonary infiltrates should be identified if the diagnosis of pulmonary infection is correct. Sputum specimens should be routinely examined bacteriologically to identify the infecting organism. Tuberculosis should also be excluded as a diagnosis, especially in areas where there is a high prevalence of HIV infection.

Critical care management must maintain oxygenation while treating the underlying infection. Peripheral oxygen saturation levels will determine the necessary respiratory support, which may include the use of facemask oxygen, the administration of continuous positive airways

pressure oxygen (CPAP) or intubation, and ventilation. Generally, respiratory infection has not been regarded as an indication for delivery of the baby, even among ventilated patients. Antibiotic therapy for community-acquired infection is usually a cephalosporin or an aminoglycoside with penicillin, whereas nosocomial infections due to gram-positive organisms will need treatment with vancomycin. A suspicion of mixed aerobic infection or anaerobic infection may lead to the use of imipenem or a combination of clindamycin/metronidazole with an aminoglycoside. Bacteriologic advice should be sought and treatment adapted to organisms identified from blood and sputum culture.

Sepsis in the Immunocompromised Patient

HIV infection predisposes the affected individual to pelvic, respiratory, and neurologic infection. Respiratory infection may be due to atypical organisms (*Mycoplasma* and *Legionella*), tuberculosis, cytomegalovirus, or the protozoan *Pneumocystis jiroveci* [formerly *carinii*] (PCP). The clinical presentation and radiographic signs may not discriminate between these different disorders, and sputum should be obtained (or bronchoscopic lavage used) to arrive at a bacteriologic diagnosis. Radiologically, PCP may present with patchy changes that progress to a diffuse pattern of bilateral pulmonary infiltrates resembling ARDS. Management consists of supportive treatment including ventilation together with high doses of trimethoprim and sulfamethoxazole (dose 20/100 mg/kg/day for 21 days) and corticosteroids. The prognosis for women with PCP who require ventilation is poor, with only one in three surviving ventilatory care that extends for more than 2 weeks.[77] Suspected atypical pneumonia requires treatment with erythromycin.

Pelvic and wound sepsis seems to occur more readily in HIV-infected women. Antibiotic prophylaxis against postoperative sepsis should be extended to 48 hours for elective surgery and for 5 days in those having emergency cesarean delivery. In managing puerperal sepsis, surgical intervention, including hysterectomy, has been practiced more aggressively than in immunocompetent women. These approaches are unsubstantiated by randomized evidence but have developed in units faced with a large burden of HIV-infected women.

Thromboembolism (See also Chapter 43)

Thromboembolism is the leading direct cause of maternal mortality in the United Kingdom. The incidence of venous thromboembolism lies between 0.5 and 1 per 1000 deliveries.[78-81] The predisposing factors giving rise to thromboembolism are pregnancy itself, underlying thrombophilia, age, and circumstantial risk factors such as surgery and immobilization. Pregnancy is a procoagulant condition because of increased hepatic synthesis of clotting factors, decreased protein S activity leading to

activated protein C resistance, and inhibition of fibrinolysis by placental production of PAI-II. Underlying hereditary or acquired thrombophilias add to the risk. These conditions include deficiencies in protein C, protein S, and antithrombin. The Leiden and prothrombin gene mutations have been described more recently. Hereditary defects also exist in factor VIII and fibrinogen genes, giving rise to increased concentrations of these clotting factors. Hyperhomocysteinemia is also considered to be a thrombogenic condition, which arises either because of a dietary deficiency in cofactors such as folate, vitamin B_6, and B_{12}, or because of enzyme deficiencies. Common mutations affect the enzyme methylene tetrahydrofolate reductase, which is required to convert folate to tetrahydrofolate. The other rarer enzyme defect is linked to cystathionine β-synthase deficiency. Thrombophilia may also be acquired as part of the antiphospholipid syndrome due to the presence of the lupus anticoagulant that interferes with the protein C mechanism and also promotes platelet activation through the release of platelet-activating factor by endothelial cells. Finally, the sticky platelet syndrome may increase the risk of clot formation.

Ileofemoral vein thrombosis occurs more commonly in pregnancy; the presenting features of venous thromboembolism are those of a swollen, red, and tender leg. These signs are unreliable, and investigation is sometimes also unhelpful. Compression ultrasound is useful in identifying proximal thrombosis, but venography remains the gold standard against which other investigations are assessed. Pulmonary embolism classically presents with sudden-onset pleuritic chest pain, dyspnea, and hemoptysis. Investigations may confirm hypoxemia and right ventricular strain ($S_1Q_3T_3$ ECG pattern). Radiologic investigation may show no lesion or an elevated hemidiaphragm. Ventilation-perfusion scanning identifies mismatched areas of ventilation and perfusion that may be indicative of embolization. More recently, spiral CT is helpful in diagnosing segmental rather than subsegmental emboli.[82,83] It is notable that measurement of D-dimer concentrations during pregnancy is not a useful way of diagnosing excessive fibrinolysis associated with venous thrombosis because D-dimer levels are normally elevated in pregnancy.

Treatment of thromboembolism consists of anticoagulation to arrest clot propagation until the clot resolves followed by prophylactic doses of low-molecular-weight heparin to prevent further clot formation. The detailed description of how heparin and warfarin are used are covered in Chapter 43. In the critical care setting, unfractionated heparin is given intravenously in a dose of 20,000 units in 200 mL of saline beginning at 13 mL/hour, with the dose titrated against the aPTT to maintain values 1.5 to 2 times the control value. Other supportive therapy may be necessary to maintain oxygenation, up to and including intubation and ventilation.

Cardiac Problems

Arrhythmias (See also Chapter 37)

The patient experiencing cardiac arrest should be resuscitated according to standard protocols, including defibrillation, external cardiac massage, and ventilatory support. The pregnant uterus restricts venous return as a result of aortocaval compression, and cesarean delivery will facilitate resuscitation. If this is to be done, it should take place within 5 minutes of the arrest.

Ventilatory support, when required, should aim for slight hyperventilation to mimic pregnancy physiology in which $PaCO_2$ falls to allow fetal excretion of carbon dioxide down a concentration gradient. Extreme hypocarbia may affect uterine blood flow adversely, and maternal $PaCO_2$ levels must be maintained above 2 kPa. Where pressure considerations permit, tidal volumes of 10 to 15 mL/kg should be used, and the ventilator rate adjusted to achieve an appropriate $PaCO_2$. The maximum ventilatory plateau pressure should (ideally) not exceed 35 cm H_2O.[84]

Arrhythmias occur more frequently in pregnancy and occasionally lead to hypotension. In the critical care setting, the drugs most likely to be used to treat arrhythmias are adenosine, short-acting β-blockers, and amiodarone.[85] Adenosine is used to treat supraventricular tachycardia, Wolf-Parkinson-White syndrome, and arrhythmias involving the AV node. Because it can cause bronchospasm, it should be avoided in asthmatics. Lignocaine has been used in pregnancy, but there is limited experience. Although β-adrenergic blocking agents given to the mother have been linked to fetal growth restriction, fetal hypoglycemia, and hyperbilirubinemia, short-acting drugs such as esmolol may be used during pregnancy for specific indications such as the treatment of arrhythmias. Amiodarone is a drug with a long half-life (>50 days) and has been linked to a risk of neonatal hypothyroidism. The use of amiodarone should therefore be restricted to the treatment of life-threatening arrhythmias unresponsive to other treatment.

Other Cardiac Problems

Arrhythmias were discussed in detail in the previous section but can additionally cause sudden hypotension. Acute pulmonary edema can result from peripartum cardiomyopathy or valvular heart disease, especially thrombosis of a prosthetic valve. Myocardial infarction is rare but can result in cardiogenic shock. Aortic dissection and pulmonary hypertension giving rise to acute right ventricular failure also enter the differential diagnosis. The reader is referred to Chapter 37 for detailed discussion of the management of these conditions.

Neurologic Disorders

Cerebral ischemia or hemorrhage will present with neurologic signs. There may also be a sudden onset of neurogenic pulmonary edema.[86,87] Management should be directed to protecting the airway. Urgent neuroradiologic investigation is required to exclude a surgical remedial cause, and the management of these cases must always take place in consultation with a neurologist. The reader is referred to Chapter 49 for detailed discussion of the management of these conditions.

Trauma

Motor vehicle accidents and assault are the most serious causes of trauma in pregnancy. Pregnancy does not increase the risk of maternal death due to trauma, but the fetus is at exaggerated risk of death due to maternal hypovolemia, placental abruption, and direct trauma to the uterus and fetus.[88]

Direct trauma to the abdomen can lead to placental separation and abruptio placentae, the clinical signs of which may be delayed by up to 6 hours after the event. More forceful blunt trauma has the potential to cause uterine rupture, although this is a rare occurrence among pregnant trauma victims. Other obstetric consequences of blunt trauma are those of premature rupture of the membranes and fetomaternal hemorrhage, which can lead to isoimmunization of babies whose blood groups are incompatible with those of the mother.

Penetrating injury to the abdomen and uterus may lead to direct fetal trauma. Conservative management of penetrating injuries below the level of the uterine fundus has been advocated, but in pregnancies in which the fetus is considered to be viable (usually over 28 weeks) many obstetricians would resort to laparotomy and operative delivery in the presence of a penetrating uterine injury.

Resuscitation and critical care should be based on normal trauma guidelines, although monitoring must be extended to include an assessment of the fetal condition. The reader is referred to Chapter 55 for detailed discussion of the management of these conditions.

Metabolic Problems

Hypoglycemia, hyperglycemia, hypocalcemia, and hyponatremia should always be considered in any patient who collapses acutely. Management will be based on the specific cause and diagnosis.

Anaphylactoid Syndrome of Pregnancy

This complication of labor or cesarean delivery gives rise to peripartum collapse as a result of embolization of amniotic fluid and fetal squames into the maternal circulation. The syndrome may be rapidly lethal in women who develop a true embolus of fetal squamae that obstruct the pulmonary circulation, leading to severe pulmonary hypertension and cardiac arrest. However, those who survive for longer periods develop an anaphylactoid

type of response to the presence of amniotic fluid in the circulation.[50]

The clinical syndrome is diagnosed in 1 in 8000 to 1 in 80,000 pregnancies. A national registry of cases that has been opened in the United States is currently the most authoritative source of information about this condition.[50] The condition usually presents during labor but may occur at the time of cesarean delivery or immediately after birth. There are no demographic predisposing factors, and obstetric practices such as prior amniotomy and oxytocin administration do not seem to influence the risk of developing amniotic fluid embolus. The onset of the condition is abrupt, and hypotension is universally present. Most patients develop pulmonary edema with cyanosis and a profound coagulopathy, which should immediately give rise to a suspicion of the diagnosis. The single most common initial presenting symptom in antenatal patients is seizure activity, which may be confused with eclampsia. The patients who survive the initial embolus and who develop the anaphylactoid picture have markedly depressed left ventricular function. Cardiac electromechanical dissociation may develop, and there is a high risk of cardiopulmonary arrest. The prognosis is poor; in the U.S. national registry, 61% of the patients died, and only 15% survived neurologically intact.

Diagnosis must be prompt, and continuous vigorous resuscitation will be needed immediately. Intensive care is mandatory and inotropic support necessary from the beginning. Hemorrhage should be anticipated, and hypovolemia is also likely to be a problem as a result of postpartum hemorrhage or bleeding after cesarean section. Continuous transfusion with blood and coagulation factors will be necessary, and obstetric intervention in the form of oxytocic drugs and hysterectomy may be necessary to control bleeding (see also Chapters 77 and 79). Intubation and mechanical ventilation along with pulmonary artery catheterization are likely adjuncts to intensive care management.

Other Causes of Acute Collapse

Several other conditions may result in acute collapse requiring emergency intensive care. The same general principles apply to all these cases: namely secure the airway, maintain respiration and circulation, and then look for and correct the underlying cause.

Respiratory Disorders

Air embolism may develop during delivery as a result of air entering the venous system and becoming trapped in the right ventricle. Paradoxical arterial emboli can develop in any individual with a patent foramen ovale. Presenting features include acute collapse, coronary insufficiency, and cerebral artery occlusion, leading to seizures and a depressed level of consciousness. Specific management is based on the use of hyperbaric oxygen to decrease the volume of the gas.

Other Systemic Disorders

These include thyroid storm, myasthenic crisis, sickle cell crisis, anaphylaxis, and transfusion reactions. The description of these disorders is found in the relevant chapters.

<hr>

CONCLUSIONS

- This chapter has given an overview rather than an exhaustive discussion of a very broad subject.
- Some would argue that many of the complications reviewed are more appropriately managed exclusively by intensivists, anesthetists, and physicians. However, the pregnant woman presents a unique challenge because of both the physiologic changes that accompany pregnancy and also the need to address the requirements of the fetus in a mother who is critically ill. Thus, obstetricians must remain involved in the care of these women if the mother and her unborn child are to receive optimal care. More importantly, there should be a thorough understanding of those conditions that commonly lead to maternal mortality.
- Substandard care of the critically ill woman arising from ignorance should not be an issue raised by confidential enquiries into maternal mortality.

SUMMARY OF MANAGEMENT OPTIONS
Critical Care of the Obstetric Patient

Management Options	Quality of Evidence	Strength of Recommendation	References
Preeclampsia-Renal Impairment			
See also Chapter 36.	–	–	–
Give two fluid challenges.	–	GPP	–
Pulmonary artery catheterization	III	B	27–29
IV dopamine	Ib	A	43,44
Single dose of furosemide in volume-replete patient who does not respond to IV dopamine	–	GPP	–

Domestic Violence

Loraine Bacchus / Susan Bewley

INTRODUCTION

Over the last decade awareness of the importance of domestic violence has increased. Obstetricians, gynecologists, and midwives have a key role in identifying women who are experiencing domestic violence; documenting the abuse; and ensuring that appropriate advice, support, and interventions are offered.

"Domestic violence" is defined in this chapter as "any behavior within an intimate relationship that causes physical, psychological, or sexual harm to those in the relationship."[1] It can be physical (hitting, slapping, kicking, punching, burning, scalding, choking, hair pulling, throwing objects, and the use of weapons), psychological (verbal threats; intimidation; isolation of the woman from friends and family; constant belittling and humiliation; deprivation of sustenance such as food, money, clothing, transportation, and health care; and restricting access to information and source of support), or sexual (forced sexual contact, rape, being forced to watch or reenact pornographic material, and sexual assault with objects).

Domestic violence is rarely isolated and the abusive behavior often begins insidiously, growing more oppressive and harmful with time.[2] In most cases, violence is directed toward a woman by her male partner.[3] Women are more likely than men to sustain physical injuries, to experience repeated assaults, report fear, emotional distress, and seek medical attention as a result of the violence.[4] This chapter will deal with violence by men against female partners in pregnancy.

PREVALENCE

Surveys in the United Kingdom show that domestic violence is common, affecting one in three to four women at some point in their lives[4,5] and one in nine in the preceding year.[6] Similar rates have been reported in surveys from Canada[7] and the United States.[8] Higher reported rates of domestic violence have been found among women attending health care settings. Two U.K. studies conducted in primary health care settings reported higher lifetime rates of about 40%.[9,10] Domestic violence accounts for a significant number of homicides amongst women. In Australia, Canada, Israel, South Africa, the United States, and England and Wales, between 40% and 70% of female murder victims were killed by their husbands or partners.[1] The corresponding figure for male victims of homicide is 8%.[11] It is often assumed that the violence will end once the woman leaves her abusive partner. However, women assume a greater risk of escalating or even fatal violence when they leave or attempt to leave the relationship.[12]

In most cases of domestic abuse that are identified in pregnancy there is pre-existing violence that continues throughout the pregnancy and following the baby's birth.[13] However, in a minority the first incident of violence takes place during pregnancy.[14] The prevalence of domestic violence in pregnancy is between 2.5%[15] and 33.7%,[16] with the greatest risk occurring during the postpartum period.[17,18] Higher rates of violence during pregnancy have been found among pregnant teenagers.[19,20] Thus domestic violence is commoner than many obstetric complications such as preeclampsia.

Domestic violence was the cause of death in 14 cases in the two most recent Confidential Enquiries into Maternal Deaths in the UK (CEMD).[21,22] In the 1997–1999 enquiry, of the 378 reported deaths, 45 (12%) women had voluntarily disclosed domestic violence to a health professional during their pregnancy. This figure could be an underestimate of the problem since women rarely volunteer information about abuse experiences.[22]

RECOGNITION

Significant associations with domestic violence include:

Demographic and Psychosocial Factors

- Young women who are single, separated, or divorced and have children living at home[5,23]
- Women who have a history of childhood physical or sexual abuse are at increased risk of experiencing violence within their adult relationships.[24]
- Psychiatric illness (depression, suicide, self-harming, post traumatic stress disorder, anxiety, and phobic symptoms.[25-28] The development of a psychological disorder resulting from domestic violence is positively correlated to the frequency and severity of the violence.[29,30]
- Higher prescription rates for tranquillizers, antidepressants, and pain medication and higher admissions rates for psychiatric illness.[31,32]
- Alcohol and substance misuse is associated with both the experience and perpetration of domestic violence.[17,23,33,34] These factors can have a significant influence on the power dynamics of an abusive relationship and isolate the woman from potential sources of support.

Behavioral Factors

- Unwanted pregnancy, sexually transmitted infections, and rapid repeat pregnancy (within 24 months)[35-38]
- Increased parity and younger age at first pregnancy[15,23,39]

Contact with Health Services

- Increased access to emergency and nonemergency health services, requiring treatment for injuries and symptoms resulting from the violence.[40-42] In most cases enquiry about domestic violence is not made.

- Late initiation of antenatal care[15,43]
- Frequent clinic or hospital visits with vague complaints or symptoms.[15]

Interactions with Partner Indicative of a Controlling Relationship

- Partner may accompany the woman to all her antenatal appointments, answer questions directed at her, or appear reluctant to leave the room.
- The woman may present as nervous, avoid eye contact with the health professional, or be afraid to speak openly in front of her partner.
- Noncompliance with treatment regimens, lack of independent transportation or access to finances, and difficulties in communicating by telephone[44]
- Failure to attend clinics with visible injuries
- Where domiciliary care is available, difficulties in gaining access can be experienced by health professionals.[45-47]

Clinical Presentations

- See Table 81–1 for the common presentations.[48,49]
- Delay in seeking treatment for injuries
- Woman's explanation for how an injury occurred seems implausible.
- Forced sex that can lead to infection of perineal sutures and delay the healing process[50]
- Difficulties having pelvic examinations in prenatally or during labor, with the woman becoming distressed, withdrawn, or even hostile.[39] This may be significant when a woman requests a female health professional for such examinations.

Although the presence of these risk factors and indicators may raise a health professional's index of suspicion, no single factor will accurately identify which women are likely to be affected by domestic violence. Abused women

---

TABLE 81–1

Physical Signs and Injuries Associated with Domestic Violence

Head, neck, or facial injuries	Multiple bruises or lacerations in various stages of healing
Back, chest, or abdominal pain or tenderness	Patterned injuries that show the imprint of the object used
Injuries to the breasts, abdomen, or genitals	Burns from cigarettes, appliances, rope, or friction
Vaginal bleeding, sexually transmitted, infections	Scalding from boiling water
Dizziness, black outs	Strangulation marks
Numbness	Fractures
Injuries to the extremities	Broken bones
Delay in seeking treatment	Knife wounds
Premature removal of and infection of perineal sutures	Dental injuries (e.g., broken or lost teeth)
Distress, aggression, or withdrawn behavior during pelvic examinations, labor, and delivery	Hair loss consistent with hair pulling
Partial loss of hearing or vision	Bite marks or scratches

may present with a range of these symptoms and behaviors or none at all.

RISKS

Maternal Risks

Women who experience domestic violence have significantly poorer health outcomes than nonabused women including

- Chronic pain[51,52] (e.g., headaches, backaches, pelvic pain), hearing or vision problems,[53] sleep disturbance, poor appetite,[54] and gastrointestinal disorders such as irritable bowel syndrome.[55] These effects may be caused directly by recurrent physical or sexual injury or indirectly from underlying stress.[56]
- Gynecologic problems (e.g., urinary tract infections, pelvic inflammatory disease, vaginal bleeding, menstrual irregularities, genital irritation, and pain during intercourse).[57,58] Possible mechanisms include stress and depression, which can affect the immune system, and infection from forced and unprotected sex.[58]
- Psychosocial stress (e.g., stressful life events, financial problems, feeling unhappy about the pregnancy; perceiving her partner or family to be unhappy about the pregnancy; lack of partner or family support, and housing problems)[23,33,59,60]
- Depression,[60] especially in the postpartum period when domestic violence may get worse[17,18,61]

Fetal and Neonatal Risks

These include

- Low-birth-weight babies[62,63]
- Trauma to the abdomen may result in separation of the placenta, premature rupture of membranes, premature labor, miscarriage, and fetal death.[64–66]
- Bruising, fractures, hemorrhaging, and deformity.[67]

MANAGEMENT OPTIONS

General

Women suffering domestic violence are more likely to seek help from health care personnel than from any other statutory organization. However, qualitative studies have reported unhelpful and ineffective responses from health professionals, including a tendency to prescribe antidepressants; not enquiring directly about domestic violence; and failing to offer information about sources of support, document the abuse, and offer follow-up planning.[42,68,69] In recognition of the serious health implications of domestic violence, in the United Kingdom the Royal College of Midwives[44] and the Royal College of Obstetricians and Gynaecologists[70] have published guidelines for the identification and support of women affected by domestic violence. The Department of Health[71] has also produced a domestic violence manual for health care professionals. Similarly, guidelines for health practitioners have been developed in North America.[45,72]

Five key stages to the clinical management of domestic violence are applicable to any stage of the pregnancy and postpartum period:[44]

- Awareness and recognition of domestic violence
- Provision of a safe and quiet environment
- Identification and aiding disclosure
- Documenting the abuse
- Safety assessment, information giving, and ongoing support

Stage 1: Awareness and Recognition of Domestic Violence

All health professionals providing care for pregnant women should be aware of the potential indicators (see earlier discussion) of domestic violence and the maternal and fetal risks. Women may present with a range of physical and emotional indicators or none at all. Although these indicators may increase the index of suspicion, if abuse is suspected, enquiry about domestic violence should be made using stages 2 and 3. Health professionals should also be aware of their personal feelings about the subject and that they too can be affected by domestic violence, either as victims or perpetrators. However, their duty of care and professionalism requires them to provide an informed and nonjudgmental response to women. To this end, maternity services should work toward the development of guidelines and good practice protocols for identifying and supporting women experiencing domestic violence.

Stage 2: Provision of a Safe and Quiet Environment

The woman should be provided with a safe and quiet environment before any enquiry about domestic violence takes place. If a partner, friend, or family member has accompanied the woman, an excuse should be sought to see her alone without raising suspicion.[71] Strategies for creating private consulting time may include: requesting to see the woman alone as a routine procedure, asking the partner to wait outside at the end of the appointment to conduct a physical examination, or taking the woman to another part of the clinic for a urine sample, blood test, or weight check. Issues of safety and confidentiality should be paramount when working with women experiencing domestic violence. Children as young as 2 years may report back to the partner or family members that abuse was discussed. The woman should be reassured that any information she provides will not be shared with her partner, family members, or friends. However, the

woman must be advised about the limitations of confidentiality. If the woman does not feel safe discussing the violence in depth with her partner waiting nearby, it may be preferable to make another appointment at a time when the partner is unable to attend. Health professionals working in the community could offer to meet women at the clinic or at the home of a trusted friend or family member. If a woman has hearing difficulties or her first language is not English, arrange for a professional interpreter, preferably female, to be present. Family or friends should never be asked to translate when discussing domestic violence. Health professionals may be confronted with an angry or threatening partner who refuses to leave the room, which may be indicative of a problem within the relationship and makes it difficult to assess for partner violence. Therefore, it is best to offer a confidential time to all women at some point during pregnancy so that it becomes easier with practice. Health professionals have the right to protect themselves and withdraw from any situation where they feel their personal safety is at risk, but must also think sympathetically about the women and children who are also at risk.

Occasionally, a health professional may become aware that a child or other vulnerable person living with the abused woman is also at risk of harm. Child protection procedures should be followed. The other exceptional circumstance in which confidentiality may be breached is when the health professional becomes aware that a victim of domestic violence is at risk of serious harm or death from a violent partner. Any referrals to social services should be discussed with the mother and her consent and cooperation sought.[70,73] Much more is likely to be achieved by working openly with the woman and reassuring her that social services are able to support her in protecting herself and her children. Any information disclosed to a third party without consent should be the minimum necessary to secure the best interests of the woman and her children.[71]

Stage 3: Identification and Aiding Disclosure

Studies conducted in a range of health care settings have shown that the use of direct questions about domestic violence, asked routinely of all patients, increases the rate of detection.[74,75] Evidence shows that the majority of women find routine enquiry for domestic violence during health care appointments acceptable.[9,10]

A woman's willingness to discuss the abuse will partly depend on the approach of the health professional, and disclosure is more likely if a sensitive and nonjudgmental manner is adopted.[76,77] Important principles are to listen and offer validation of the woman's experiences, to acknowledge the seriousness of the situation, to emphasize that domestic violence is very common, that she is not to blame for the violence, and that she does not have to deal with it by herself. An expression of shock or dis-

belief could dissuade the woman from telling you more, so acknowledge her courage for being able to discuss it. These skills of providing an empathic response are similar to those used in cases of bereavement, for example.

It is recommended that the health professional begin by asking a few open-ended questions before following up with specific questions about abuse. For example:

> "How are things at home?"
> "Are you getting the support you need?"
> "Is there anything you are unhappy about?"

This will help to establish some degree of rapport with the woman.[44,70] Women often talk around the issue of domestic violence, for example, referring to feeling stressed, overwhelmed, not coping, financial worries, or housing problems. When asking directly about domestic violence, the question should be framed in a way that conveys you recognize domestic violence is an important health issue and difficult to talk about. For example:

> "Many of the women I see are experiencing some form of emotional or physical abuse from their partner, but find it difficult to bring the subject up themselves. That is why I've started to ask about it routinely."

This can be followed up with one or more direct questions that are appropriate to the situation. For example:

> "Do you ever feel afraid of your partner?"

> "Do you and your partner argue or fight? Do the arguments get physical?"

> "I've noticed a number of bruises/cuts/scratches; has someone at home hurt you?"

> "Some women tell me that their partners are cruel, sometimes emotionally and sometimes physically hurting them—is this happening to you?"

> "Does your partner ever treat you badly such as shout at you, constantly call you names, push you around, or threaten you?"

If a woman makes a disclosure of abuse, stages 4 and 5 should be followed. If a woman tells you that she has not been abused, it is important to accept her response even if you suspect otherwise as this conveys respect. However, it is important to allow the opportunity for future disclosure, by reminding her that she can talk to you about any concerns or problems at home at any time. It has been demonstrated that repeated enquiry about domestic violence increases the detection rate and it can facilitate detection of violence that begins later in pregnancy.[78]

A study from the United States tested the effectiveness of routine questioning for domestic violence in maternity settings, followed by various interventions such as referral to community resources, a counseling intervention, and counseling plus regular support from an outreach advocacy worker. This has proven to be effective in helping women to initiate seeking help and adopt safety behaviors. It has also reduced the severity of the violence over

time.[79–81] A randomized controlled trial of a community-based advocacy intervention for women entering a refuge to escape from domestic violence found that 2 years later, 1 in 4 of the intervention group did not experience further violence compared with 1 in 10 of the control group. Women who received the intervention reported a higher quality of life, increased effectiveness in obtaining their goals, and improved ability to access community resources.[82] A qualitative study of women's experiences of routine questioning during pregnancy demonstrated that simply asking about domestic violence is an important intervention in itself, by reducing the stigma attached to it, creating an environment that encourages disclosure of abuse, and directing women to sources of help.[76] Health professionals have a key role in providing women with information about services and options available to them, assessing current and future risk, and documenting the abuse. Maternity services can raise public awareness of domestic violence as an important health issue and convey the message that violence of any kind is unacceptable. Posters and leaflets about domestic violence and support services should be placed in clinic waiting rooms and areas where women will be able to access the information safely (e.g., the toilets, baby-changing rooms). These should be available in a range of languages that reflect the local community.

Stage 4: Documenting the Abuse

The medical records of treatment for any injuries or symptoms resulting from the violence are important documents. Women experiencing domestic violence are often required to provide evidence of the abuse when seeking help from agencies (e.g., housing, divorce proceedings, obtaining injunctions), and medical evidence can be important to support her statement. Documentation is also important to ensuring the flow of information to other health professionals involved in the woman's care, which will facilitate ongoing support and monitoring. Inform the woman of the benefits of documentation, even if she does not wish to take immediate action.[44,70] To maintain the woman's safety and confidentiality, domestic violence should never be recorded in places accessible to her partner (e.g., in hand-held maternity records) but in a separate record that is kept in the clinic or hospital.[71] Clear and accurate notes are important, including:

- Date and time that the abuse took place
- Where the incident occurred
- Name and relationship of the perpetrator to the woman
- Any new or old injuries sustained including psychological symptoms, information, advice or treatment offered, and whether the woman accepted this
- A body map picture can be used to indicate the location of any injuries sustained.[83]

Injuries consistent with domestic violence that are explained implausibly should also be documented in the confidential records. Records should be signed and dated. The woman's permission to share the information with other relevant health professionals must be obtained, emphasizing that information will only be shared on a "need to know" basis.

Stage 5: Safety Assessment, Information Giving, and Ongoing Support

The immediate safety of the mother and her children should be assessed by asking whether it is safe for her to return home. Inform the woman of her options and of the specialist domestic violence services in and out of her area that can provide emergency help and long-term support.[71] Provide written information about domestic violence organizations and other support services, after confirming that it is safe for her to take the information away with her. Discreet credit-sized cards may be preferable. The woman may prefer to use a telephone in a private room to contact the agencies herself, if she cannot do this at home. It is always best to encourage the woman to talk to the agencies herself so that she is in control of her sources of help and gains confidence in explaining her situation and asking for help. Health professionals can best facilitate the woman's exploration of her options by maintaining a supportive position, but avoiding personal and emotional investment in the choices she makes. Within the context of an abusive relationship, the woman's position is generally one of powerlessness.[28] By exerting medical power and seeking to control events, the health professional may increase the woman's sense of isolation and entrapment. Although it may be frustrating for the health professional when a woman does not act on advice offered, it is important to be aware of the dangers of coercing her into taking action that she is uncomfortable with. Domestic violence tends to escalate in frequency and severity when the woman attempts to leave or has left the abusive relationship, and many women are at increased risk of being murdered by their partners. Each week in the United Kingdom, two women are killed by former or current partners.[84]

Women require time to assess the risks and benefits of pursuing different options available to them. A variety of emotional and situational factors make leaving an abusive relationship difficult, and women often return to their partners several times before terminating the relationship. Isolation from friends and family, lack of self-esteem, guilt, and self-blame are just some of the reasons that women may find it difficult to confide in health professionals and other individuals for assistance. Even when women do attempt to leave, they are often forced to return to their partners because of the difficulties they encounter in trying to remain hidden.[28] For example, inappropriate accommodation, financial hardship, lack of support, loss of social networks, unemployment,

loneliness, and living in constant fear of retaliation by the abuser. Other factors that may undermine the woman's capacity to initiate change or increase her dependence on her partner include alcohol and substance misuse, mental health needs, pregnancy, having dependent children, and cultural or religious values that emphasize family and marriage over the woman's well-being.[28]

When providing information about services, health professionals should be mindful of the needs of women who may have additional issues (e.g., women with disabilities or mental health needs, black women and women from ethnic minority, asylum seekers, refugees, travelers, and lesbians). All organizations should ensure that the service they provide is accessible and competent to handle language needs and cultural sensitivity when working with women who face additional problems.

It is suggested that each woman is provided with a mutually agreed basic safety plan that can be modified over time.[71] This may include the following:

- Making a list of important phone numbers, including emergency numbers that can be called at any time of the day or night (e.g., social services, housing, the police, refuges)
- Identifying a trusted friend or family member that the woman can stay with in an emergency
- Leaving a bag packed with clothes, medicines, other essential items with a trusted friend or family member
- Having money for bus, train, cab fares
- Getting an extra set of house and car keys
- Taking original copies or photocopies of any important legal and financial papers (e.g., passport, birth and marriage certificate, bank book, rent book, credit cards)

If the woman agrees to being referred to a specialized domestic violence service, the health professional can offer to speak to someone from the organization to make an introduction, give basic details of the situation, and identify any needs. It is good practice to ensure that, wherever possible, the woman is given the option of seeing the same health professional at subsequent appointments.[71] Reconciliation work with the couple should not be attempted, as this may jeopardize the safety of both the woman and the health professional.

Domestic violence cannot be approached or managed within the traditional medical model. One public health parallel may be smoking; clinicians ask about it routinely and give advice. Even though some women will act on the advice, others may continue to smoke, though over time when the circumstances are right, many will stop. Early identification of domestic violence and support may result in improved outcomes for the mother and her baby in the long term. A woman may not take up referral options immediately, but keep the information and call for help in the future. Therefore, the quality of the health professional's response will influence future help-seeking attempts by the woman. Domestic violence is a complex issue, and health professionals should not work in isolation since many local and national initiatives offer expertise on the subject, and no single agency or professional will meet the varied needs of women and children affected by domestic violence. All statutory and voluntary organizations have a responsibility to work together to provide a high-quality, coordinated response. This requires the individuals within these organizations to have a better understanding of one another and an appreciation of the services they provide. Having a lead practitioner on domestic violence can facilitate and maintain the process of change in health professionals' attitudes and practice. Health professionals should equip themselves with the skills and knowledge necessary to provide an informed response to women affected by violence by requesting and accessing opportunities for training and education.

Finally, health professionals working with abused women should take their concerns about domestic violence to their clinical supervisor, named child protection nurse, and peers for support and supervision, while being mindful of the boundaries of confidentiality. Given the frequency of domestic violence, it is important to recognize that health professionals may themselves have experienced domestic violence, which can affect their ability to work supportively with women.[85] In these circumstances, confidential support and advice may be sought from occupational counseling services, a supervisor, or specialist domestic violence services in the community.

CONCLUSIONS

- Domestic violence is common, affecting one in three women at some point in their lives and may begin during pregnancy or escalate in frequency and severity.
- Domestic violence is an important public health issue that has serious consequences for women's physical and mental well-being. During pregnancy, there are risks to the fetus.
- No woman is immune, but those most at risk are young women, who are single, separated or divorced, and have children living at home. Other risk factors include a history of childhood sexual abuse, depression, suicide attempts, and substance misuse. Not all abused women present in the same way.
- Asking direct questions routinely about domestic violence in health settings increases the detection rate.

CONCLUSIONS (Continued)

- The woman should be provided with a private environment, and direct questions about domestic violence should be asked in a sensitive and nonjudgmental manner. Any disclosure of abuse should be followed up with an assessment of the immediate safety of the woman and any children, referral to the appropriate community resources, and clear documentation of the abuse and information offered in the confidential medical record. Ongoing monitoring and support should be provided at follow-up appointments.
- Referral to community resources may result in a reduction in the violence and increased use of community resources. Working in partnership with other health professionals and community organizations will result in a coordinated response to women and children affected by domestic violence.
- Health professionals must accept the limitations of their intervention and should not expect immediate results.

SUMMARY OF MANAGEMENT OPTIONS
Domestic Violence

Management Options (any stage of pregnancy or the postpartum)	Quality of Evidence	Strength of Recommendation	References
Stage 1: Awareness and Recognition			
Increase awareness and recognition of domestic violence and its health effects through training and education.*	IV	C	70,71
Develop guidelines for identifying and supporting women affected by domestic violence, in conjunction with other health professionals and community groups.	IV	C	70
Stage 2: Provision of Safe Environment			
Provide the woman with a safe and private environment away from partners, family, or friends.	IV	C	70,71
Stage 3: Identification and Aiding Disclosure			
When language translation is required, professional interpreters, preferably female, should be arranged.	IV	C	70,71
Ask direct questions about domestic violence, routinely.	IV	C	79,89,90
Adopt a supportive and nonjudgmental response.	III	B	70,71
Stage 4: Documenting the Abuse			
Document the abuse and any interventions offered in the confidential maternity record.	IV	C	70,71,73
Stage 5: Safety Assessment, Information Giving, and Ongoing Support			
Offer referral information about local and national organizations that provide immediate and long-term support to women and children affected by domestic violence.†	IV	C	79–81,89
Assess the immediate safety of the woman and any children.	III	B	71,73
Provide ongoing support and monitoring at subsequent appointments, ensuring continuity of care wherever possible.	IV	C	71
Display and disseminate information about local and national domestic violence organizations and other helpful agencies so that it is accessible to users and providers of maternity services.	IV	C	70,71,73
Work in partnership with local multiagency domestic violence initiatives.	IV	C	70,71,91

*Good evidence from qualitative work about the effectiveness of education and training, in increasing health professionals' knowledge and confidence in supporting abused women.[85–88]

†Little experimental work on interventions, but one randomized controlled trial showing a reduction in violence, decreased difficulty in obtaining community resources and a higher quality of life at 2 years in the intervention group compared with the control group.[82] Good evidence from qualitative work on referral systems, support, and advocacy to services outside the health sector.[92,93]

Resuscitation and Immediate Care of the Newborn

Neil Marlow / Philip Baker

INTRODUCTION

"Every maternity unit, whether or not care of sick babies is undertaken, must have clearly established arrangements for the prompt, safe and effective resuscitation of babies and for the care of babies who require continuing support, either in the maternity unit or by safe transfer elsewhere."

From: Standards for Hospitals Providing Neonatal Intensive and High Dependency Care (2nd Edition) London: BAPM 2001

Few babies need any assistance to establish normal respiration and circulation at birth, and of those who do most require only simple measures. Less than 5% of babies will need more than simple mouth suction, and most of these will require only initial help with lung inflation by mask ventilation. Very few need full resuscitation with intubation, chest compressions, and the use of drugs. All babies need care to maintain their temperature.

Formal resuscitation for about 20% of babies who require it is not predictable from clinical observations in pregnancy and during labor.[1] Prompt resuscitation of babies without apparent signs of life at birth will result in a significant number of healthy survivors.[2] Hence, wherever babies are delivered someone must be present who is trained and experienced to commence neonatal resuscitation, and someone must be available to provide expert back up for the complicated resuscitation. Generally, the local pediatric neonatal service provides the necessary expertise for the anticipated resuscitation problem, but other professionals must be prepared to commence resuscitation when it has not been anticipated. All professionals attending delivery must understand the principles of neonatal resuscitation and be able to institute effective respiration with a suitable mask ventilation system or intubation.[3]

Many centers conduct their own neonatal resuscitation training programs, which all obstetricians and midwives should attend. In addition neonatal life support courses (NLS or NALS) are now widely available. Formal training and certification by an appropriate route is encouraged for all staff.

Therefore the obstetrician must:

- Ensure the adequate provision of facilities and staff for resuscitation
- Understand the principles of resuscitation of the newborn
- Be prepared to institute neonatal resuscitation if pediatric support is unavailable, at least until help arrives

STRUCTURE OF A NEONATAL RESUSCITATION SERVICE

In many settings the service is provided by a neonatal team. However, in some settings where pediatric support is not available the obstetrician (or midwife) must assume this role. The critical elements are described in the British Paediatric Association document, "Neonatal Resuscitation,"[3] and comprise:

- Provision of training in resuscitation for all professionals involved
- Establishment of unit protocols
- Rostering individuals who are to be responsible for neonatal resuscitation and distribution of rotas to appropriate areas, such as labor suite, switchboard, neonatal unit

- Ensuring that equipment is available and working (Table 82–1)—local policy should determine who is responsible for checking this on a daily basis
- A protocol for summoning expert assistance where resuscitation is anticipated
- Ensuring a draught-free delivery room with a temperature of 24°C or greater

PHYSIOLOGY AND PERINATAL ADAPTATION

All professionals should be familiar with the normal respiratory and cardiovascular changes at birth. Acute total hypoxia in animals at delivery results in primary apnea. This is associated with initial tachycardia and rise in blood pressure, followed by bradycardia. Redistribution of blood flow occurs to essential organs (brain and heart) at the expense of others (skin, gut, and kidneys). If hypoxia persists, deep slow gasping occurs every 10 to 20 seconds before a further final period of apnea occurs, called terminal apnea. During this phase, hypotension, progressive bradycardia, and decreased cardiac output result in organ damage and death unless active resuscitation is commenced. A similar sequence of changes seems to occur

in the human newborn, but it is not always possible to differentiate primary from terminal apnea: a baby in poor condition should be assumed to be in terminal apnea, and cardiopulmonary resuscitation must be initiated without delay.

ANTICIPATION OF HIGH RISK DELIVERIES

Normal practice should be to call pediatric assistance when resuscitation may be likely (Table 82–2). Few randomized studies have been conducted in this area; evidence from them is summarized at the end of the chapter. One study identified that attending 20% of deliveries resulted in identification of 50% of deliveries with low or medium Apgar scores.[4] Most services, however, now identify three levels of pediatric input at delivery: those where attendance is required, those where pediatric help may be informed that a delivery is taking place, and those where early postnatal review is necessary (see Table 82–2). For these services, where pediatric help is readily and immediately available it may be possible simply to inform the rostered individual of the impending delivery of a fetus that is unlikely to require assistance (elective cesarean delivery at term with regional analge-

TABLE 82–1

Delivery Room Resuscitation Equipment

Equipment

Warmed towels and plastic bag
Gloves
Resuscitation trolley with overhead heater, lighting, and stop-clock
Oxygen and air supply (with reducing valve, flow meter, pressure blowoff device [set at 30 cm H_2O], pressure measuring device [e.g., manometer], and connecting tubes to supply air or oxygen to a bag and mask and (with a side hole) an endotracheal tube
Face masks (e.g., Bennett sizes 2 and 3)
500-mL resuscitation bag with a fitting for a face mask and an endotracheal tube adaptor and blowoff valve (e.g., Ambu, Laerdal)
Laryngoscopes with preterm- and term-sized straight blades (e.g., Wisconsin, Magill) and spare bulbs and batteries
Endotracheal tubes (2.5, 3.0, and 3.5 mm) with connectors and fixation devices and an endotracheal tube introducer (nylon or metal)
Oropharyngeal airways (sizes 00 and 0)
Nasogastric tubes (sizes 5 and 8)
Suction device and suction catheters (no. 4, 6, or 8 French)
Oral mucus extractors
Stethoscope
Sterile towel, scissors, and cord clamps
Antiseptic cleaning solution (e.g., povidone-iodine, chlorhexidine)
Intravenous cannulaes, three-way taps, and connecting tubing
Sterile syringes (2, 5, and 10 mL) and needles
Adhesive tape
Capillary blood sugar test strips
Alcohol swabs
Sterile containers and specimen bottles for blood tests (e.g., complete blood count, packed cell volume, electrolytes, blood sugar, bilirubin, blood typing, and Coomb's test)
Equipment for umbilical catheterization
Pneumothorax drains and Heimlich valves

Drugs and Fluids

Epinephrine	1:10,000 (10-mL ampule)
Dextrose	10% solution
Sodium chloride	0.9% solution for injection
Water for injection	
Naloxone	400 μg/mL
Volume expanders	Plasma and albumin solutions
Blood	Fresh group O Rh-negative (cytomegalovirus-negative)

TABLE 82-2

Risk Factors That Require Pediatric Staff or Staff Trained in Resuscitation

FACTOR	PRESENT	INFORMED*
Labor and Delivery		
Cesarean section for fetal indications	✓	
Cesarean section for nonfetal reasons, with regional anesthesia		✓†
Breech delivery or other malpresentation	✓	
Forceps or ventouse delivery (not simple "lift-outs")	✓	
Delivery after significant antepartum hemorrhage	✓	
Prolapsed cord	✓	
Maternal		
Maternal medical disorder that may affect the fetus	✓	
Current maternal drug or alcohol abuse		✓
Delivery under heavy sedation or general anesthesia	✓	
Fever		✓
Fetal		
Multiple pregnancy (one pediatrician for each infant)	✓	
Preterm delivery (<37 wk)	✓‡	
Prolonged membrane rupture (>24 hr) or suspected chorioamnionitis		✓
Hydramnios	✓	
Fetal distress	✓	
Known or suspected Fetal abnormality or disease	✓	
Isoimmunization	✓	

*Informed of delivery and freely available to attend within 3 to 4 minutes, if required.
†Elective cesarean section at term if the individual is available to attend, as discussed above.
‡Two individuals are advisable before 31 weeks' gestation or if the anticipated birth weight is <1500 g.

sia,[5-7] deliveries for maternal [nonfetal] reasons, simple "lift-out" forceps deliveries, certain maternal medical problems, prolonged rupture of membranes with no other risk factors). If a pediatrician is not present at delivery, prime responsibility for initiating resuscitation and summoning help, if required, remains with the delivery suite team.

PREPARATION FOR RESUSCITATION

Any individual who expects to initiate neonatal resuscitation should always introduce themselves to the parents and explain what is happening or likely to happen. He or she should obtain as full a history as possible from the mother, midwife, or obstetrician and examine the mother's chart notes to establish:

- Gestational age
- Drugs given to mother
- Evidence of fetal distress (e.g., heart rate abnormality, acidosis, meconium)
- Presence of vaginal bleeding
- Prolonged rupture of membranes
- Maternal health in labor[8]
- Number of fetuses[9]
- Relevant obstetric or medical history

In addition the person performing the resuscitation should check and prepare the necessary equipment

- Ensure the delivery room is warm (>24°C) and free of drafts

- Check that equipment is available and in working order
- Turn on overhead heater
- Ensure that warmed towels are available
- If the mother has recently received a narcotic such as pethidine (meperidine), ensure that antagonist (naloxone [Narcan]) is readily available[10]
- Wash hands, put on gloves, or take other precautions against blood-borne viruses as per hospital policy

TIMING OF BIRTH

The time of the baby's birth should be recorded so that the timing of subsequent interventions can be accurately documented.

ASSESSMENT OF CONDITION AT BIRTH

Apgar Score

Condition at birth is traditionally assessed using the Apgar score (Table 82-3), which was designed as a guide for the need for resuscitation. Measures may be made at 1 and 5 minutes with further recordings at 5-minute intervals if resuscitation continues. Ideally the Apgar score should be assessed and recorded at the time of resuscitation (originally this was done by a second observer)—retrospective assignation is fraught with errors. The Apgar score is a poor prognostic guide for later outcome, except that low Apgar scores that persist beyond 10 minutes suggest significant

TABLE 82–3

Apgar Score

	0	1	2
Heart Rate	Absent	<100 beats min	>100 beats min
Respiratory Effort	Absent	Weak	Good, crying
Muscle Tone	Flaccid	Some flexion of extremities	Well flexed
Reflex Irritability	No response	Grimace	Cough or sneeze
Color	Pale or blue	Body pink with blue extremities	Completely pink

hypoxia.[11] In practice, careful assessment of heart rate and respiration may be preferable as a simpler guide to condition of the newborn (Figs. 82–1, through 82–4).

Cord Blood Acid–Base

For babies born after fetal distress or for those needing resuscitation, the cord blood pH and base excess may indicate the severity of perinatal asphyxia. Blood from both the umbilical artery and vein should be sampled. Some infants, however, may have suffered significant intrapartum asphyxia despite a normal pH. As is true with the Apgar score, extremes of acidosis are most strongly associated with poor outcome. Cord blood acid–base status cannot be used to determine the need for resuscitation.

DIVIDING THE UMBILICAL CORD

Modern obstetric practice usually involves division of the cord while the placenta is still in utero. The time of occlusion of the umbilical cord determines the distribution of blood between the infant and placenta. Optimal distribution has not been clearly defined, but for preterm infants in particular, even a short delay in cord clamping may cause major hemodynamic advantage. The optimum distribution of blood volume and the least hemodynamic

Time of birth — Note time to calculate timings of other events if needed/start clock.

Dry and wrap baby — Even healthy babies have difficulty maintaining body temperature after birth, the risk is increased if the baby is growth impaired, preterm, ill, or sedated.

- *Minimize heat loss* by drying immediately, discarding the wet towels and wrapping the infant in a warm towel. For tiny babies, place baby inside a plastic bag without drying.
- Cover head—up to 85% heat loss may be via the head and therefore a bonnet is used during prolonged resuscitation or for very preterm children.
- *Use a radiant heater*–If resuscitation is required place the baby under a radiant heater–note that silver foil should not be used as it will reflect heat away from the baby.
- *Use an incubator or silver foil wrap (swaddler)* to transfer at risk babies.

Clear airway — Most babies do not require aspiration of the upper airway with a suction device–wipe the lips and nares during drying or with gauze (if suction is required see Figure 82-2)

Assess condition at 1 minute

- *Regular respiration and heart rate about 100 bpm*
  - Wrap infant to prevent heat loss and hand to mother or lay on mother's chest and cover with warm towels
  - Reassure mother that all is well
  - Return to make surface examination of infant when delivery procedure complete

- *No regular respiration or heart rate below 100 bpm*
  - Transfer to resuscitaire/radiant heater
  - Summon pediatric help
  - Commence resuscitation (see below)
  - Start clock to time events
  - Go to Figure 82-2

FIGURE 82–1
Basic neonatal Management after birth (1). If meconium present at birth, see Figure 82–4.

disturbance may be achieved by clamping the cord about 30 seconds after delivery.[12] By this time the infant usually has taken his or her first breath and will have received a partial placental transfusion.

After division, the cord should be firmly occluded about 2 cm from the umbilicus using a suitable umbilical cord clamp.

TREATMENT OF THE NORMAL INFANT AT BIRTH

When early assessment reveals no resuscitative problems or congenital abnormality, the baby should be handed at once to the mother. This may be done even before dividing the umbilical cord, but care should be taken to prevent heat loss (see Fig. 82–1).[13,14] The baby may be wrapped in a warmed towel or nursed skin-to-skin on the mother's chest, covered with a warm towel. If the mother intends to breast-feed, the baby should be put to the breast. This not only improves the success of lactation,[15,16] but also may aid delivery of the placenta, by encouraging the release of endogenous oxytocin. Extra care to avoid cold stress must be taken when a baby is preterm or growth restricted.

MANAGEMENT WHEN RESUSCITATION IS REQUIRED

This is approached differently for the very preterm infant (<30 wks' gestation) (see below).

RESUSCITATION OF THE FULL-TERM AND NEAR-TERM INFANT

Algorithms for management of poor condition at birth are given in Figures 82–2, 82–3, and 82–4.

Airway suction must be performed gently. There is little value in blind probing with the catheter, and pharyngeal suction should never be attempted except under direct vision using a laryngoscope. When suction is required do not use direct mouth suction because of the risk of virus transmission—a double mucus trap system or mechanical suction is preferred. The place of suction in uncomplicated resuscitation is detailed in Figure 82–1 and in the face of meconium stained liquor in Figure 82–4.[17-19]

If obstruction is suspected (cyanosis despite good respiratory effort with no audible breath sounds), direct inspection using a laryngoscope is preferred to blind aspiration;

FIGURE 82–2
Management of the moderately depressed newborn (2). If meconium present at birth, see Figure 82–4.

Severe depression at 1 minute (apnea and HR <100 bpm)

OR

No response to face mask ventilation

Secure airway

Intubate the trachea (see Procedure in Box 82-2)

Commence IPPV

First five inflations: hold 1–2 seconds ('rescue' breaths)
- Is chest wall moving?—if no, consider
  - Is the ETT displaced?
  - Is the apex beat displaced? (congenital diaphragmatic hernia)
  - Is the ETT blocked? (e.g. with meconium)
- Chest wall is moving satisfactorily—continue at 60 inflations per minute (0.5 sec inflation time)

If HR <60 bpm

Commence chest compressions

Second operator:
From the caudal end, place both hands around the chest with both thumbs meeting over the sternum and fingers behind.
Compress sternum, aiming for approximately 1–2 cm depression, at 120 bpm.
Synchronize with lung inflation 3–5 compressions: 1 inflation.

Re-evaluate in 1 min

If no heart beat or HR <60 bpm

Establish intravenous access:
- Proceed to umbilical vein cannulation
- Alternatives are peripheral venous cannula or intraosseous routes (rarely necessary)

Reassess:
- If poor heart rate persists give 10µg/kg epinephrine (0.1 ml/kg of 1:10,000 solution) followed by a saline flush
- Continue chest compressions and inflations

Reassess after 1–2 minutes
- If poor heart rate persists consider volume replacement (20 ml/kg plasma or blood) if there has been peripartum hemorrhage
- Give increased epinephrine dose (30 µg/kg adrenaline (0.3 ml/kg of 1:10,000 solution))
- Continue chest compressions and inflations

Reassess after 1–2 minutes
- If poor heart rate persists consider 1–2 mmol/kg 4.2% sodium bicarbonate
- Give final epinephrine dose (30 µg/kg adrenaline (1.0 ml/kg of 1:10,000 solution)); some sources recommend this dose every 3–5 minutes till resuscitation stops
- Continue chest compressions and inflations and reassess after a further 2 minutes

---

No response to 3 doses adrenaline

- If no response to full resuscitation detailed above after 12 minutes, discontinue further attempts

Weak pulse returns

- Consider volume replacement
- Continue attempts to establish circulation and compressions until pulse palpable >120 bpm
- If cardiac output established admit to neonatal unit for detailed assessment

Good pulse returns

- Continue lung inflation until respirations established; extubate and consider admission to neonatal unit for assessment
- If respirations do not return, admit to neonatal unit for detailed assessment

FIGURE 82–3

```

Notes:

1. The consistency of meconium is a poor guide to the need for resuscitation and for meconium aspiration syndrome.
2. If the infant is vigorous and breathing well or crying, suction under direct vision may harm the mouth and airway—simple nasal and mouth suction should suffice.
3. There is no evidence that lavage with saline is beneficial and may cause harm by removing surfactant during aspiration.

FIGURE 82–4
Management after birth when meconium present in liquor (4).

this should be followed by the placement of an oral airway. Obstruction is usually nasal and due to debris or choanal atresia/stenosis:

- Check nasal patency with stethoscope (while obstructing contralateral side).
- Aspirate nose (in choanal atresia a clear gel cast of the nasal cavity may be aspirated).
- Check for small jaw and cleft palate (in Pierre Robin syndrome, the posteriorly placed tongue may obstruct the airway in the cleft).

Face Mask Ventilation

All medical, midwifery, and nursing staff involved in care in labor must know how to instigate face mask ventilation using either a bag and mask or a mask and Y or T piece. This technique provides the initial intervention in neonatal resuscitation.[20] It is usually all that is required and may be preferred when the resuscitator is not experienced in placing an endotracheal tube; in this situation intubation may be more dangerous than continuing well-applied mask ventilation. Regular updating of skills in

mask ventilation is mandatory for all staff. Initial resuscitation should include five larger prolonged inflations (or "rescue breaths"), as a way of stimulating Heads', paradoxical reflex (a well described respiratory reflex) and starting respiration.

The relative advantages of mask ventilation using a bag set versus a Y or T piece are poorly defined and depend on local practice.

<div style="text-align:center">PROCEDURE</div>

MASK VENTILATION

Apply the correct size of face mask to fit well over the nose and mouth providing a close fit (it should not extend over the eyes or tip of the mandible (Fig. 82–5).

Hold the chin gently forward using a finger under the tip of the mandible or upward from the angle of the jaw.

Using a bag, valve, and mask (blow-off valve set at 30 cm H_2O):

- Squeeze slowly to produce an inflation time of 1 to 2 seconds for the first five ("rescue") breaths.

  Using a Y or T piece:

- Check pressure relief valve set at 30 cm H_2O or manometer in line.
- Occlude Y or T-piece for 2-second breaths for five breaths.

  Assess chest movement, if satisfactory proceed at 30 to 40 breaths/minute. If not satisfactory check:

- Is the mask application satisfactory?
- Is the airway obstructed? Consider position, oral airway.
- Is higher pressure required?

The Use of Oxygen and Air in Resuscitation

The use of air to resuscitate newborn infants is controversial.[21] For most full-term or near-term infants, it probably does not matter. However in a well-conducted randomized trial, infants of 31 weeks' gestation or more were satisfactorily resuscitated using room air,[22] oxygen concentration being increased if cyanosis persisted. For preterm infants high arterial oxygen concentrations should be avoided (generally this is taken to be above 80 mm Hg or 10 kPa[23]; there is evidence that hyperoxia may lead to cerebral vasoconstriction.[24] Moreover, oxygen-induced retinal vasoconstriction may be crucial to the early pathogenesis of retinopathy of prematurity in preterm infants.

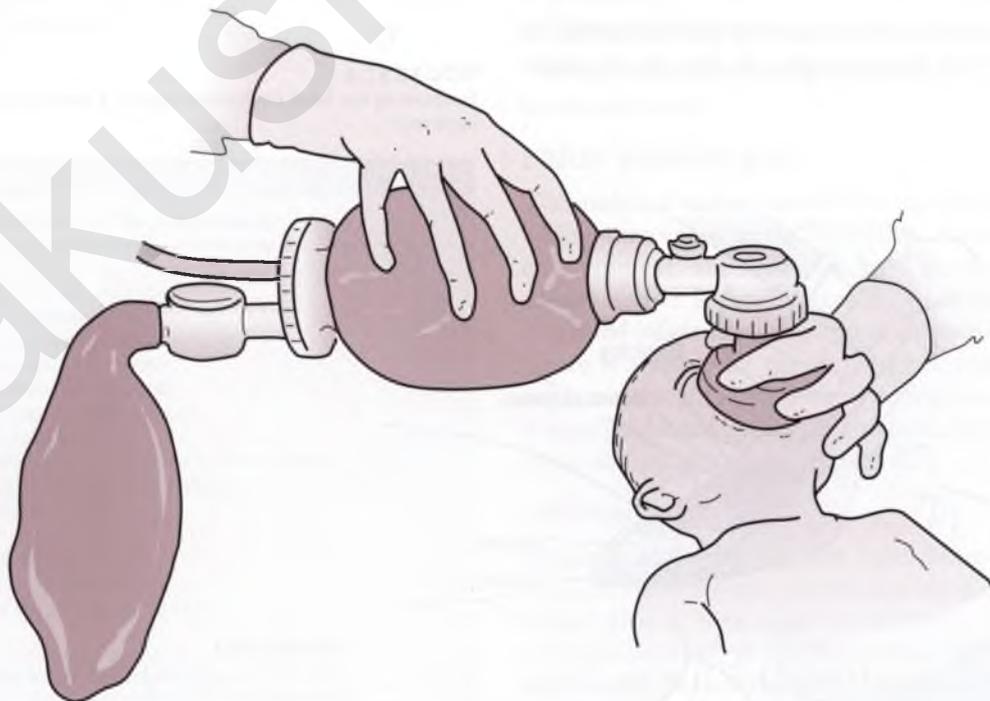
For best practice, a device for varying the inspired oxygen concentration is therefore necessary. Self-inflating (e.g., Laerdal) bags rely on the oxygen (or mixed gas) supply filling a reservoir to provide gas for ventilation. They may be used without reservoirs and with low flow rates of oxygen (4 L/min) to produce low inspired oxygen concentrations (25%–40%); this may provide a useful alternative method of resuscitating with low oxygen concentrations in the absence of a mixing device. If resuscitation is difficult, or the infant remains cyanotic, the


FIGURE 82–5
Using a bag, valve, and mask. (Reproduced with permission from Textbook of Neonatal Resuscitation, The American Heart Association.)

reservoir must be reattached before high concentrations of oxygen can be achieved.

Endotracheal Intubation

This method of ventilation is preferred for infants not responding rapidly to mask ventilation (within 1 min)[20] see Figure 82–7. Training in intubation should be undertaken by those likely to be required to perform intubation reasonably frequently, for example those likely to be called to difficult resuscitations. Formal training using models is useful before attempting it in the clinical situation.

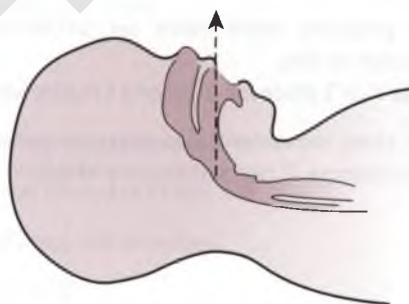
PROCEDURE

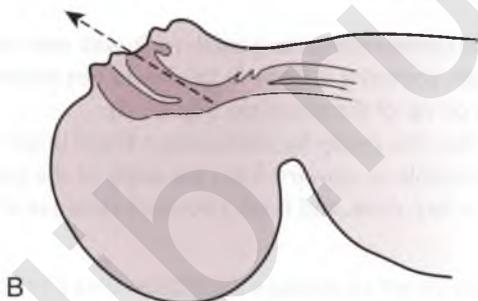
NEONATAL ENDOTRACHEAL INTUBATION

Endotracheal Tube Sizes

TUBE SIZE (MM)	GESTATIONAL AGE (WK)	ESTIMATED OR ACTUAL WEIGHT (G)
2.5	<29	<1000
3.0	30–34	1000–2000
3.0 or 3.5	34–36	2000–3000
3.5	>36	>3000

Technique

- Ensure head and neck are in line with body and neck, in the "sniffing" position (Fig. 82–6).
- Insert the laryngoscope blade over the tongue to the back of the larynx, the uvula and epiglottis will come into view (Fig. 82–7).
- Lift the epiglottis forward by exerting traction parallel to the handle of the laryngoscope—do not tilt the blade handle.




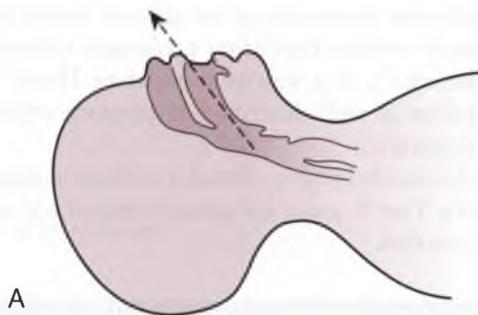


FIGURE 82–6

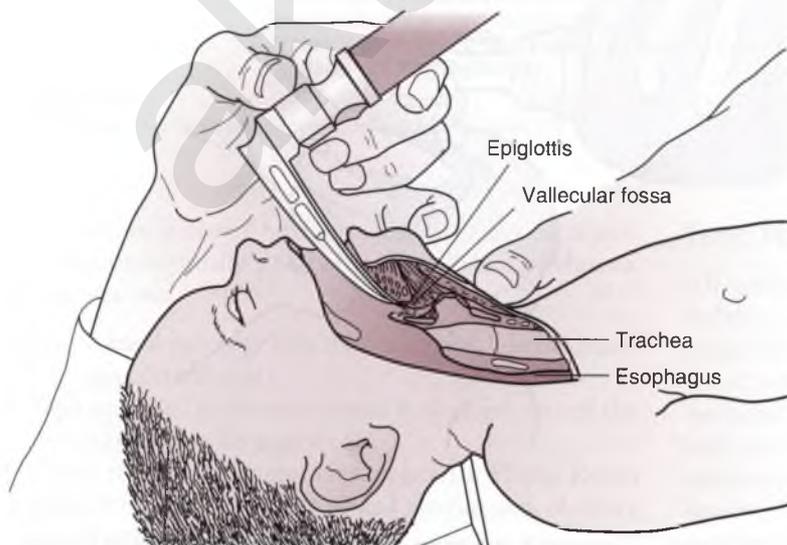
Epiglottis
Vallecular fossa
Trachea
Esophagus


FIGURE 82–7
The technique for endotracheal intubation.
(Reproduced with permission from Fleming PJ, Speidel BD, Marlow N, Dunn PM (1991). A Neonatal Vade-Mecum. London, Edward Arnold.)

- The vocal cords should then be visible. Brief suction to clear secretions may be needed. Apply gentle cricoid pressure with the fifth finger of the left hand, or an assistant may help your view.
- Keeping the trachea central, insert the appropriate size endotracheal tube (ETT) through the cords until the shoulder or 2-cm mark is at the vocal cords.
- Firmly fix the position of the ETT with the thumb and forefinger of the right hand while fixing the hand against the side of face and jaw with the other three fingers.
- Carefully remove the laryngoscope from the mouth.
- Ask an assistant to connect ETT to the ventilation device (mask or bagging set).
- Observe chest movement with ventilation, auscultate both sides—unequal air entry usually means the ETT is too far down and should be withdrawn slightly.

After intubation and five long breaths (approximately 1-second inflation time), chest wall movement is usually observed. Careful assessment to determine if the infant has improved after 30 seconds of positive pressure breaths is necessary. Tube displacement, misplacement, blockage, or congenital abnormalities may be responsible for a lack of improvement (Table 82–4). Ventilation at 40 to 60 inflations/minute (approximately 0.5-second inflation time) should continue until the infant has regular spontaneous respirations. Extubation may then be performed after mouth suction.

An ETT should never be disconnected from positive pressure for other than brief periods because of the danger of progressive atelectasis after removal of a positive end-expiratory pressure.

TABLE 82–4

Causes of Difficulty at Resuscitation

Respiratory
   Meconium aspiration syndrome
   Diaphragmatic hernia
   Pneumothorax or pneumomediastinum
   Pleural or pericardial effusion
   Congenital pneumonia or sepsis
   Pulmonary edema or hemorrhage
   Pulmonary hypoplasia
   Extreme prematurity or severe respiratory distress syndrome
   Malformation of the respiratory tract, such as congenital lobar emphysema
Cardiovascular
   Congenital heart disease
   Persistent fetal circulation
   Hypovolemia as a result of blood loss
Neurologic
   Cerebrospinal trauma, hypoxia, of malformation
   Cerebral depression caused by drugs
Other
   Severe metabolic disturbance

Chest Compressions and Cardiac Massage

Chest compressions should be commenced if the heart rate does not respond to ventilation (see Fig. 82–3). Two techniques are described: the two-hand approach has advantage under experimental conditions and is preferred. Chest compressions are performed by an assistant:

- From the caudal end, place both hands around the chest with both thumbs meeting over the sternum and fingers behind the infant's back.
- Compress the sternum using thumbs acting against fingers, aiming for approximately 1 to 2 cm depression, at a rate of about 100 to 120 compressions per minute.
- Compressions should be coordinated with lung inflations (3 compressions:1 inflation; count aloud "1-2-3-breath" until a rhythm is established). The combined rhythm should produce 30 to 40 breaths and 100 to 120 compressions per minute.

(An alternative technique is often used if a sole resuscitator is providing cardiopulmonary support: place two fingers over the sternum at the level of the nipples, depressing the sternum as previously described.)

Compressions should continue until a palpable pulse of >120 beats/minute returns or until resuscitation is discontinued. Overvigorous chest compression may cause rib fractures or liver injury.

Intravenous Drugs

Before progressing to the administration of drugs it is mandatory that the following are secured:

- Airway
- Breathing
- Chest compressions

If the infant fails to respond, intravenous drugs should be administered.

ESTABLISH INTRAVENOUS ACCESS

The umbilical venous route is the most effective for establishing intravenous access. Alternative routes are via peripheral cannulae and intraosseous infusions. Intracardiac administration is rarely necessary and dangerous in the ventilated infant as a pneumothorax could be precipitated. There is a vogue for the intratracheal instillation of epinephrine; this is an unproven route with no evidence-based dosage guidelines. Generally this route should be avoided and umbilical venous access sought.

EPINEPHRINE

Epinephrine is the first-line medication in the face of bradycardia.[25] Recent recommendations[26,27] have concurred that a first dose of 10 μg/kg (0.1 mL/kg of 1:10,000 solution) should be followed by increased doses of 30 μg/kg (0.3 mL/kg of 1:10,000 solution). If intratracheal instillation is desired, doses of 10, 20, 30 or 100 μg/kg have all been recommended. Current practice

is to give 20 μg/kg followed by 5mL saline and five long inflation breaths. In between doses of adrenaline, chest compressions per inflations should continue for at least 1 minute before reassessment. Further doses are unnecessary once the heart rate has risen above 60 beats/minute and pulses are palpable.

COLLOID (PLASMA/WHOLE BLOOD)

Hypovolemia should be considered if there is:

- Evidence of bleeding or twin-twin transfusion
- Poor pulse volume after adequate resuscitation
- Poor peripheral circulation despite adequate pulse volume
- Suspicion of hemolysis

A dose of 10 to 20 mL/kg should be administered over 5 to 10 minutes and repeated depending on response.

SODIUM BICARBONATE

Administration of alkali during resuscitation is controversial; sodium bicarbonate is a negative inotrope and correction of extracellular acidosis may worsen intracellular pH. However, one unevaluated justification for its use may be the vasodilation of coronary arteries and improvement of adrenaline delivery to the myocardium. It is not necessary to correct acidosis fully. Many neonatal units do not use sodium bicarbonate, those that do recommend 1 to 2 mmol/kg (2–4 mL 4.2% $NaHCO_3$), which may be given before the *third* dose of adrenaline.

NALOXONE

Naloxone is an opiate antagonist and is not administered as part of resuscitation after hypoxia. It may be of value for infants who have established good cardiac output but in whom respiratory depression persists and the mother has received an opiate in labor. Care should be taken not to give naloxone to infants of opiate-dependent mothers as it may precipitate acute withdrawal. Dosage is 100 mg/kg intramuscularly.[28]

OTHER MEDICATIONS

Calcium is no longer given as part of resuscitation because it may cause coronary artery constriction. Glucose solutions are generally unnecessary except as flush solutions. Hypoglycemia is unusual during the first 30 minutes because of high circulating stress hormone concentrations, but it may occur occasionally. Current recommendations are to give 2.5 mL/kg glucose intravenously if the resuscitation is prolonged (>10 min).

Failure to Respond to Resuscitation

The decision to cease resuscitative efforts should be taken by a senior and experienced doctor. Usually the obstetrician is not faced with this problem as the neonatal team will have arrived. Rarely this does not occur.

Generally, if the full resuscitation process has been carried out as detailed earlier, efforts may be stopped if there is no response after 12 minutes. However, in practice, resuscitation is rarely that efficient. It is wise to consider stopping after 20 minutes if there is no response. One senior member of the resuscitation team should discuss this with the parents wherever possible.

RECORDING OF INFORMATION

As much information about the procedures taken should be entered into the clinical notes, including the persons present (and the time of arrival if summoned), procedures undertaken, and medications given with doses and times. The results of telephone discussions should be accurately recorded.

STABILIZATION OF THE VERY PRETERM BABY AFTER BIRTH

Although most conventional teaching suggests that an identical approach is taken to the very preterm infant (babies born at 30 weeks' gestation or less), recent evidence suggests that a different approach may have value. Although this is the province of the neonatal intensive care team, all staff should be aware of the differences if called upon to help. Furthermore the use of surfactant replacement therapy is often best commenced in the delivery room for maximal effect. Many centers use endotracheal intubation less frequently and allow infants longer to establish their own respiratory drive or use continuous positive airways pressure (CPAP) from soon after birth. Where the baby is in poor condition and not responding to simple measures, including intubation, resuscitation should progress in a similar manner to that described earlier. The major areas of difference are as follows.

Prior Discussion with Parents

When possible and well before delivery, members of the neonatal team should meet with women and their partners who are expecting a very preterm baby, and both parents should visit the neonatal intensive care unit. This allows for a planned approach to the stabilization of the infant. The preliminary discussions with parents concerning prognosis should be shared between obstetric and neonatal staff, and agreed prognostic information should be available.

Thermal Care

Allowing a very preterm baby to get cold may significantly worsen the likelihood of death through increasing

the severity of the respiratory illness. Current best practice is to:

- Place the infant immediately into a plastic bag (before drying) and bring the bag up to the neck.[29]
- Dry the head and put on a bonnet before continuing with resuscitation. Leave the infant inside the bag until stabilized in an incubator.
- Cover the infant and bag with warm towels before transfer.

Surfactant Replacement Therapy

The smallest babies (i.e., babies of 26 wks' or less gestational age) should be intubated immediately after being placed in the plastic bag, and surfactant should be administered as soon as is practicable afterward.[30] Some doctors

prefer to give surfactant before the first breath. For more mature babies, surfactant is given in the neonatal unit.

Inflation Breaths

There is evidence from animal studies that large tidal volumes given after birth may produce lung injury.[31] The use of large inflation breaths should be avoided and positive end-expiratory pressure (PEEP) should be provided during resuscitation with either mask or endotracheal support. The chest excursions should be barely visible during initial inflations.

These variations from standard practice are really the province of the specialist neonatal team and we therefore reemphasize that they should be called early to provide for optimal stabilization.

CONCLUSIONS

- Someone trained in neonatal resuscitation should be immediately available for all deliveries.
- In most hospitals, a pediatrician is available to perform neonatal resuscitation.
- As far as possible deliveries where such skills may be required should be identified in advance and the pediatric staff alerted in well in advance of the delivery.
- Since some deliveries occur for which such specialists are not immediately available, all health professionals responsible for delivery (obstetricians, midwives) should receive training in and be competent to carry out effective neonatal resuscitation using, as a minimum, face mask ventilation.
- Only those who can maintain skills should receive formal training in intubation.

SUMMARY OF MANAGEMENT OPTIONS
Neonatal Resuscitation (Obstetric Perspective)

Management Options	Quality of Evidence	Strength of Recommendation	References
General and Organizational Issues			
Planning			
Wherever babies are delivered, someone capable of initiating expert resuscitation must be present.	IV	C	3, 26
Training			
Obstetricians must be able to institute effective neonatal resuscitation because neonatal staff may not be immediately available at every delivery.	–	GPP	–
Resources			
Service requirements:	IV	C	3,26,27
• Training of all professionals involved in delivery room care			
• Written protocols and lines of communication			
• Published list of available individuals who are on call for resuscitation			
• Resuscitation equipment available and working			
• Delivery room temperature at least 75°F (24°C) and no drafts

Normal Values

CONTENTS

INTRODUCTION

What Is a "Normal" Value?

"Normal" has different meanings. In the context of physical or laboratory measurements, "normal" may mean "average," "disease-free," or "within a given statistical range." However, it is important to know the characteristics of the population yielding "normal" values before deciding whether these values provide an appropriate reference range with respect to an individual. Many laboratories now print reference ranges on their reports and highlight test values that fall outside these values as "abnormal." When the test subject is a pregnant woman, a fetus, or a newborn, and the reference population is composed predominantly of middle-aged men, then comparisons are patently inappropriate. It is important to understand how the physiologic changes of pregnancy affect the results of various tests and measurements before deciding whether an out-of-range result is actually abnormal.

Changes in Pregnancy

Pregnancy results in profound changes in maternal physiology and metabolism, orchestrated by hormonal changes. Thus, physical and laboratory measurements may be very different in the pregnant state compared with the nonpregnant state and may change as pregnancy advances. Similarly, physical, biochemical, hormonal, and hematologic measurements of the fetus change markedly as the fetus increases in size and maturity. Thanks to ultrasound techniques, the fetus, once hidden within the uterus, is now accessible. Fetal structures can be measured, fetal behavior observed, and blood velocity measured with Doppler ultrasound, and a sampling needle can be used to access blood, liquor, urine, and placental and other tissues.

Statistical Terms

The terms used to define normal values depend on the distribution characteristics of data points. The entire range of values encountered in a healthy population may be quoted as reference points, or distribution may be described by terms that express central tendency and scatter. When data are distributed symmetrically around a central value (i.e., normal distribution), mean, standard deviation (SD), and standard error of the mean (SEM) are the appropriate statistics. From these, ranking values, or percentiles, may be calculated (e.g., 5th and 95th percentiles, which encompass the central 90% of data points, with 5% on either side of them). When the data distribution is skewed, median and percentiles should be used. When the data distribution is exponential, median and multiples of the median (MOM) can be used rather than percentiles. Specialized texts provide a more detailed critical

appraisal of the statistical analyses used in these studies (Altman, 1991).

Study Methods Used to Derive Normal Values During Pregnancy

Two basic designs are used for studies addressing changes in physical or laboratory values during pregnancy.

1. Longitudinal studies follow a group of women sequentially through pregnancy and compare measurements of a particular parameter with those obtained well before or at an interval after the pregnancy. Because these studies are very labor-intensive and require committed research subjects, they usually do not involve large numbers of subjects. They are very effective at showing changes with time, either between the nonpregnant and pregnant states or with advancing gestation. The variability of the data is small because the same subjects are studied sequentially. These studies are very helpful in showing how pregnancy affects measurement of a particular parameter. This benefit has particular relevance when prepregnancy values are known and the effect of pregnancy must be differentiated from disease-related changes over time. A limitation of longitudinal studies is that a narrow range of "normal" values is defined from a small number of subjects. This narrow range may not correspond to the wider range of values found in a larger group of healthy subjects studied on a single occasion.

2. Cross-sectional studies involve large numbers of subjects, each contributing one data point to the study. If the number of study subjects is large enough, then the findings provide a good idea of the true scatter of data points. These studies allow accurate characterization of mean values, standard deviations, and percentiles. For pregnancy studies, subjects must be evenly distributed throughout gestation and values must not be extrapolated beyond the gestational range actually included. These studies are essential when the ranking of a particular measurement must be determined (e.g., fetal ultrasonic measurement of abdominal circumference for a known gestational age). Most studies of fetal ultrasonic measurements and Doppler waveform indices are of this design, and their statistical methods have been described in detail (Altman and Chitty, 1994).

Opportunistic studies are also used. For example, fetal blood sampling may be done to identify infection or karyotype in a fetus unaffected by the condition. The portion of the blood sample that is not used for specific tests can be used to measure other substances. Much information available about fetal hematologic, biochemical, and endocrine function has been collected in this way. There are obvious ethical concerns about planning studies in normal fetuses requiring invasive sampling because of the risks of fetal injury and loss. However,

the selection of fetuses for study after exclusion of a particular problem means that they are not truly normal or representative of the entire fetal population. Opportunistic studies do not cover the entire range of gestational ages. Nevertheless, they provide information that would not be known otherwise.

The pregnancy studies in the literature are of mixed quality in terms of numbers of subjects included, selection criteria for subjects, sampling and laboratory techniques, and statistical interpretation. The best studies found are reported here. The methods used for each study included are described briefly and presented alongside the results. Comment sections provide interpretation of the data or a discussion of the robustness of the statistical methods, and references to the original papers are given for readers who wish to explore in greater detail. Few studies address the possible effect of maternal age, gravidity, or ethnic differences on the parameters under study. Data on many normal ranges are deficient or limited and are occasionally unreliable.

Use of Normal Ranges in Pregnancy

Some disease states are diagnosed from characteristic symptoms or signs, but others have agreed biochemical definitions. For example, diabetes mellitus is diagnosed with reference to fasting blood glucose measurements and those after a known glucose challenge (see Fig. 24). These values represent the upper limits of the normal ranges found in studies of healthy subjects. Differences in blood glucose values in pregnancy led to the suggestion that diagnostic criteria for diabetes should be adjusted in pregnancy.

Disease or organ dysfunction does not always occur at a given value of a physical or laboratory measurement outside its derived normal range. Elevated liver enzyme levels indicative of liver cell dysfunction may be 2, 10, or 50 times the normal values. However, even minimal deviation of pH from its closely clustered normal values may be biologically important.

Another use of normal values is to calculate odds ratios. Assessment of the risk or likelihood of genetic abnormalities (e.g., Down syndrome) is possible from measurement of serum α-fetoprotein, chorionic gonadotropin, or placental protein A (see Figs. 44–46). Measured values of these hormones are compared with expected values at known gestational age (derived from healthy pregnancies). The degree of difference is expressed in terms of multiples of the median values. Absolute values cannot be used for mathematical calculations because these hormonal concentrations change with gestation. For each hormone, multiple regression analysis has shown the relationships between deviations in values and the risk of Down syndrome. Thus, a woman's age-related risk of aneuploidy may be adjusted after measurement of serum hormones (Wald and associates, 1996).

Units of Measurement

When possible, both SI and traditional units are given for ease of interpretation. It is important to check the units of measurement carefully when comparing a physical or laboratory value with a normal range. In SI units, grams (g) and liters (L) are used, whereas traditional units commonly use milligrams (mg) and deciliters (dL). To avoid errors of interpretation, the prefixes d-, m-, μ-, and n-, signifying 10^{-1}, 10^{-3}, 10^{-6}, and 10^{-9} must be observed and used with care.

The terminology milliequivalents (mEq) has not been used because it has been superseded by millimoles (mmol). For monovalent ions (Na^+, K^+, Cl^-), 1 mmol = 1 mEq. For divalent ions (Mg^{2+}, Ca^{2+}, PO_4^{2+}, SO_4^{2-}), 1 mmol = 2 mEq.

MATERNAL VALUES

Physiology

Nutrition

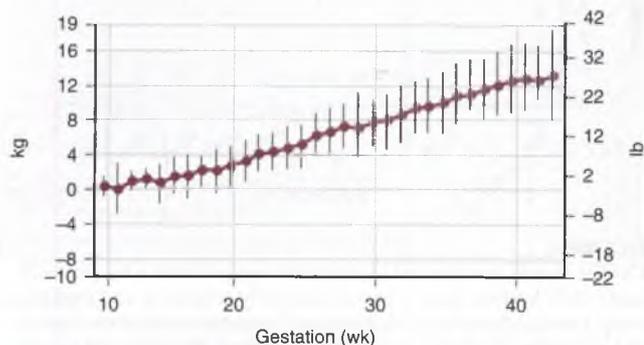
WEIGHT GAIN


FIGURE 1
Longitudinal study of maternal weight gain (mean ± SD) in 988 normal women who had uneventful pregnancies. All of the study subjects underwent initial evaluation at less than 20 weeks' gestation and were delivered between 37 and 41 weeks. *Data source:* ref. 1, with permission.

Weight-for-height category	Recommended total weight gain	
	kg	lb
Low (BMI <19.8)	12.5–18	28–40
Normal (BMI 19.8–26.0)	11.5–16	25–35
High (BMI 26.0–29.0)	7–11.5	15–25
Obese (BMI >29.0)	7	15
BMI = weight/height^2		

FIGURE 2
Recommended ranges for total weight gain during pregnancy for women with a singleton gestation, classified by prepregnancy body mass index (BMI). *Data source:* ref. 2, with permission.

> **Comment:** Average total weight gain during pregnancy is approximately 10 kg. Low weight gain during pregnancy in nonobese women has been associated with delivery of small-for-gestational-age infants.[3] However, overweight women often deliver large-for-gestational-age infants, regardless of their weight gain during pregnancy.[3]

NUTRITIONAL REQUIREMENTS

Nutritional requirements		
Nutrient (unit)	Pregnant	Lactating
Energy (kcal)	+300	+500
Protein (g)	60	65
Fat-soluable vitamins		
Vitamin A (µg retinol equivalents)	800	1300
Vitamin D (µg as cholecalciferol)	10	10
Vitamin E (mg α-tocopherol equivalents	10	12
Vitamin K (µg)	65	65
Water-soluble vitamins		
Vitamin C (mg)	70	95
Thiamin (mg)	1.5	1.6
Riboflavin (mg)	1.6	1.8
Niacin (mg niacin equivalent)	17	20
Vitamin B_6 (mg)	2.2	2.1
Folate (µg)	400	280
Vitamin B_{12} (µg)	2.2	2.6
Minerals		
Calcium (mg)	1200	1200
Phosphorous (mg)	1200	1200
Magnesium (mg)	300	355
Iron (mg)	30	15
Zinc (mg)	15	19
Iodine (µg)	175	200
Selenium (µg)	65	75

FIGURE 3
Recommended daily dietary allowance and energy intake for pregnant and lactating women. These should be used as a guide to nutritional requirements when formulating a balanced diet. *Data source:* ref. 4, with permission.

> **Comment:** The increased requirements for vitamins and minerals during pregnancy can usually be met through the diet. Therefore, routine supplementation with multivitamin preparations is not necessary. However, periconceptual supplementation with folic acid for all women is now advocated in an attempt to reduce the incidence of neural tube defects. Vitamin supplementation should be considered in women with inadequate standard diets, heavy smokers, those who abuse drugs or alcohol, and those with multiple pregnancies. Excessive intake (i.e., more than twice the recommended daily allowance) of fat- or water-soluble vitamins may have toxic effects.

Cardiovascular Function

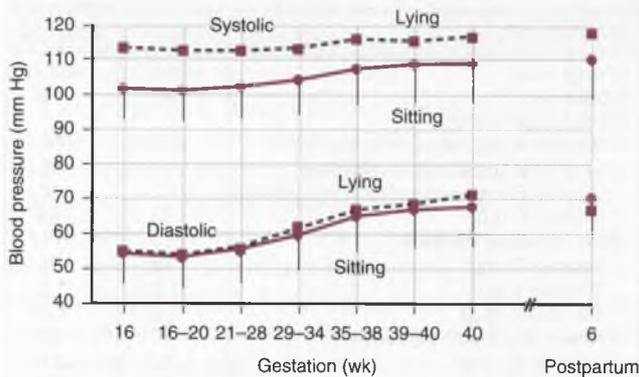
BLOOD PRESSURE


FIGURE 4

Blood pressure measurements (mean and standard deviation) from a longitudinal study of 226 primigravidae whose first attendance at the antenatal clinic was before 20 weeks' gestation. Their mean age was 24.3 years (SD, 4.9). Blood pressure measurements were taken with the London School of Hygiene sphygmomanometer to avoid terminal digit preference and observer bias. Diastolic pressures were recorded at the point of muffling (phase 4). *Data source:* ref. 5, with permission.

Comment: Systolic pressure changes little during pregnancy, but diastolic pressure decreases markedly toward midpregnancy, then rises to near nonpregnant levels by term. Thus, widening of pulse pressure occurs for most of pregnancy.

PULSE RATE

FIGURE 5

Pulse rate (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. "Nonpregnant" measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source:* ref. 6, with permission.

Comment: The typical increase in heart rate during pregnancy is approximately 15 beats/min, beginning as early as 4 weeks after the last menstrual period.[7]

CARDIAC OUTPUT

FIGURE 6

Cardiac output (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. "Nonpregnant" measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. Cardiac output was measured by an indirect Fick method. *Data source:* ref. 6, with permission.

Comment: Cardiac output increases significantly during the first trimester and remains elevated until the puerperium. When changes in body weight are considered, it is apparent that cardiac output reaches maximal values at 12 to 15 weeks' gestation and then declines gradually toward term.

INVASIVE MONITORING

Invasive monitoring		
	Non-pregnant	Pregnant
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10	83 ± 10
Systemic vascular resistance (dyne/sec/cm^5)	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dyne/sec/cm^5)	119 ± 47	78 ± 22
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure— pulmonary capillary wedge pressure (mm Hg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mm Hg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g–m/beat/m^2)	41 ± 8	48 ± 6

FIGURE 7

Findings of a study involving 10 healthy, primigravid women with a singleton pregnancy who were examined at 36 to 38 weeks' gestation and again 11 to 13 weeks postpartum. All women were younger than 26 years old. They did not smoke and were not anemic. Fetal anatomy and growth and amniotic fluid volume were normal. A pulmonary artery catheter was placed through the subclavian vein, and baseline hemodynamic assessment was made in the left lateral position after 30 minutes' rest. Cardiac output was measured with a thermodilution technique. For each subject, the result represented the mean of five independent measurements, with the highest and lowest values excluded. Central pressures were measured over three consecutive respiratory cycles. Results quoted are mean ± SD. *Data source:* ref. 8, with permission.

Comment: Systemic vascular resistance is 21% lower and pulmonary resistance is 34% lower in the late third trimester than in the nonpregnant state. Both colloid oncotic pressure and the colloid oncotic–pulmonary capillary wedge pressure gradient are lower (by 14% and 28%, respectively). Mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, and left ventricular stroke work index show no significant changes in the third trimester. These results indicate that the systemic and pulmonary vascular beds accommodate higher vascular volumes at normal pressures during pregnancy. The ventricles are dilated, and cardiac contractility does not change significantly. Because the colloid oncotic pressure–pulmonary capillary wedge pressure gradient is reduced in pregnancy, an increase in cardiac preload or an alteration in pulmonary capillary permeability predisposes the patient to pulmonary edema.

Pulmonary Function and Respiration

ARTERIAL BLOOD GASES

A

B

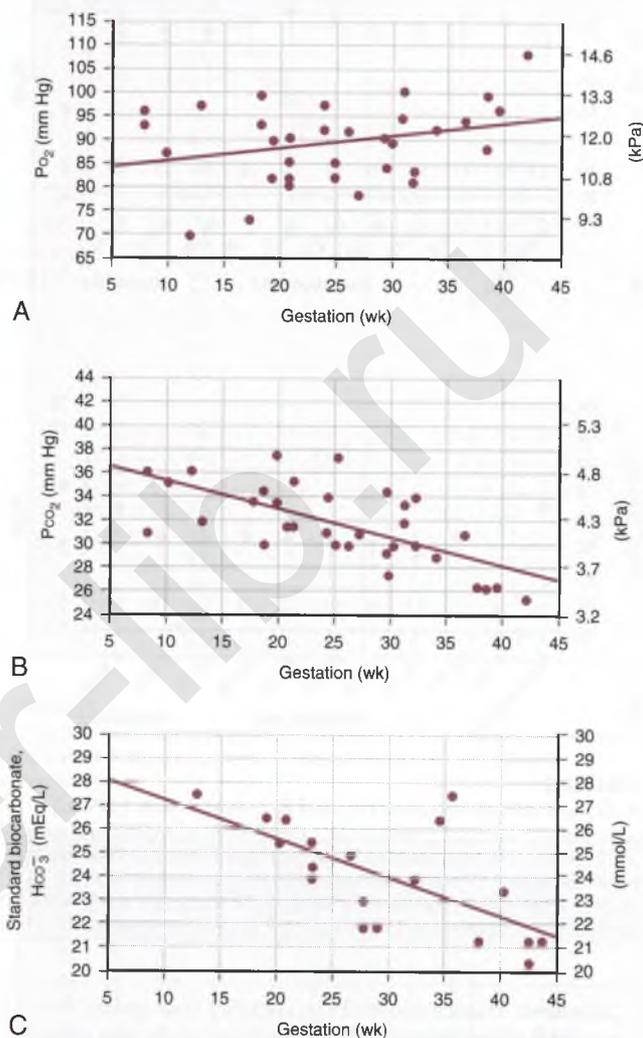
C


FIGURE 8

Arterial blood gas pressures: *A*, oxygen (PO_2), *B*, carbon dioxide (PCO_2), and *C*, standard bicarbonate (individual values, with regression lines shown) from a cross-sectional study of 37 women at 8 to 42 weeks' gestation. Blood sampling was done from a cannula inserted into the brachial artery under local anesthesia, after 30 minutes' rest in a quiet, darkened room. *Data source:* ref. 9, with permission of Elsevier Science NL, Amsterdam, The Netherlands.

Comment: Arterial pH was constant (7.47) during pregnancy in this study. PCO_2 and standard bicarbonate levels showed a significant decrease with advancing gestation, but PO_2 levels did not change significantly.

TRANSCUTANEOUS GASES

A

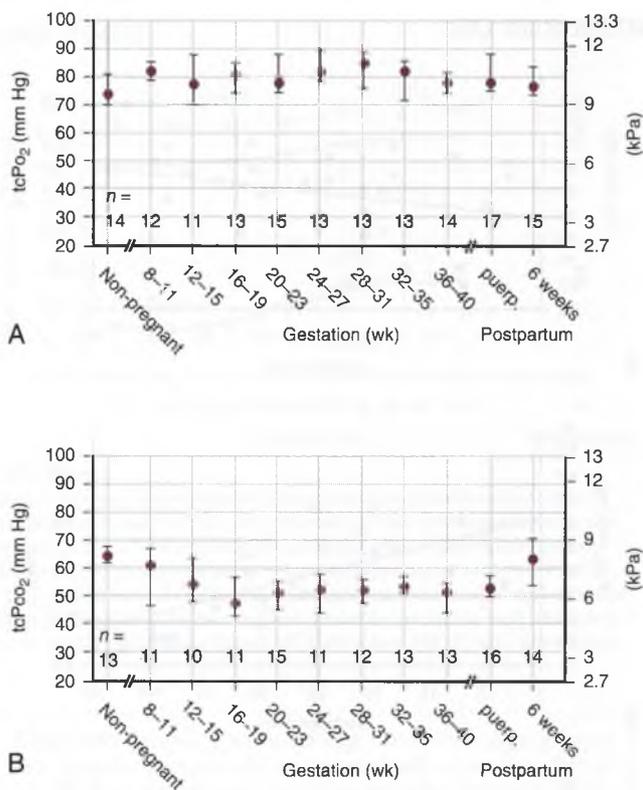
B


FIGURE 9

A, Transcutaneous oxygen ($tcPO_2$) and *B,* carbon dioxide ($tcPCO_2$) pressures (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. Nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source:* ref. 6, with permission.

Comment: Transcutaneous PCO_2 is higher than arterial PCO_2 as a result of temperature differences between the skin surface and blood as well as the addition of CO_2 by skin metabolism (conversion factor, approximately 1.4).[6] Transcutaneous PO_2 values in adults are 10% to 20% lower than arterial PO_2 values. In this study, the increase in $tcPO_2$ and the decrease in $tcPCO_2$ during pregnancy were significant.

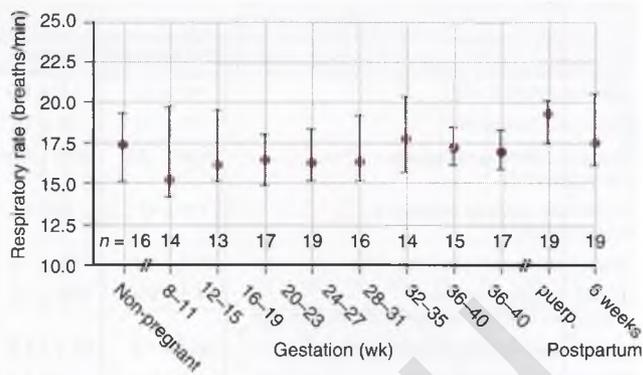
RESPIRATION RATE


FIGURE 10

Respiration rate (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter; nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source:* ref. 6, with permission.

Comment: The respiration rate is similar in pregnant and nonpregnant women.

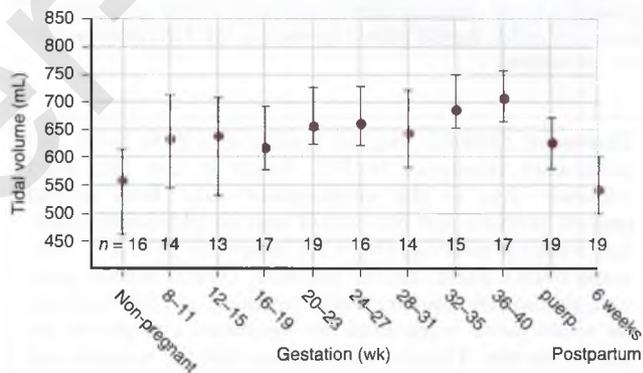
TIDAL VOLUME


FIGURE 11

Tidal volume (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. Nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source:* ref. 6, with permission.

Comment: Tidal volume increases early in pregnancy and continues to rise until term; overall, a 30% to 40% rise occurs. By 6 to 8 weeks postpartum, tidal volumes return to nonpregnant values. Minute ventilation increases in parallel with tidal volume; typical values are 7.5 L/min in nonpregnant women and 10.5 L/min in late pregnancy.[10]

RESPIRATORY FUNCTION TESTS

	During pregnancy			After delivery
Respiratory function tests	10 weeks	24 weeks	36 weeks	10 weeks postpartum
Vital capacity (L)	3.8	3.9	4.1	3.8
Inspiratory capacity (L)	2.6	2.7	2.9	2.5
Expiratory reserve volume (L)	1.2	1.2	1.2	1.3
Residual volume (L)	1.2	1.1	1.0	1.2

FIGURE 12

Respiratory volumes (mean values) from a longitudinal study of eight healthy women 18 to 29 years old who were studied through pregnancy and again 10 weeks postpartum. All tests were done with the patient in the sitting position. *Data source:* ref. 10, with permission.

Comment: In some women, vital capacity increases by 100 to 200 mL during pregnancy, but the converse is seen in obese women.[11] Anatomic changes (flaring of the lower ribs, a rise in the diaphragm, and an increase in the transverse diameter of the chest) are responsible for alterations in lung volume subdivisions.[11] Forced expiratory volume in 1 second (FEV_1) and peak expiratory flow rate (PEFR) are unaffected by normal pregnancy.[10] The gas transfer factor (i.e., pulmonary diffusing capacity with carbon monoxide) decreases in pregnancy.[10] This decrease has been attributed to altered mucopolysaccharides in the alveolar capillary walls as well as lower circulating levels of hemoglobin.

Chromosomal Abnormalities

Maternal age at delivery (years)	Risk of Down's syndrome
15	1 : 1578
20	1 : 1528
25	1 : 1351
30	1 : 909
31	1 : 796
32	1 : 683
33	1 : 574
34	1 : 474
35	1 : 384
36	1 : 307
37	1 : 242
38	1 : 189
39	1 : 146
40	1 : 112
41	1 : 85
42	1 : 65
43	1 : 49
44	1 : 37
45	1 : 28
46	1 : 21
47	1 : 15
48	1 : 11
49	1 : 8
50	1 : 6

FIGURE 13

The risk of having a pregnancy affected by Down syndrome according to maternal age at the time of birth. *Data source:* ref. 12, with permission.

Maternal age	Rate per 1000				
	Trisomy 21	Trisomy 18	Trisomy 13	XXY	All chromosomal anomalies
35	3.9	0.5	0.2	0.5	8.7
36	5.0	0.7	0.3	0.6	10.1
37	6.4	1.0	0.4	0.8	12.2
38	8.1	1.4	0.5	1.1	14.8
39	10.4	2.0	0.8	1.4	18.4
40	13.3	2.8	1.1	1.8	23.0
41	16.9	3.9	1.5	2.4	29.0
42	21.6	5.5	2.1	3.1	37.0
43	27.4	7.6		4.1	45.0
44	34.8			5.4	50.0
45	44.2			7.0	62.0
46	55.9			9.1	77.0
47	70.4			11.9	96.0

FIGURE 14

Chromosomal abnormalities by maternal age at the time of amniocentesis performed at 16 weeks' gestation (expressed as rate per 1000). *Data source:* ref. 13, with permission.

Comment: The incidence of chromosomal disorders increases with maternal age but is not affected by paternal age.[13] Trisomy 21 (Down syndrome) is the most important numerically of these disorders, with an overall population incidence of 1 in 650 live births. Trisomies 13, 18, and 22 are rare in live births. Other autosomal trisomies are nonviable and are common in spontaneous abortions.

Biochemistry

Hepatic Function

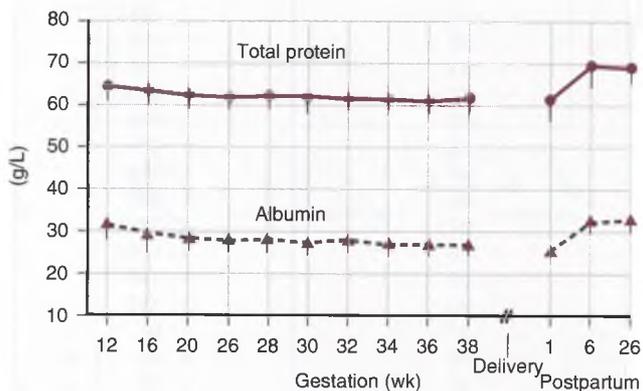
TOTAL SERUM PROTEIN AND ALBUMIN


FIGURE 15

Total serum protein and albumin (mean and SD) from a longitudinal study of 83 healthy pregnant women (77 of whom were primigravidae) who were recruited at 12 weeks' gestation. Samples were collected every 4 weeks during pregnancy, 7 days postpartum, and again 6 and 26 weeks postpartum. *Data source:* ref. 14, with permission.

Comment: Decreased total serum protein and albumin concentrations in pregnancy are associated with a decrease in colloid osmotic pressure.[14] Serum immunoglobulin levels do not change significantly in pregnancy.[15]

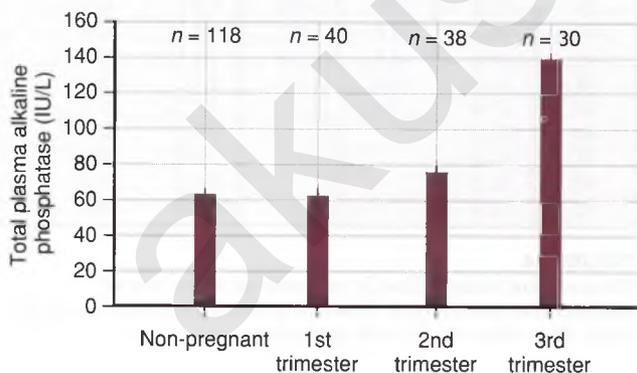
LIVER ENZYMES, SERUM BILE ACIDS, BILIRUBIN, AMYLASE, COPPER, AND ZINC


FIGURE 16

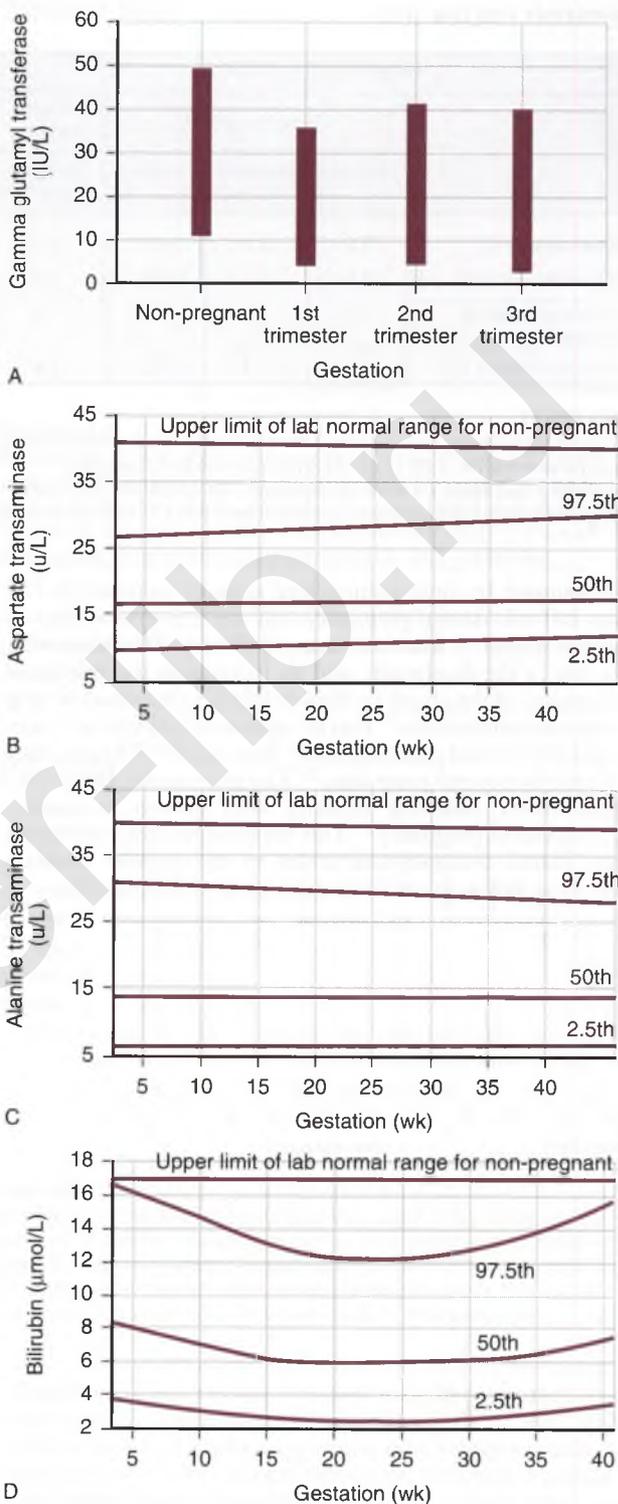
Total alkaline phosphatase levels (mean and SEM) from a cross-sectional study of 108 women attending a hospital antenatal clinic in Nigeria. The nonpregnant control subjects of similar age were patients attending the gynecologic clinic. No patients were clinically anemic, and all were normotensive. *Data source:* ref. 16, with permission.


FIGURE 17

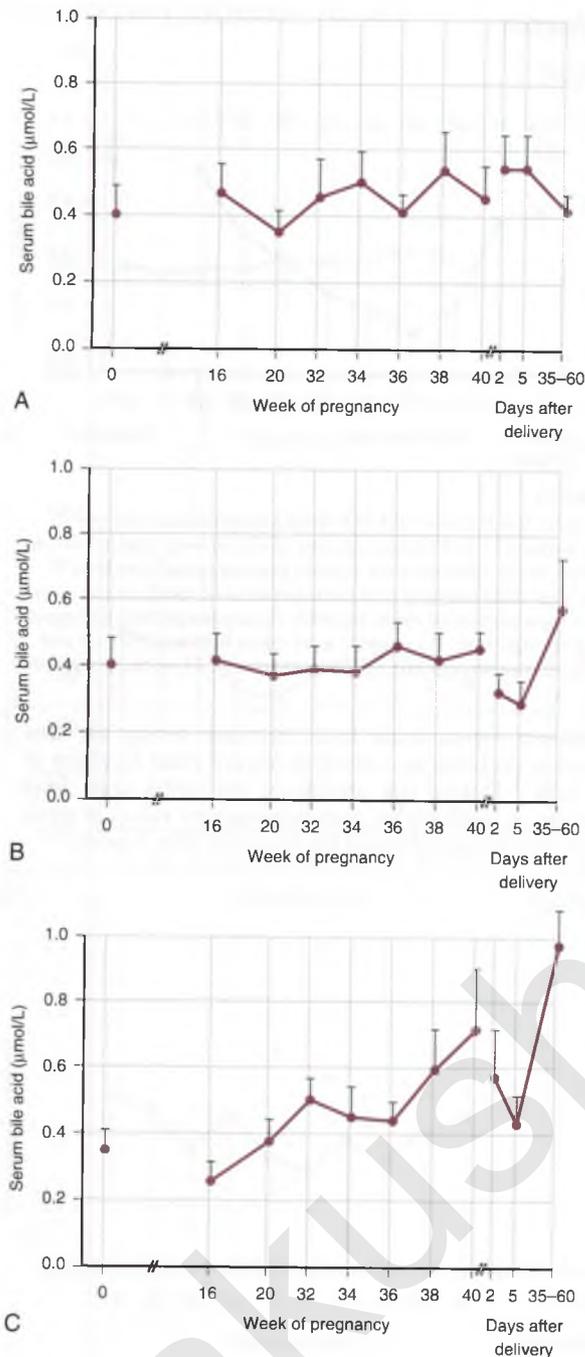
A, Serum γ-glutamyl transferase (GGT), *B*, aspartate transaminase (AST), *C*, alanine transaminase (ALT), and *D*, bilirubin (95% reference ranges) from a cross-sectional study of 430 women with uncomplicated singleton pregnancies. No subjects had hypertension or liver disease, were taking drugs associated with liver dysfunction, or were consuming more than 10 units of alcohol weekly. Data for GGT were not normally distributed, and the results presented are calculated from the nonparametric determination of percentiles. Data for AST, ALT, and bilirubin were normally distributed after logarithmic transformation, allowing gestation-specific percentiles to be calculated. *Data source:* ref. 17, with permission.


FIGURE 18

A, Serum cholic acid (CA), B, deoxycholic acid (DCA), and C, chenodeoxycholic acid (CDCA) (mean and SD) from a longitudinal study of 30 healthy pregnant women. The subjects had uncomplicated pregnancies and no history of hepatobiliary disease. Blood samples were taken after an overnight fast. Most women were recruited at 12 to 17 weeks' gestation and gave blood samples at 18 to 22 weeks, every 2 weeks in the third trimester, and on three occasions up to 35 to 60 days after delivery. Bile acids were measured separately by radioimmunoassay, and the results presented are for total concentrations (i.e., free plus conjugated bile acid). *Data source:* ref. 18, with permission.

Comment: Total plasma alkaline phosphatase (AP) levels are approximately doubled by late pregnancy. Almost half of the total plasma AP in pregnancy is placental AP isoenzyme, but bone AP isoenzyme levels are also markedly increased. Liver AP isoenzyme levels do not change significantly in pregnancy.[16] Serum γ-glutamyl transferase (GGT) and transaminase levels overall are lower in pregnancy than in the nonpregnant adult population. There are no significant gestational changes in GGT, AST, or ALT, but all increase after delivery, especially after cesarean section.[19] During pregnancy, bilirubin levels remain within the normal range for adults.[20] Serum concentrations of the primary bile acid, cholic acid (CA), and the secondary bile acid, deoxycholic acid (DCA), do not change during pregnancy, but chenodeoxycholic acid (CDCA) levels increase significantly toward term.[18] These minor changes in serum bile acid levels may be caused by changes in bile acid metabolism and excretion as a result of high circulating levels of estrogen and progesterone, but may show a tendency to cholestasis in normal pregnancy. No data are available on serum amylase in pregnancy, but decreased concentrations may be expected as a dilutional effect. Serum copper levels are increased in pregnancy, but zinc levels are decreased compared with those in nonpregnant women.[21] There are considerable differences between laboratories with regard to liver enzyme assays and resultant variability in "normal ranges" in adults. These differences should be borne in mind when interpreting individual results from pregnant women.

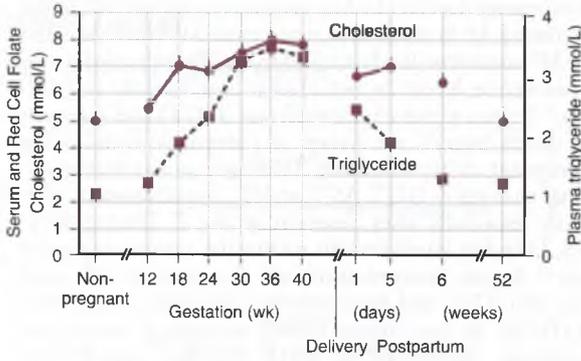
LIPIDS: CHOLESTEROL AND TRIGLYCERIDE


FIGURE 19

Plasma cholesterol and triglyceride levels (mean and SEM) from a longitudinal study of 43 women 20 to 41 years old. Samples were taken after an overnight fast and 10 minutes' supine rest at 4- to 6-week intervals through pregnancy, during labor, and in the puerperium. Samples were also taken 12 months after delivery in 14 of the subjects. The nonpregnant reference samples were obtained from 15 subjects of comparable age. No dietary restrictions were imposed. *Data source:* ref. 22, with permission. *Conversion factors:* cholesterol, mmol/L × 38.5 = mg/dL; triglyceride, mmol/L × 88 = mg/dL.

Comment: During pregnancy, plasma cholesterol doubles and a threefold increase in plasma triglyceride concentration occurs. The lipid content of low-density lipoproteins increases in pregnancy, as does the high-density lipoprotein triglyceride content.[22] Serum lipid levels decrease rapidly after delivery, but cholesterol and triglyceride concentrations remain elevated 6 to 7 weeks postpartum. Lactation does not affect lipid levels.[22]

Renal Function

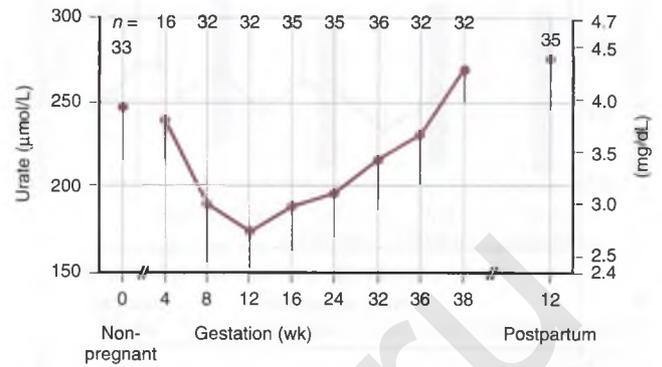
SERUM URATE


FIGURE 20

Serum urate levels (mean and SD) from a longitudinal study of 31 healthy women 23 to 37 years old, five of whom were studied during two pregnancies. Subjects were studied preconceptually, at least 3 months after discontinuing oral contraceptives (if used), in the luteal phase of their menstrual cycle, monthly during pregnancy, and again 12 weeks postpartum. All samples were taken between 9:00 AM and 9:30 AM, after overnight fasting. *Data source:* ref. 23, with permission.

Comment: Serum urate levels decrease during the first trimester, probably as a result of altered renal handling of uric acid.[23] During late pregnancy, the serum urate level increases to levels higher than nonpregnant values at term. Levels may remain elevated for 12 weeks after delivery.[23]

SERUM OSMOLALITY, ELECTROLYTES, AND UREA

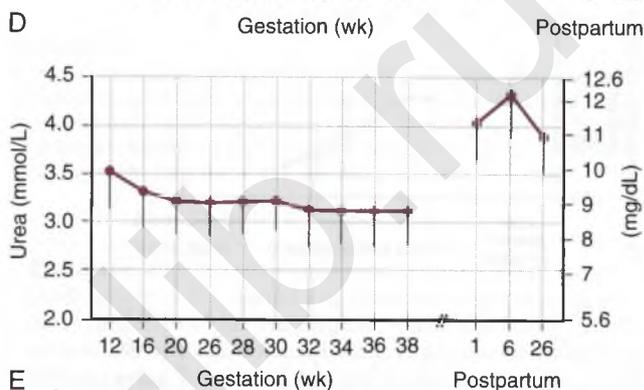
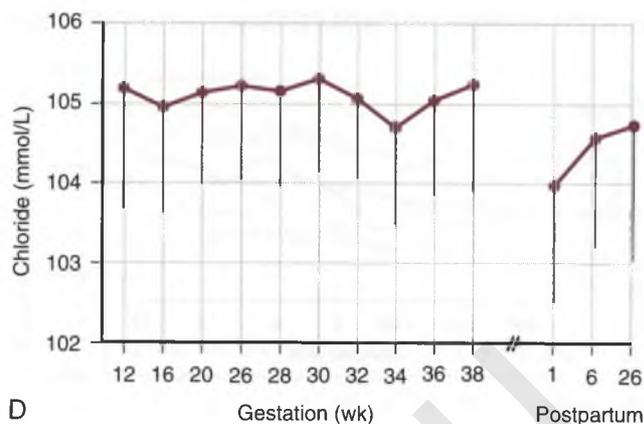
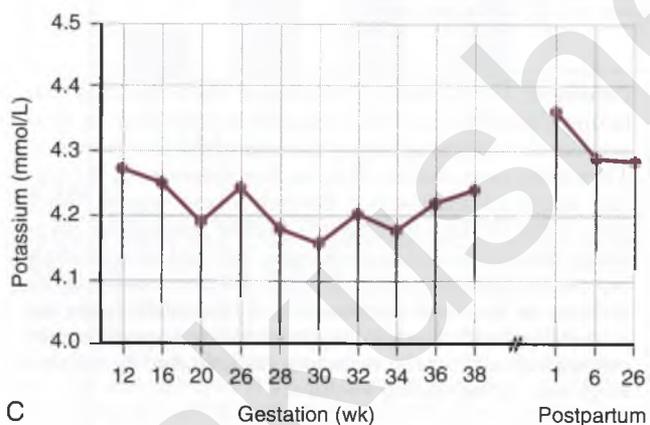
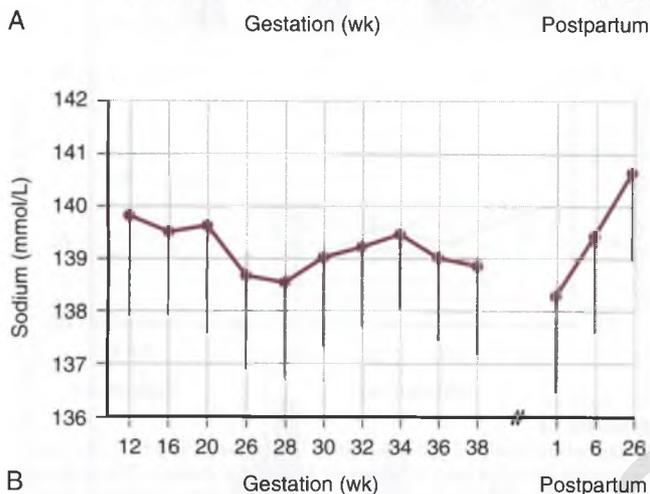
E








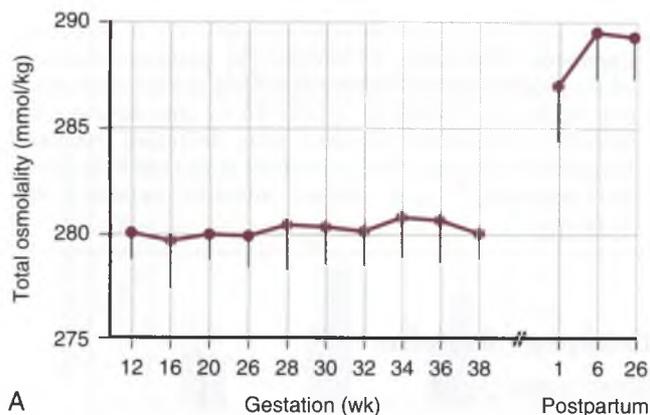


FIGURE 21
Serum osmolality (*A*), electrolytes (*B–D*), and urea (*E*), (mean and SD) from a longitudinal study of 83 healthy pregnant women (77 of whom were primigravidae), recruited at 12 weeks' gestation. Samples were collected every 4 weeks during pregnancy, 7 days postpartum, and then 6 and 26 weeks postpartum. *Data source:* ref. 14, with permission.

Comment: Total osmolality decreases by the end of the first trimester to a nadir 8 to 10 mmol/kg below nonpregnant values. Concentrations of the major serum electrolytes (sodium, potassium, chloride) are almost unchanged during pregnancy. Bicarbonate and phosphate concentrations decrease during pregnancy.[24] Plasma urea and creatinine decrease during pregnancy; typical mean (SD) values for plasma creatinine are 60 (8), 54 (10), and 64 (9) μmol/L in the first, second, and third trimesters, respectively, increasing to 73 (10) μmol/L by 6 weeks postpartum[25,26] (see also Fig. 22b).

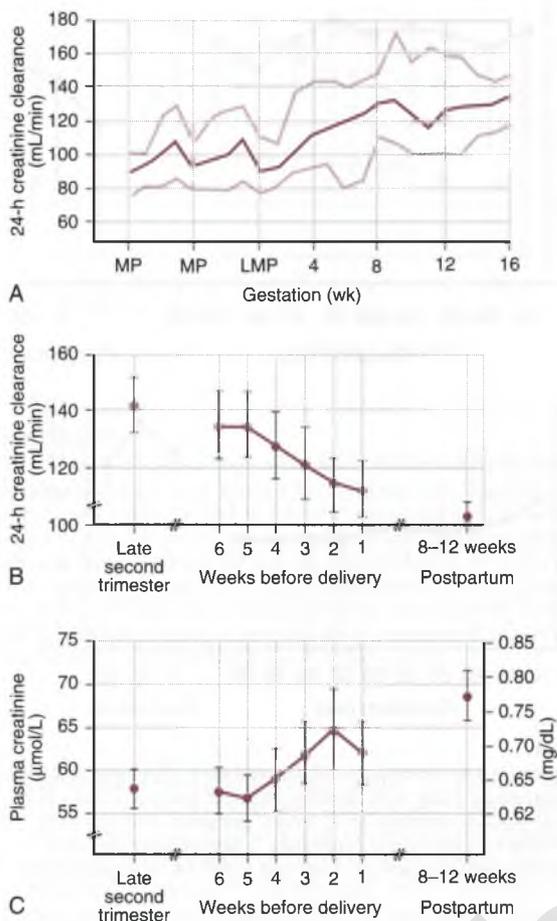
CREATININE CLEARANCE AND PLASMA CREATININE


FIGURE 22

A, Creatinine clearance (mean and range) in early pregnancy from a longitudinal study of nine healthy women who were recruited before pregnancy. Measurements of 24-hour creatinine clearance were made weekly, through the different phases of the menstrual cycle, and up to 16 weeks' gestation. No diet, fluid, or exercise restrictions were imposed. *Data source:* ref. 27, with permission. *B,* Creatinine clearance and *C,* plasma creatinine (mean ± SEM) in the second and third trimesters from a longitudinal study of 10 healthy pregnant women. Creatinine clearance was measured once between 25 and 28 weeks' gestation, weekly from 32 weeks until delivery, and once between 8 and 12 weeks postpartum. *Data source:* ref. 28, with permission.

Comment: The glomerular filtration rate (GFR) and effective renal plasma flow increase in early pregnancy to levels approximately 50% above nonpregnant values. In the third trimester, the GFR decreases by approximately 15%.[28] The 24-hour creatinine clearance measurements mirror these changes. During the menstrual cycle, a 20% mean increase in creatinine clearance occurs between the week of menstruation and the late luteal phase.[27]

URINE COMPOSITION: GLUCOSE, AMINO ACIDS, AND PROTEIN

Comment: Glycosuria is common in pregnant women whose plasma glucose concentrations and glucose tolerance test results are normal. It is believed to arise because of increased glomerular filtration plus decreased tubular resorption of glucose.[29] Aminoaciduria is also reported during pregnancy,[30] and urinary albumin excretion is increased.[31]

Carbohydrate Metabolism

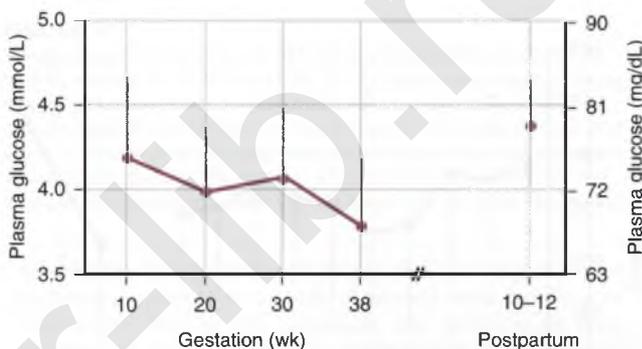
FASTING PLASMA GLUCOSE


FIGURE 23

Longitudinal study of plasma glucose levels (mean and SD) after an overnight fast of at least 10 hours in 19 healthy women. The subjects were not obese and had no family history of diabetes mellitus. *Data source:* ref. 32, with permission.

Comment: Other studies[33] confirmed these findings that fasting plasma glucose levels decrease in pregnancy. In most women, the decline occurs by the end of the first trimester. Thereafter, most studies show further decreases in the second and third trimesters.[33] Severely obese women (body mass index [BMI] >30.0 kg/m^2) studied throughout pregnancy did not show these changes, but had progressively increasing plasma glucose levels.[33] Plasma insulin levels increase in the third trimester.[32,34] Ethnic differences are seen in insulin production (as measured by C-peptide concentrations) and insulin resistance (as indicated by insulin-to-glucose ratios) during pregnancy.[34]

GLUCOSE TOLERANCE TEST (GTT)

A

SERUM FRUCTOSAMINE AND GLYCOSYLATED HEMOGLOBIN

FIGURE 25
Serum fructosamine (median, 5th, and 95th percentiles) from a cross-sectional study of 1200 pregnant women at different gestational ages, compared with 1650 nonpregnant women 15 to 40 years old. Women with known diabetes or previous gestational diabetes were excluded from the study. *Data source:* ref. 38, with permission.

Comment: Serum fructosamine concentrations are significantly lower in the second and third trimesters than in the first trimester or the nonpregnant state. Decreasing total protein and albumin concentrations in pregnancy may contribute to this reduction.[38] In some studies, values for glycosylated hemoglobin (Hb A$_1$ and Hb A$_{1c}$) during pregnancy in healthy women were lower in the first and second trimesters,[33,39] but in other studies, they were similar to values in nonpregnant women.[40]

B

FIGURE 24
A, Plasma glucose values (median, 2.5th, and 97.5th percentiles) after a 75-g oral glucose load. Cross-sectional study of 111 healthy women younger than 35 years old, weighing less than 85 kg, with singleton pregnancies (*n* = 43 and 168 in the second and third trimesters, respectively). None had a personal or family history of diabetes mellitus. *Data source:* ref. 35, with permission. *B,* Plasma glucose values (median, 5th, and 95th percentiles) after a 100-g oral glucose load. The study involved 93 women in the first trimester, 121 in the second trimester, and 98 in the third trimester. All were healthy, were not obese, had no family history of diabetes, and had no obstetric complications. *Data source:* ref. 36, with permission.

Comment: Women in the third trimester have decreased glucose tolerance, as judged by criteria used to diagnose diabetes outside pregnancy. Gestational diabetes may be diagnosed when two or more of the following plasma glucose levels are found on 100-g GTT: ≥105 mg/dL (fasting), ≥190 mg/dL (1 hour), 165 mg/dL (2 hours), and ≥145 mg/dL (3 hours). These values are 5.8 mmol/L (fasting), 10.6 mmol/L (1 hour), 9.2 mmol/L (2 hours), and 8.1 mmol/L (3 hours).[37]

AMNIOTIC FLUID INSULIN, GLUCOSE, AND C-PEPTIDE

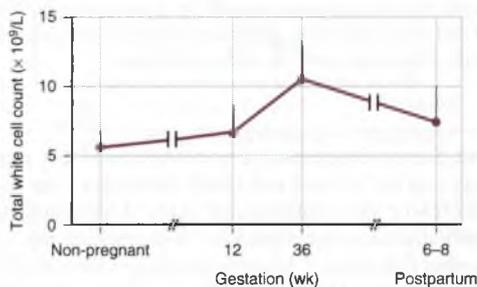
Amniotic fluid insulin, glucose, and C-peptide					
		Glucose (nmol/L)	Immunoreactive insulin (pmol/L)	C-peptide (pmol/L)	C-peptide/ insulin molar ratio
Early pregnancy	*n* = 77	3.44 ± 0.22	44.2 ± 2.1	38 ± 2.0	0.97 ± 0.06
Late pregnancy	*n* = 33	0.72 ± 0.11	45.5 ± 2.6	218 ± 54	4.3 ± 1.2

FIGURE 26
Insulin, glucose, and C-peptide levels in amniotic fluid (mean ± SD) from a cross-sectional study of 110 nondiabetic women who had amniocentesis in pregnancy (mostly for karyotyping). *Data source:* ref. 41, with permission.

Comment: Insulin and C-peptide levels in amniotic fluid can be studied as markers of fetal pancreatic β cell function. C-peptide and insulin are normally secreted in equimolar amounts from β cells. C-peptide may be the more reliable marker because insulin is degraded in the fetal liver and circulating insulin antibodies may be present.[41] In pregnant women with diabetes, concentrations of these substances are greater and third-trimester values are correlated with neonatal complications (macrosomia, hypoglycemia, jaundice, respiratory distress).[42] The midtrimester insulin concentration in amniotic fluid is also greater in women who subsequently had gestational diabetes.[43]

Antioxidants

> **Comment:** In pregnancy, levels of vitamin E (a free radical scavenger that opposes the effects of lipid peroxides) are increased compared with the nonpregnant state.[43] Vitamin E levels increase progressively with gestation, whereas lipid peroxide levels are constant.[44] Ascorbic acid concentrations in maternal serum during the third trimester and in breast milk during lactation are related to dietary consumption of fruit and vegetables.[45]

Hematology
White Blood Cell Count (Total and Differential)


A

	Week 33 (n = 151)	Week 36 (n = 146)	Week 39 (n = 130)	Postpartum (n = 91)	Non-pregnant range
Total white cell count (WBC) 10^9/L	9.1 (5.7–14)	8.9 (6.1–15)	9.0 (6.0–16)	16 (9.4–25)	(4.0–9.0)
Neutrophils 10^9/L	6.5 (3.5–11)	6.4 (4.1–11)	6.5 (3.7–13)	14 (6.6–23)	(1.8–6.7)
Lymphocytes 10^9/L	1.7 (0.9–2.8)	1.8 (1.1–2.8)	1.8 (1.1–2.9)	1.1 (0.5–2.4)	(0.8–4.0)
Monocytes 10^9/L	0.50 (0.2–1.0)	0.50 (0.3–1.0)	0.50 (0.28–0.90)	0.53 (0.3–1.2)	(0.10–0.90)

B

FIGURE 27

A, Total white cell count (mean and SD) from a longitudinal study of 24 women who were recruited at 12 weeks and were delivered after 37 weeks. Nonpregnant samples were taken 4 to 6 months after delivery. Samples were analyzed in a Coulter counter. *Data source:* ref. 46, with permission. *B,* Total and differential white cell counts from a semilongitudinal study of 153 healthy pregnant women who were taking iron supplementation. All of the subjects had at least one previous normal pregnancy. Postpartum samples taken from women who were eventually delivered by cesarean section were excluded from analysis. *Data source:* ref. 47, with permission.

> **Comment:** Supplementation with iron and folate does not affect the total white blood cell (WBC) count during or after pregnancy.[46] No studies reported WBC values during labor, but in the early postpartum period, very high values (up to 25 × 10^9/L) may be normal.[47] Pregnancy-related changes in the WBC count are still present 6 to 8 weeks after delivery. Immature granulocytes (myelocytes and metamyelocytes) are often found in peripheral blood smears during pregnancy.[48]

Hemoglobin and Red Blood Cell Indices

Hemoglobin and red blood cell indices				
Parameter	Non-pregnant (SD)	12 weeks (SD)	36 weeks (SD)	Postpartum (SD)
Red blood cell count (× 10^{12}/L)	4.688 (0.309)	4.008 (0.247)	3.880 (0.304)	4.493 (0.338)
Hemoglobin concentration (g/dl)	13.20 (0.77)	12.03 (0.70)	11.07 (0.84)	12.69 (0.92)

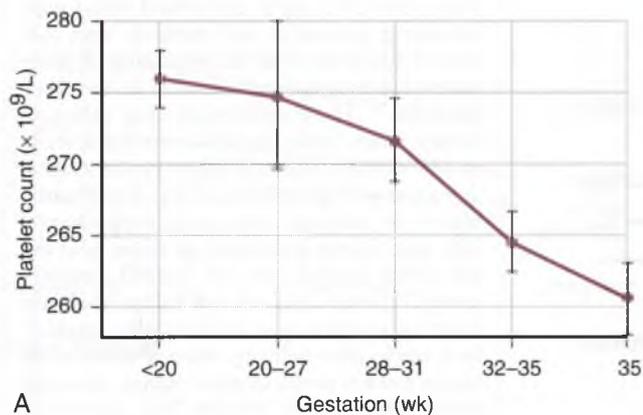
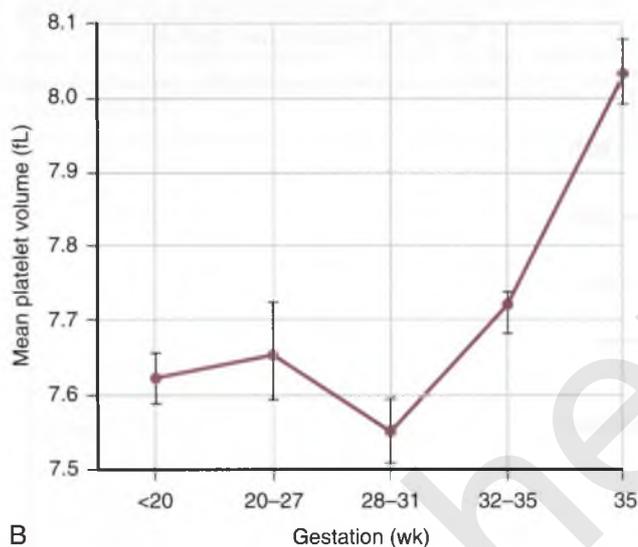
B

FIGURE 28

A, Hemoglobin and red blood cell indices (mean and SD) from a longitudinal study of women who were recruited at 12 weeks and were delivered after 37 weeks (*n* = 24). No iron or folate supplements were given. Nonpregnant samples were taken 4 to 6 months after delivery. Samples were analyzed in a Coulter counter. *B,* Hemoglobin and red blood cell indices (mean and SD) from a longitudinal study of women who were recruited at 12 weeks and were delivered after 37 weeks (*n* = 21). All were given iron and folate supplements from 12 weeks' gestation. Nonpregnant samples were taken 4 to 6 months after delivery. Samples were analyzed in a Coulter counter. *Data source:* ref. 46, with permission.

> **Comment:** Hemoglobin concentration decreases in the first trimester, regardless of whether iron and folate supplements are given. Pregnancy-induced hematologic changes are still present 6 to 8 weeks postpartum.

Platelet Count and Indices


A


B

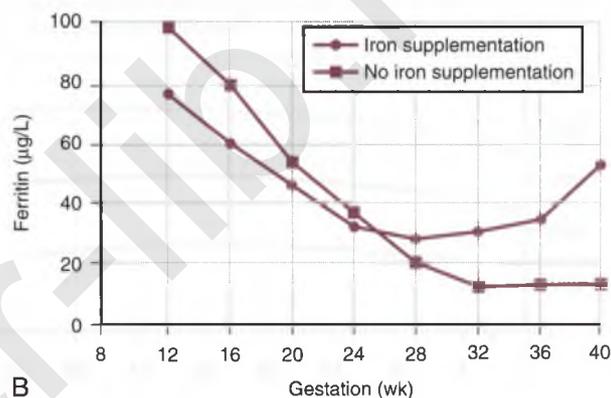
FIGURE 29

A, Platelet count and *B*, mean platelet volume (mean ± SEM) during pregnancy. The study was largely cross-sectional in design (2881 samples from 2114 women). Samples were analyzed in a Coulter counter. At the end of the study, patients who had hypertension were excluded. *Data source:* ref. 49, with permission.

Comment: Hyperdestruction of platelets may occur in pregnancy, with a consequent decrease in platelet life span. Young platelets are larger than old platelets. In a large study of 6770 women in late pregnancy, mean platelet counts were $213 \times 10^9/L$ and the 2.5th percentile value was $116 \times 10^9/L$.[50] Another longitudinal study[51] with much smaller numbers (*n* = 44) did not find evidence of a significant change in platelet count with gestational age.

Iron Metabolism

Iron metabolism					
Patients	Hb (g/dL)	Serum iron		Transferrin/ TIBC saturation (%)	Serum ferritin (mg/L)
		(µmol/L)	(mg/dL)		
Non-treated (*n* = 30)					
First trimester	12.9	23	129	36	96
Term	12.0	14	78	13	13
Given FeSO₄ (*n* = 82)					
First trimester	12.5	22	123	33	67
Term	12.5	25	140	27	41

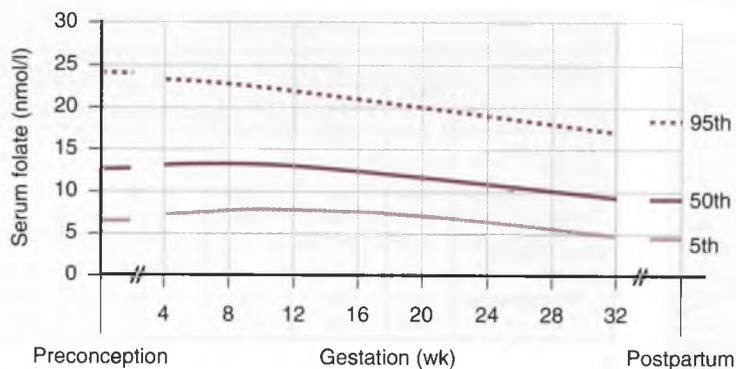
A


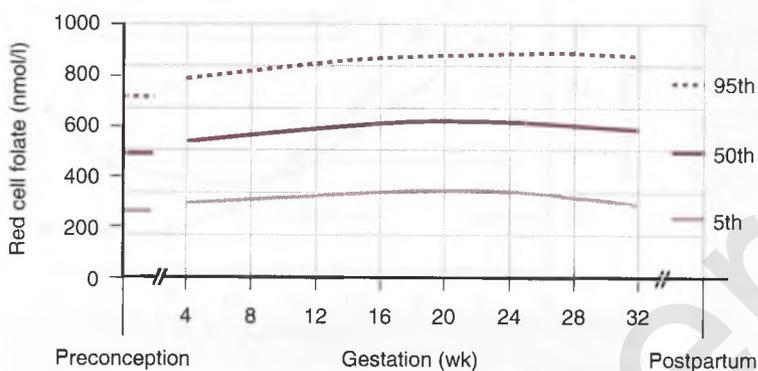
B

FIGURE 30

A, Mean hemoglobin (Hb) and iron indices from a longitudinal study of women recruited in the first trimester. At the start of the study, 72 were randomized to the no-treatment group, but any whose Hb fell below 11 g/dL were prescribed ferrous sulfate 60 mg three times daily. Only 30 progressed through pregnancy without iron supplements. *B*, In all of the subjects studied, serum ferritin levels rose rapidly postpartum, reaching values similar to those found in early pregnancy by 5 to 8 weeks after delivery. No iron supplements were given after delivery. *Data source:* ref. 52, with permission.

Comment: Iron stores, as indicated by the serum ferritin level, are depleted during pregnancy, regardless of whether iron supplements are given.

Serum and Red Cell Folate


A


B

FIGURE 31

Longitudinal study of (*A*), serum and (*B*), red cell folate levels (5th, 50th, and 95th percentiles) in healthy nulliparous women during an uneventful singleton pregnancy. None of the study subjects took iron or vitamin supplements (*n* = 102). Nonfasting blood samples were taken within 3 months of conception, at 6, 10, 20, and 32 weeks' gestation, and again 6 weeks postpartum. All women had spontaneous labor at term and had infants of normal size. *Data source:* ref. 53, with permission. *Conversion factor for folate:* nmol/L × 0.044 = μg/dL.

Comment: In other studies, red cell folate levels showed a slight downward trend with advancing gestation, and patients with low red cell folate levels at the beginning of pregnancy had megaloblastic anemia in the third trimester.[54] These differences may relate to dietary folate intake. In a cross-sectional study of 155 women, red cell folate concentration increased with gestation and was significantly higher in subjects who took supplemental folic acid (1 mg daily) than in those who did not (1056 nmol/L vs. 595 nmol/L, respectively).[55] Serum and red cell folate levels are lower in pregnancy in women who smoke.[56] By 6 weeks after delivery, red cell folate levels return toward preconception values, although serum folate levels remain low. Lactation, which is an added folate stress, may be one reason.[57] Serum folate levels may remain low for up to 6 months after delivery.[53]

Homocysteine

Comment: Plasma homocysteine levels are significantly lower in all trimesters of pregnancy compared with nonpregnant control values. A small longitudinal study confirmed these findings.[53] The lowest levels are found in the second trimester. Homocysteine is 70% to 80% albumin-bound, so these gestational changes mirror those of serum albumin (Fig. 15). Homocysteine is negatively correlated with red cell folate, and lower concentrations are found in women who take folic acid supplements.[55] Hyperhomocysteinemia, which can result from genetic and environmental factors, is associated with deep venous thrombosis, recurrent miscarriage, abruption, stillbirth, and neural tube defects.

FIGURE 32

Plasma homocysteine (mean and 95% confidence interval [CI]) in a cross-sectional study of 155 normal women in the first, second, and third trimesters of pregnancy and in nonpregnant control subjects. Homocysteine concentrations were determined by high-pressure liquid chromatography. *Data source:* ref. 55, with permission.

Vitamin B$_{12}$

Other Vitamins

> **Comment:** Vitamin concentrations during pregnancy are available from a large longitudinal study performed in the Netherlands on women who were not using iron, folate, or other vitamin supplementation. Vitamins studied included retinol, thiamin, riboflavin, pyridoxal 5′-phosphate, and α-tocopherol.[53]

FIGURE 33
Serum vitamin B$_{12}$ levels (5th, 50th, and 95th percentiles) in 102 healthy nulliparous women during an uneventful singleton pregnancy. Subjects were those described in Figure 31. *Data source:* ref. 53, with permission.

> **Comment:** Serum vitamin B$_{12}$ levels are approximately 100 pmol/L lower in pregnancy, but recovery occurs by 6 weeks postpartum.[53] Levels tend to be lower in women who smoke.[56] Muscle and red cell vitamin B$_{12}$ concentrations also fall during pregnancy; however, vitamin B$_{12}$ absorption does not change.[57,58] Saturation of vitamin B$_{12}$-binding proteins decreases steadily during pregnancy.[58] These changes in vitamin B$_{12}$ status do not represent a deficiency state, however, because they are not associated with evidence of reduced red blood cell count or hemoglobin or homocysteine concentrations, once correction is made for serum ferritin concentrations.[58]

Coagulation Factors

Coagulation factors

FIGURE 34

Coagulation factors (mean and 95% ranges) from a longitudinal study of 72 women, 19 to 42 years old (healthy primigravidae or multigravidae whose previous pregnancies were uncomplicated). Postdelivery samples were taken between 6 hours and 4 days after delivery (mean, 52 hours); postnatal samples were taken after 6 weeks. The postnatal samples yielded values similar to those from an age-matched nonpregnant group of women (n = 66). Where no units are stated, values are expressed as percentage of standard. *Data source:* ref. 59, with permission.

Comment: Normal pregnancy is a hypercoagulable state associated with increased levels of factors VII, VIII, and X and a marked increase in fibrinogen levels as a result of increased synthesis. Factor IX levels increase, whereas factor XI levels decrease.[57] Not shown is the first-trimester increase in fibrinopeptide A.

Naturally Occurring Anticoagulants and Fibrinolytic Factors

FIGURE 35

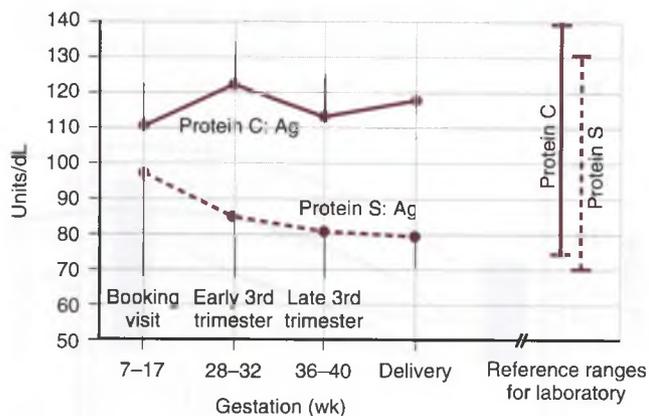
Naturally occurring anticoagulants and fibrinolytic factors (mean and 95% ranges), fibrinolytic activity (full range), and fibrin degradation products (mean values) from a longitudinal study. Where no units are stated, values are expressed as percentage of standard. Patients were those described in Figure 34. *Data source:* ref. 59, with permission.


FIGURE 36

Protein S and protein C levels (mean ± SD) from a longitudinal study in 14 healthy women 24 to 38 years old. *Data source:* ref. 60, with permission.

Comment: Free protein S levels fall progressively during pregnancy but remain within the normal reference ranges; protein C levels change little. Antithrombin III levels are stable during pregnancy, decrease in labor, and then increase 1 week postpartum.[57] Fibrinolysis is depressed during pregnancy; fibrinogen and plasminogen levels are elevated, but levels of circulating plasminogen activator are decreased.[61] In late normal pregnancy, D-dimer levels are also elevated.[47]

Immunology

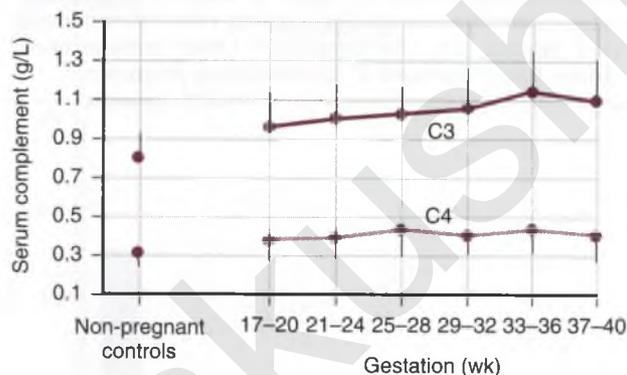
Complement System and Immune Complexes


FIGURE 37

Complement factors C3 and C4 (mean and SD) from a longitudinal study of 147 healthy women who were normotensive throughout pregnancy. The control population was 32 normal nonpregnant women 15 to 41 years old, 11 of whom were taking oral contraceptives. *Data source:* ref. 62, with permission.

Comment: Levels of C3 and C4 are significantly elevated during the second and third trimesters. Another cross-sectional study[63] showed elevated levels of C4, but not C3, during the first trimester. Levels of circulating immune complexes are low during pregnancy.[63] There is disagreement as to whether levels of C3 degradation products are elevated[63] or normal[64]; no longitudinal studies have been done.

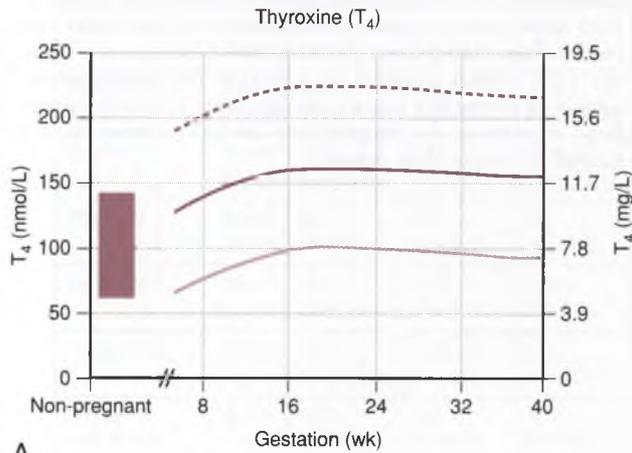
Markers of Inflammation

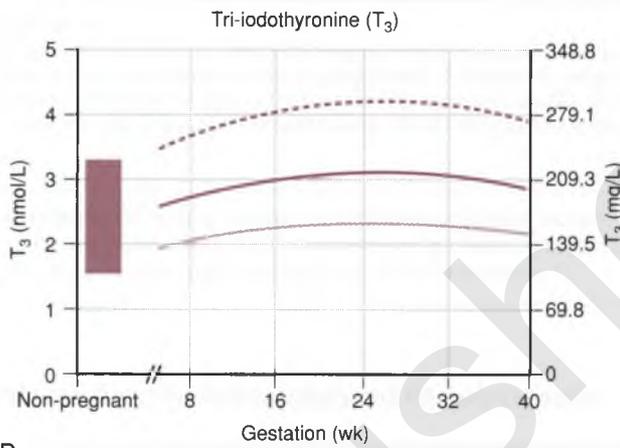
ERYTHROCYTE SEDIMENTATION RATE (ESR) AND C-REACTIVE PROTEIN (CRP)

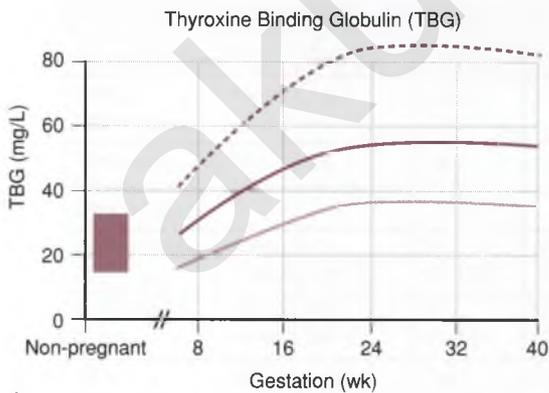
Comment: The erythrocyte sedimentation rate (ESR) is high in pregnancy (typically >30 mm in the first hour) as a result of elevated plasma globulins and fibrinogen.[65] Thus, the ESR cannot be used as a marker for inflammation. Levels of C-reactive protein are the same in healthy pregnant women as in nonpregnant adults[47]; elevations are caused by intercurrent disease.

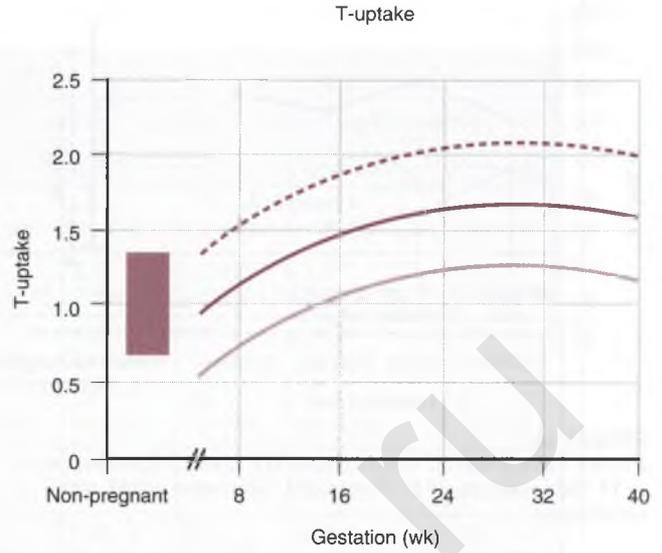
Endocrinology

Thyroid Function

TOTAL THYROXINE (T$_4$), TRI-IODOTHYRONINE (T$_3$), THYROID UPTAKE, AND THYROID-BINDING GLOBULIN (TBG)


A


B


C


D

FIGURE 38

A, Total T$_4$, *B*, total T$_3$, *C*, thyroid-binding globulin, and *D*, T uptake (2.5th, 50th, and 97.5th percentiles) from a longitudinal study of 60 women who each had blood samples three times during pregnancy, once each trimester. Control values were taken from 30 healthy nonpregnant women. *Data source:* ref. 66, with permission.

Comment: Serum total T$_4$ and T$_3$ concentrations are elevated in pregnancy. Thyroid-binding globulin concentrations are doubled by the end of the first trimester, remain elevated throughout pregnancy, and decrease slowly in the 6 weeks after delivery.[67] T$_3$ uptake is believed to represent total serum thyroxine-binding capacity rather than unoccupied binding site concentration.[66] Other cross-sectional studies found decreased T$_3$ uptake during pregnancy.[68]

FREE THYROXINE (FREE T₄), FREE THYROXINE INDEX (FTI), THYROID-STIMULATING HORMONE (TSH), AND FREE TRI-IODOTHYRONINE (FREE T₃)

D

FIGURE 39

A, Free T_4 levels, *B*, free T_4 index, and *C*, thyroid-stimulating hormone (TSH) levels (2.5th, 50th, and 97.5th percentiles) from the same study described in Figure 38. *Data source:* ref. 66, with permission. *D*, Free T_3 concentrations (mean ± 2 SDs) from a cross-sectional study of 159 women attending antenatal clinics; none had metabolic illness. The control samples were obtained from 109 patients (male and female), taken from the routine workload of the laboratory (excluding those with thyroid disease, diabetes, cardiac disease, or carcinoma, and postoperative patients). *Data source:* ref. 69, with permission.

Comment: Free T_4 and free T_3 concentrations, measured directly (rather than derived from resin uptake measurements) decrease during pregnancy but remain within normal nonpregnant ranges.[66,69,70] TSH levels increase with gestation but remain within the reference range for nonpregnant women.[66] Some studies found low TSH levels toward the end of the first trimester in association with the highest circulating concentrations of hCG.[68] The increase in TSH in response to thyrotropin-releasing hormone during early pregnancy is enhanced, similar to responses found in central hypothyroidism.[71]

Adrenal Function

CATECHOLAMINES

Comment: This study showed a decrease in plasma levels of both epinephrine and norepinephrine as pregnancy progressed. Other studies (in which blood samples were taken from indwelling intravenous cannulas) showed steady levels throughout pregnancy, with no difference between values during pregnancy and those in the early puerperium.[73] In healthy pregnant women, plasma epinephrine and norepinephrine levels show a diurnal pattern, with the lowest levels reported at night.[74] Urinary vanillylmandelic acid (VMA) excretion has not been studied in healthy pregnancies but is likely to be within the normal adult range.

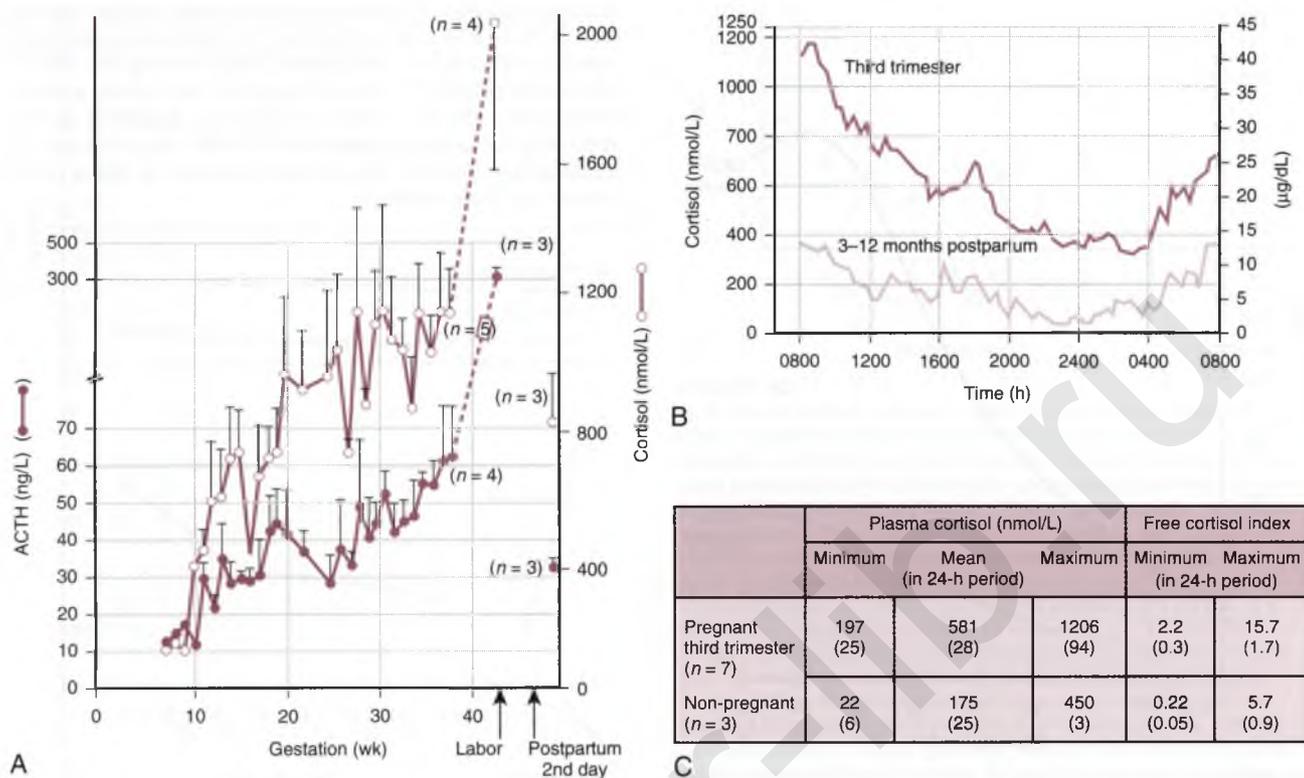
GLUCOCORTICOIDS


FIGURE 41

A, Adrenocorticotropic hormone (ACTH) and cortisol concentrations (mean and SEM) from a longitudinal study of five healthy pregnant women 17 to 28 years old. Blood samples were taken weekly, from early pregnancy until delivery. Samples were obtained between 8:00 AM and 9:00 AM after an overnight fast. Samples for ACTH measurement were collected improperly from one woman and had to be discarded. Samples were also taken from three of these subjects during labor and on the second postpartum day. *Data source:* ref. 75, with permission. *B*, Mean plasma cortisol levels throughout a 24-hour period from a study of seven primigravidae in the third trimester and three nonpregnant women, two of whom had been studied during pregnancy. The nonpregnant women were at least 3 months postdelivery and were not breast-feeding or using oral contraceptives. Samples were taken every 20 minutes. *Data source:* ref. 76, with permission. *C*, Plasma cortisol and free cortisol index (mean and SD) from a study of seven primigravidae in the third trimester and three nonpregnant women, two of whom had been studied during pregnancy. Subjects were those described in Figure 41b. *Data source:* ref. 76, with permission.

Comment: The total, bound, and free plasma cortisol levels and the free cortisol index are increased in pregnancy compared with the nonpregnant state.[76,77] ACTH levels during pregnancy are variously reported as remaining within the normal range for nonpregnant subjects, increasing, or decreasing,[75,78] but there is agreement that levels increase with advancing gestation. The rise in ACTH during pregnancy is attributed to placental production of the peptide.[78] Despite overall elevated levels, normal diurnal patterns of cortisol are found during pregnancy (i.e., lowest values at 12:00 AM, highest values at 8:00 AM).[76,77] The biologic half-life of cortisol is increased in pregnancy.[76] Cortisol-binding globulin (CBG) concentrations rise steadily during pregnancy, reaching twice the normal values by midgestation.[77,79] The cortisol production rate during pregnancy has been described as depressed[80] or elevated.[76] Urinary free cortisol more than doubles during pregnancy.[81] After 1 mg dexamethasone given orally at 11:00 PM, plasma cortisol levels measured at 8:00 AM are less than 139 nmol/L or 5 μg/dL (a normal response).[82] However, urinary cortisol levels are not suppressed as much in pregnant subjects as in nonpregnant subjects.[78] The cortisol response to an ACTH challenge (Synacthen test) is unchanged in pregnancy.[83]

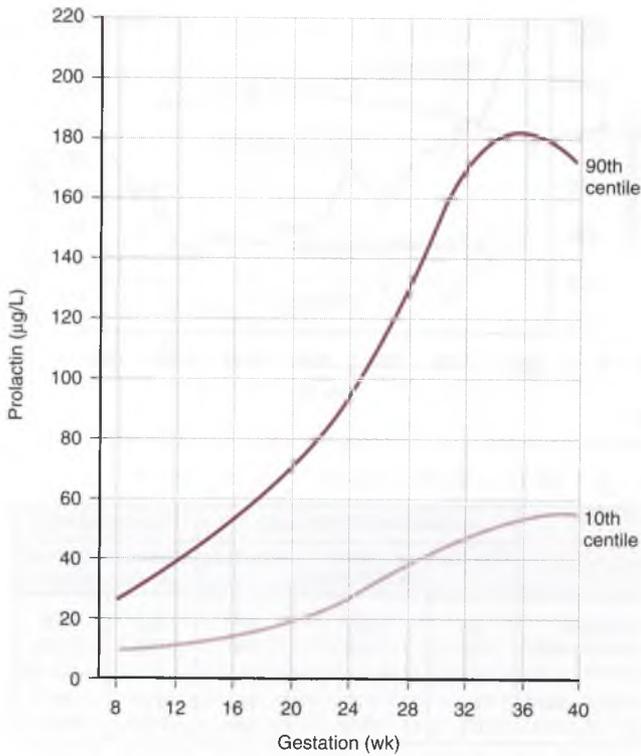
Prolactin


FIGURE 42

Serum prolactin (10th and 90th percentiles) from a mostly cross-sectional study of 839 women with uncomplicated singleton pregnancies at 8 to 40 weeks' gestation; 980 blood samples were taken. All of the samples were collected between 9:00 AM and 11:00 AM. Women who had a pregnancy complication were rejected from the normal series. *Data source:* ref. 84, with permission.

Comment: Prolactin concentrations increase 10- to 20-fold during pregnancy. The concentrations show a normal circadian rhythm, with a nocturnal rise.[85] In labor, levels decrease acutely, followed by a postpartum surge during the first 2 hours after delivery.[86] These changes are not seen in women undergoing elective cesarean delivery. Prolactin levels approach the normal range 2 to 3 weeks after delivery in nonlactating women, but remain elevated in those who breast-feed their infants.[87]

Calcium Metabolism

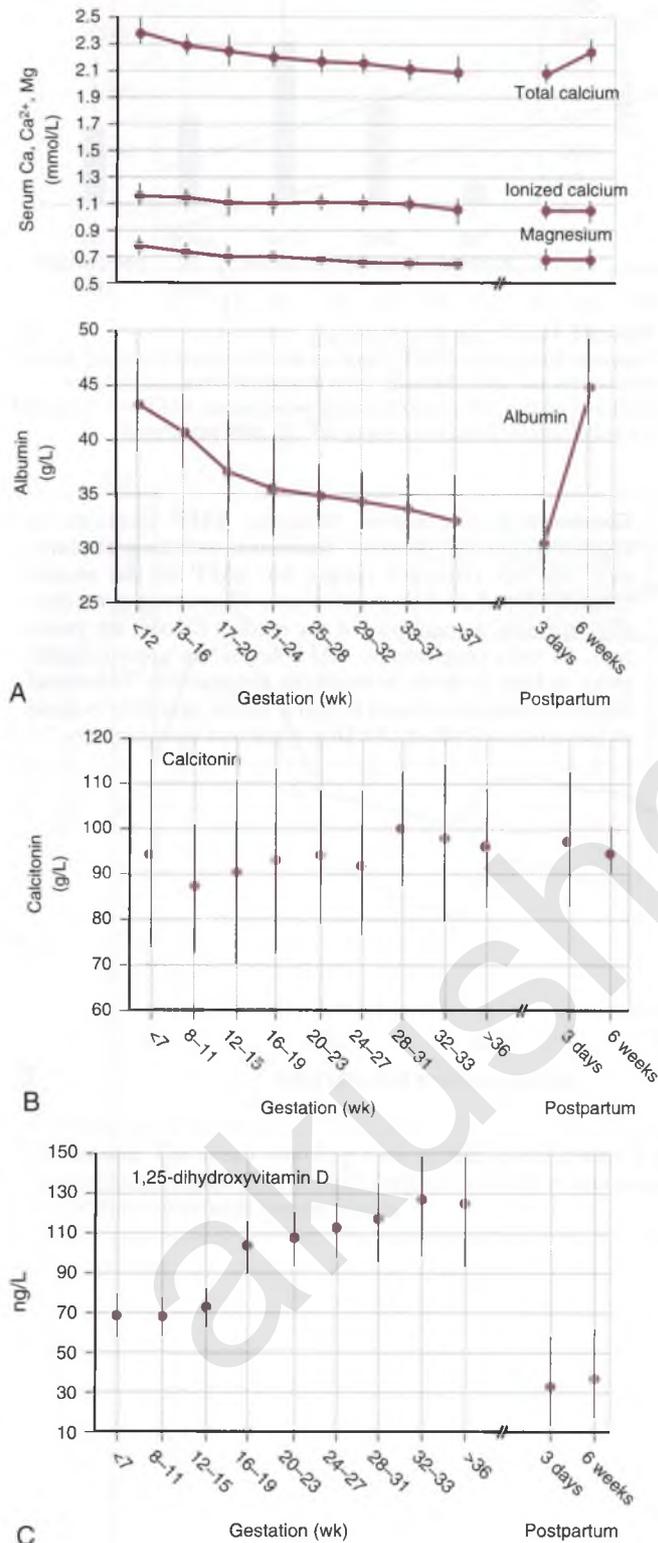
TOTAL AND IONIZED CALCIUM, MAGNESIUM, ALBUMIN, PARATHYROID HORMONE (PTH), CALCITONIN, AND VITAMIN D


FIGURE 43

A, Total and ionized calcium, magnesium, and albumin (mean ± SD) from a longitudinal study of 30 women who were recruited in the first trimester and studied at 4-week intervals. Samples were taken on the third postpartum day and during the sixth postpartum week. Subjects ranged in age from 19 to 33 years; 20 were primigravidae. Samples were collected by venepuncture after an overnight fast. Calcium, mmol/L × 4 = mg/dL; magnesium, mmol/L × 2.4 = mg/dL. *Data source:* ref. 88, with permission. *B,* Calcitonin, *C,* 1,25-dihydroxyvitamin D, and *D,* parathyroid hormone (PTH) (mean ± SD) from a longitudinal study of 20 women 22 to 34 years old, 12 of whom were nulliparous. All had uncomplicated pregnancies of more than 38 weeks' gestation. The only medication they received was ferrous sulfate. Blood samples were taken in the morning after an overnight fast. Samples were collected at 4-week intervals, with the first taken before 7 weeks' gestation. Samples were also taken on the third postpartum day and during the sixth postpartum week. *Data source:* ref. 89, with permission.

Comment: Total serum calcium decreases during pregnancy, in association with the fall in serum albumin; however, ionized calcium levels remain constant. Serum intact PTH levels are lower in pregnancy than at 6 weeks postpartum; they reach a nadir in midpregnancy. A menstrual cyclicity in PTH has also been noted, with higher values corresponding to times of increased estrogen secretion.[88] Calcitonin levels are not significantly altered in pregnancy. 1,25-Dihydroxyvitamin D levels increase with advancing gestation and are significantly higher than during the puerperium. 1α-Hydroxylation of 25-hydroxyvitamin D in the placenta accounts for this increase and the consequent suppression of PTH.[89]

Placental Biochemistry

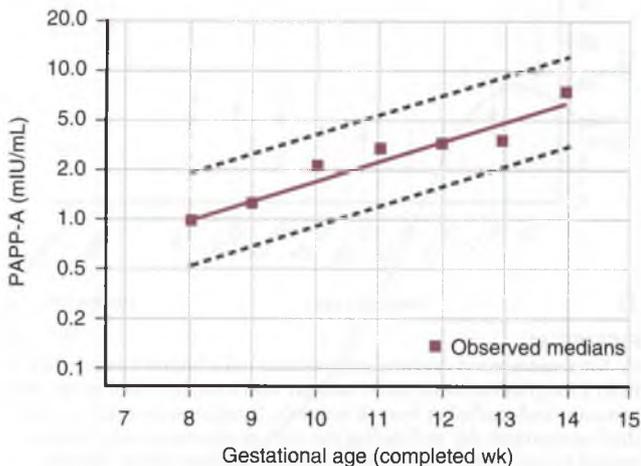
PLASMA PROTEIN A (PAPP-A)


FIGURE 44

Plasma protein A (PAPP-A) levels in maternal serum (median, 0.5 MoM and 2 MoM) from a cross-sectional study of 379 healthy women at 8 to 14 weeks' gestation. These women had been selected to match 77 women whose fetuses had Down syndrome. Their median age was 39 years (10th and 90th percentiles, 34 and 42 years, respectively). *Data source:* ref. 90, with permission.

Comment: PAPP-A and free βhCG are useful markers for discriminating pregnancies affected by Down syndrome from normal pregnancies at 8 to 14 weeks' gestation. PAPP-A levels are lower in affected pregnancies than in normal pregnancies (particularly at 11 weeks' gestation or less).[90,91]

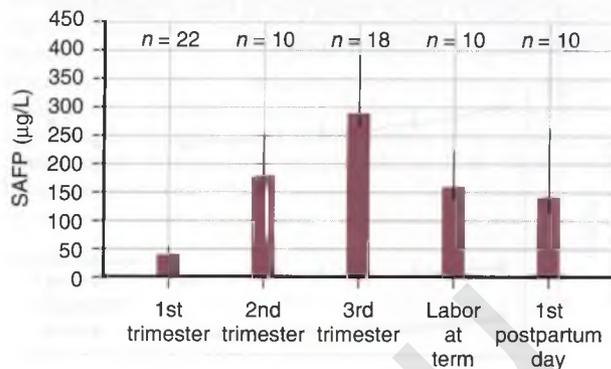
SERUM α-FETOPROTEIN (SAFP)


FIGURE 45

Serum α-fetoprotein (SAFP) (median and interquartile ranges) from a cross-sectional study. Samples from women in labor and samples obtained on the first postpartum day were paired. SAFP was measured by radioimmunoassay. *Data source:* ref. 92, with permission.

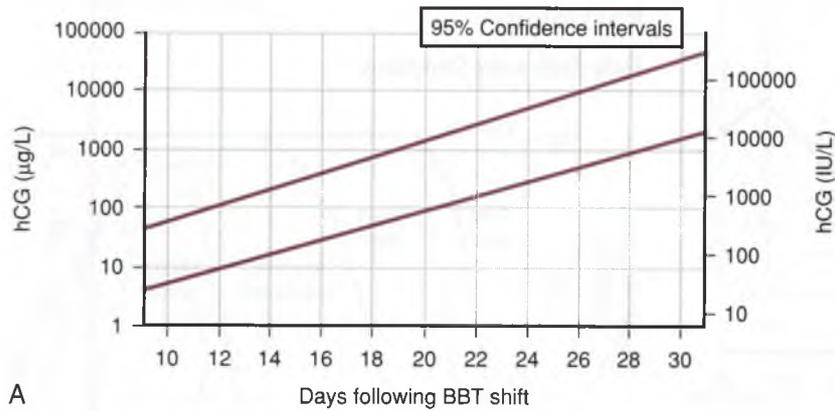
Comment: In the second trimester, SAFP increases by approximately 15% weekly.[93] Individual screening laboratories establish reference ranges for SAFP in the second trimester for their own populations. These ranges are usually expressed as multiples of the median (MoM) for gestation. In twin pregnancies, SAFP levels are approximately twice as high as those in singleton pregnancies.[93] Maternal weight is inversely related to SAFP levels, probably because of the dilutional effect of a larger vascular compartment.[93]

HUMAN CHORIONIC GONADOTROPIN (HCG)

A

Days following BBT shift

B

Days after last menstrual period


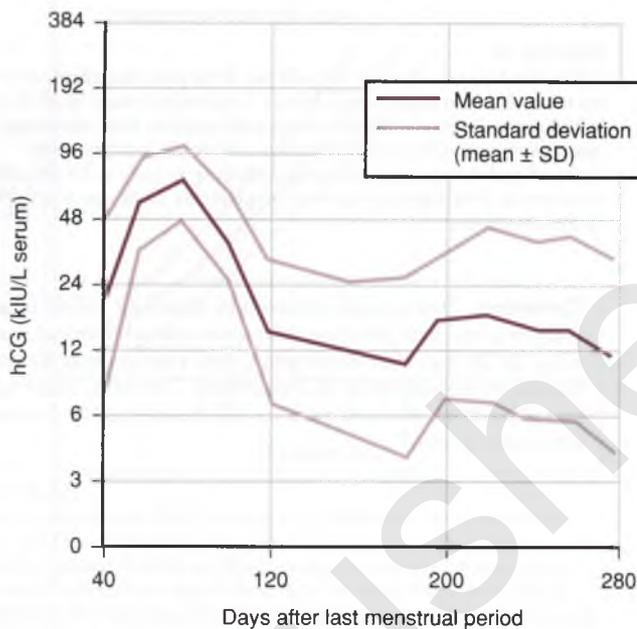


FIGURE 46

A, Serum values of the β subunit of hCG (95% CI) measured in 189 women who subsequently had successful pregnancies (total of 280 samples analyzed). The study subjects were patients in an infertility clinic and were keeping basal body temperature (BBT) charts to indicate the timing of ovulation. Some conceptions were spontaneous; other patients were treated with clomiphene citrate, human menopausal gonadotropin, or hCG (a single injection of 5000 IU to induce ovulation). A radioimmunoassay was used for βhCG. *Data source:* ref. 94, with permission. *B*, Total serum hCG (mean ± SD) from a longitudinal study of 20 healthy women. The first samples were obtained as early in pregnancy as possible, with subsequent samples obtained every 3 to 4 weeks. The last sample was taken during labor. Samples were classified into groups, with a class interval of 30 days. Radioimmunoassay was used to obtain the hCG level; the international hCG standard was used as a reference. *Data source:* ref. 95, with permission.

Comment: The mean doubling time of βhCG is 2.2 days ± 1.0 (2 SDs).[94] Low hCG values that do not double to within this range are associated with ectopic pregnancy or spontaneous abortion.[94] Women with male fetuses have significantly lower hCG levels than those with female fetuses.[95]

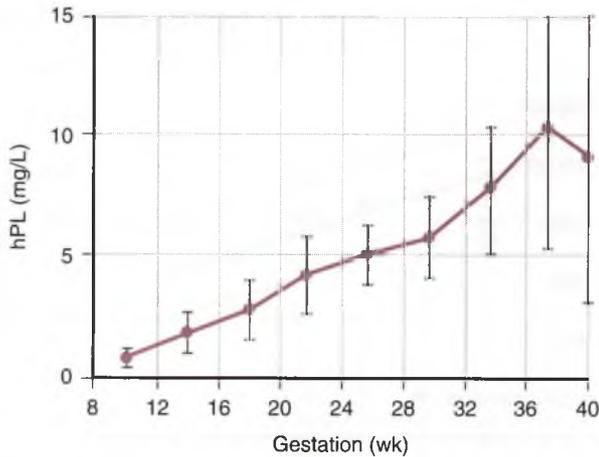
HUMAN PLACENTAL LACTOGEN (HPL)


FIGURE 47

Serum human placental lactogen (hPL) values (mean ± SD) from a cross-sectional study of 151 normal women with singleton pregnancies attending a antenatal clinic. Radioimmunoassay was used to measure hPL. *Data source:* ref. 96, with permission.

Comment: In women with multiple pregnancies, hPL levels are outside these ranges; however, if values are corrected for predicted placental weight, then they are appropriate for gestational age.[96] Four hours after delivery of the placenta, plasma hPL is virtually undetectable; the half-life of hPL in the plasma is 21 to 23 minutes.[97]

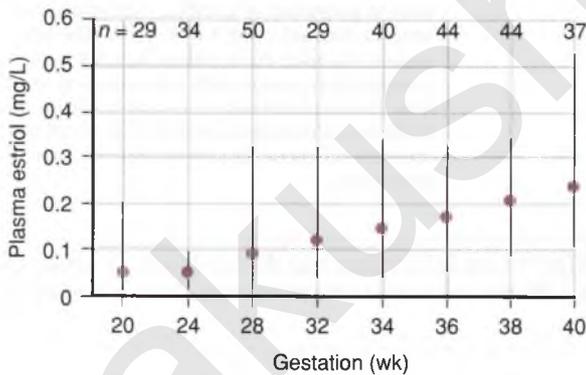
ESTRIOL (E₃)


FIGURE 48

Plasma estriol (mean and range) from a cross-sectional study in women with uncomplicated pregnancies. Plasma estriol was measured fluorometrically. *Data source:* ref. 98, with permission.

Comment: The normal range of plasma estriol in pregnancy is wide. To assess the significance of values outside this range, trends should be studied over several days.

FETAL VALUES

Physiology

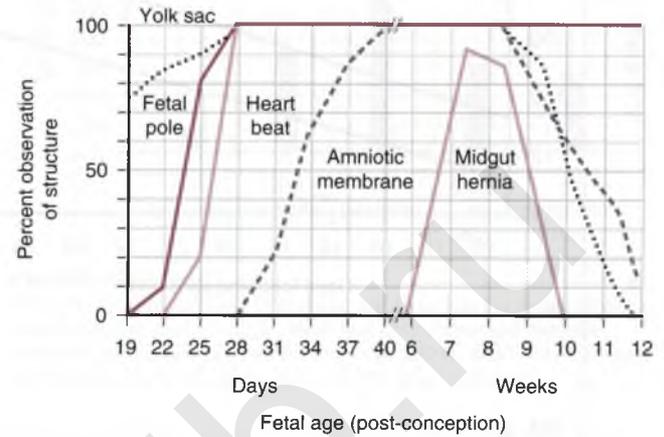
Early Embryonic Structures


FIGURE 49

Ultrasound visualization of the yolk sac, fetal pole, heartbeat, amniotic membrane, and midgut hernia from a longitudinal study of 39 women with known dates of ovulation; most were patients from an assisted conception unit. Once pregnancy was confirmed, patients were scanned with a vaginal probe weekly, starting as early as 18 days after conception. Five subjects had twin pregnancies. *Data source:* ref. 99, with permission.

Comment: Transvaginal ultrasound scanning yields better images in the first trimester than does transabdominal scanning. By 28 days after conception, fetal viability may be confirmed by visualization of a heartbeat. The fetal heart rate increases from 90 beats/min to 145 beats/min by 7 weeks after conception.[99]

Biometry

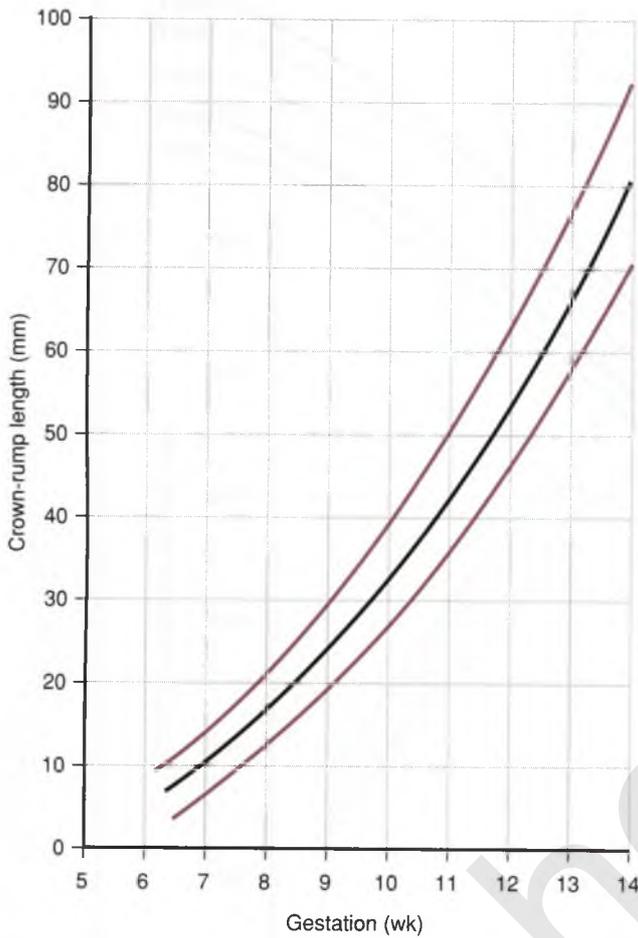
CROWN–RUMP LENGTH (CRL)


FIGURE 50
Crown–rump length (CRL) (mean ± 2 SDs) from a cross-sectional
study of 334 women who were certain of the date of their last
menstrual period (LMP) and had normal, regular menstrual cycles.
The study covered the period from 6 to 14 weeks after the LMP. A
transabdominal ultrasound technique was used, and the longest length
of fetal echoes was found and measured. *Data source:* ref. 100, with
permission.

Comment: CRL measurements can be used effectively only
in the first trimester. Other studies found similar CRL val-
ues; measurements are not affected by maternal age, height,
or parity.[101] In a smaller longitudinal study, CRL was signif-
icantly lower in female than in male fetuses.[101] No differ-
ences in CRL measurements have been found between
Asian and European patients.[102]

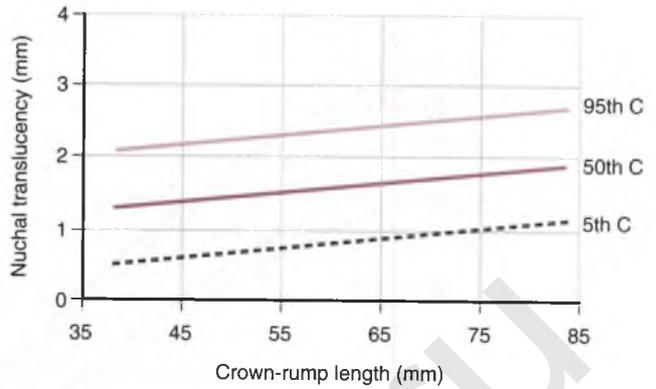
NUCHAL TRANSLUCENCY (NT)


FIGURE 51
Nuchal translucency (NT) measurements (5th, 50th, and 95th
percentiles) from a cross-sectional study of 20,217 chromosomally
normal fetuses examined at 10 to 14 weeks' gestation. Most
examinations were done with transabdominal ultrasound, and all
operators were carefully trained in the technique before the study.
A saggital section of the fetus was obtained perpendicular to the
ultrasound beam, allowing measurement of crown–rump length and
the maximum thickness of the subcutaneous translucency between
skin and soft tissue overlying the cervical spine.[103] Care was taken to
avoid confusion between fetal skin and amnion, both of which appear
as thin membranes. *Data source:* ref. 104, with permission.

Comment: Abnormal fluid collections in the cervical region
(as shown by increased NT measurements) are strongly
associated with chromosomal abnormalities. The upper
limit of normal may be set at 2.5 or 3.0 mm when these
measurements are used as a screening test.[104,105] However, it
is preferable to use the 95th percentile of NT as plotted
against CRL, because measurements increase with gesta-
tional age.[104]

BIPARIETAL DIAMETER (BPD)

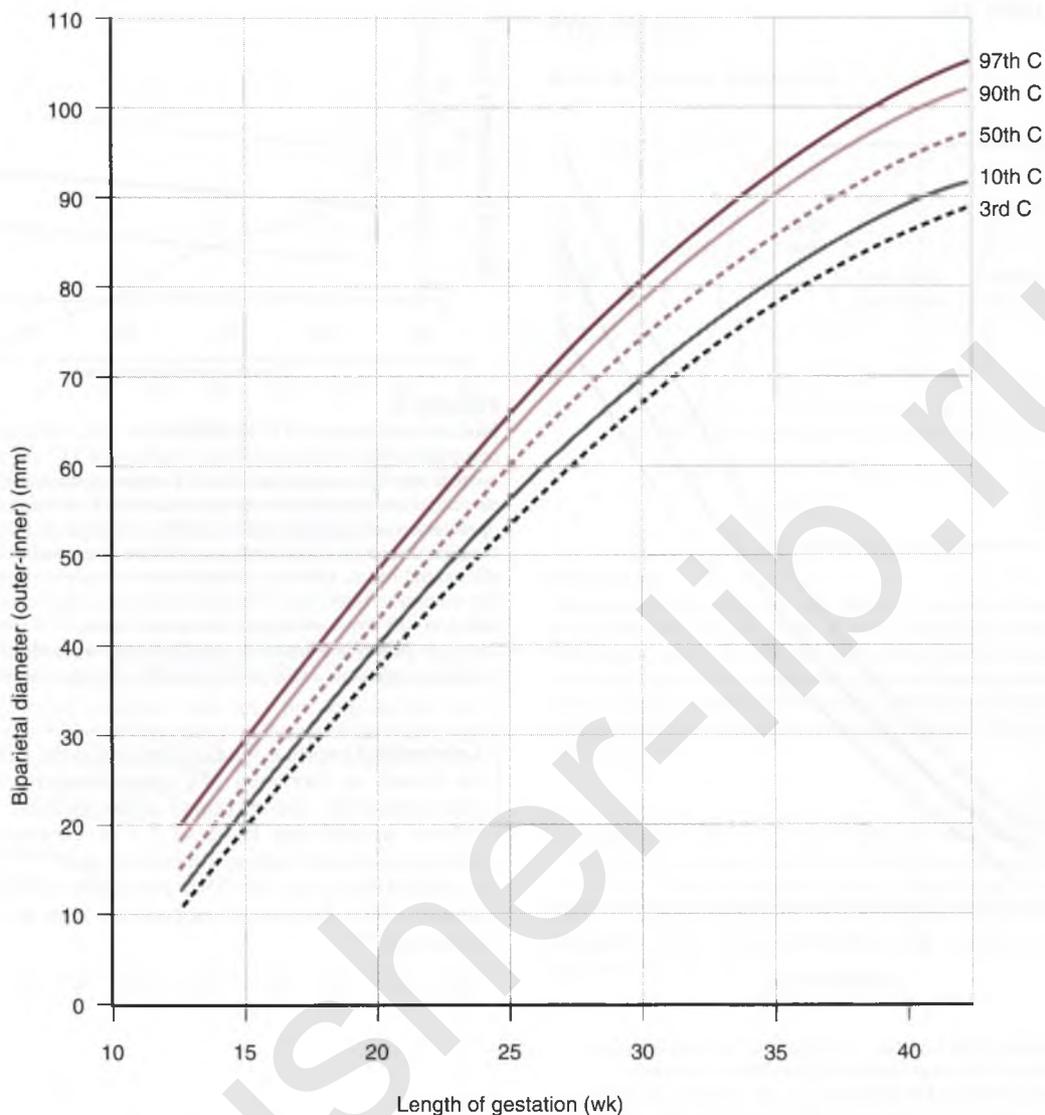
Length of gestation (wk)


FIGURE 52

Biparietal diameter (BPD) (3rd, 10th, 50th, 90th, and 97th percentiles) of 594 fetuses from a prospective cross-sectional study of 663 women with singleton pregnancies carried out in London. Each fetus was measured only once between 12 and 42 weeks' gestation for the study. All women had certain menstrual dates, and menstrual and ultrasound ages at 18 to 22 weeks did not differ by more than 10 days. The study population consisted of 75% Western European and 25% African Caribbean women. No women had disease or used medication that was likely to affect fetal growth (e.g., diabetes, hypertension, renal disease). Measurements from two fetuses subsequently found to have abnormal karyotypes were excluded from the study. BPD measurements were obtained in the axial plane of the skull at the level where the continuous midline echo is broken by the cavum septum pellucidum in the anterior third. Measurements presented are those from the proximal edge of the skull closest to the transducer to the proximal edge of the deep border (i.e., outer-inner edges of bone). The statistical methods used to derive graphs and tables from the raw data are described in detail. *Data source:* refs. 106 and 107, with permission.

Comment: Other large studies are in close agreement with these measurements.[108,109] Information about growth in BPD is available from a longitudinal study.[110] Charts and graphs are also available for outer-outer BPD measurements,[107] and regression equations are given for both parameters. Racial differences in fetal measurements are likely to be found, so charts or percentile graphs appropriate for the population should be used. A small study found no significant differences between Asian and European women living in the same city.[102]

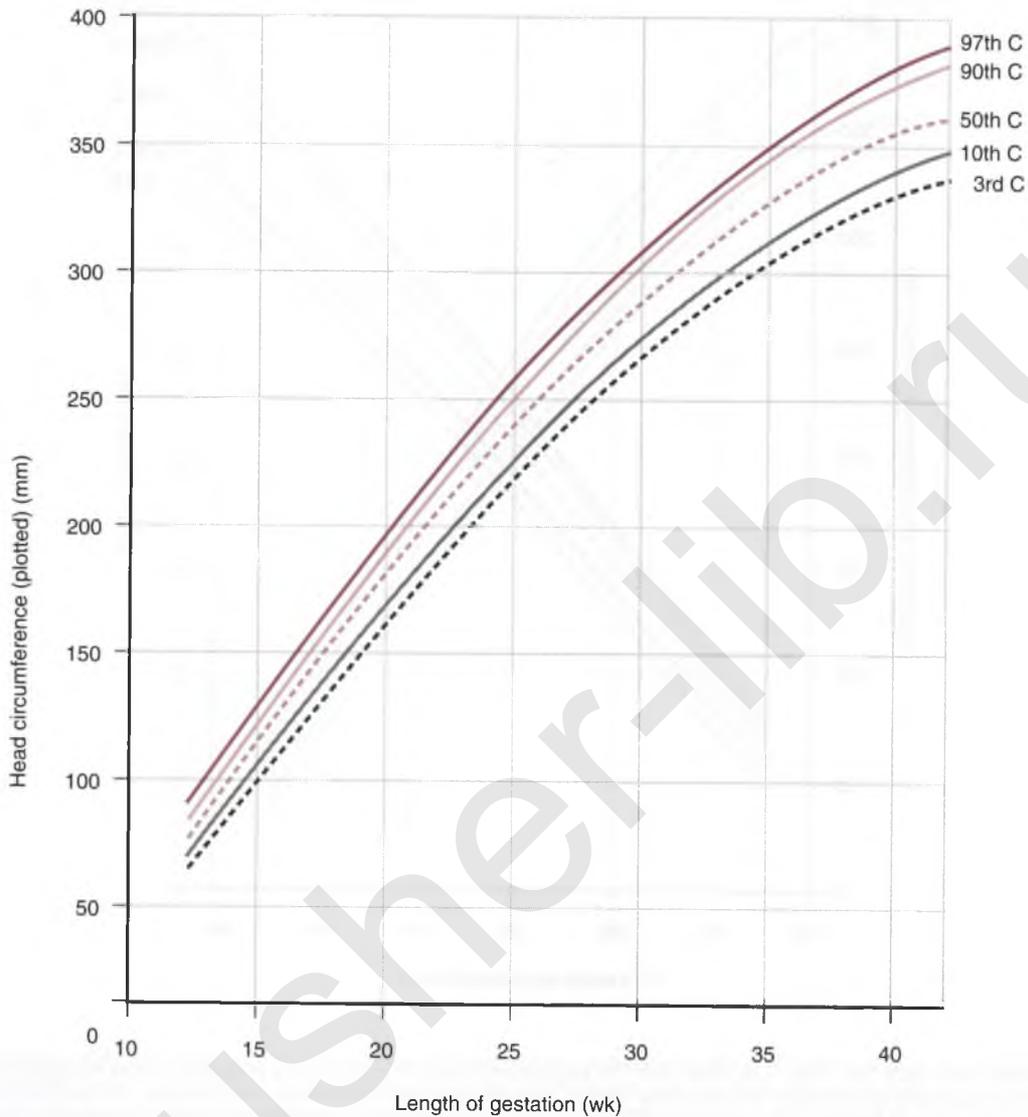
HEAD CIRCUMFERENCE (HC)


FIGURE 53
Head circumference (HC) (3rd, 10th, 50th, 90th, and 97th percentiles) from a prospective cross-sectional study of 594 fetuses, as described in Figure 52. HC was measured directly by tracing around the perimeter of the skull in the same plane used for biparietal diameter measurements. *Data source:* refs. 106 and 107, with permission.

Comment: HC measurements as derived from the biparietal and occipitofrontal diameters are also available[107,108] as well as regression equations for each parameter. Other studies yielded similar data, with some differences seen in the late third trimester.[108,111] These differences have been attributed to patient recruitment characteristics (whether only women delivering at term were included in the study) and the numbers of ultrasound operators used to collect data. HC measurements are particularly useful in the assessment of gestational age when the fetal head shape is abnormal (e.g., dolichocephaly).

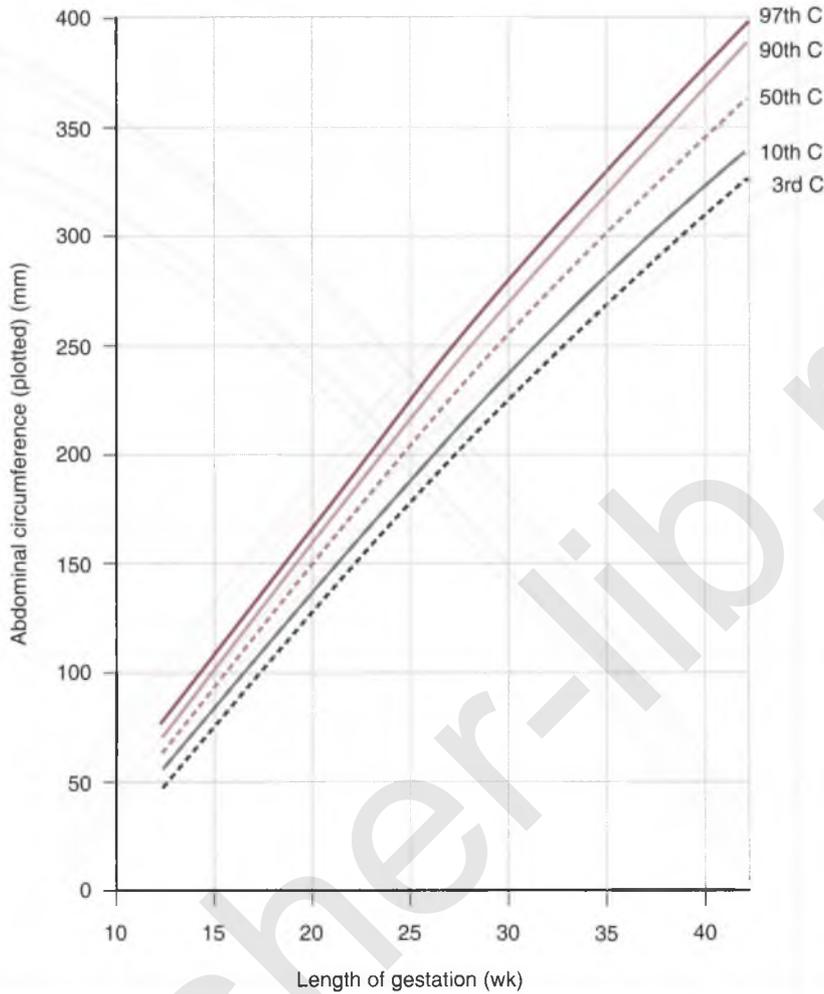
ABDOMINAL CIRCUMFERENCE (AC)


FIGURE 54

Abdominal circumference (AC) (3rd, 10th, 50th, 90th, and 97th percentiles) from 610 fetuses in the prospective cross-sectional study described in Figure 52. The fetal abdomen was measured in a transverse section, with the spine and descending aorta posterior, the umbilical vein in the anterior third, and the stomach bubble in the same plane. Care was taken to ensure that the section was as close as possible to circular, perpendicular to the spine. The circumference was measured by tracing around the perimeter. *Data source:* refs. 106 and 112, with permission.

Comment: Variability in AC increases with gestational age, as shown by widening of the percentiles. Other large studies are in close agreement[109,113,114] with these findings. Studies in which all women delivered at term did not find flattening of the growth velocity curves in late pregnancy.[115,116] Some of the discrepancies are the result of differences in mathematical curve-fitting techniques applied to the experimental data and differences in study design and the numbers of subjects and operators involved. AC is not a good indication of gestational age, but is used to assess fetal size (e.g., in relation to head and limb measurements). A method has been described[113] for assigning Z-scores to measurements, so that deviation from median values can be expressed without graphic presentation of the data. Measurements can also be compared between subjects or between the same subject at different times. Regression equations for AC, both plotted and derived from abdominal diameter measurements, are described.[112,113]

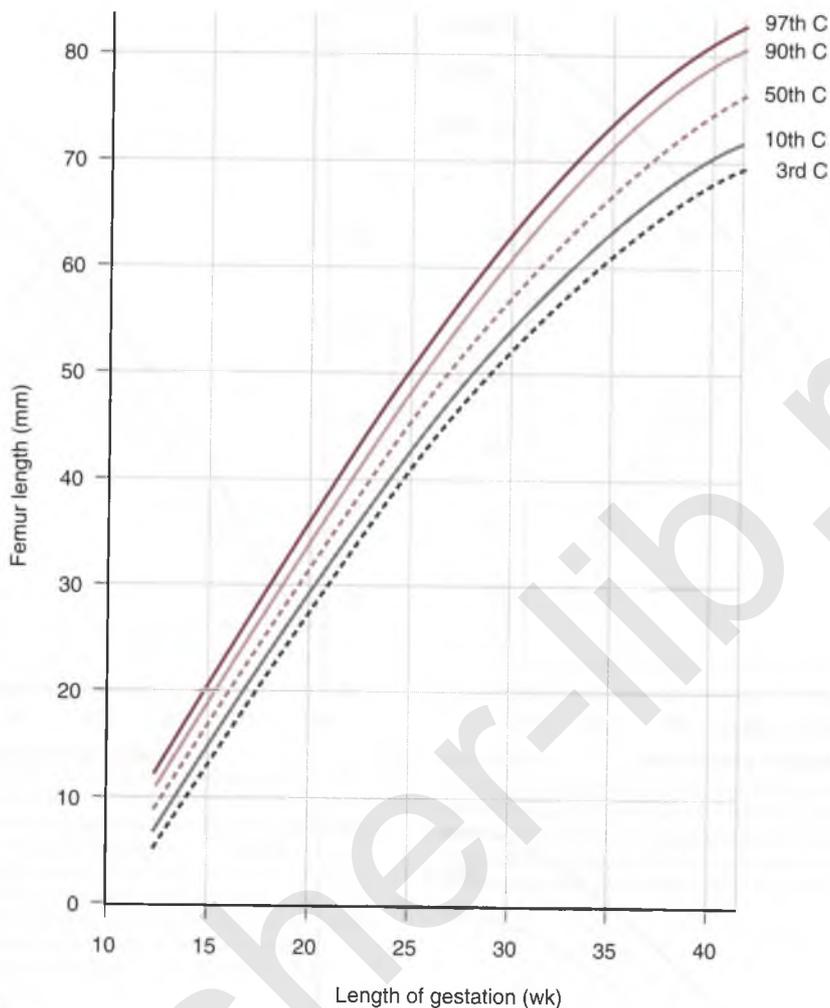
FEMUR LENGTH (FL)


FIGURE 55

Femur length (FL) (3rd, 10th, 50th, 90th, and 97th percentiles) from 649 fetuses in the prospective cross-sectional study described in Figure 52. The femur was identified and the transducer rotated until the full femoral diaphysis was seen in a plane almost at a right angle to the ultrasound beam. The measurement was made from one end of the diaphysis to the other, disregarding curvature and ignoring the distal femoral epiphysis. *Data source:* refs. 106 and 117, with permission.

Comment: Other cross-sectional studies of FL provide similar measurements,[109,113] although one has wider percentiles in late pregnancy.[118] This difference is likely to be related to a difference in the statistical approach to the calculation of percentiles from the regression line. Regression equations are available.[109,113,117]

LIMB BONE LENGTHS

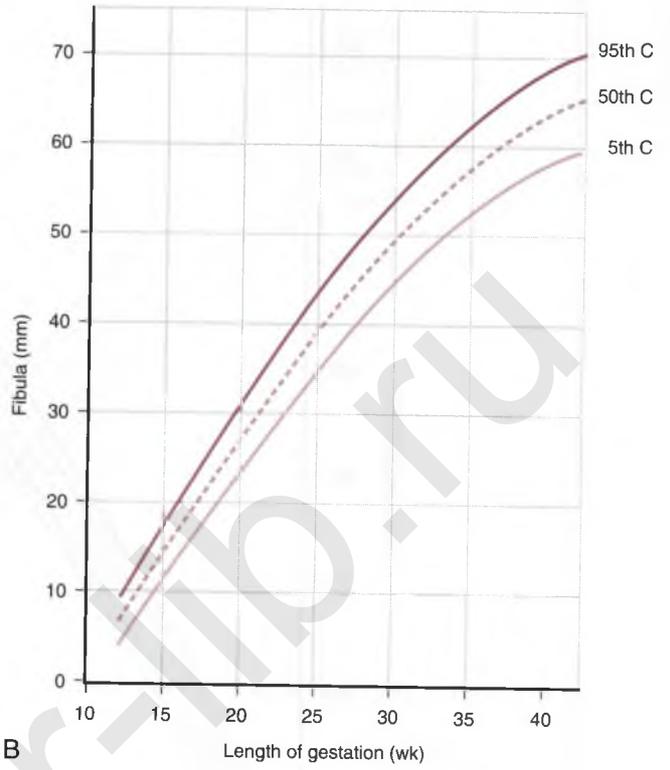
A

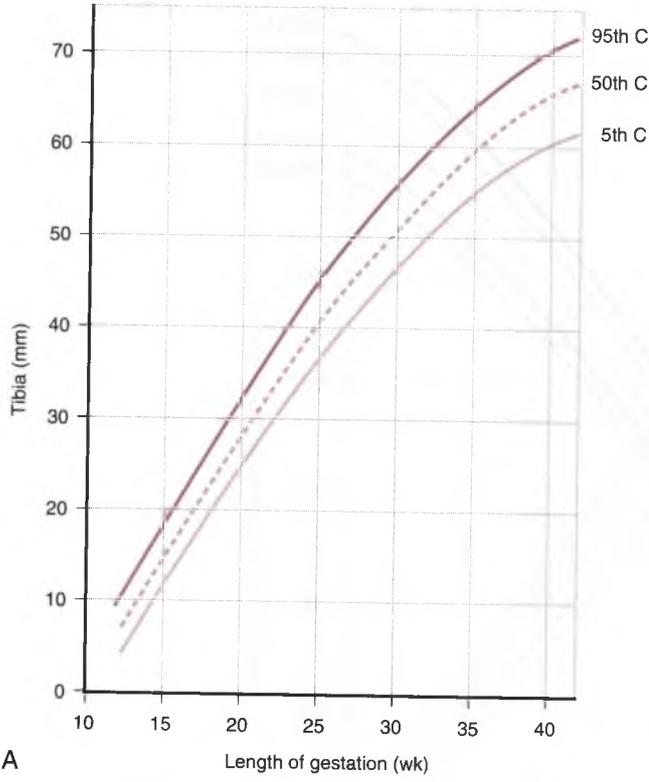
B

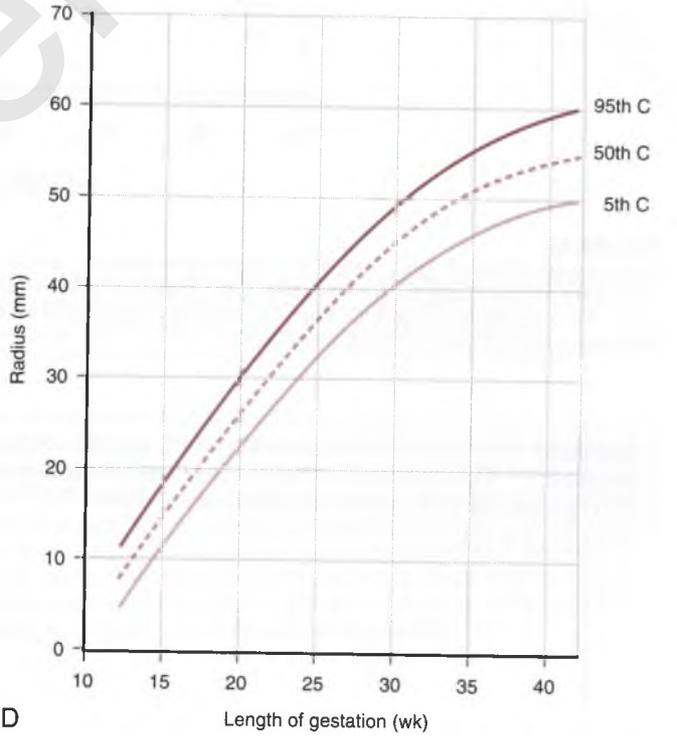
C

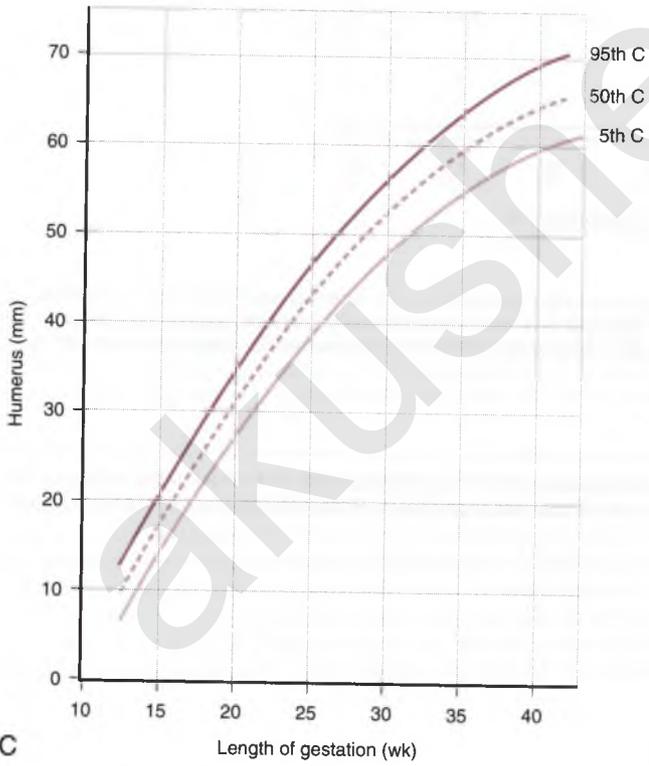
D

Continued

E








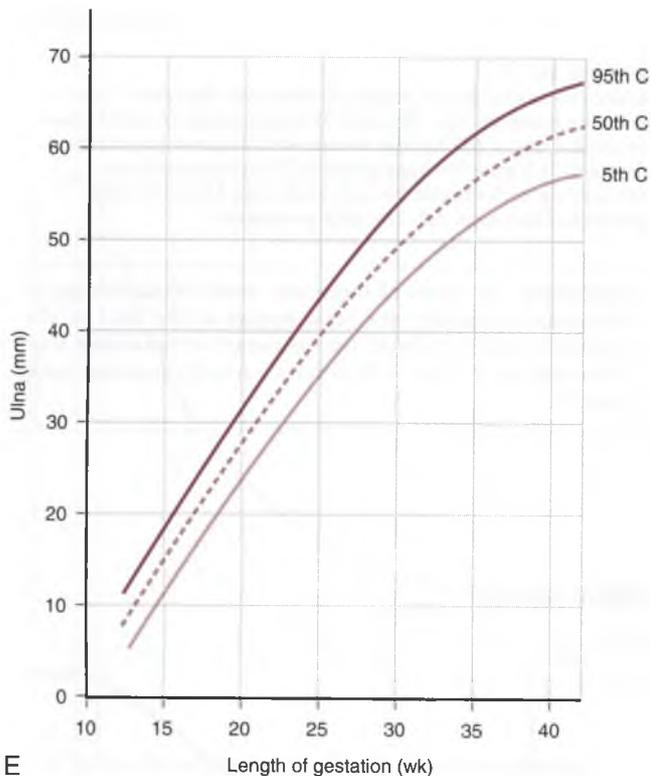


FIGURE 56 cont'd
Lengths of the *A*, tibia, *B*, fibula, *C*, humerus, *D*, radius, and *E*, ulna (5th, 50th, and 95th percentiles) from a cross-sectional study of 669 healthy women with singleton pregnancies. Women who subsequently delivered an infant with an abnormal karyotype, a significant malformation, or any other disease were excluded from the analysis. In all women, menstrual dating was certain and there was agreement between menstrual age and ultrasound dates at the time of the initial scan. Approximately 20 measurements were obtained for each parameter for each week of gestation from 12 to 42 weeks. *Data source:* ref. 119, with permission.

FOOT

FIGURE 57
Length of the foot (5th, 50th, and 95th percentiles) from the cross-sectional study of 669 healthy women with singleton pregnancies described in Figure 56. Approximately 20 measurements were obtained for each variable for each week of pregnancy at 12 to 42 weeks' gestation. *Data source:* ref. 119, with permission.

> **Comment:** All limb bones show linear growth from 13 to 25 weeks' gestation; thereafter, growth is nonlinear. Other studies confirmed these findings.[120] Good agreement has been found between ultrasound and x-ray measurements of limb bone lengths. Tables are available to allow assessment of gestational age from measurement of limb bone lengths.[121] This use of limb bone measurements should be distinguished from tables or graphs of normal measurements at known gestational age that allow assessment of possible skeletal dysplasia.[119,122]

KIDNEY

A

B

C

FIGURE 58

Kidney measurements; *A*, length, *B*, transverse diameter, *C*, antero-posterior diameter (5th, 50th, and 95th percentiles) from the cross-sectional study of 669 healthy women with singleton pregnancies described in Figure 56. Approximately 20 measurements were obtained for each variable for each week from 12 to 42 weeks' gestation. *Data source:* ref. 119, with permission.

> *Comment:* The ratio of transverse renal circumference to abdominal circumference (in a section at the level of the umbilical vein) is a simple way to assess normal kidney size. This ratio is 0.27 to 0.30 from 17 weeks' gestation until term.[123]

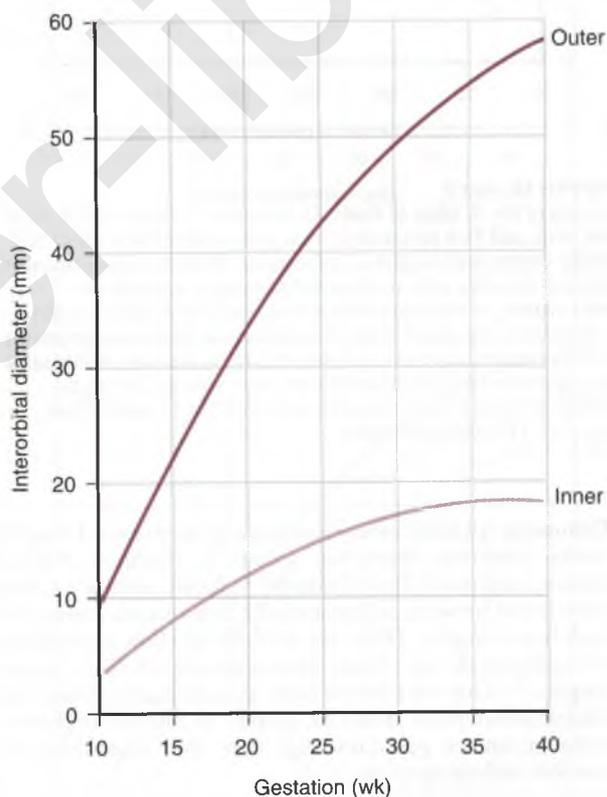
ORBITAL DIAMETERS


FIGURE 59

Interorbital distance (mean) from a cross-sectional study of 180 healthy women at 22 to 40 weeks' gestation. The scan plane that was used transected the occiput, orbits, and nasal processes. *Data source:* ref. 124, with permission.

> *Comment:* Outer-orbital diameter is closely related to biparietal diameter. This measurement is useful when the fetal position precludes accurate measurement of biparietal diameter.

CEREBRAL VENTRICLES

A — Gestational age (wk)

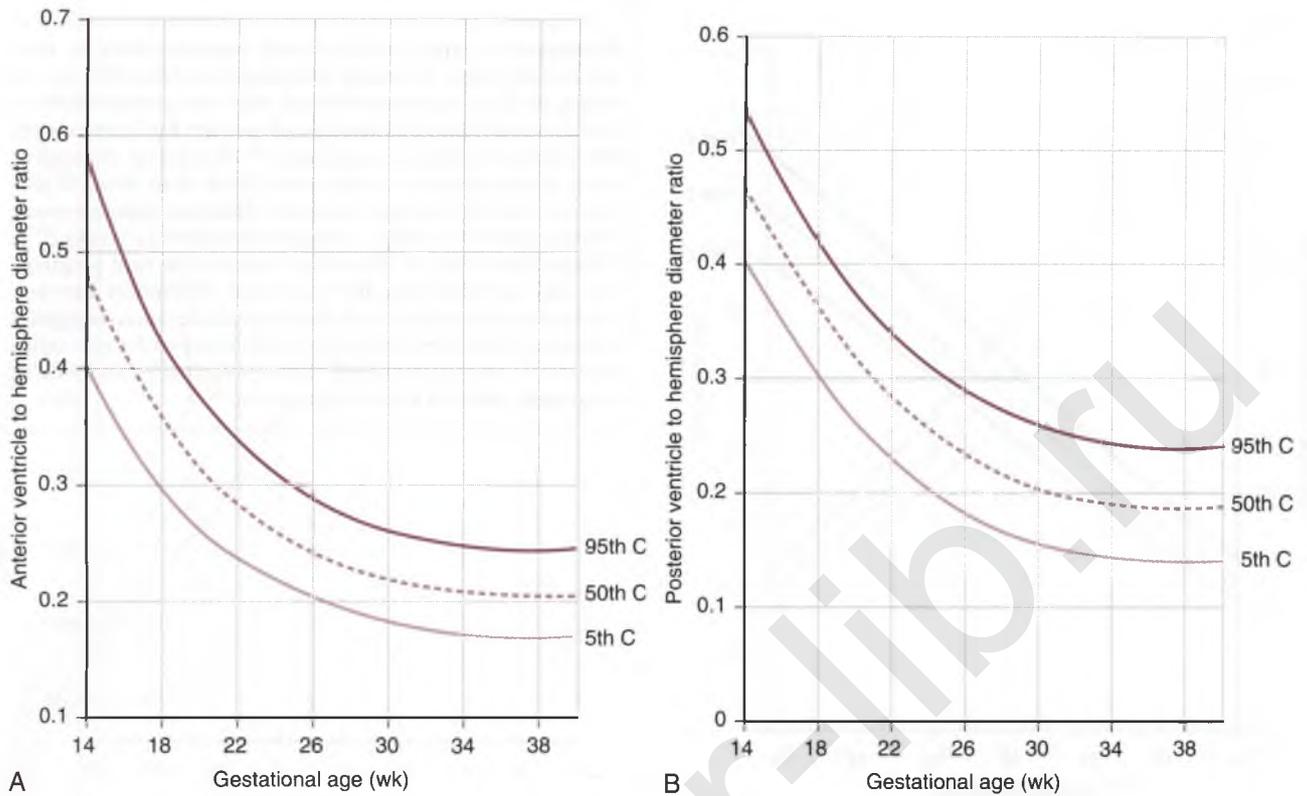
B — Gestational age (wk)


FIGURE 60

Ventriculohemispheric ratios (5th, 50th, and 95th percentiles) from a cross-sectional study of 1040 singleton pregnancies at 14 to 40 weeks' gestation, selected from a large database. All women had known last menstrual period dates, with a cycle length of 26 to 30 days. They had no pregnancy complications. Only data from structurally normal fetuses who were liveborn at 37 weeks' gestation or more and who had birth weights between the 3rd and 97th percentiles for gestation were included. For each week, measurements from 40 fetuses were obtained. Each fetus contributed measurements to the data pool on only one occasion. *A*, Measurement of the anterior horn of the lateral cerebral ventricle was made in a transverse axial plane of the fetal head (as for biparietal diameter or head circumference measurements), from the lateral wall of the anterior horn to the midline. *B*, Posterior horn measurements were made from the medial to the lateral wall of the posterior horn. Hemispheric measurements were made from the midline to the inner border of the skull. *Data source:* ref. 109, with permission.

Comment: The most reliable measurements of the ventricular system are made with the frontal horns of the lateral cerebral ventricles because they are the easiest to identify. In general, ventricular diameter should be less than 10 mm.

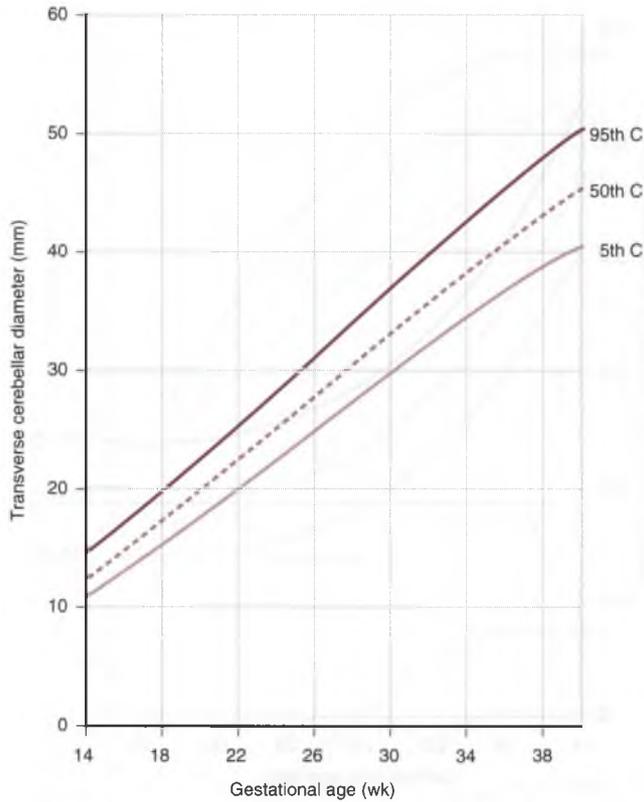
CEREBELLUM


FIGURE 61

Transverse cerebellar diameter (5th, 50th, and 95th percentiles) from the cross-sectional study of 1040 singleton pregnancies described in Figure 60. Measurements were made in the suboccipitobregmatic plane of the fetal head. *Data source:* ref. 109, with permission.

Comment: The cerebellum may be visualized as early as 10 to 11 weeks' gestation. Other studies found similar measurements.[125]

OTHER FETAL MEASUREMENTS

Comment: Normal ranges for many other fetal structures are described in the literature. Each may be useful under certain circumstances. Charts of liver length are useful in the assessment of isoimmunized fetuses, where liver length is inversely correlated with fetal hemoglobin levels.[126] Fetal ear measurements are helpful in the detection of fetuses with abnormal karyotypes.[127,128]

BIOMETRY IN MULTIPLE GESTATIONS

Comment: A study of ultrasound measurements in twin pregnancies after 24 weeks' gestation (involving 884 sets of twins, each of whom contributed only one measurement to the data set) found that the growth pattern for femur length was similar to that of singletons.[129] Abdominal circumference measurements in twins were lower than those in singletons after 32 weeks; biparietal diameter measurements were greater than those in singletons before 32 weeks.[129] A longitudinal study of 35 healthy women with twin pregnancies did not find clinically important differences between measurements of fetal size (head circumference, biparietal diameter, limb bone lengths) in twins compared with singletons.[130,131] Studies in normal triplet pregnancies found delay in growth patterns after midgestation.[132]

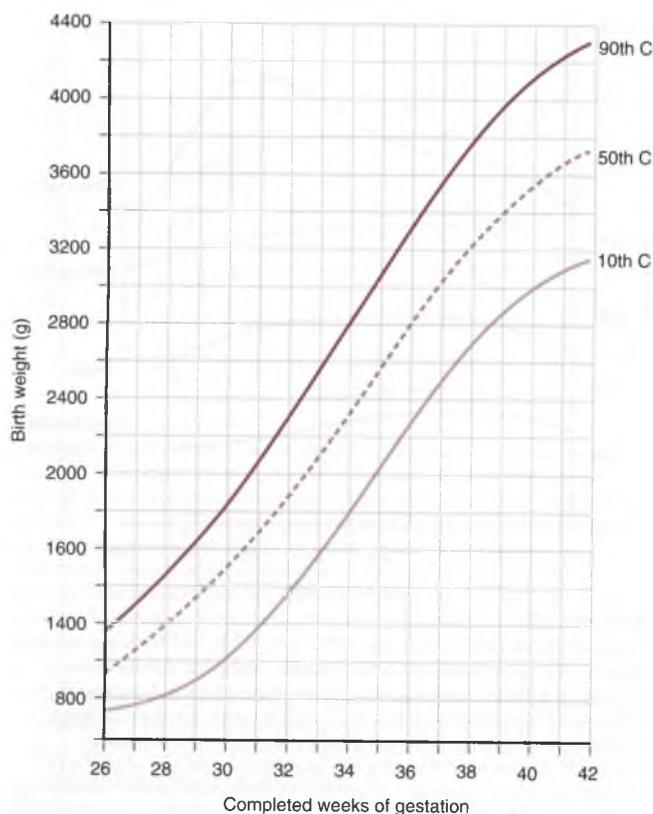
BIRTH WEIGHT


FIGURE 62

Birth weight (10th, 50th, and 90th percentiles) from an analysis of 41,718 singleton births in Nottingham, UK, between 1986 and 1991. All women had dates confirmed by ultrasound measurements (crown–rump length up to 13 weeks and biparietal diameter thereafter) before 24 weeks, and they delivered between 168 and 300 days' gestation. The population was of mixed ethnicity. *Data source:* ref. 133, with permission.

Comment: This study differs from previous reports[134,135] (which did not have ultrasound confirmation of gestational age) in that it found a continued increase, rather than flattening, of birth weight curves toward term. Birth weights of preterm infants (≤32 weeks' gestation) were negatively skewed, consistent with the observation that growth-restricted infants may be born earlier than those of appropriate size.[133] Birth weight is also dependent on ethnic origin, altitude, socioeconomic factors, maternal size, birth order, and maternal cigarette smoking.[133,136,137] All of the studies described here are for singletons. Different ranges apply to multiple pregnancies.

WEIGHT ESTIMATED FROM ULTRASOUND MEASUREMENTS

FIGURE 63

Weight estimated from ultrasound measurements (5th, 50th, and 90th percentiles) in a study of 138 women who underwent ultrasound examination within 48 hours of delivery for the measurement of fetal abdominal circumference (AC). Actual birth weights were compared with AC measurements, and a polynomial equation was derived to describe the relationship. *Data source:* ref. 138, with permission.

Comment: Equations have been derived for estimating fetal weight from various combinations of ultrasonic measurements (AC, biparietal diameter, head circumference, and femur length).[139,140] These estimates are reported to be more accurate than those based on AC measurements alone.

Amniotic Fluid

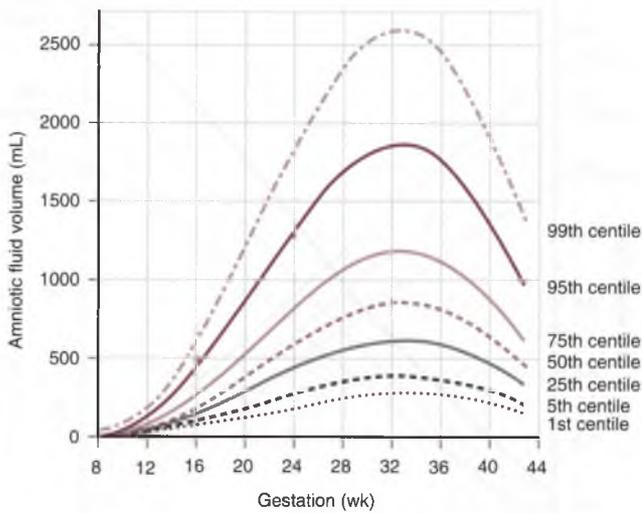
TOTAL VOLUME


FIGURE 64
Total amniotic fluid volume (1st, 5th, 25th, 50th, 75th, 95th, and 99th percentiles). Composite analysis of 12 published reports of amniotic fluid volume in human pregnancy, totaling 705 measurements. Amniotic fluid volume was measured directly at the time of hysterotomy or indirectly with an indicator dilution technique. Only healthy pregnancies were included; any complicated by fetal death or anomaly or by maternal disease were excluded. *Data source*: ref. 141, with permission.

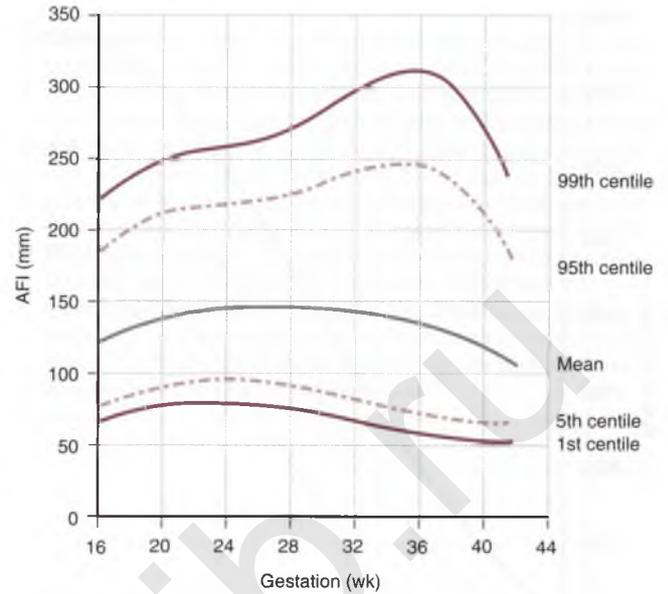
AMNIOTIC FLUID INDEX (AFI)


FIGURE 65
Amniotic fluid index (AFI) (1st, 5th, 50th, 95th, and 99th percentiles) from a prospective study of 791 patients. Any who did not have a normal pregnancy outcome (i.e., infant born at term, between the 10th and 90th percentiles for birth weight, with a 5-minute Apgar score >6, and without congenital anomaly) were subsequently excluded. Ultrasound imaging was performed, and the uterus was divided into four quadrants along the sagittal midline and midway up the fundus. The AFI was calculated as the sum of the deepest vertical dimension (in millimeters) of the amniotic fluid pocket in each quadrant of the uterus. *Data source:* ref. 142, with permission.

Comment: The volume of amniotic fluid increases to a plateau of 700 to 850 mL between 22 and 39 weeks' gestation. This volume corresponds to an AFI of 140 to 150 mm. After term, amniotic fluid volume decreases significantly.

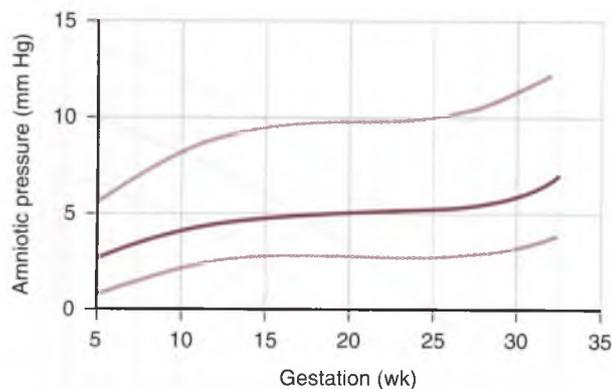
PRESSURE


FIGURE 66

Amniotic fluid pressure (mean and 95% CI) from a cross-sectional study of 171 singleton pregnancies subsequently shown to have a normal karyotype. Amniotic fluid volume was subjectively assessed as normal, based on ultrasonic appearance. All patients were scheduled to undergo an invasive diagnostic transamniotic procedure or therapeutic termination of pregnancy. Amniotic fluid pressure was measured with a manometry technique referenced to the top of the maternal abdomen. *Data source:* ref. 143, with permission.

Comment: Amniotic fluid pressure increases with gestation, reaching a midtrimester plateau of 4 to 5 mm Hg. Pressure was not affected by parity or maternal age and was similar in twin and singleton pregnancies.[143]

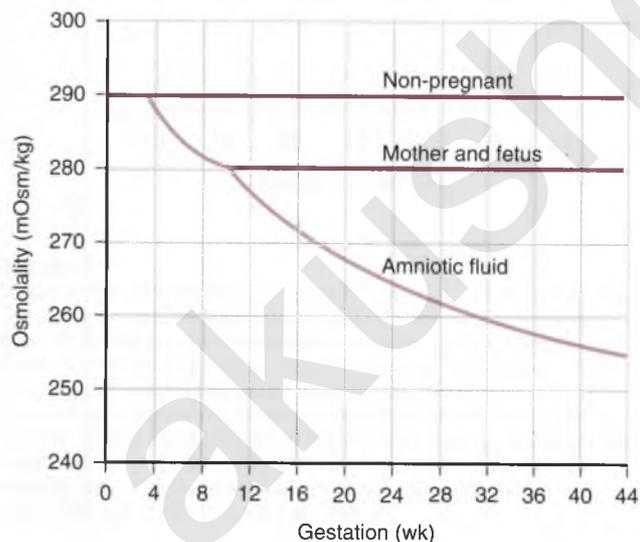
OSMOLALITY


FIGURE 67

Amniotic fluid osmolality (mean) from a composite analysis of six published reports. *Data source:* ref. 144, with permission.

Comment: In early pregnancy, the composition of amniotic fluid is consistent with a transudate of maternal or fetal plasma.[145] The fetal skin becomes keratinized by midpregnancy, and amniotic fluid solute concentrations decrease as fetal urine becomes more dilute.[145] Thus, there is an osmotic gradient between amniotic fluid and both maternal and fetal plasma.

Cardiac Dimensions

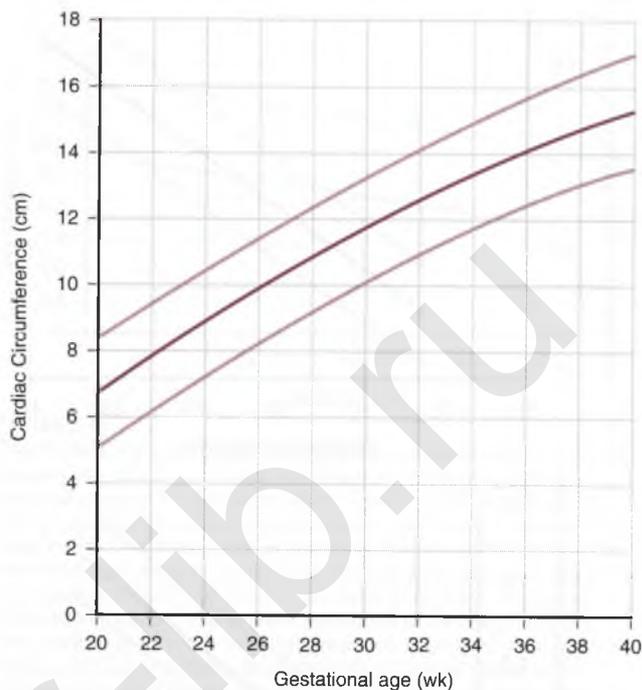
CARDIAC CIRCUMFERENCE


FIGURE 68

Cardiac circumference (mean and 95% CI) from a longitudinal study of 45 healthy women with known menstrual dates that were confirmed by early ultrasound scan. Study subjects were recruited before 20 weeks' gestation and underwent scanning every 4 weeks. Fetal cardiac and thoracic circumference was measured in a transverse plane through the chest, at the level of the four-chamber view of the fetal heart. *Data source:* ref. 146, with permission.

Comment: The cardiac-to-thoracic circumference ratio is normally approximately 0.5 (95% CI at 20 weeks, 0.40–0.58; at 30 weeks, 0.44–0.60; at 40 weeks, 0.46–0.65).[146]

VENTRICULAR DIMENSIONS

A

B

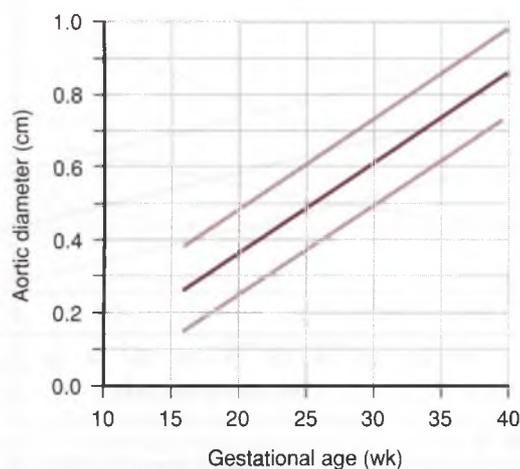
VENTRICULAR AND SEPTAL WALL THICKNESS

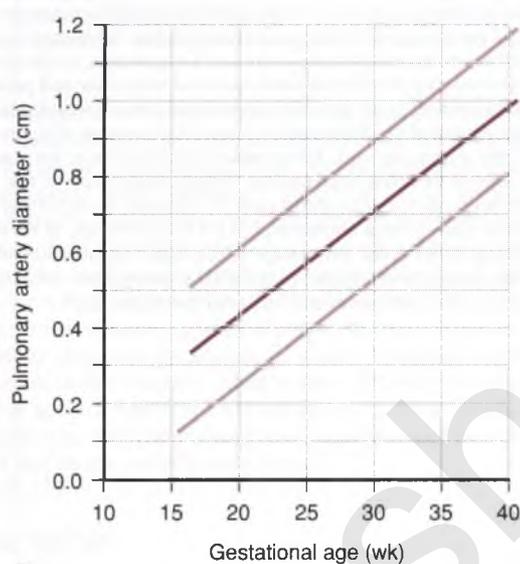
FIGURE 70
Thickness of the interventricular septum (regression line and 95% CI) from a study with cross-sectional and longitudinal data ($n = 100$ observations). Subjects were healthy and had their menstrual dates confirmed by ultrasound measurements; all subsequently were delivered at term. Interventricular septal thickness was measured in the four-chamber view of the fetal heart, just below the atrioventricular valves. *Data source:* ref. 148, with permission.

Comment: The thickness of the left or right ventricular wall is similar to that of the interventricular septum.

FIGURE 69
End-diastolic dimensions of *A*, the left ventricle and *B*, the right ventricle (regression line and 95% prediction interval) from a cross-sectional study of 117 normal women at 16 to 41 weeks' gestation. All fetuses were anatomically normal, and gestational age was confirmed by first-trimester ultrasound measurements. A four-chamber view of the heart was obtained in a transverse plane through the fetal chest. The transducer was adjusted so that the intraventricular septum was perpendicular to the ultrasound beam. In this view, transverse endocardial–endocardial dimensions of both ventricles were measured just below the valves, at the end of diastole. *Data source:* ref. 147, with permission.

Comment: This study found narrower confidence intervals for cardiac measurements than those described in earlier reports.[148] This finding was attributed to improved resolution of newer ultrasound equipment and the use of imaging planes perpendicular to the ultrasound plane (which reduces lateral resolution error). Close correlation was seen between measurements made by two observers in this study.

ASCENDING AORTA AND PULMONARY ARTERY DIAMETER


A


B

FIGURE 71

Diameter of *A*, the ascending aorta and *B*, the main pulmonary artery (regression line and 95% prediction interval) from a cross-sectional study of 117 fetuses at 16 to 41 weeks' gestation, as described in Figure 69. The aorta was measured in a long axis view of the heart, found by moving cephalad from the four-chamber view. Measurements were made between intimal surfaces when the aorta had been aligned perpendicular to the ultrasound beam, just above the sinuses of Valsalva. The main pulmonary artery was measured in a long axis view, with its vessel walls perpendicular to the ultrasound beam. *Data source:* ref. 147, with permission.

Comment: During intrauterine life, the diameter of the pulmonary artery is slightly larger than that of the aorta. It may not be possible to obtain good views of these vessels in the planes described. However, similar values were reported in other studies in which measurements were made in different scan planes.[148]

Cardiovascular Doppler Indices

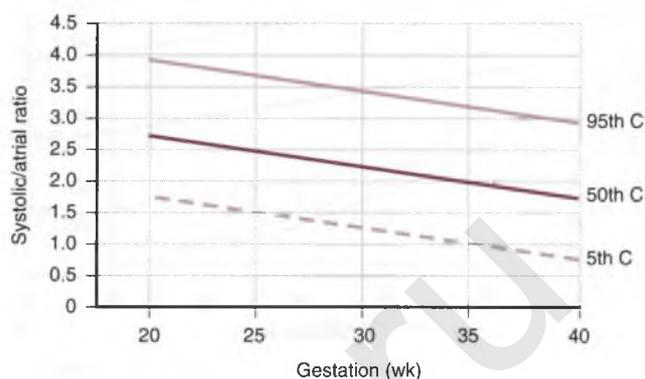
DUCTUS VENOSUS


FIGURE 72

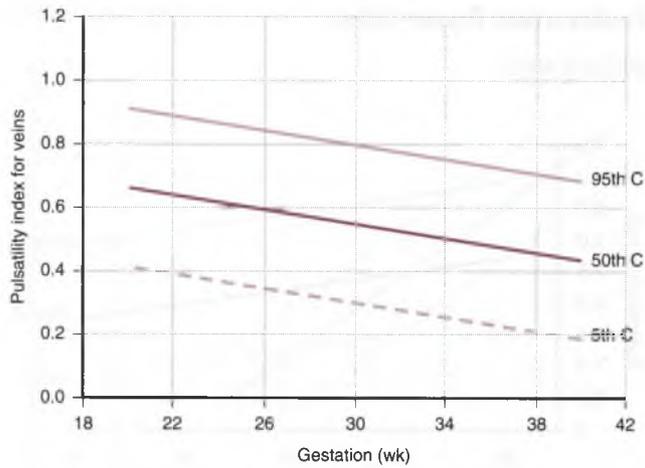
Systolic-to-atrial ratio (5th, 50th, and 95th percentiles) from ductus venosus Doppler flow velocity waveforms recorded in a cross-sectional study of 164 fetuses at 16 to 42 weeks' gestation. Fetal size was appropriate for gestational age, and no structural or chromosomal abnormalities were reported. Velocity waveforms were recorded from the ductus venosus at its origin from the umbilical vein, as visualized in a transverse section of the fetal abdomen with color and pulsed Doppler recordings. The angle of insonation of the vessel was kept low; recordings in which this angle exceeded 20 degrees were rejected. Ductus venosus waveforms were recognized by their characteristic biphasic pattern. The ratio between peak systolic velocity and velocity during atrial contraction (nadir of the waveform) was calculated. *Data source:* ref. 149, with permission.


FIGURE 73

Pulsatility index for veins from the ductus venosus (5th, 50th, and 95th percentiles) from a cross-sectional study of 143 women with singleton pregnancies at 20 to 40 weeks' gestation. All fetuses were anatomically normal. Gestational age was calculated from menstrual history and confirmed by fetal measurements made at 20 weeks' amenorrhea. At the time of the study, measurements of fetal head and abdominal circumference were within the 90% CI for gestational age. Movements, amniotic fluid volume, and umbilical artery Doppler pulsatility index were also normal. All measurements were made in the absence of fetal breathing movements. Flow velocity waveforms were recorded from the ductus venosus and visualized in an oblique transverse plane through the upper abdomen or in a midsagittal longitudinal plane. Good signals were obtained from 134 cases. The pulsatility index for veins was calculated as (peak systolic velocity − minimum atrial velocity/time-averaged maximum velocity). *Data source:* ref. 150, with permission.

Comment: Color-flow mapping Doppler equipment is necessary for correct identification of the ductus venosus. Waveforms from the intrahepatic portion of the umbilical vein and the inferior vena cava are different. The decreasing systolic-to-atrial ratio is interpreted as indicating a relative increase in blood flow during end diastole (i.e., improved cardiac filling).

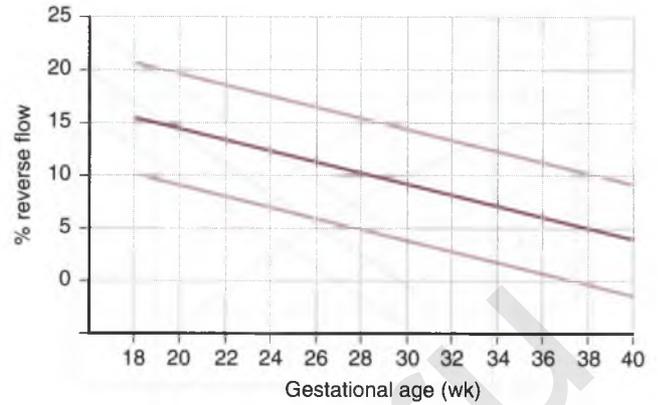
INFERIOR VENA CAVA


FIGURE 74

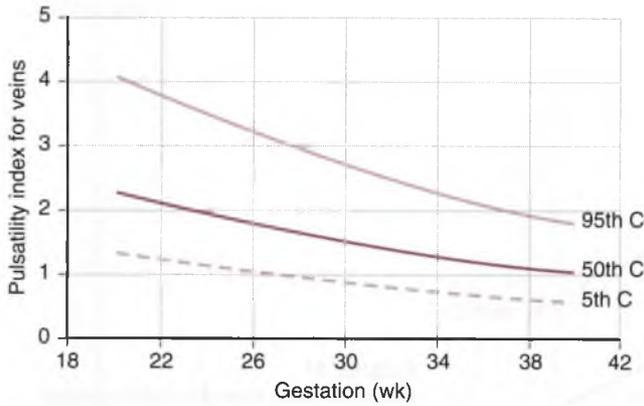
Percentage of reverse flow from the inferior vena cava (mean and linear regression of the 95th CI) from a cross-sectional study of 118 appropriate-for-gestational-age fetuses at 18 to 40 weeks' gestation. All pregnancies were singleton and were dated by certain last menstrual period and early second-trimester ultrasonography. All fetuses were structurally normal and of appropriate size for gestation at the time of study. Flow velocity waveforms were recorded with color and pulsed Doppler equipment from the inferior vena cava, which was identified in a saggital view of the fetal trunk between the entrance of the renal vein and the ductus venosus. Measurements were made in the absence of fetal body or breathing movements. Three components of the waveform were identified: systolic peak (S), diastolic wave (D), and reverse flow during atrial contraction (A). The percentage of reverse flow was calculated as the percentage of the time–velocity intervals during the A wave, with respect to the total forward time–velocity intervals (S + D). *Data source:* ref. 151, with permission.


FIGURE 75
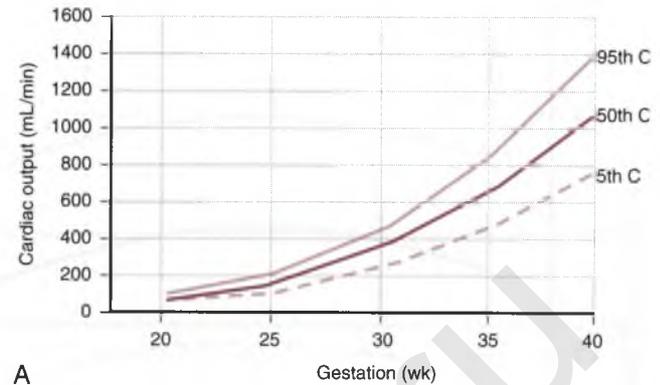
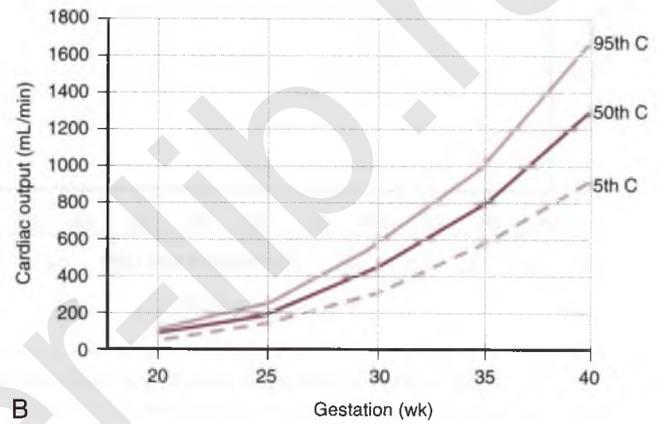
Pulsatility index for veins from the inferior vena cava (5th, 50th, and 95th percentiles) from the cross-sectional study of 143 women described in Figure 73. Flow velocity waveforms were recorded from the inferior vena cava in a longitudinal section of the fetal abdomen, with the sample volume placed in the portion between the renal and hepatic veins. Clear signals were obtained from 127 fetuses. The pulsatility index for veins was calculated as (peak systolic velocity – minimum atrial velocity/time-averaged maximum velocity). *Data source:* ref. 150, with permission.

Comment: Flow velocity waveforms in the inferior vena cava are characteristically triphasic, with reverse velocities found during atrial contraction. These reverse velocities decrease significantly with advancing gestation. This decrease is attributed to a decrease in the pressure gradient between the right atrium and right ventricle at end diastole as a result of improved ventricular compliance and reduced end-diastolic pressure. Right ventricular afterload declines with decreasing placental resistance, contributing to the reduction in end-diastolic pressure. In studies in which Doppler waveforms were recorded from the inferior vena cava and ductus venosus in growth-restricted fetuses before cordocentesis, fetal hypoxemia, and acidemia were associated with more reverse flow and more pulsatile waveforms.[152,153]

CARDIAC FUNCTION

Comment: Normal ranges have been defined for Doppler flow velocity waveform indices derived from across the mitral, tricuspid, aortic, and pulmonary valves.[150,154,155] These have potential use in the assessment of cardiac function in growth-restricted fetuses and fetuses with structural heart defects. Waveforms from the ductus arteriosus show considerable individual variability[156] and do not appear to be useful in the detection of fetal compromise. Waveforms from peripheral pulmonary arteries show decreasing pulsatility with advancing gestation in healthy fetuses.[157]

CARDIAC OUTPUT


A


B

FIGURE 76
A, Left cardiac output (LCO) *B*, right cardiac output (RCO) calculated at the level of the outflow tracts (5th, 50th, and 95th percentiles) from a longitudinal study of 26 healthy singleton fetuses studied at weekly intervals. Velocity waveforms were recorded from the ascending aorta and pulmonary artery with the flow parallel to the Doppler beam. Recordings obtained with a beam angle greater than 20 degrees were rejected. Valve diameter measurements were made from videotape images, and valve areas were calculated by assuming a circular cross-section. *Data source:* ref. 154, with permission.

Comment: Cardiac output rises progressively with gestation, with RCO slightly higher than LCO (RCO/LCO ratio, approximately 1.3). Peak flow velocity at both the aortic and pulmonary valves increases with gestation. This increase is attributed to progressive improvement in cardiac contractility, reduction in afterload, and increase in preload.[154] This type of calculation of volume flow is susceptible to high coefficients of variation because an error in the measurement of diameter (e.g., valve ring diameter) is magnified as the cross-sectional area is computed.

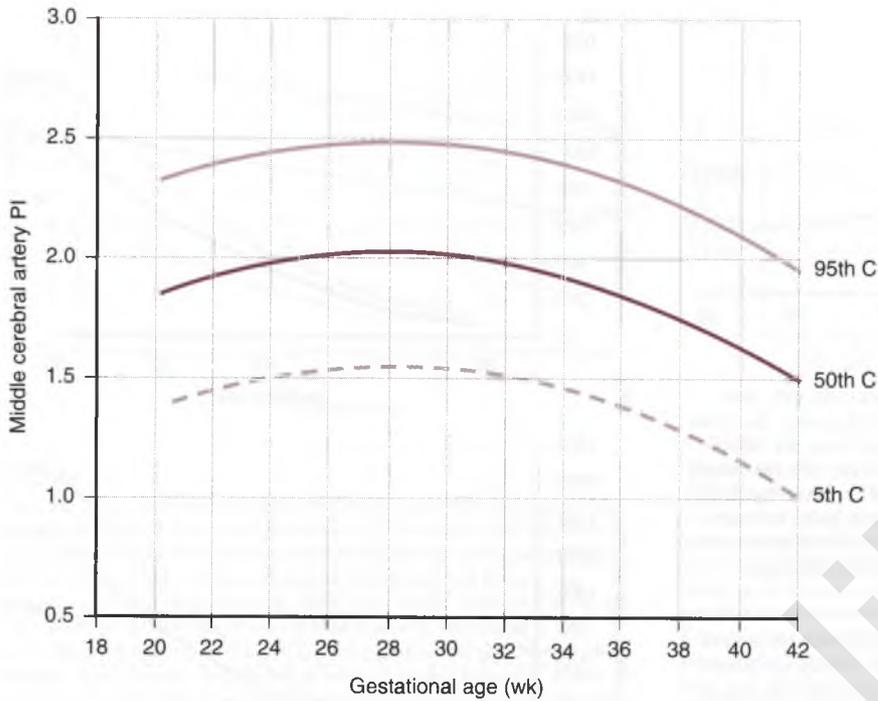
MIDDLE CEREBRAL ARTERY


FIGURE 77
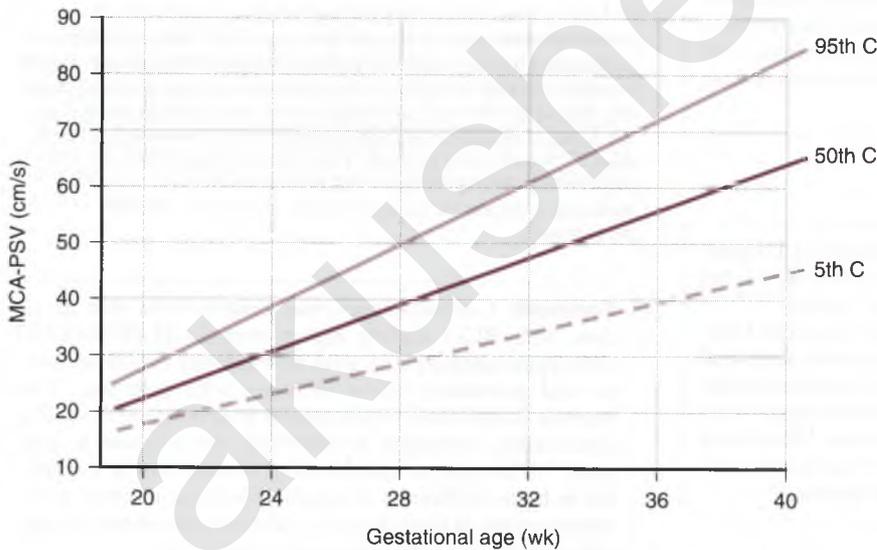
Pulsatility index from the middle cerebral artery (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 fetuses at 20 to 42 weeks' gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of crown–rump length. Color flow imaging was used to identify the fetal middle cerebral artery, and waveforms were recorded at a low angle of insonation. Good signals were obtained from 1467 fetuses. Pulsatility index was calculated as (maximum systolic velocity – diastolic velocity/mean velocity). *Data source:* ref. 158, with permission.


FIGURE 78
Peak systolic velocity from the middle cerebral artery (5th, 50th, and 95th percentiles) from a cross-sectional study of 331 women at 19 to 40 weeks' gestation. All fetuses were singletons, and none of the pregnancies were complicated by blood group antibodies, hypertension, diabetes, or congenital abnormalities. Only one measurement from each fetus was included in the study. The middle cerebral artery was identified in an axial section of the fetal brain and insonated at a low angle. The highest point on the waveform (peak systolic velocity) was measured. *Data source:* ref. 159, with permission.

Comment: A longitudinal study of middle cerebral artery (MCA) Doppler waveforms found that pulsatility index values are higher at 25 to 30 weeks' gestation than those at 15 to 20 weeks, or toward term.[160] Diameter of the fetal MCA increases with gestational age. In one study,[161] calculated volume blood flow in the artery increased from 23 mL/min at 19 weeks' gestation to 133 mL/min at term. Doppler waveforms from the MCA may also be quantitated with a resistance index (maximum systolic velocity – minimum diastolic velocity/systolic velocity).[162] When MCA waveforms are recorded, care must be taken to apply minimal pressure to the maternal abdomen because fetal skull compression may alter MCA flow.[163] Different signals are obtained in the distal portion of the MCA, and most studies have concentrated on the proximal portion, close to the circle of Willis.[164] Changes in MCA Doppler waveforms are noted in growth-restricted fetuses, suggesting that fetal cardiac output may be redistributed to preserve brain blood.[60,163,164] High MCA peak systolic velocities are associated with fetal anemia in pregnancies complicated by maternal alloimmunization.[165,166]

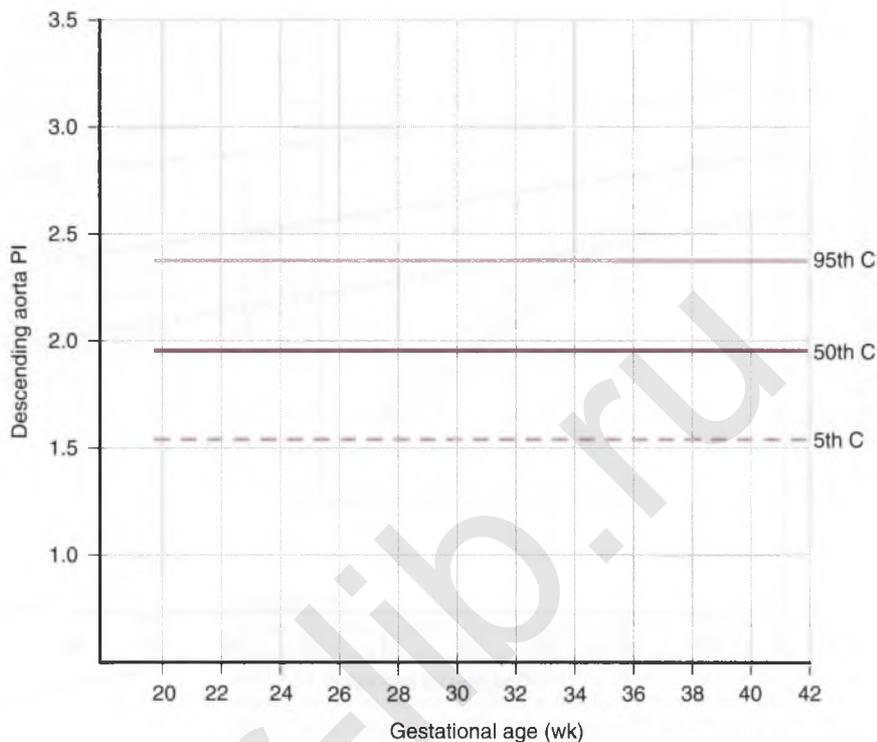
DESCENDING AORTA


FIGURE 79

Descending aorta pulsatility index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 healthy pregnancies at 20 to 42 weeks' gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of crown–rump length. Recordings from the thoracic portion of the descending aorta were made in the absence of fetal body or breathing movements. Satisfactory recordings were obtained in 1398 fetuses. The pulsatility index was calculated as (systolic velocity – diastolic velocity/mean velocity). *Data source:* ref. 158, with permission.

Comment: Unlike in other fetal vessels, no significant change with gestation was seen in the aortic pulsatility index.

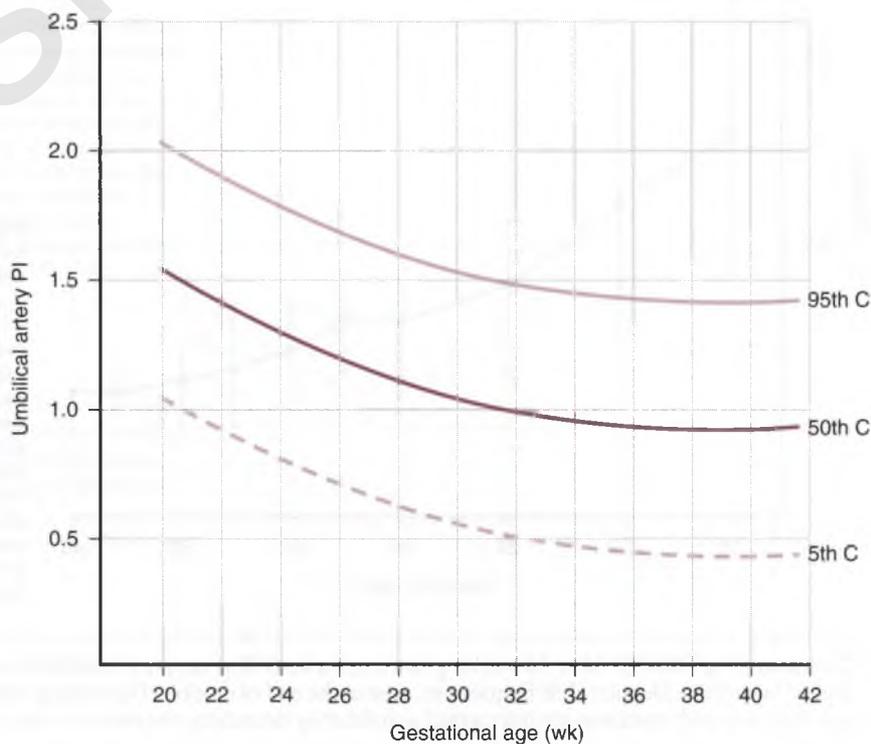
UMBILICAL ARTERY


FIGURE 80

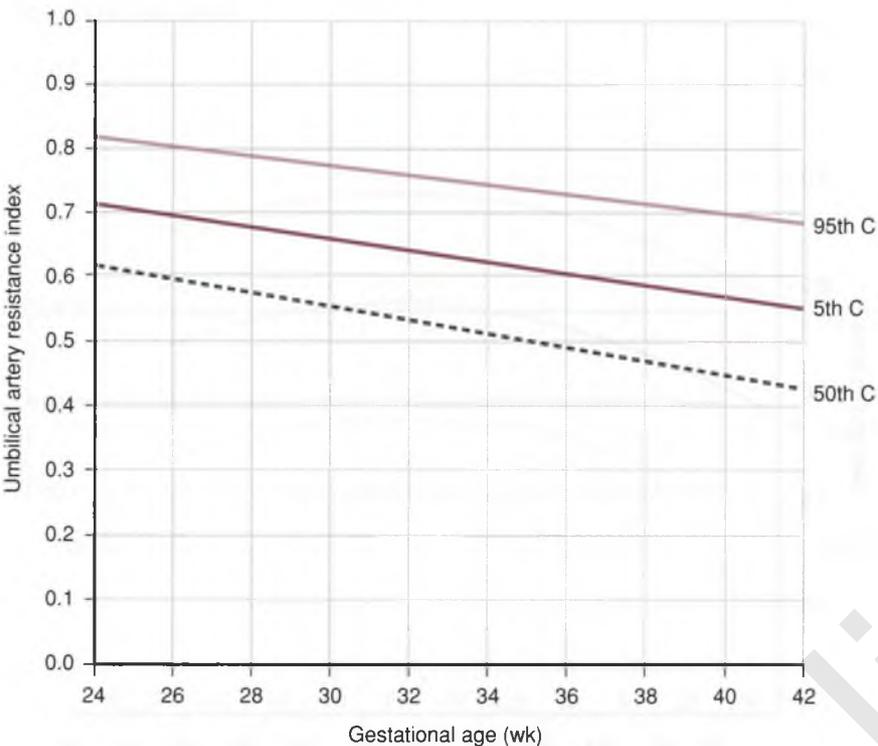
Umbilical artery pulsatility index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 healthy pregnancies at 20 to 42 weeks' gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of crown–rump length. Recordings from the umbilical artery were made in the absence of fetal body or breathing movements. The pulsatility index was calculated as (systolic velocity – diastolic velocity/mean velocity). *Data source:* ref. 158, with permission.


FIGURE 81
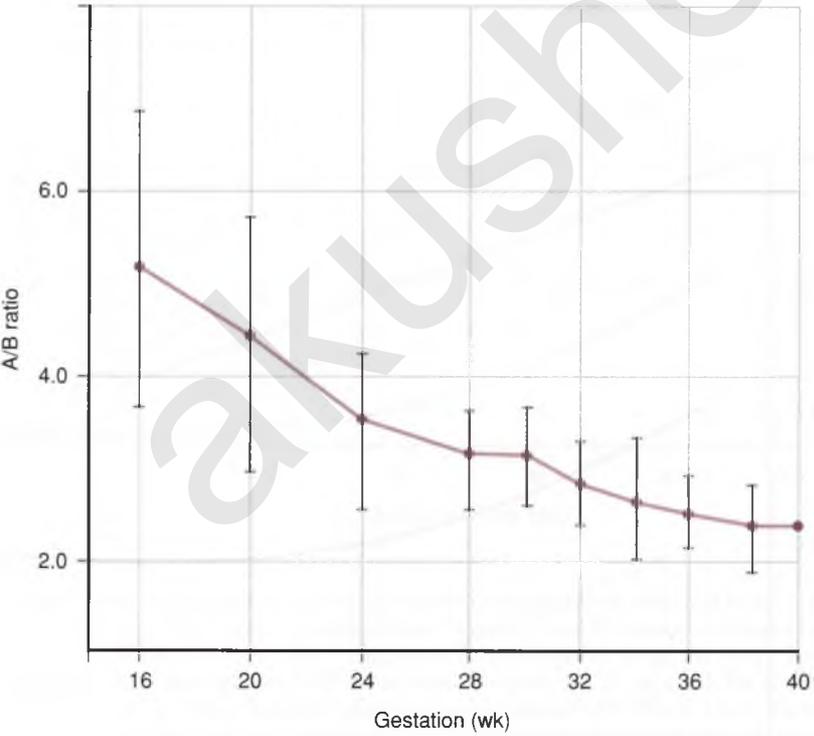
Umbilical artery resistance index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1675 pregnancies at 24 to 42 weeks' gestation. Each fetus contributed only one measurement to the study. Signals were recorded from a free-floating loop in the middle of the umbilical cord. Resistance (Pourcelot) index was calculated as (systolic diastolic velocity/systolic velocity). *Data source:* ref. 162, with permission.


FIGURE 82
Systolic-to-diastolic ratio (A/B ratio) calculated from umbilical artery flow velocity waveforms (mean ± 2 SDs) obtained in a longitudinal study of 15 normal pregnancies. Study subjects were scanned every 2 weeks, from 24 to 28 weeks' gestation until delivery. Eight of the study subjects had been recruited at 16 weeks and were also scanned every 4 weeks throughout the second trimester. In all subjects, gestational age was confirmed by ultrasound scanning at 16 weeks' gestation. A range-gated pulsed Doppler beam was guided from the ultrasound image to insonate the umbilical artery. *Data source:* ref. 167, with kind permission from Elsevier Science Ireland Ltd, Co. Clare, Ireland.

Comment *(Figs. 80–82):* After 16 weeks' gestation, forward flow occurs in umbilical arteries throughout the cardiac cycle, as evidenced by positive Doppler shift frequencies, even at the end of diastole. Decreasing values for the resistance index, pulsatility index, and A/B ratio with gestation are interpreted as indicating decreasing resistance in the placental circulation.

FETAL–PLACENTAL DOPPLER RATIOS

Comment: Various ratios have been suggested to compare fetal cerebral flow velocity waveforms with those from the umbilical artery or aorta. These waveforms may be useful in detecting alterations in fetal cardiac output distribution (e.g., in response to fetal hypoxemia ["brain-sparing" effect]). The placentocerebral ratio[162] describes resistance indices from the umbilical artery and middle cerebral artery. The cerebroplacental ratio[168] describes resistance indices from the middle cerebral artery and umbilical artery. The umbilical artery-to-middle cerebral artery ratio[158] describes pulsatility indices from the umbilical artery and middle cerebral artery. The descending thoracic aorta-to-middle cerebral artery ratio[158] describes pulsatility indices from the descending thoracic aorta and middle cerebral artery.

Cardiovascular and Behavioral Parameters

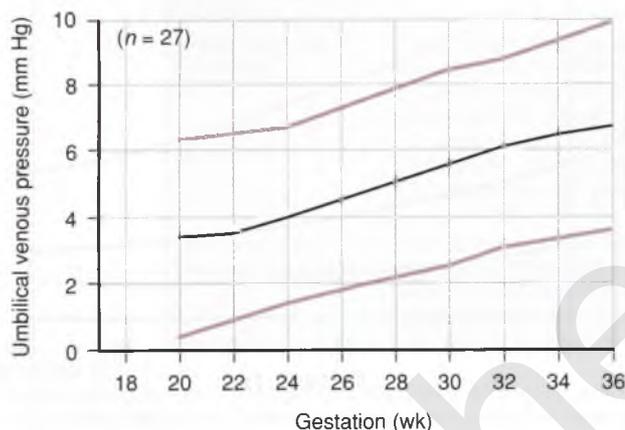
UMBILICAL VENOUS PRESSURE (UVP)


FIGURE 83
Umbilical venous pressure (mean and 95% CI) from 27 fetuses referred for assessment of possible intrauterine infection or hemolysis, but subsequently shown to be unaffected. All of the fetuses underwent cordocentesis; after the necessary blood samples were obtained, the needle was connected to a pressure transducer. The transducer was placed at the level of the fetal heart, and the pressure was read at its nadir. The needle was confirmed to be in the umbilical vein by the nonpulsatile pressure tracing that was obtained and by observing the direction of flow of injected saline. As the needle was withdrawn, pressure in the amniotic cavity was recorded. Umbilical venous pressure was calculated by subtracting the amniotic pressure from the measured umbilical venous pressure. *Data source:* ref. 169, with permission.

Comment: Umbilical venous pressure increases with advancing gestation, but remains within a narrow range. Values above the confidence interval are associated with cardiac failure.[170]

MEAN UMBILICAL ARTERIAL PRESSURE (MAP)

FIGURE 84
Mean umbilical arterial pressure (mean and 95% CI) from 30 normal fetuses referred for assessment of possible infection or hemolysis, but found to be unaffected. The method was identical to that described in Figure 66. It was apparent that the needle tip was in an umbilical artery rather than a vein (because of a pulsatile pressure signal). *Data source:* ref. 171, with permission.

Comment: The normal range of arterial pressure in the fetus is much more narrow than the range of umbilical venous pressure. Arterial pressure increases with gestational age.

FETAL HEART RATE (FHR)

A   Baseline heart rate

B   Amplitude of variability

C   Amplitude of accelerations

D

FIGURE 85

Fetal heart rate (FHR) parameters (mean and 95% CI) showing *A*, the baseline heart rate, *B*, the amplitude of variability, Fetal heart rate (FHR) Parameters (mean and 95% CI) showing *C*, the amplitude of accelerations, and *D*, the number of decelerations. Data were obtained from a cross-sectional study of 119 pregnancies at 20 to 39 weeks' gestation. Study subjects were referred for prenatal diagnosis by cordocentesis. In all cases, fetal blood gas values, hemoglobin, and karyotype were subsequently shown to be normal; none of the fetuses had hydrops fetalis or a cardiac defect. FHR monitoring was performed immediately before cordocentesis for 30 minutes, and tracings were examined for baseline heart rate, variability, accelerations, and decelerations. *Data source:* ref. 172, with permission from S Karger AG, Basel.

FIGURE 86

Features of a normal antepartum cardiotocogram (nonstress test). *Data source:* ref. 173, with permission.

- At least two accelerations (>15 beats for >15 s) in 20 min, baseline heart rate 110–150 bpm, baseline variability 5–25 bpm, absence deacceleration.

- Sporadic deaccelerations amplitude <40 bpm are acceptable if duration <15 s, or <30 s following an acceleration.

- When there is moderate tachycardia (150–170 bpm) or bradycardia (100–110 bpm) a reactive trace is reassuring of good health.

Comment: Baseline FHR decreases with gestation, but the variability of the baseline increases. The number and amplitude of accelerations increase with gestation. Spontaneous decelerations are common in the second and early third trimesters, but rarely in healthy fetuses approaching term. Definitions of the features of normal and abnormal cardiotocograms are available.[174] During labor, criteria for the interpretation of FHR tracings are different (see Fig. 104).

BIOPHYSICAL PROFILE SCORE (BPS)

Fetal variable	Normal behavior (score = 2)	Abnormal behavior (score = 0)
Fetal breathing movements	More than one episode of 30 s duration, intermittent within a 30 min overall period. Hiccups count. (Not continuous throughout the observation time)	Repetitive or continuous breathing without cessation. Completely absent breathing or no sustained episodes
Gross body/limb movements	Three or more discrete body/limb movements in a 30 min period. Continuous active movement episodes are considered as a single movement. Also included are fine motor movements, positional adjustments and so on.	Two or fewer body/limb movements in a 30 min observation period
Fetal tone and posture	Demonstration of active extension with rapid return of flexion of fetal limbs, brisk repositioning/trunk rotation. Opening and closing of hand, mouth, kicking, etc.	Only low-velocity movements, incomplete return to flexion, flaccid extremity positions; abnormal fetal posture. Includes score = 0 when FM absent
Fetal heart rate reactivity	Greater than 2 significant accelerations associated with maternally palpated fetal movement during a 20 min cardiotocogram. (Accelerations graded for gestation: 10 beats/min for 10 s before 26 weeks; 15 beats/min for 15 s after 26 weeks; 20 beats/min for 20 s at term)	Fetal movement and accelerations not coupled. Insufficient accelerations, absent accelerations, or decelerative trace. Mean variation <20 on numerical analysis of CTG
Amniotic fluid volume evaluation	One pocket of >3 cm without umbilical cord loops. More than 1 pocket of >2 cm without cord loops. No elements of subjectively reduced amniotic volume.	No cord-free pocket >2 cm, or elements of subjectively reduced amniotic fluid volume definite

FIGURE 87

Scoring system for five fetal biophysical variables (breathing movements, gross body and limb movements, tone and posture, heart rate reactivity, and amniotic fluid volume) developed for the assessment of patients with high risk pregnancies. This scoring system was evaluated in 216 patients who were studied in the week before delivery and whose eventual pregnancy outcome was documented. No perinatal deaths occurred in this study when all five variables were present at the time of examination with ultrasound and cardiotocography. Low scores (≤6 of 10) were associated with an increased incidence of adverse outcomes (i.e., fetal distress in labor, Apgar scores ≤7 at 5 minutes, perinatal death). *Data source:* ref. 175, with permission.

Comment: Various means of monitoring fetal well-being antenatally have been proposed (i.e., cardiotocography, observation of fetal breathing patterns, measurement of amniotic fluid volume). Scoring systems that consider a combination of behavioral parameters are better able to detect a compromised fetus and allow early delivery.[176] The use of these scoring systems led to improved perinatal mortality rates, even in a high risk group of pregnant women.[176] Fetal behavior is periodic and is affected by external factors (e.g., maternal ingestion of stimulant or depressant drugs, maternal hypoglycemia or hyperglycemia) and by structural or genetic abnormalities. Fetal behavior changes abruptly from a quiescent pattern to an active pattern and vice versa; therefore, ultrasound observation may need to be extended for 30 or 40 minutes to confirm the absence of fetal movements or breathing. Most biophysical profile score (BPS) studies are completed in less than 10 minutes.[175] Acute events may occur that invalidate the predictive accuracy of the BPS (e.g., abruptio placentae, diabetic ketoacidosis, eclampsia).

Biochemistry

Proteins

A

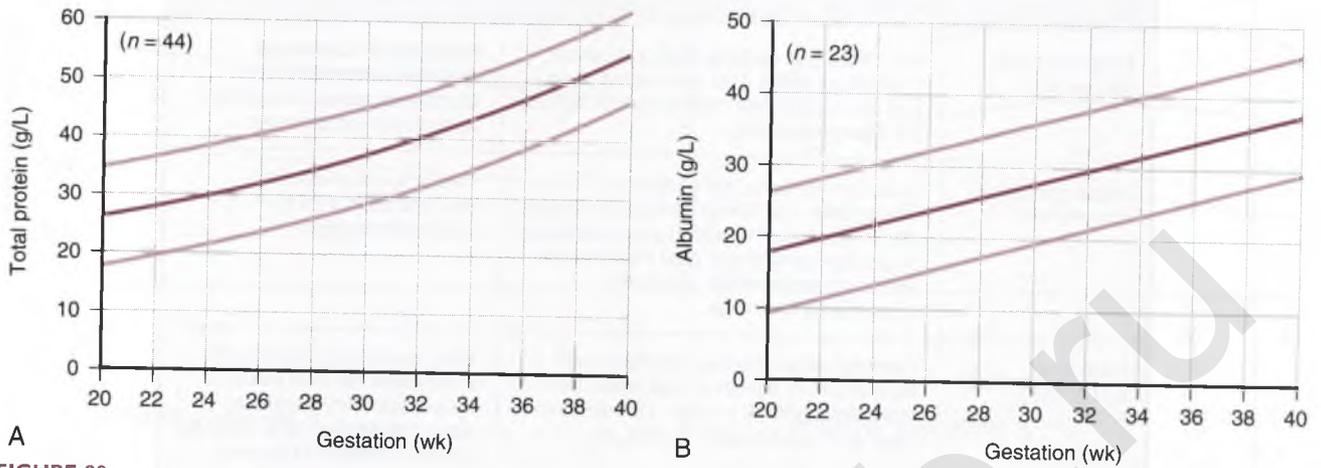
B


FIGURE 88

A, Total protein and *B,* albumin concentrations (regression curve and 95% CI) from a cross-sectional study of 45 fetuses subsequently shown to be normal at birth. Blood samples were obtained by ultrasound-guided cordocentesis. *Data source:* ref. 177, with permission.

Renal Function Tests, Liver Function Tests, and Glucose

FIGURE 89

Glucose, calcium, liver function, and renal function test results (mean ± SD) from a cross-sectional study of 78 fetuses at 20 to 26 weeks' gestation; all fetuses were subsequently shown to be healthy at birth. Blood samples were obtained by ultrasound-guided cordocentesis. *Data source:* ref. 178, with permission.

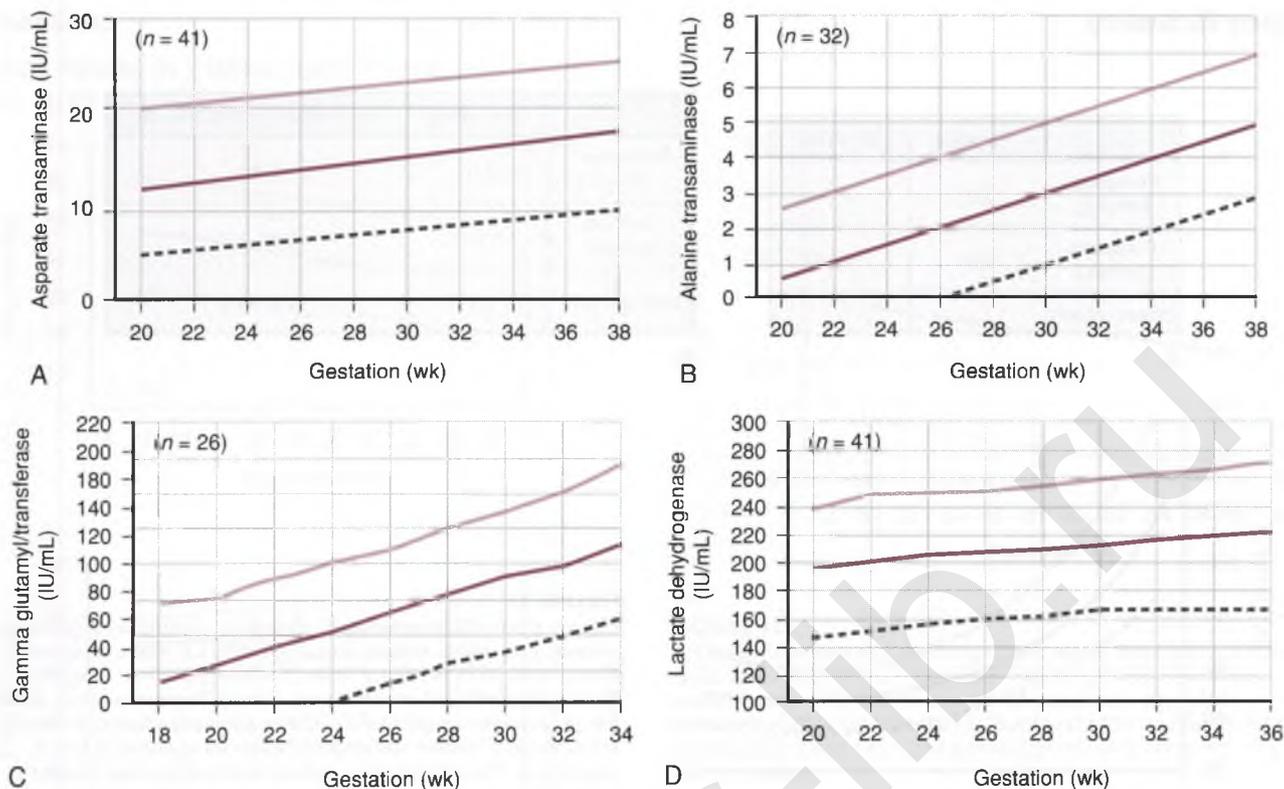
	SI units (mean ± SD)	Traditional units (mean ± SD)
Glucose	4.3 ± 0.6 mmol/L	7.7 ± 1.1 mg/dL
Cholesterol	1.5 ± 0.3 mmol/L	59 ± 11 mg/dL
Uric acid	179 ± 39 mol/L	2.8 ± 0.6 mg/dL
Triglycerides	4.5 ± 1.1 µmol/L	40 ± 10 mg/dL
Total bilirubin	26.3 ± 5.8 µol/L	15 ± 0.3 mg/dL
Alkaline phosphatase	260 ± 65 IU/L	
Gamma glutamyl transferase	60 ± 34 IU/L	
Asparate transaminase	17 ± 6.5 IU/L	
Creatinine	1.8 ± 0.3 mol/L	0.02 ± 0.003 mg/dL
Calcium	2.3 ± 0.2 mmol/L	9.2 ± 0.8 mg/dL


FIGURE 90

A, Aspartate transaminase (AST), *B*, alanine transaminase (ALT), *C*, γ-glutamyl transferase (GGT), and *D*, lactate dehydrogenase (LDH) concentrations (regression line and 95% CI) from a cross-sectional study of 80 fetuses referred for assessment of possible intrauterine infection or hemolysis, but subsequently shown to be unaffected. All study subjects underwent cordocentesis, and blood samples were obtained for liver enzyme assays. Individual graphs show the number of assays performed for each enzyme. *Data source:* ref. 169, with permission.

Comment *(Figs. 88–90):* Plasma total protein and albumin concentrations increase significantly with gestational age.[177] Little information is available about many other biochemical variables. Triglyceride levels decrease with advancing gestation,[178] bilirubin levels increase,[179] and liver enzyme concentrations (other than LDH) increase.[169] Fetal concentrations of bilirubin are higher and triglyceride and cholesterol concentrations are lower than those in maternal serum.[178] Fetal plasma insulin levels increase with gestation.[180]

Urinary Biochemistry

A

	16 weeks	33 weeks
Phosphate (mmol/L)	0.91	0.10
Creatinine (μmol/L)	99.9	172.9
(mean values)		

B
	Mean value	95% confidence intervals (CI)
Potassium (mmol/L)	3.0	0–6.1
Calcium (μmol/L)	0.21	0.04–1.2
Urea (μmol/L)	7.9	2.6–13.1

C

FIGURE 91

Urinary electrolytes, including *A*, phosphate, creatinine, *B*, potassium, calcium, urea and *C*, sodium (mean and 95% CI, where computed) from a study of 26 women at 16 to 33 weeks' gestation. Amniotic fluid volume and fetal anatomy were normal. Seventeen of the women had pregnancies complicated by Rhesus alloimmunization; in these cases, the fetal bladder was emptied before intraperitoneal blood transfusion. The other women had aspiration of the fetal bladder before therapeutic termination. *Data source:* ref. 181, with permission.

FIGURE 92

Urinary creatinine (5th, 50th, and 95th percentiles) from a study of 20 fetuses with obstructive uropathy and no features of renal dysplasia. All fetuses had normal postnatal renal function. Ultrasound-guided needle aspiration of fetal urine was performed. The fetal bladder was aspirated when it was distended, and both kidneys appeared similar; the renal pelvis was aspirated when unilateral pelvicalyceal dilation was seen. In all cases, the fetal karyotype was normal. *Data source:* ref. 182, with permission.

Comment *(Figs. 91 and 92):* Previously, fetal urinary biochemistry had been studied only indirectly from examination of the amniotic fluid.[145] These direct studies found that urinary sodium and phosphate levels decreased significantly with gestational age over the period studied (16–33 weeks); creatinine levels increased. Urinary potassium, calcium, and urea did not show gestational changes. The pattern of electrolyte changes suggests parallel maturation of glomerular and tubular function with advancing gestation. Fetuses with obstructive uropathy but normal postnatal renal function[182] had sodium and urea values similar to those shown in Figure 91. However, reference ranges for urinary calcium were calculated as 0.25, 0.95, and 1.65 mmol/L (5th, 50th, and 95th percentiles, respectively).[182] Various groups have suggested urinary electrolyte values that predict an adverse outcome (e.g., sodium level >100 mmol/L, creatinine level >150 μmol/L [1.7 mg/dL], calcium level >2 mmol/L [8 mg/dL], osmolality >200 mOsm/L). However, these values are not universally accepted.[183,184] These data show that sodium concentration of greater than 100 mmol/L may be normal for fetuses at less than 20 weeks' gestation.

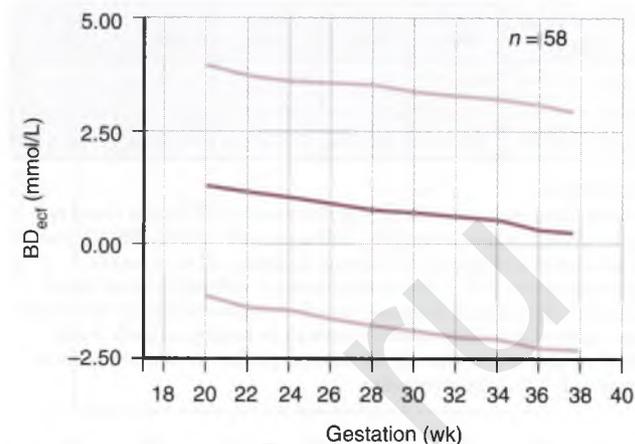
Blood Gases

OXYGEN PRESSURE (P_{O_2}), CARBON DIOXIDE PRESSURE (P_{CO_2}), PH, AND BASE DEFICIT

A

B

C

D


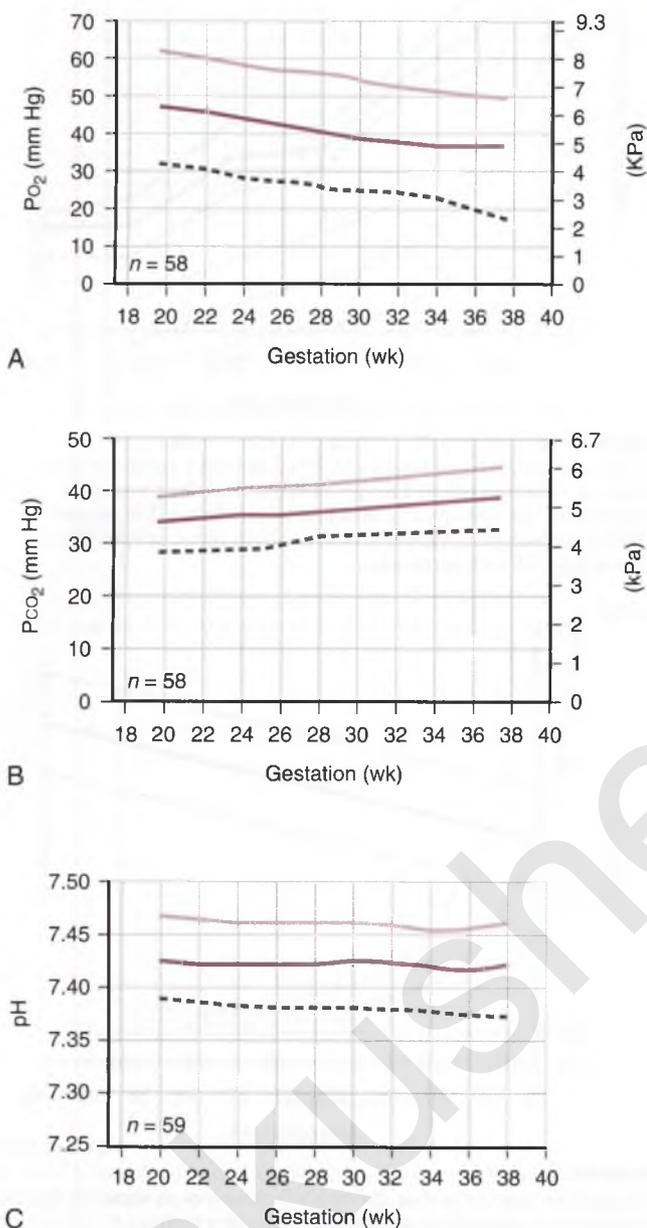


FIGURE 93

A, Umbilical venous P_{O_2}, *B*, P_{CO_2}, *C*, pH, and *D*, base deficit of the extracellular fluid (2.5th, 50th, and 97.5th percentiles) from a cross-sectional study of 59 fetuses referred for assessment of possible intrauterine infection or hemolysis, but found to be unaffected. All were healthy at birth and appropriately grown. *Data source:* ref. 185, with permission.

Comment: Umbilical arterial and venous P_{O_2} and pH decrease, and P_{CO_2} increases with gestational age.[186] Concentrations of lactate do not change with gestation; mean (SD) values are 0.99 mmol/L (0.32) for the umbilical vein and 0.92 mmol/L (0.21) for the umbilical artery.[186] Intervillous blood has higher P_{O_2} and lower P_{CO_2} than umbilical venous blood, but similar pH and lactate concentrations.[187] The decrease in P_{O_2} in umbilical venous blood that is seen with advancing gestation is offset by the increasing fetal hemoglobin concentration. As a result, the blood oxygen content remains constant; mean umbilical venous oxygen content is 6.7 mmol/L (0.6).[187]

Hematology

Complete Blood Count (CBC)

Gestational age (weeks)	WBC (10^9/L)	PLT (10^9/L)	RBC (10^{12}/L)	Hb (g/dL)	MCV (fL)
18–23 ($n = 771$)	4.41 ± 1.2	241 ± 45	2.87 ± 0.2	11.7 ± 0.8	131.2 ± 7.3
24–29 ($n = 407$)	4.6 ± 1.3	267 ± 49	3.38 ± 0.32	12.8 ± 1.1	119.1 ± 5.6
30–35 ($n = 55$)	5.8 ± 1.6	265 ± 59	3.86 ± 0.43	14.1 ± 1.4	114.3 ± 7

FIGURE 94

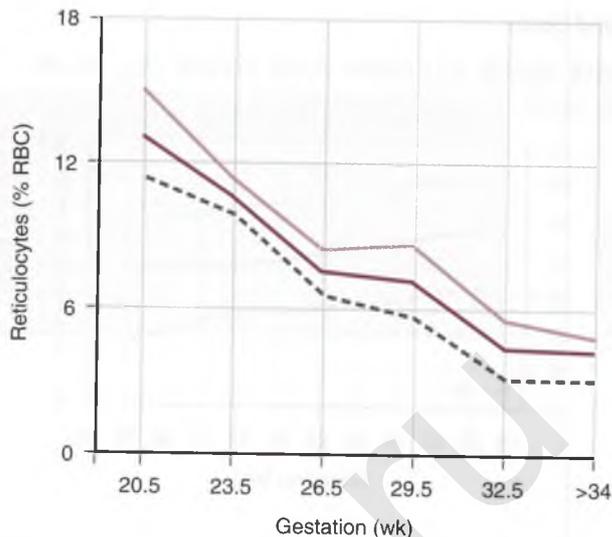
White blood cell count (WBC), platelet count (PLT), red blood cell count (RBC), hemoglobin (Hb), and mean cell volume (MCV) from a cross-sectional study of 1233 normal fetuses at 18 to 36 weeks' gestation (mean ± SD). Study subjects were referred for fetal blood sampling for prenatal diagnosis (mostly toxoplasmosis), but the fetuses were normal and subsequently shown to be healthy at birth. Fetal blood samples were taken by ultrasound-guided cordocentesis. *Data source:* ref. 178, with permission.


FIGURE 96

Fetal reticulocyte count (mean and 95% CI) from a cross-sectional study of 81 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently shown to be unaffected. Ultrasound-guided cordocentesis was performed to obtain blood samples. *Data source:* ref. 189, with permission.

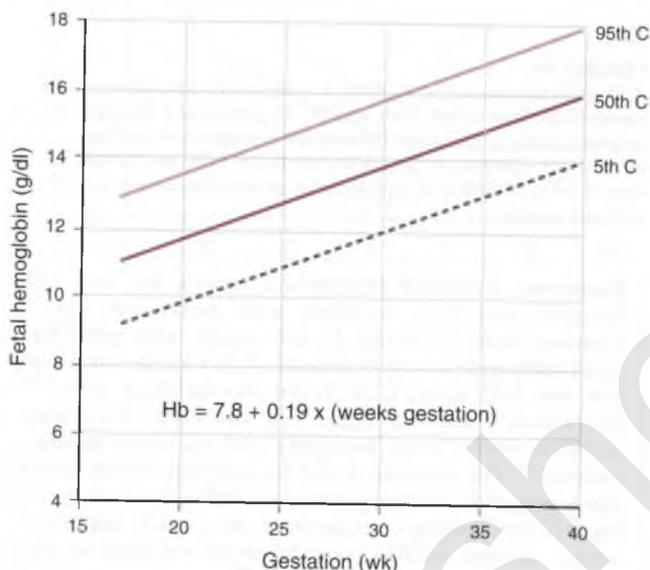
Hb = 7.8 + 0.19 x (weeks gestation)


FIGURE 95

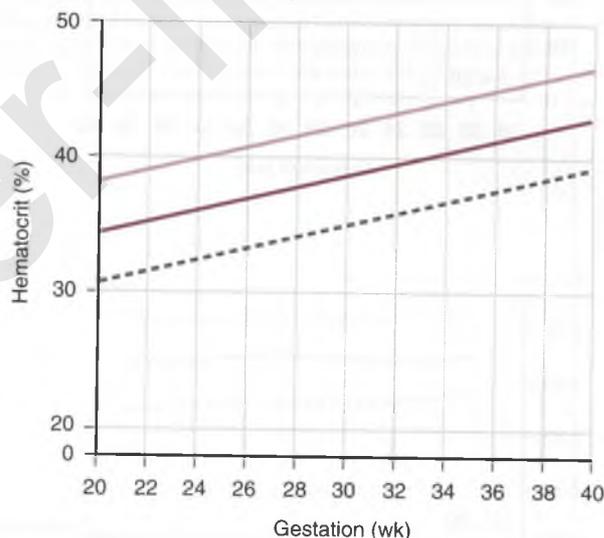
Hemoglobin (5th, 50th, and 95th percentiles) from a study of 194 fetuses at 17 to 40 weeks' gestation. The fetuses were undergoing prenatal diagnosis, but were unaffected for the condition tested. *Data source:* ref. 188, with permission.


FIGURE 97

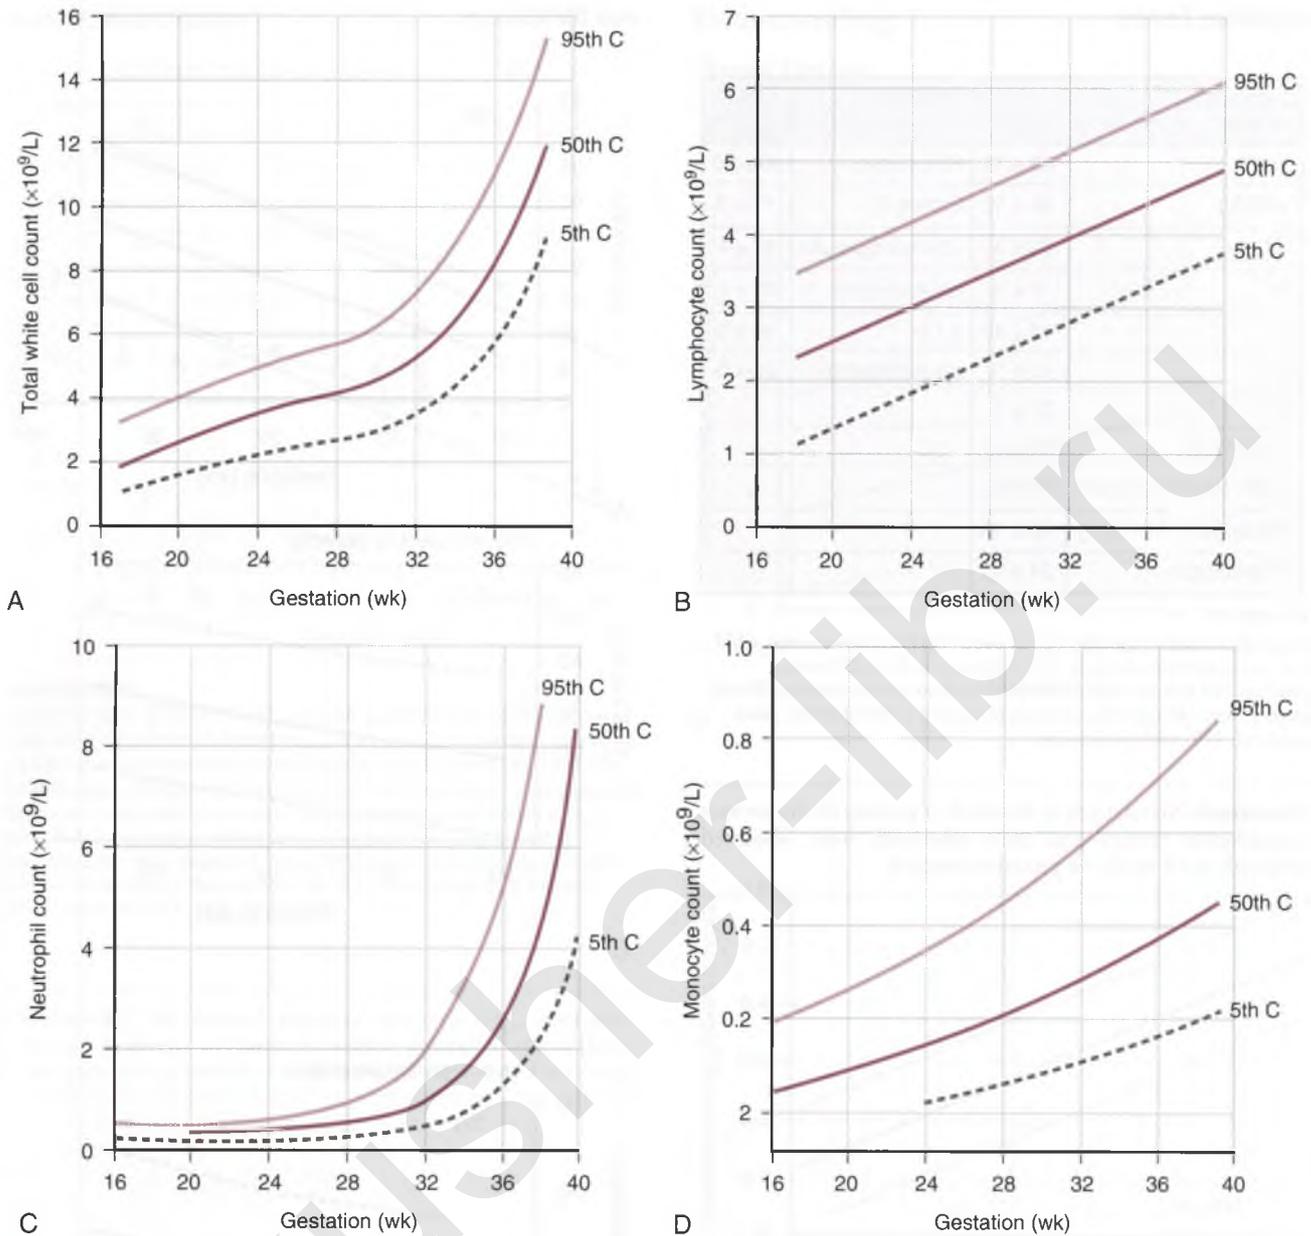
Hematocrit (regression line and 95% CI) from a cross-sectional study of 81 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently shown to be unaffected. Ultrasound-guided cordocentesis was performed to obtain blood samples. *Data source:* ref. 189, with permission.


FIGURE 98
A, Total white blood cell, *B*, lymphocyte, *C*, neutrophil, and *D*, monocyte counts (5th, 50th, and 95th percentiles) from umbilical cord blood samples obtained at cordocentesis (*n* = 316) or elective cesarean delivery (*n* = 11) from fetuses at 18 to 40 weeks' gestation. Cordocentesis was performed for karyotyping, prenatal diagnosis, evaluation of infection, or blood typing, but all fetuses included in the study were unaffected by the condition being studied. The fetuses studied at the time of elective cesarean delivery were normal and appropriately grown; the indication for cesarean delivery was breech presentation or uterine scar. *Data source:* ref. 190, with permission.

Comment *(Figs. 94–98):* Fetal red blood cell count and total hemoglobin increase linearly, reticulocyte count decreases linearly, and erythroblast count decreases exponentially with gestation.[188–190] Platelet count does not change.[178] Lymphocytes form the main population of white cells in the fetus until 37 to 38 weeks' gestation.[190] From 32 weeks onward, neutrophils become more plentiful, and by term, they form approximately 60% of the total white cell count.[190] Natural killer cells are the main type of circulating white cell in the first trimester.[190,191] Interferon-γ concentrations (5th–95th percentiles) are high in the first trimester (0.4–3.1 U/mL) and decrease to 0.2 to 1.7 U/mL in the third trimester.[191] Fetal hemoglobin decreases with advancing gestation, from more than 80% of total hemoglobin in midpregnancy to approximately 70% by term.[178]

Coagulation Factors

Coagulation factors	%	Inhibitors	%

C

FIGURE 100

A, Fetal iron, *B,* total iron-binding capacity (TIBC), and *C,* percentage of iron saturation from a cross-sectional study of 33 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently found to be unaffected. Blood samples were taken by ultrasound-guided cordocentesis. *Data source:* ref. 192, with permission.

Comment: Fetal iron, TIBC, and percentage of iron saturation increase with advancing gestation.

Amniotic Fluid Bilirubin

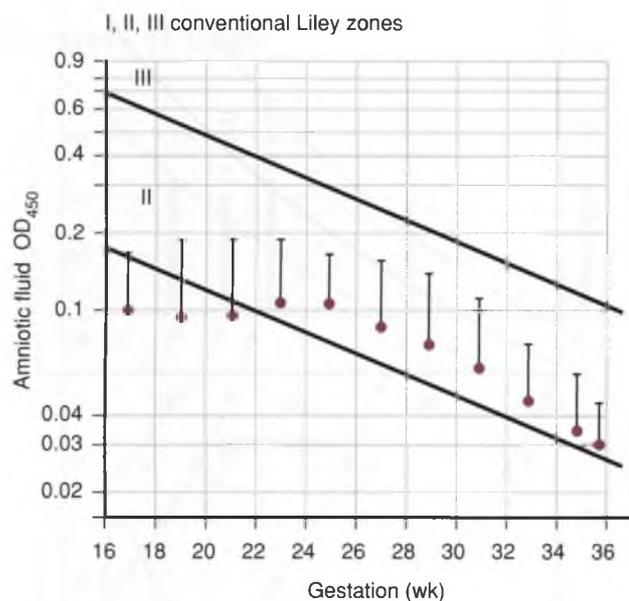
I, II, III conventional Liley zones


FIGURE 101

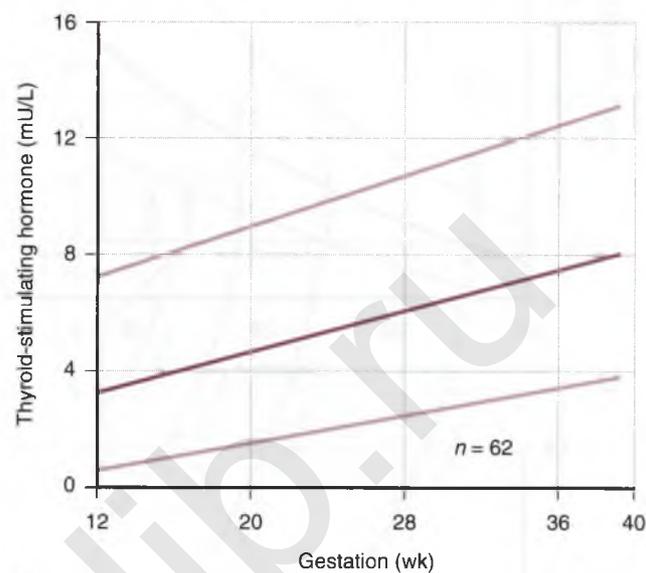
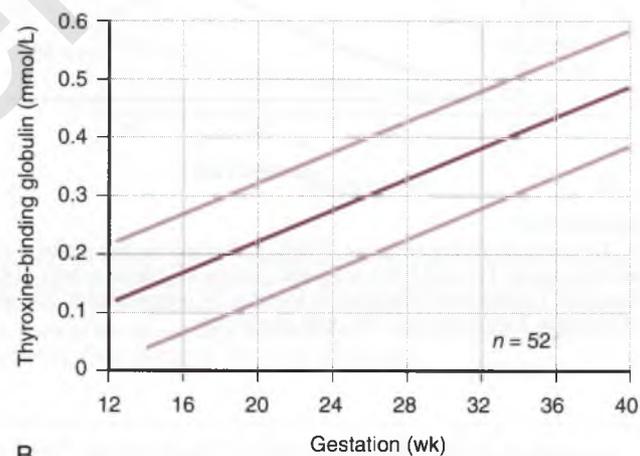
Amniotic fluid bilirubin ΔOD_{450} (mean ± 2 SDs) from 475 samples of amniotic fluid obtained from pregnancies at 16 to 36 weeks' gestation. The pregnancies were not complicated by fetal hemolysis. Amniotic fluid samples obtained at fetoscopy or by amniocentesis were placed in darkened containers to protect against photodecomposition and centrifuged to remove vernix and cellular debris. The bilirubin concentration was measured spectrophotometrically by the deviation in optical density of the amniotic fluid at a wavelength of 450 nm. *Data source:* ref. 193, with permission.

Comment: The normal range of liquor ΔOD_{450} does not change between 16 and 25 weeks' gestation, but values decrease during the third trimester and are widely scattered.

Endocrinology

Thyroid Function


A


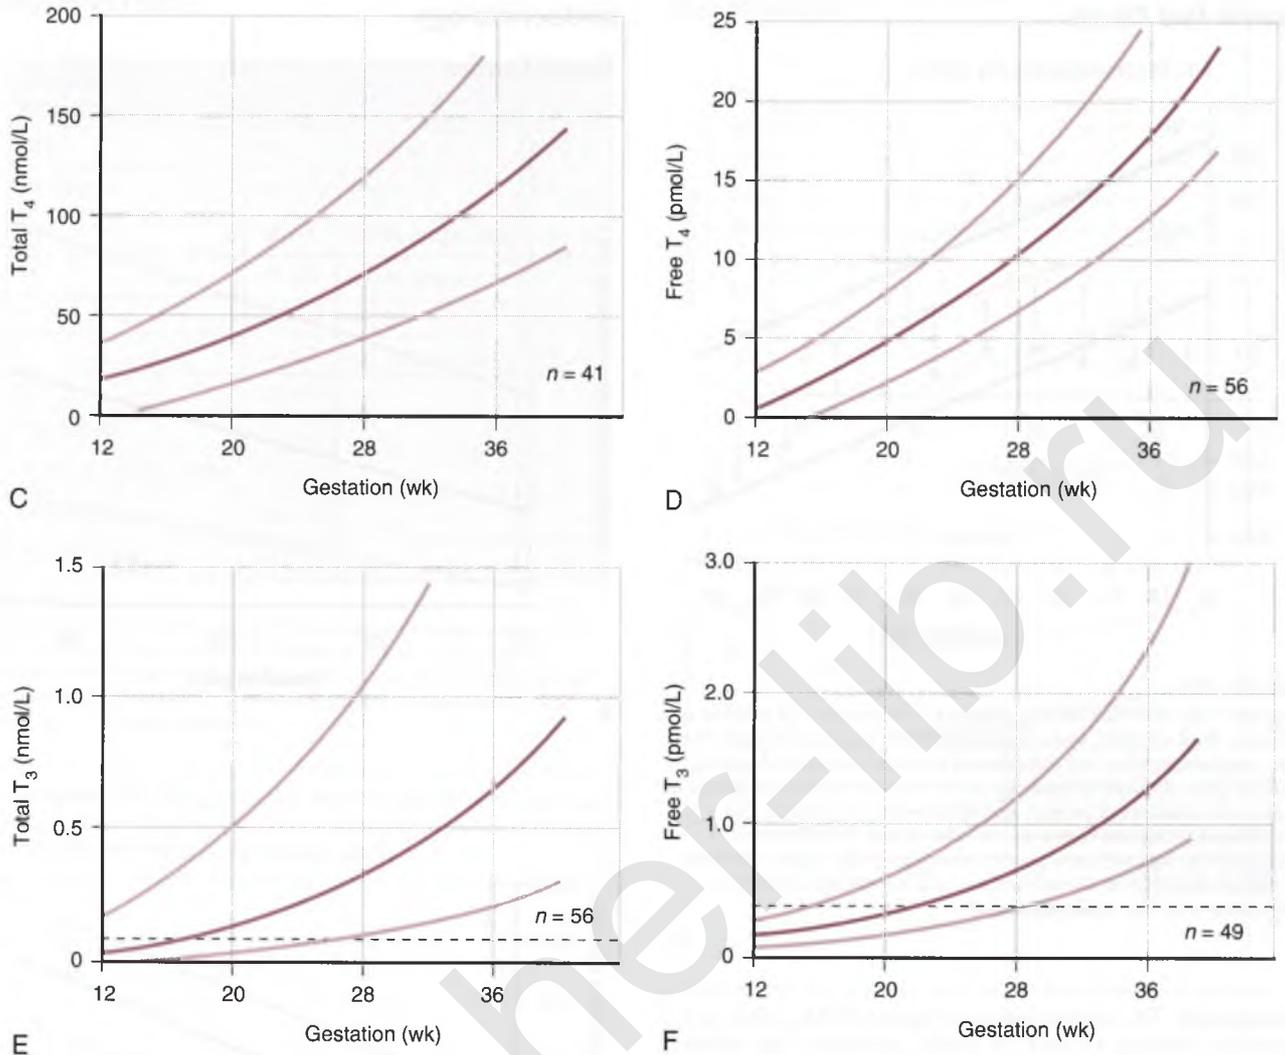
B


FIGURE 102

A, Thyroid-stimulating hormone (TSH), *B*, thyroid-binding globulin (TBG), *C*, total thyroxine (total T_4), *D*, free thyroxine (free T_4), *E*, total tri-iodothyronine (T_3), and *F*, free tri-iodothyronine (T_3) from a study of 62 women who underwent cordocentesis or cardiocentesis for prenatal diagnosis. Fetuses were subsequently found to be normal (mean, 5th, and 95th percentiles). The cross-hatched area is the lower limit of sensitivity of the assay. *Data source:* ref. 194, with permission.

Comment: No significant associations have been found between fetal and maternal thyroid hormones and TSH concentrations, suggesting that the fetal pituitary-thyroid axis is independent of the maternal axis.[194] Fetal TSH levels are always higher than maternal levels. Fetal free and total T_4 levels and TBG levels increase throughout pregnancy and reach adult levels by 36 weeks' gestation; however, fetal free and total T_3 levels are always substantially lower than adult levels. The increase in fetal levels of TSH, thyroid hormones, and TBG during pregnancy indicates independent and autonomous maturation of the pituitary, thyroid, and liver, respectively.[194] There does not appear to be feedback control of pituitary secretion of TSH by circulating thyroid hormones in utero.

LABOR

Progress of Labor

A

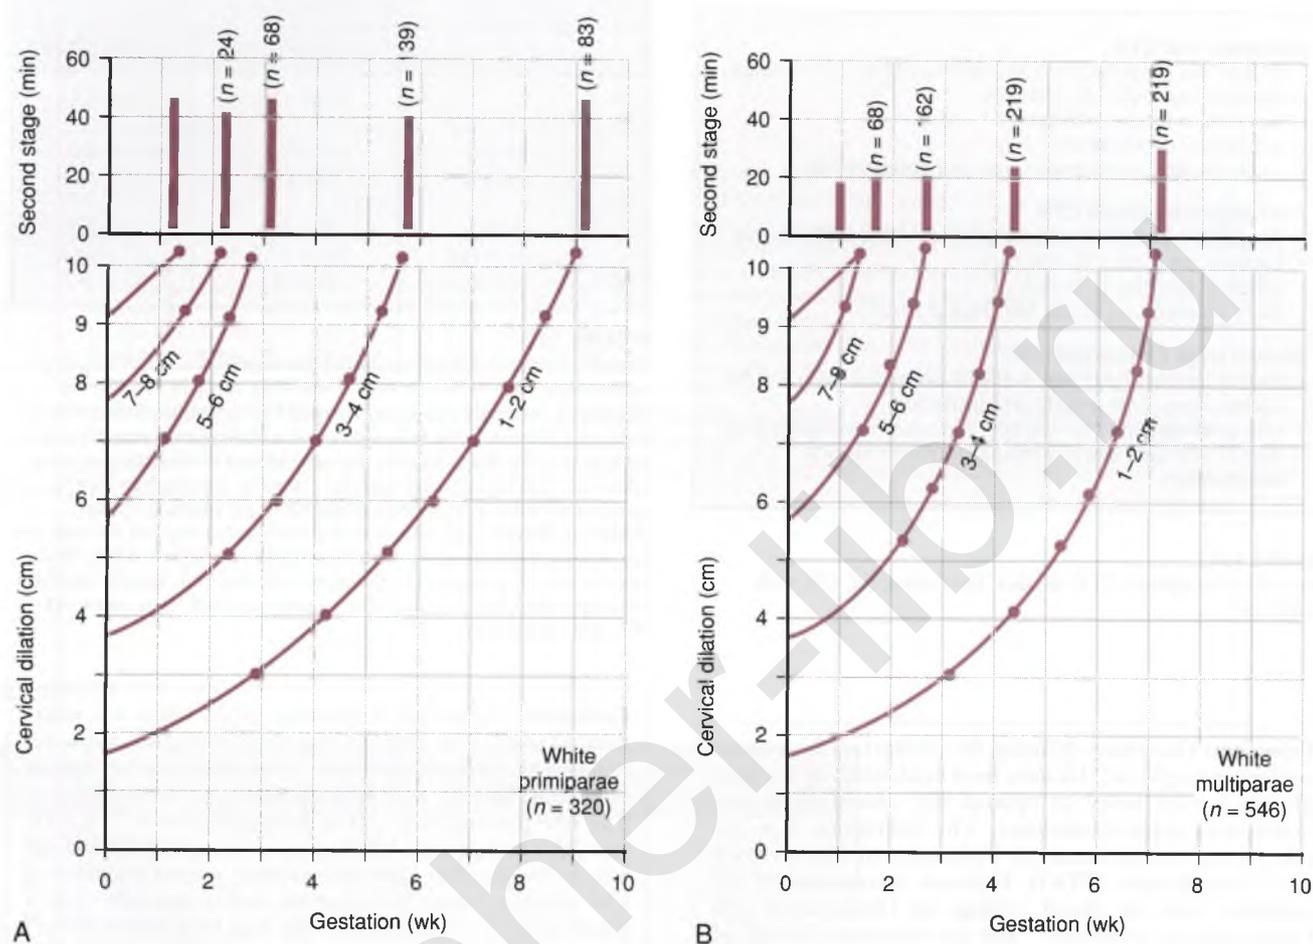
B


FIGURE 103

Mean cervimetric progress of *A*, white primigravidae and *B*, white multigravidae from a study of 3217 consecutive women in labor, from which a group of 1306 who had normal labor were identified (i.e., women with a cephalically presenting fetus who did not have epidural block, receive oxytocic drugs, or require instrumental delivery). The progress of labor was followed by vaginal examination to establish cervical dilation. The first examination was performed soon after admission to the labor suite. The onset of the second stage was confirmed when full cervical dilation was found on routine examination or when the patient was beginning to bear down. *Data source:* ref. 195, with permission.

Comment: This study found that mean cervimetric progress from 1 to 7 cm was faster in white multiparae than in primiparae, but thereafter, progress in the two groups was similar. No significant differences in the cervimetric progress of labor between women from different racial groups has been found.[195] The mean duration of the second stage of labor is approximately 42 minutes in primiparae and 17 minutes in multiparae,[195] although the precise onset of full cervical dilation is difficult to establish.

Fetal Heart Rate Parameters by Cardiotocography (CTG)

Admission test CTG
- At least two accelerations (>15 beats for >15 s) in 20 minutes.
- Baseline heart rate 110–150 bpm.
- Baseline variability 5–25 bpm.
- Absence of decelerations.
- Moderate tachycardia/bradycardia and accelerations.

First stage intrapartum CTG
- At least two accelerations (>15 beats for >15 s) in 20 minutes.
- Baseline heart rate 110–150 bpm.
- Baseline variability 5–25 bpm.
- Early decelerations (in late first stage of labor).

Second stage intrapartum CTG
- Normal baseline heart rate, normal baseline variability and no decelerations, both periodic and scattered.
- Baseline heart rate 110–150 bpm and baseline variability 5–25 bpm or >25 bpm, with or without early and/or variable decelerations.

FIGURE 104
Features of the normal CTG in labor. *Data source:* ref. 173, with permission.

Comment: Guidelines defining the parameters for normal cardiotocography (CTG) have been established by working groups, but are based on opinion and clinical experience rather than research evidence. The definitions here are taken from the International Federation of Obstetricians and Gynecologists (FIGO). Different interpretations are available from the Royal College of Obstetricians and Gynaecologists in Britain[196] and the American College of Obstetricians and Gynecologists in the United States.[174] There are differences in the range of baseline heart rates accepted as normal (lower limit, 110–120 beats/min; upper limit, 150–160 beats/min) and the definitions of variability. Decelerations that are considered abnormal if identified antepartum (see Fig. 86) often occur intrapartum. Early decelerations (i.e., synchronous with contractions) are common toward the end of the first stage of labor; during the second stage of labor, both early and variable decelerations can be normal findings. Accelerations and normal baseline variability are important features of a normal CTG finding.

Umbilical Cord Blood Sampling

BLOOD GASES

Blood Gases		Umbilical artery	Umbilical vein
pH		7.06–7.36	7.14–7.45
P_{O_2}			
	(kPa)	1.3–5.5	1.7–6.0
	(mmHg)	9.8–41.2	12.3–45.0
P_{CO_2}			
	(kPa)	9.1–3.7	7.5–3.2
	(mm Hg)	68.3–27.8	56.3–24.0
BD ecf	(mmol/L)	15.3–0.5	12.6–0.7

FIGURE 105
Umbilical arterial and venous blood gas values (pH, P_{O_2}, P_{CO_2}, and extracellular base deficit) from a 2-year-long study in a university hospital in the Netherlands, where cord blood samples were taken from all deliveries (95% CI). A piece of umbilical cord was isolated as soon as possible after delivery, and arterial and venous samples were taken into two heparinized syringes. Samples were analyzed within 75 minutes of delivery by an automated blood gas machine. If the difference between pH values in the umbilical artery and the vein was not at least 2 pH units, the arterial sample was rejected. Thus, 4667 arterial and 5151 venous pH samples were obtained. Smaller numbers of samples also had P_{O_2} and P_{CO_2} values measured. *Data source:* ref. 197, with permission.

Comment: The overall distribution of pH values was negatively skewed. This data set was large enough to allow for subanalysis. Values for pH were lower after cesarean section or breech delivery than after spontaneous vertex delivery. The 10th percentiles for pH in these groups were 7.12, 7.11, and 7.15, respectively. Optimal cases (no problems antenatally or during labor, spontaneous labor, second stage lasting <30 minutes, vertex presentation, and a normally grown infant in good condition at birth) had 10th percentile pH values of 7.17. There were only small differences in pH between samples obtained from premature, mature, and postmature infants. Guidelines are available for optimal collection and analytical techniques.[185]

LACTATE

Comment: Mean umbilical cord lactate values were reported as 1.87 mmol/L (SD, 0.94) in a study of more than 3000 spontaneous vaginal deliveries.[198] Lower values were found after elective cesarean delivery (mean, 1.44 mmol/L; SD, 0.10; $n = 300$).

COMPLETE BLOOD COUNT

Complete blood count			
Analyte	25th centile	50th centile	75th centile
Red cell count ($\times 10^{12}$/L)	4.13	4.40	4.62
Hemoglobin (mmol/L)	9.5	10.0	10.7
(g/dl)	15.3	16.1	17.2
Hematocrit (%)	45.2	47.9	50.9
Mean cell volume (fl)	107.4	109.8	113.3
Mean cell hemoglobin (fmol)	2.2	2.3	2.4
(pg)	35.4	37.1	38.7
Reticulocyte count ($\times 10^9$/L)	145.8	170.0	192.6
Platelet count ($\times 10^9$/L)	237	270	321
Total white cell count ($\times 10^9$/L)	11.1	13.3	16.2
Neutrophil ($\times 10^9$/L)	5.4	7.4	8.8
Lymphocyte ($\times 10^9$/L)	3.3	3.8	5.1
Monocyte ($\times 10^9$/L)	1.2	1.6	2.3
Eosinophil ($\times 10^9$/L)	0.23	0.39	0.54
Basophil ($\times 10^9$/L)	0.04	0.06	0.09

FIGURE 106

Red blood cell count, hemoglobin, hematocrit, mean cell volume, mean cell hemoglobin, reticulocyte count, platelet count, and differential white blood cell count (25th, 50th, and 75th percentiles) from a study of 89 women who had been healthy during pregnancy and were nonsmokers. All were delivered after 34 weeks' gestation, and their infants were of normal birth weight and had umbilical cord pH greater than 7.20. Umbilical venous samples were taken and analyzed within 3 hours. *Data source:* ref. 199, with permission.

Comment: In this study, infants of smokers had lower reticulocyte and neutrophil counts.[199] Reticulocyte counting was done by flow cytometry, which is more precise than manual counting. Full-term cord blood has more immature reticulocyte forms than does adult blood.[200] Another recent study found similar blood counts[201] and recommended that the lower limit for normal hemoglobin be designated as 12.5 g/dL for term newborns.

BIOCHEMISTRY

Analyte	Cord arterial ($n = 179$)	Cord venous ($n = 390$)	Adult
Na$^+$ (mmol/L)	135–143	135–143	136–146
K$^+$ (mmol/L)	3.7–6.4	3.8–6.8	3.6–4.8

			6–50 (female)
Triglyceride (mmol/L)	0.10–1.04	0.13–0.97	0.55–1.7
Mg^{2+} (mmol/L)	0.49–0.80	0.50–0.79	0.6–1.0

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; LD, lactate dehydrogenase

FIGURE 107

Clinical chemistry analytes (95% CI) from umbilical arterial and venous blood compared with adult blood values. Samples were taken into heparinized tubes from the umbilical cords of 397 infants delivered at 37 to 41 weeks' gestation, before placental expulsion from the uterus. There were 310 vaginal deliveries and 87 cesarean deliveries. All infants included in the study had 5-minute Apgar scores of 8 or greater. Samples were stored at 40°C until analysis. Complete biochemistry profiles were obtained from 390 venous plasma and 179 arterial plasma samples. These were compared with the adult reference ranges from the institution (Ottawa Civic Hospital, Ottawa, Canada). *Data source:* ref. 202, with permission.

Comment: All cord blood chemistry values were significantly different from adult values. No male-to-female differences were identified. Cord creatine kinase concentrations were very high, although they were similar in infants after vaginal or cesarean delivery, suggesting that this change did not relate to physical trauma.
