**Notice**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

# PREFACE

Major advances in biology and medicine made during the past several decades have contributed greatly to our understanding of infections that affect the fetus and newborn. As the medical, social, and economic impact of these infections becomes more fully appreciated, the time is again appropriate for an intensive summation of existing information on this subject. Our goal for the sixth edition of this text is to provide a complete, critical, and contemporary review of this information. We have directed the book to all students of medicine interested in the care and well-being of children and hope to include among our readers medical students, practicing physicians, microbiologists, and health care workers. We believe the text to be of particular importance for obstetricians and physicians who are responsible for the pregnant woman and her developing fetus; pediatricians and family doctors who care for newborn infants; and primary care physicians, neurologists, audiologists, ophthalmologists, psychologists, and other specialists who are responsible for children who suffer the sequelae of infections acquired in utero or during the first month of life.

The scope of this book encompasses infections of the fetus and newborn, including those acquired in utero, during the delivery process, and in the early months of life. When appropriate, sequelae of these infections that affect older children and adults are included as well. Infection in the adult is described when pertinent to the developing fetus and newborn infant. Each chapter includes a review of the history, microbiology, epidemiology, pathogenesis and pathology, clinical signs and symptoms, diagnosis, prognosis, treatment, and prevention of the infection. The length of the chapters varies considerably. In some instances, this variation is related to the available fund of knowledge on the subject; in others (e.g., the chapters on toxoplasmosis, neonatal diarrhea, varicella, measles, and mumps), the length of the chapter is related to the fact that no recent comprehensive reviews of these subjects are available.

The first, second, third, fourth, and fifth editions of this text were published in 1976, 1983, 1990, 1995, and 2001, respectively. As of this writing, in the spring of 2005, it is most interesting to observe the changes that have occurred in the interval since publication of the last edition. New authors provide fresh perspectives. Major revisions of most chapters suggest the importance of new information about infections of the fetus and newborn infant.

Each of the authors of the different chapters is a recognized authority in the field and has made significant contributions to our understanding of infections in the fetus and newborn infant. Most of these authors are individuals whose major investigative efforts on this subject have taken place during the past 25 years. Almost all were supported, in part or totally, during their training period and subsequently, by funds obtained from the National Institutes of Health or from private agencies such as March of Dimes. It is clear that the major advances of this period would not have been

possible without these funding mechanisms and the freedom given to the investigators to pursue programs of their own choosing. Thus, the advances present in this text are also a testimony to the trustees of agencies and the legislators and other federal officials who provided unencumbered research funds from the 1960s to the present day.

We were Fellows at the Thorndike Memorial Laboratory (Harvard Medical Unit, Boston City Hospital) in the early 1960s. Although subsequently we worked in separate areas of investigation on the two coasts, one of us as an internist and the other as a pediatrician, we maintained close contact, and, because of a mutual interest in infections of the fetus and newborn infant and their long-term effects, we joined our efforts to develop this text. For this edition, we are proud to have added, as Associate Editors, Carol J. Baker and Christopher B. Wilson. Carol trained in infectious diseases in Boston with J.O.K. and Maxwell Finland, and Chris trained in immunology and infectious diseases in Palo Alto with J.S.R. Carol has become a world-recognized expert in all aspects of group B streptococcal infections and is the Texas Children's Hospital Foundation Chair in Pediatric Infectious Diseases in Houston. Chris has become a prominent developmental immunologist and is now Chair of the Department of Immunology at the University of Washington School of Medicine. We look to Carol and Chris to help us maintain the quality and value of this text for many editions to come.

We are indebted to our teachers and associates and especially to the one individual who had a dominant influence in our training, Dr. Maxwell Finland. We deeply appreciate the example he set, his wise counsel, and his interest in and support of our investigative programs. We also wish to express our appreciation to Todd Hummel, Jennifer Ehlers, Lee Ann Draud, and the staff of Elsevier, Inc., for guiding this project to a successful conclusion; to Ms. Nancy Ahonen and Robin Schroeder for secretarial assistance; and to Ms. Trisha Mitchell for her editorial assistance.

**Jack S. Remington  
Jerome O. Klein**

We are pleased to have joined Jack and Jerry in editing this book, which since its inception has been a unique resource for physicians caring for the mother, fetus, and newborn infant. We are also grateful for the investigators working in the field, who have improved life for mother and infant, and for the chapter authors, who bring their comprehensive understanding of their topics to enlighten readers.

**Carol J. Baker  
Christopher B. Wilson**

## OVERVIEW

---

Current concepts of pathogenesis, microbiology, diagnosis, and management of infections of the fetus and newborn infant are briefly reviewed in this chapter. Also in this first section of the book are chapters providing a global perspective on fetal and neonatal infections and chapters addressing obstetric factors, immunity, host defenses and the role of human breast milk in fetal and neonatal infections. Chapters containing detailed information about specific bacterial, viral, protozoan, helminth, and fungal infections follow. This edition concludes with chapters addressing nosocomial infections and the diagnosis and therapy of infections in the fetus and neonate.

A number of changes have occurred in epidemiology, diagnosis, prevention, and management of infectious diseases of the fetus and newborn infant since publication of the last edition of this book. Some of these changes are noted in Table 1-1 and are discussed in this and the relevant chapters.

Substantial progress has taken place to reduce the burden of infectious diseases in the fetus and newborn infant. The incidence of early-onset group B streptococcal disease has been reduced by aggressive use of intrapartum chemoprophylaxis and, in particular, by the culture-based chemoprophylaxis strategy now recommended for universal use in the

United States; vertical transmission of human immunodeficiency virus (HIV) has been reduced by identification of the infected mother with subsequent treatment, including the use of brief regimens that are practical for use in countries with high prevalence but limited resources; there has been a commitment of resources by government agencies and philanthropies, such as the Bill and Melinda Gates Foundation, to combat global infectious diseases in mothers and children; use of polymerase chain reaction (PCR) techniques in etiologic diagnosis has expanded, permitting more rapid and specific identification of microbial pathogens; and in the United States, national legislation on postpartum length of hospital stay has been enacted to prevent insurers from restricting insurance coverage for hospitalization to fewer than 48 hours after vaginal deliveries or 96 hours after cesarean deliveries.

Setbacks in initiatives to reduce the global burden of infectious disease in the fetus and newborn infant include the continuing increase in the prevalence of HIV infection in many developing countries, particularly among women; the lack of finances to provide effective treatment for these women and their newborn infants; and in the United States, the increase in antimicrobial resistance among nosocomial pathogens, as well as in incidence of invasive fungal infections among infants of extremely low birth weight.

Use of the Internet has grown further, allowing access to information hitherto unavailable to physicians or parents. The physician may obtain current information about diseases and management and various guidelines for diagnosis and treatment. The interested parent who has access to the Internet can explore a variety of Internet sites that present a vast array of information and, unfortunately, misinformation. As an example of the latter, a case of neonatal tetanus was associated with the use of cosmetic facial clay (Indian Healing Clay) as a dressing on an umbilical cord stump. The product had been publicized as a healing salve by midwives on an Internet site on "cordcare."<sup>1</sup> Because much of the information on the Internet is from commercial sources and parties with varying interests and expertise, the physician should assist the interested parent and patient in finding Internet sites of value. A selected list of Internet sites pertinent to infectious diseases of the fetus and newborn infant is provided in Table 1-2.

Vital statistics relevant to infectious disease risk in neonates in the United States for 2001 are listed in Table 1-3.<sup>2</sup> Of importance are the disparities in birth weight, prenatal care, and neonatal mortality among different racial and ethnic groups.

The number of infectious diseases in fetuses and newborn infants must be extrapolated from selected studies (see chapters on diseases). Approximately 1% of newborn infants excrete cytomegalovirus (CMV), greater than 4% of infants are born to mothers infected with *Chlamydia trachomatis*, and bacterial sepsis develops in 1 to 4 infants per 1000 live births. Since the institution of intrapartum chemoprophylaxis in the United States, the number of infants with early-onset group B streptococcal disease has declined, with

**Table 1-1 Recent Changes in Epidemiology and Management of Infectious Diseases of the Fetus and Newborn Infant**

#### Epidemiology

Increased viability of very low birth weight infants at risk for invasive infectious diseases  
 Increased number of multiple births (often of very low birth weight) due to successful techniques for management of infertility  
 Global perspective of vertically transmitted infectious diseases  
 Early discharge from the nursery mandated by insurance programs reversed by legislation to ensure adequate observation for infants at risk for sepsis

#### Diagnosis

Polymerase chain reaction assay for diagnosis of infection in mother, fetus, and neonate  
 Decreased use of fetal blood sampling and chorionic villus sampling for diagnosis of infectious diseases

#### Prevention

Intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal infection widely implemented  
 Antiretroviral therapy in pregnancy to prevent transmission of human immunodeficiency virus (HIV) to fetus

#### Treatment

Antiretroviral therapy in mother to treat HIV infection in fetus  
 Antitoxoplasmosis therapy in mother to treat infection in fetus  
 Spread within nurseries of multiple antibiotic-resistant bacterial pathogens  
 Increased use of vancomycin for  $\beta$ -lactam-resistant gram-positive infections  
 Increased use of acyclovir for infants with suspected herpes simplex infection

reduction in incidence from approximately 1.5 cases to 0.4 case per 1000 live births, and is expected to decline further with the universal adoption of the culture-based strategy.<sup>3</sup> In the United States, the use of maternal highly active antiretroviral treatment (HAART) and peripartum chemoprophylaxis has led to a reduction in the rate of mother-to-child transmission of HIV from approximately 25% of infants born to mothers who received no treatment to 2%; less complex but practical regimens of intrapartum prophylaxis have helped to reduce the rate of transmission in the developing world.<sup>4</sup> Among sexually transmitted diseases, the rate of congenital syphilis declined substantially in the United States to 13.4 per 100,000 live births in 2000, and although rates remain higher in the South, only two states have rates greater than 40 per 100,000 live births.<sup>5</sup> Immunization has virtually eliminated congenital rubella syndrome in newborn infants of mothers who were themselves born in the United States, but cases continue to occur in infants of foreign-born mothers; 24 of 26 infants with congenital rubella born between 1997 and 1999 were born to foreign-born mothers, and 21 of these were born to Hispanic mothers.<sup>6</sup>

Infection acquired in utero can result in resorption of the embryo, abortion, stillbirth, malformation, intrauterine growth retardation, prematurity, and the untoward sequelae of chronic postnatal infection. Infection acquired during the birth process or soon after birth may result in severe systemic disease that leads to death or persistent postnatal infection. Both in utero infection and infection acquired during the birth process may lead to late-onset disease. The infection may not be apparent at birth but may manifest with signs of disease weeks, months, or years later, as exemplified by the chorioretinitis of *Toxoplasma gondii* infection, the hearing loss of rubella, and the immunologic defects that result from HIV infection. The immediate as well as the long-term effects of these infections constitute a major problem throughout the world.

## INFECTIONS OF THE FETUS

### Pathogenesis

Pregnant women not only are exposed to the infections prevalent in the community but also are likely to reside with young children or to associate with groups of young children,

which represents a significant additional factor in exposure to infectious disease. The vast majority of infections in the pregnant woman affect the upper respiratory and gastrointestinal tracts and either resolve spontaneously without therapy or are readily treated with antimicrobial agents. Such infections usually remain localized and have no effect on the developing fetus. The infecting organism may invade the bloodstream, however, and subsequently infect the placenta and fetus.

Successful pregnancy is a unique example of immunologic tolerance—the mother must be tolerant of her allogeneic fetus (and vice versa). The basis for maternal-fetal tolerance is incompletely understood, but is known to reflect both local modifications of host defenses at the maternal-fetal interface and more global changes in immunologic competence in the mother. Specific factors acting locally in the placenta include indoleamine 2,3-dioxygenase, which suppresses cell-mediated immunity by catabolizing the essential amino acid tryptophan, and regulatory proteins that prevent complement activation.<sup>7,8</sup> As pregnancy progresses, a general shift from T<sub>H</sub>1-type cell-mediated immunity to T<sub>H</sub>2-type responses also occurs in the mother, although this description probably constitutes an overly simplistic view of more complex immunoregulatory changes.<sup>9,10</sup> Nonetheless, because T<sub>H</sub>1-type cell-mediated immunity is important in host defense against intracellular pathogens, the T<sub>H</sub>2 bias established during normal gestation may compromise successful immunity against organisms such as *T. gondii*. In addition, it has been proposed that a strong curative T<sub>H</sub>1 response against an organism may overcome the protective T<sub>H</sub>2 cytokines at the maternal-fetal interface, resulting in fetal loss.

Transplacental spread after maternal infection and invasion of the bloodstream is the usual route by which the fetus becomes infected. Uncommonly, the fetus may be infected by extension of infection in adjacent tissues and organs, including the peritoneum and the genitalia, during parturition, or as a result of invasive methods for the diagnosis and therapy of fetal disorders, such as the use of monitors, sampling of fetal blood, and intrauterine transfusion.

The microorganisms of concern are listed in Table 1-4 and include those identified in the acronym TORCH: *Toxo-*

Table 1-4 Suggested Acronym for the Microorganisms Responsible for Infection of the Fetus

T	<i>Toxoplasma gondii</i>
R	Rubella virus
C	Cytomegalovirus
H	Herpes simplex virus
E	Enteroviruses
S	Syphilis ( <i>Treponema pallidum</i> )
C	Chickenpox (varicella-zoster virus)
L	Lyme disease ( <i>Borrelia burgdorferi</i> )
A	AIDS (human immunodeficiency virus)
P	Parvovirus B19

AIDS, acquired immunodeficiency syndrome.

*plasma gondii*, rubella virus, CMV, and herpes simplex virus (HSV) (as a point of historical interest, the O in TORCH originally stood for “other infections/pathogens,” reflecting an early appreciation of this possibility). A new acronym is needed to include the other well-described causes of in utero infection: syphilis, enteroviruses, varicella-zoster virus (VZV), HIV, Lyme disease (*Borrelia burgdorferi*), and parvovirus. In certain geographic areas, *Plasmodium* and *Trypanosoma cruzi* are responsible for in utero infections. TORCHES CLAP (see Table 1-4) is an inclusive acronym. THE BAC PORCH is easily remembered but relies on an idealized spelling for the word *back*. CHAST LOVER includes a truncated spelling of the word *chaste*.<sup>11</sup> CHEAP TORCHES has been suggested to include congenital and perinatal infections; it includes an H for hepatitis B and C and an E for everything else that is sexually transmitted (gonorrhea and *Chlamydia*, *Ureaplasma*, and papillomavirus infections) but ignores Lyme disease.<sup>12</sup> Because no clear successor to TORCH has been devised, other acronyms are still welcome. New pathogens are being discovered, however, so it is unlikely that any acronym will be “permanent.”

Case reports indicate that other organisms are unusual causes of infections transmitted by the pregnant woman to her fetus, including *Brucella melitensis*,<sup>13</sup> *Coxiella burnetii* (Q

fever),<sup>14</sup> *Babesia microti* (babesiosis),<sup>15</sup> human T lymphotropic virus types I and II (although the main route of transmission of these viruses is through breast-feeding),<sup>16,17</sup> hepatitis G and TT viruses,<sup>18,19</sup> human herpesvirus 6,<sup>20,21</sup> and dengue.<sup>22</sup>

Before rupture of fetal membranes, organisms in the genital tract may invade the amniotic fluid and produce infection of the fetus. These organisms can invade the fetus through microscopic defects in the membranes, particularly in devitalized areas overlying the cervical os. It also is possible that microorganisms gain access to the fetus from descending infection through the fallopian tubes in women with salpingitis or peritonitis, or from direct extension of an infection in the uterus, such as myometrial abscess or cellulitis. Available evidence, however, does not suggest that transtubal or transmyometrial passage of microbial agents is a significant route of fetal infection.

Invasive techniques that have been developed for in utero diagnosis and therapy are potential sources of infection for the fetus. Abscesses have been observed in infants who had scalp punctures for fetal blood sampling or electrocardiographic electrodes clipped on their scalps. Osteomyelitis of the skull and streptococcal sepsis have followed local infection at the site of a fetal monitoring electrode<sup>23</sup>; HSV infections at the fetal scalp electrode site also have been reported. Intrauterine transfusion for severe erythroblastosis diagnosed in utero also has resulted in infection of the fetus: In one case, CMV infection reportedly resulted from intrauterine transfusion<sup>24</sup>; in another instance, contamination of donor blood with a gram-negative coccobacillus, *Acinetobacter*

*calcoaceticus*, led to an acute placentitis and subsequent fetal bacteremia.<sup>25</sup>

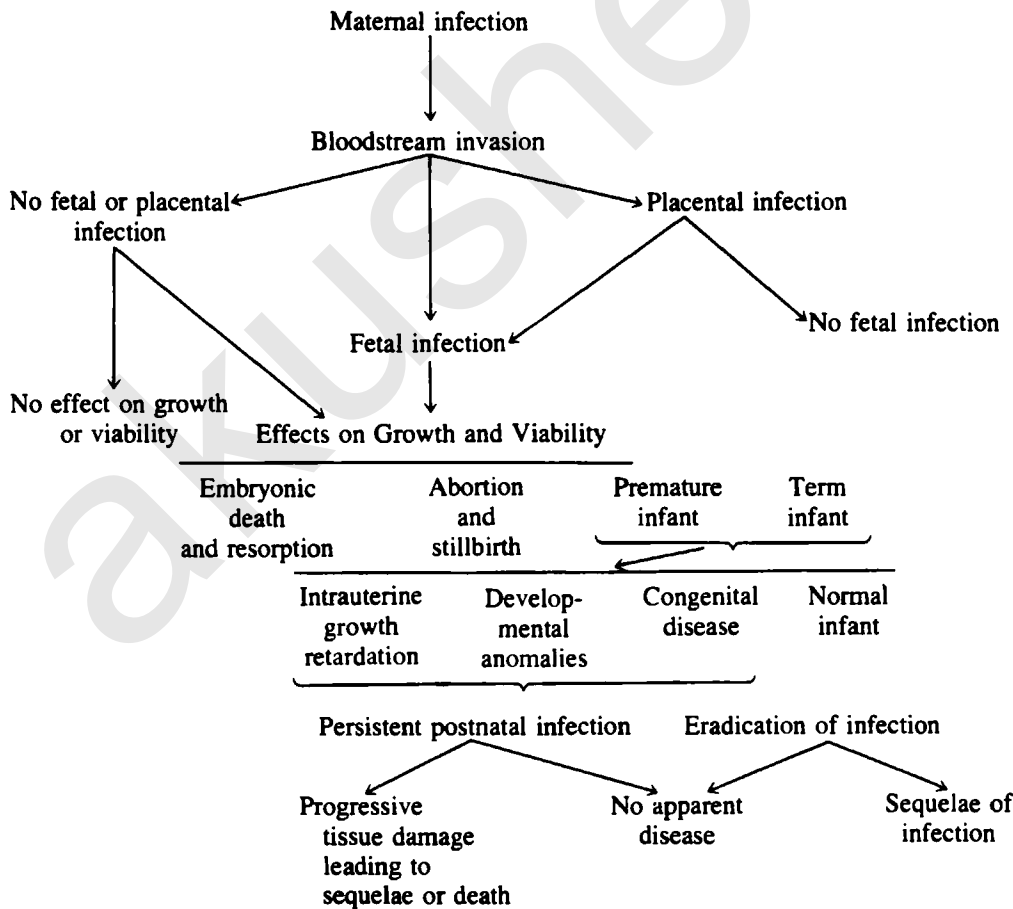

Fetal infection in the absence of rupture of internal membranes usually occurs by the transplacental route after invasion of the maternal bloodstream. Microorganisms in the blood may be carried within white blood cells or attached to erythrocytes, or they may be present independent of cellular elements.

**Microbial Invasion of the Maternal Bloodstream**

The potential consequences of invasion of the mother's bloodstream by microorganisms or their products (Fig. 1-1) include (1) placental infection without infection of the fetus, (2) fetal infection without infection of the placenta, (3) absence of both fetal and placental infection, and (4) infection of both placenta and fetus.

**PLACENTAL INFECTION WITHOUT INFECTION OF THE FETUS**

After reaching the intervillous spaces on the maternal side of the placenta, organisms can remain localized in the placenta without affecting the fetus. Evidence that placentitis does occur independently of fetal involvement has been demonstrated after maternal tuberculosis, syphilis, malaria, coccidioidomycosis, and CMV, rubella virus, and mumps vaccine virus infection. The reasons for the lack of spread to the fetus after the placental infection has been established are unknown. Defenses of the fetus that may operate after infection of the placenta include the villous trophoblast, placental macrophages, and locally produced immune factors such as antibodies and cytokines.

**Figure 1-1** Pathogenesis of hematogenous transplacental infections.

**FETAL INFECTION WITHOUT INFECTION OF THE PLACENTA**

Microorganisms may traverse the chorionic villi directly through pinocytosis, placental leaks, or diapedesis of infected maternal leukocytes and erythrocytes. Careful histologic studies, however, usually reveal areas of placentitis sufficient to serve as a source of fetal infection.

**ABSENCE OF FETAL AND PLACENTAL INFECTION**

Invasion of the bloodstream by microorganisms is not uncommon in pregnant women, yet in most cases neither fetal nor placental infection results. Bacteremia may accompany abscesses or cellulitis, bacterial pneumonia, pyelonephritis, appendicitis, endocarditis, or other pyogenic infections; nevertheless, placental or fetal infection as a consequence of such bacteremias is rare. In most cases, the fetus probably is protected through efficient clearance of microbes by the maternal reticuloendothelial system and circulating leukocytes.

A number of bacterial diseases of the pregnant woman, including typhoid fever, pneumonia, sepsis caused by gram-negative bacteria, and urinary tract infections, may affect the developing fetus without direct microbial invasion of the placenta or fetal tissues. Similarly, protozoal infection in the mother, such as malaria, and systemic viral infections, including varicella, variola, and measles, also may affect the fetus indirectly. Fever, anoxia, circulating toxins, or metabolic derangements in the mother during these infections can affect the pregnancy—abortion, stillbirth, and premature delivery are among the possible results.

The effect of microbial toxins on the developing fetus is uncertain. The fetus may be adversely affected by toxic shock in the mother due to *Staphylococcus aureus* or *Streptococcus pyogenes* infection. Botulism in pregnant women has not been associated with disease in the infant.<sup>26,27</sup> A unique case of Guillain-Barré syndrome in mother and child shows that infection-induced antibody-mediated autoimmune disease in the mother may be transmitted to her infant. In this case, the disease was diagnosed in the mother during week 29 of pregnancy. A healthy infant was delivered per vagina at 38 weeks of gestation, while the mother was quadriplegic and on respiratory support. On day 12 of life, however, flaccid paralysis of all limbs, with absence of deep tendon reflexes, developed in the infant, and cerebrospinal fluid examination revealed increased protein concentration without white blood cells.<sup>28</sup> The delay in onset of paralysis in the infant appeared to reflect the fact that the transplacentally transferred blocking antibodies were specifically directed at epitopes of the mature but not the fetal neuromuscular junction. The infant improved following administration of intravenous immune globulin (IGIV).<sup>29</sup>

The association of maternal urinary tract infection with premature delivery and low birth weight is a well-studied example of a maternal infection that adversely affects growth and development of the fetus, even though there is no evidence of fetal or placental infection. Asymptomatic bacteriuria in pregnancy has been linked to an excess in the number of low-birth-weight infants.<sup>30,31</sup> In one early study, when the bacteriuria was eliminated by appropriate antibiotic therapy, the incidence of pyelonephritis was lower in the women who received treatment than in the women who did not, and the rate of premature and low-birth-weight infants was the same among the women in the treatment group as among nonbacteriuric women.<sup>32</sup> A recent meta-

analysis concluded that antibiotic treatment is effective in reducing the risk of pyelonephritis in pregnancy and also appears to reduce risk for preterm delivery, although the evidence supporting this latter conclusion is not as strong.<sup>33</sup> The basis for the premature delivery and low birth weight of infants of bacteriuric women remains obscure.<sup>34</sup>

**INFECTION OF PLACENTA AND FETUS**

Microbes may be disseminated from the infected placenta to the fetal bloodstream through infected emboli of necrotic chorionic tissues or through direct extension of placental infection to the fetal membranes, with secondary amniotic fluid infection and aspiration by the fetus.

**Infection of the Embryo and Fetus**

Hematogenous transplacental spread may result in death and resorption of the embryo, abortion and stillbirth of the fetus, and live birth of a premature or term infant who may or may not be healthy. The effects of fetal infection may appear in the live-born infant as low birth weight (resulting from intrauterine growth retardation), developmental anomalies, congenital disease, or none of these. Infection acquired in utero may persist after birth and cause significant abnormalities in growth and development that may be apparent soon after birth or may not be recognized for months or years. The variability of the effects of fetal infection is emphasized by reports of biovular twin pregnancies that produced one severely damaged infant and another with minimal or no detectable abnormalities.<sup>35-40</sup>

**Embryonic Death and Resorption.** A variety of organisms may infect the pregnant woman in the first few weeks of gestation and produce death and resorption of the embryo. Because loss of the embryo usually occurs before the woman realizes she is pregnant or seeks medical attention, it is difficult to estimate the incidence of this outcome for any single infectious agent. The incidence of early pregnancy loss after implantation from all causes has been estimated to be 31%. The proportion of cases of loss due to infection is unknown.<sup>41</sup>

**Abortion and Stillbirth.** The earliest recognizable effects of fetal infection are seen after the sixth to eighth week of pregnancy and include abortion and stillbirth. Intrauterine death may result from overwhelming fetal infection, or the microorganisms may interfere with organogenesis to such an extent that the development of functions necessary for continued viability is interrupted. The precise mechanisms responsible for early spontaneous termination of pregnancy are unknown; in many cases, it is difficult to ascertain whether fetal death caused or resulted from the expulsion of the fetus.

A number of modifying factors probably determine the ultimate outcome of intrauterine infection; these include virulence or tissue tropism of the microorganisms, stage of pregnancy, associated placental damage, and severity of the maternal illness. Primary infection is likely to have a more important effect on the fetus than recurrent infection.<sup>42</sup> For example, recurrence of CMV infection is less severe than primary infection. Available studies do not distinguish between the direct effect of the microorganisms on the developing fetus and the possibility of an indirect effect attributable to illness or poor health of the mother.

Table 1-5 Effects of Transplacental Fetal Infection on the Fetus and Newborn Infant

Organisms or Disease	Prematurity	Intrauterine Growth Retardation/Low Birth Weight	Developmental Anomalies	Congenital Disease	Persistent Postnatal Infection

+, evidence for effect; -, no evidence for effect; (+), association of effect with infection has been suggested and is under consideration.

**Prematurity.** Prematurity is defined as the birth of a viable infant before week 37 of gestation. Premature birth may result from almost any agent capable of establishing fetal infection during the last trimester of pregnancy. Those microorganisms commonly responsible for stillbirth and abortion also are implicated as significant causes of prematurity (Table 1-5).

Previous studies have demonstrated that women in premature labor in whom results of amniotic fluid cultures for bacteria are positive have elevated levels of multiple proinflammatory cytokines in their amniotic fluid.<sup>43-48</sup> In many patients with elevated levels of interleukin-6 (IL-6), results of amniotic fluid culture were negative. Premature births are invariably observed, however, in women in premature labor in whom results of amniotic fluid culture are positive and who also have elevated amniotic fluid levels of IL-6. To further clarify the role of measurement of levels of IL-6 in amniotic fluid, Hitti and colleagues<sup>44</sup> amplified bacterial 16S recombinant RNA (rRNA) encoding DNA by PCR to detect amniotic fluid infection in women in premature labor whose membranes were intact. PCR assay detected bacterial infection in significantly more patients in whom results of amniotic fluid cultures were negative but IL-6 levels were elevated. These data suggest that as many as 33% of women in premature labor in whom results of amniotic fluid culture are negative but IL-6 amniotic fluid

levels are elevated have amniotic fluid infection. The investigators concluded that the association between amniotic fluid infection and premature labor may be underestimated on the basis of amniotic fluid cultures. They further suggested that use of the broad-spectrum bacterial 16S rDNA PCR assay may be useful for diagnosis of infected amniotic fluid. In any case, elevated levels of amniotic fluid IL-6 are clearly associated with an increased risk of preterm delivery, even in cases in which cultures and PCR assay have failed to detect infection.<sup>49</sup> Although this finding is likely to reflect infection undetected by either technique, it remains possible that factors other than infection contribute to preterm labor and elevated amniotic fluid IL-6.

#### **Intrauterine Growth Retardation and Low Birth Weight.**

Infection of the fetus may result in birth of an infant who is small for gestational age (SGA). Although low birth weight and "small for date" infants are associated with many maternal infections, evidence for a causal relationship is only sufficient for congenital rubella, VZV infection, toxoplasmosis, and CMV infection.

The organs of infants dying with congenital rubella syndrome or CMV infection contain a decreased number of morphologically normal cells.<sup>50,51</sup> By contrast, in small-for-dates infants whose growth deficit is due to noninfectious causes such as maternal toxemia or placental abnormalities,

the parenchymal cells are normal in number but have a reduced amount of cytoplasm, presumably because of fetal malnutrition.<sup>52,53</sup>

**Developmental Anomalies and Teratogenesis.** CMV, rubella virus, and VZV cause developmental anomalies in the human fetus. Coxsackieviruses B3 and B4 have been associated with congenital heart disease. The pathogenetic mechanisms responsible for the fetal abnormalities produced by most infectious agents remain obscure. Histologic studies of abortuses and congenitally infected infants have suggested, however, that the ultimate mode of action of some viruses rests in their ability to cause cell death, alterations in cell growth, or chromosomal damage. Lesions resulting from the inflammatory processes caused by the microorganisms must be distinguished from defects that arise from a direct effect of the organisms on the growth of cells and tissues in the developing embryo or fetus. Inflammation and tissue destruction, rather than teratogenic activity, appear to be responsible for the widespread structural abnormalities characteristic of congenital syphilis, transplacental HSV and VZV infection, and toxoplasmosis. Infants with congenital toxoplasmosis may have microcephaly, hydrocephalus, or microphthalmia, but these manifestations usually result from an intense necrotizing process containing numerous organisms and are more appropriately defined as lesions of congenital infection rather than as effects of teratogenic activity of the organism.

Some mycoplasmas<sup>54</sup> and viruses<sup>55,56</sup> produce chromosomal damage in circulating human lymphocytes or in human cells in tissue culture. The relationship of these changes in structure to the production of congenital abnormalities in the fetus is unknown.

**Congenital Disease.** Clinical evidence of intrauterine infections may be present at birth or may manifest soon thereafter or years later. The signs result from tissue damage or secondary physiologic changes caused by the invading organisms. The clinical manifestations in the newborn infant of infection acquired in utero or at delivery are given in Table 1-6. In infants with congenital rubella, toxoplasmosis, syphilis, or congenital CMV, HSV, or enterovirus infection, signs of widely disseminated infection may be evident during the neonatal period. Such signs include jaundice, hepatosplenomegaly, and pneumonia, each of which reflects lesions caused by microbial invasion and proliferation rather than by defects in organogenesis. These signs of congenital infection are not detected until the neonatal period, although the pathologic processes responsible for their occurrence have been progressing for weeks or months before delivery. In some infants, the constellation of signs is sufficient to suggest the likely congenital infection (Table 1-7). In other infants, the signs are transient and self-limited and resolve as neonatal defense mechanisms control the spread of the microbial agent and tissue destruction. If damage is severe and widespread at the time of delivery, the infant is likely to die.

It is frequently difficult to determine whether the infection in the newborn infant was acquired in utero, during the delivery process, or post partum. If the onset of clinical signs after birth occurs within the minimal incubation period for the disease (e.g., 3 days for enteroviruses, 10 days for VZV and rubella viruses), it is likely that the infection was acquired before delivery. The interval between exposure to

malaria in the mother and congenital malaria in the infant can be prolonged; one case of congenital malaria resulting from *Plasmodium malariae* occurred in the United States in an infant born 25 years after the infant's mother had emigrated from China.<sup>57</sup> Children infected with HIV perinatally can be diagnosed by 6 months of age using the DNA (or RNA) PCR method, which has largely replaced other approaches for viral detection.<sup>58</sup> A variable fraction (less than half) of perinatally infected children are infected with HIV in utero, depending on the setting and maternal treatment.<sup>59</sup> Virus-negative infants who later become virus-positive may have been infected at or shortly before delivery.

**Healthy Infants.** A majority of newborn infants infected in utero by rubella virus, *T. gondii*, CMV, HIV, or *Treponema pallidum* have no signs of congenital disease. Fetal infection by a limited inoculum of organisms or with a strain of low virulence or minimal potential for pathology may be responsible for this low incidence of clinical disease in infected infants. Alternatively, gestational age may be the most important factor in determining the ultimate consequences of prenatal infection. When congenital rubella and toxoplasmosis are acquired during the last trimester of pregnancy, the incidence of clinical disease in the infected infants is lower than when microbial invasion occurs during the first or second trimester. Congenital syphilis results from exposure during the second or third but not the first trimester.

Absence of clinically apparent disease in the newborn may be misleading. Careful observation of infected but healthy-appearing children over the course of months or years often reveals defects that were not apparent at birth. The failure to recognize such defects early in life may be due to the inability to test young infants for the functions involved. Hearing defects identified years after birth may be the only manifestation of congenital rubella. Significant sensorineural deafness and other central nervous system deficiencies have afflicted children with congenital CMV infection who were considered to be normal during the neonatal period. Delayed recognition of other manifestations of in utero infection, including failure to thrive, visual defects, and minimal to severe brain dysfunction (including motor, learning, language, and behavioral disorders), can follow toxoplasmosis, rubella, and CMV infections. Infants infected with HIV usually are asymptomatic at birth and for the first few months of life. The median age for onset of signs of congenital HIV infection is approximately 3 years, but many children remain asymptomatic for more than 5 years. Failure to thrive, persistent diarrhea, recurrent suppurative infections, and diseases associated with opportunistic infections that occur weeks to months or years after birth are signs of perinatal infection related to HIV. Of particular concern is the report by Wilson and colleagues<sup>49</sup> that found stigmata of congenital *T. gondii* infection, including chorioretinitis and blindness, in almost all 24 children at follow-up evaluations; the children had serologic evidence of infection but were without apparent signs of disease at birth and did not receive treatment or received inadequate treatment.

Because abnormalities may become obvious only as the child develops and reaches or fails to reach appropriate physiologic or developmental milestones, it is of utmost importance to give careful and thorough follow-up examin-

**Table 1-6 Clinical Manifestations of Neonatal Infection Acquired in Utero or at Delivery**

**Table 1-7 Syndromes in the Neonate Caused by Congenital Infections**

Microorganism	Signs
<i>Toxoplasma gondii</i>	Hydrocephalus, diffuse intracranial calcification, chorioretinitis
Rubella virus	Cardiac defects, sensorineural hearing loss, cataracts; microcephaly, "blueberry muffin" skin lesions, hepatomegaly, interstitial pneumonitis, myocarditis, disturbances in bone growth, intrauterine growth retardation
Cytomegalovirus	Microcephaly, periventricular calcifications, jaundice, petechiae or purpura, hepatosplenomegaly, intrauterine growth retardation
Herpes simplex virus	Skin vesicles or scarring, eye scarring, microcephaly or hydranencephaly; vesicular skin rash, keratoconjunctivitis, meningoencephalitis; sepsis with hepatic failure
<i>Treponema pallidum</i>	Bullous, macular, or eczematous skin lesions involving the palms and soles; rhinorrhea; dactylitis and other signs of osteochondritis and periostitis; hepatosplenomegaly; lymphadenopathy
Varicella-zoster virus	Limb hypoplasia, cicatricial skin lesions, ocular abnormalities, cortical atrophy
Parvovirus B19	Nonimmune hydrops fetalis
Human immunodeficiency virus	Severe thrush, failure to thrive, recurrent bacterial infections, calcification of the basal ganglia

ations to infants born to women known to be infected during pregnancy.

**Persistent Postnatal Infection.** Microbial agents may continue to survive and replicate in tissues for months or years after in utero infection. Rubella virus and CMV have been isolated from various body fluids and tissues over long periods of time from children with abnormalities at birth, as well as from those who appeared healthy. In some congenital infections, including rubella, toxoplasmosis, syphilis, tuberculosis, malaria, and CMV, HSV, and HIV infection, progressive tissue destruction has been demonstrated. Recurrent eye and skin infections can occur as a result of HSV infection acquired in utero or at the time of delivery. A progressive encephalitis has occurred with congenital rubella infection.<sup>60,61</sup> The clinical manifestations of congenital infection in these children had been stable for many years when deterioration of motor and mental functions occurred at ages 11 to 14 years. Rubella virus was isolated from the brain biopsy specimen of a 12-year-old child. Fetal parvovirus B19 infection can persist for months after birth with persistent anemia due to suppressed hematopoiesis.<sup>62</sup>

The mechanisms responsible for maintaining or terminating chronic fetal and postnatal infections are only partially understood. Humoral immune responses, as determined by measurement of either fetal immunoglobulin M (IgM) antibodies or specific IgG antibodies that develop in the neonatal period, appear to be intact in almost all infants (see Chapter 4). The importance of cell-mediated immunity, cytokines, complement, and other host defense mechanisms remains to be defined. The evidence is insufficient at present to support a causal relation between deficiencies in any one of these factors and persistent postnatal infection. It is noteworthy that all of the diseases associated with persistent postnatal infection—with the exception of rubella but including syphilis, tuberculosis, malaria, toxoplasmosis, hepatitis, and CMV, HSV, VZV, and HIV infections—also can produce prolonged and, in certain instances, lifelong infection when acquired later in life.

### Efficiency of Transmission of Microorganisms from Mother to Fetus

The efficiency of transmission from the infected, immunocompetent mother to the fetus varies among microbial agents and also can vary with the trimester of pregnancy. In utero transmission of rubella virus and *T. gondii* occurs primarily as a result of primary infection, whereas in utero transmission of CMV, HIV, and *T. pallidum* can occur in consecutive pregnancies. The risk of congenital rubella infection in fetuses of mothers with symptomatic rubella was high in the first trimester (90% before 11 weeks of gestation), declined to a low of 25% at 23 to 26 weeks, and then rose to 67% after 31 weeks. Infection in the first 11 weeks of gestation was uniformly teratogenic, whereas no birth defects occurred in infants infected after 16 weeks of gestation.<sup>63</sup> By contrast, the frequency of stillbirth and clinical and subclinical congenital *T. gondii* infection among offspring of women who acquired *T. gondii* infection during pregnancy was least in the first trimester (14%), increased in the second trimester (29%), and was highest in the third trimester (59%).<sup>64</sup>

Congenital CMV infection results from primary and recurrent infections. On the basis of studies in Birmingham, Alabama, and other centers, Whitley and Stagno and their colleagues<sup>65,66</sup> estimate that 1% to 4% of women have primary infection during pregnancy, that 40% of these women transmit the infection to the fetus, and that 5% to 15% of the infants have signs of CMV disease. Congenital infection due to recurrent CMV infection occurs in 0.5% to 1% of livebirths, but less than 1% of the infected infants have clinically apparent congenital disease.

The transmission rate of HIV infection from the infected mother who received no treatment to the fetus is estimated to be about 25%, but the data are insufficient to identify efficiency of transmission by trimester. Risk of transmission does not appear to be greater in mothers who acquire primary infection during pregnancy than mothers who were infected before they became pregnant.<sup>67</sup>

## Diagnosis of Infection in the Pregnant Woman

### Clinical Diagnosis

**Symptomatic or Clinical Infection.** In many instances, the diagnosis of infection in the pregnant woman and congenital infection in the newborn infant can be suspected on the basis of clinical signs or symptoms. Careful examination can be sufficient to suggest a specific diagnosis, particularly when typical clinical findings are accompanied by a well-documented history of exposure (see Tables 1-6 and 1-7).

**Asymptomatic or Subclinical Infection.** Many infectious diseases with serious consequences for the fetus are difficult or impossible to diagnose in the mother solely on clinical grounds. Asymptomatic or subclinical infections may be caused by rubella virus, CMV, *T. gondii*, *T. pallidum*, HSV, and HIV. The vast majority of women infected during pregnancy with these organisms have no apparent signs of disease; only 50% of women infected with rubella virus have a rash, and although occasional cases of CMV mononucleosis are recognized, these make up a very small proportion of women who acquire primary CMV infection during pregnancy. Similarly, the number of women with clinical manifestations of toxoplasmosis is less than 10%, and few women have systemic illness associated with primary HSV infection. The genital lesions associated with HSV infection and syphilis often are not recognized.

**Recurrent and Chronic Infection.** Some microorganisms can infect a susceptible person more than once, and when such reinfections occur in a pregnant woman, the organism can affect the fetus. These reinfections generally are associated with waning host immunity, but low levels of circulating antibodies may be detectable. Such specific antibodies would be expected to provide some protection against hematogenous spread and transplacental infection. Fetal disease, however, has followed reexposure of immune mothers to vaccinia,<sup>68</sup> variola,<sup>69</sup> and rubella<sup>70</sup> viruses.

In addition, an agent that causes infection capable of persisting in the mother as a chronic asymptomatic infection could infect the fetus long after the initial infection had occurred. Such delayed infection is common for congenital CMV and HIV infections, which have been observed in infants from consecutive pregnancies of the same mother. Reports of infection of the fetus as a result of chronic infection of the mother have been cited in cases of malaria<sup>71</sup> syphilis,<sup>72</sup> hepatitis,<sup>73</sup> herpes zoster<sup>40</sup> and herpes simplex,<sup>74</sup> and *T. gondii* infection.<sup>75</sup> In the case of *T. gondii*, congenital transmission from the chronically infected woman occurs almost solely when the woman is immunocompromised during pregnancy.

**Preconceptional Infection.** The occurrence of acute infection immediately before conception may result in infection of the fetus, and the association may go unrecognized. Congenital rubella has occurred in the fetus in cases in which the mother was infected 3 weeks to 3 months before conception. A prolonged viremia or persistence of virus in the maternal tissues may be responsible for infection of the embryo or fetus. The same has occurred rarely in cases of maternal infection with *T. gondii*.<sup>76</sup>

## Isolation and Identification of the Infectious Agents

**General Approach.** Diagnostic tests for microorganisms or infectious diseases are part of routine obstetric care; special care is warranted for selected patients who are known or suspected to be exposed to the infectious agent or have clinical signs of the infectious disease. A list of diagnostic tests and the types of intervention that may be required if a diagnosis is made is provided in Table 1-8. The specific interventions for each disease are provided in subsequent chapters.

The most direct mode of diagnosis is isolation of the microbial agent from tissues and body fluids such as blood, cerebrospinal fluid, or urine. Isolation of the agent must be considered with knowledge of its epidemiology and natural history in the host. For example, isolation of an enterovirus from feces during the summer months may represent colonization rather than significant infection that might result in hematogenous spread to the fetus. Isolation of an enterovirus from a body fluid in which it is never present under normal circumstances or identification of a significant rise in antibody titer would be necessary to define an acute infectious process.

Tests for the presence of hepatitis B virus surface antigen (HBsAg) should be performed in all pregnant women. The Centers for Disease Control and Prevention (CDC) has estimated that 16,500 births occur each year in the United States to women who are positive for HBsAg. Infants born to mothers who are positive for this antigen have up to a 90% chance of acquiring perinatal hepatitis B virus infection. If infection is identified soon after birth, use of hepatitis B immune globulin combined with hepatitis B vaccine is an effective mode of prevention of infection. For these reasons, the Advisory Committee on Immunization Practices of the U.S. Public Health Service<sup>77</sup> and the American Academy of Pediatrics<sup>78</sup> recommend universal screening of all pregnant women for HBsAg.

Because the amniotic fluid contains viruses or bacteria shed from the placenta, skin, urine, or tracheal fluid of the infected fetus, this fluid, which can be obtained earlier during gestation and with somewhat less risk than with fetal blood sampling, also may be used to detect the infecting organism by culture, antigen detection test, or PCR assay. Amniocentesis and the analysis of desquamated fetal cells in the amniotic fluid have been used for the early diagnosis of genetic disorders for some time. The seminal publication in 1983 by Daffos and colleagues,<sup>79</sup> in which fetal blood sampling for prenatal diagnosis was first described, provided a method for diagnosing a variety of infections in the fetus that previously could be diagnosed only after birth. Their methods were widely adopted and have contributed significantly both to our understanding of the immune response of the fetus to a variety of pathogens, including rubella virus, VZV, CMV, and *T. gondii*,<sup>80-83</sup> and to a more objective approach to treatment of infection in the fetus before birth.

Fetal blood sampling and amniocentesis are performed under ultrasound guidance. The method is not free of risk; amniocentesis alone carries a risk of fetal injury or death as high as 1%,<sup>47,84</sup> and fetal blood sampling, a risk of approximately 1.4%.<sup>85</sup> Amniotic fluid may be examined for the presence of the infecting organism or its antigens, DNA, or RNA. Fetal blood can be examined for the same parameters, as well as to detect antibodies formed by the fetus against the pathogen (e.g., IgA or IgM antibodies that do not normally

cross the placental barrier). Fetal blood sampling usually is performed during or after week 18 of gestation.

The fetus that is diagnosed as being infected with a specific pathogen or that is at high risk for infection (e.g., the fetus of a nonimmune woman who acquires her infection with *T. gondii* or rubella virus during pregnancy) may be followed by ultrasound examination to detect abnormalities such as dilation of the cerebral ventricles.

#### Isolation, Culture, and Polymerase Chain Reaction Assay.

Isolation of CMV and rubella virus<sup>86</sup> and demonstration of HBsAg<sup>87</sup> from amniotic fluid obtained by amniocentesis have been reported. The PCR technique has proved to be both sensitive and specific for diagnosis of many infections in the pregnant woman, fetus, and newborn. Thus, detection of the DNA/RNA of an organism has, in many instances, replaced the necessity for its isolation to make a definitive diagnosis. The PCR method decreases the time to diagnosis and increases the sensitivity for diagnosis of many of these infectious agents, as exemplified by the prenatal diagnosis of infections caused by parvovirus,<sup>88,89</sup> CMV,<sup>90–92</sup> *T. gondii*,<sup>93,94</sup> and rubella virus.<sup>95,96</sup> As with all diagnostic testing, however, caution is required in interpreting the results of prenatal PCR testing. The sensitivity of PCR results on amniotic fluid is uncertain. For example, a negative result on amniotic fluid PCR assay occurs in up to one third of cases of congenital toxoplasmosis,<sup>94,96</sup> and in infants with congenital rubella, results of amniotic fluid PCR assay can be negative while those for fetal blood are positive. Combined diagnostic approaches in which PCR is used in concert with fetal serology

and other diagnostic modalities (e.g., serial fetal ultrasonography) to test amniotic fluid and fetal blood may offer the greatest sensitivity and predictive power in cases in which congenital infection is suspected and this information is important in management decisions.<sup>94,97</sup> Also, false-positive detection of viral DNA has been observed at frequencies as high as 5% in fluids obtained for genetic testing when congenital fetal infection was not suspected or documented.

#### Cytologic and Histologic Diagnosis.

Review of cytologic preparations and tissue sections may provide a presumptive diagnosis of certain infections. For example, cervicovaginal smears or cell scrapings from the base of vesicles are valuable in diagnosing VZV and HSV infections. Typical changes include multinucleated giant cells and intranuclear inclusions. These morphologic approaches, however, have largely been replaced by more specific testing methods to detect VZV, HSV, and CMV infection using direct immunofluorescence techniques or immunoperoxidase staining. The diagnosis of acute toxoplasmosis can be made from the characteristic histologic changes in lymph nodes or by demonstration of the tachyzoite in tissue specimens obtained by biopsy of infected tissues or at autopsy.

Detailed descriptions of the changes associated with infections of the placenta are presented in a monograph by Fox.<sup>98</sup> Examination of the placental parenchyma, the membranes, and the cord may provide valuable information leading to diagnosis of the infection and identification of the mode of transmission to the fetus (in utero or ascending infection).

**Serologic Diagnosis.** The serologic diagnosis of infection in the pregnant woman most often requires demonstration of a significant rise in antibody titer against the suspected agent. Ideally, the physician should have available information about the patient's serologic status at the onset of pregnancy to identify women who are unprotected against *T. pallidum*, *T. gondii*, and rubella virus or who are infected with hepatitis B virus or HIV. This valuable procedure has already been adopted by many obstetricians.

Difficulties in interpretation of serologic test results seldom arise when patients are seen shortly after exposure or at the onset of symptoms. In certain infections (e.g., rubella, toxoplasmosis), however, a relatively rapid increase in antibody levels may preclude the demonstration of a significant rise in titer in patients who are tested more than 7 days after the onset of the suspected illness. A diagnosis may be obtained in these circumstances through the measurement of antibodies that rise more slowly over a period of several weeks. Demonstration of IgA and IgE antibodies (in addition to the more conventional use of tests for IgG and IgM antibodies) is useful in the early diagnosis of infection in the pregnant woman, fetus, and newborn and should serve as an impetus to commercial firms to make these methods more widely available for use by health care providers. The same pertains to IgG avidity tests. For example, the latter have proved accurate in ruling out recently acquired infection with *T. gondii*,<sup>99</sup> cytomegalovirus,<sup>100,101</sup> and rubella virus.<sup>102,103</sup> At present, these tests require special techniques and are not performed routinely by most laboratories, so local or state health departments should be consulted for further information regarding their availability.

**Use of Skin Tests.** Routine skin tests for diagnosis of tuberculosis should be considered a part of prenatal care. Tuberculin skin tests can be administered to the mother without risk to the fetus.

### Universal Screening

Prenatal care in the United States includes routine screening for serologic evidence of syphilis and rubella; culture or antigen evidence of *Chlamydia trachomatis*, group B *Streptococcus*, or hepatitis B virus infection; screening for urinary tract infection; and skin testing for tuberculosis. The demonstration that treatment of the HIV-infected mother significantly reduces the transmission of the virus to the fetus has led to recommendations by some authorities for universal HIV screening for all pregnant women in the United States. Current CDC guidelines support voluntary HIV testing under conditions that simplify consent procedures while preserving a woman's right to refuse testing if she does not think it is in her best interest.<sup>104</sup>

Pregnant women with known HIV infection should be monitored and given appropriate treatment to enhance mother and fetal well-being and to prevent maternal-to-fetal transmission. Pregnant women should be examined carefully for the presence of HIV-related infections including gonorrhea, syphilis, and *C. trachomatis* infection. Baseline antibody titers should be obtained for those opportunistic infections, such as *T. gondii*, which are observed commonly in HIV-infected women and which may be transmitted to their fetuses. More detailed information on management of an HIV-infected pregnant woman and her infant is given in Chapter 21.

### Diagnosis of Infection in the Newborn Infant

Infants with congenital infection due to rubella virus, CMV, HSV, *T. gondii*, or *T. pallidum* may present similarly with one or more of the following abnormalities: purpura, jaundice, hepatosplenomegaly, pneumonitis, and meningoencephalitis. Some findings have specific diagnostic significance (see Tables 1-5 and 1-6).

In certain congenital infections, the organism may be isolated from tissues and body fluids. Infants may excrete CMV and rubella virus in the urine for weeks to months after birth. *T. pallidum* may be found in the cerebrospinal fluid, in nasal secretions, and in the skin lesions of syphilis. Results of HIV culture or PCR assay are positive at birth in approximately 30% to 50% of congenitally infected infants, but results are positive in nearly 100% of infected infants by 4 to 6 months of life.

Serologic tests are available through state or commercial laboratories for the TORCH group of microorganisms (*T. gondii*, *T. pallidum*, rubella virus, CMV, and HSV) and for certain other congenitally acquired infections. To distinguish passively transferred maternal IgG antibody from antibody synthesized by the neonate in response to infection in utero, it is necessary to obtain two blood specimens from the infant. Because the half-life of IgG is approximately 3 days, the first sample is obtained soon after birth, and the second sample should be obtained at least two half-lives or approximately 6 weeks after the first specimen.

IgA, IgE, and IgM antibodies do not cross the placenta. Antigen-specific IgA, IgE, and IgM antibodies in the infant's blood provides evidence of current infection, but few commercial laboratories employ reliable assays for these antibodies for the purpose of identifying congenital infections, as described in a Public Health Advisory from the Food and Drug Administration outlining the limitations of *Toxoplasma* IgM commercial test kits.

Although most congenital infections occur as a single entity, many HIV-infected mothers are co-infected with other infectious agents that may be transmitted to the newborn. The neonate born to an HIV-infected mother should be considered at risk for other sexually transmitted infections such as syphilis, gonorrhea, and *C. trachomatis* infection. In addition, co-infection has been documented for CMV.<sup>105,106</sup>

### Prevention and Management of Infection in the Pregnant Woman

#### Prevention of Infection

Pregnant women should avoid contact with persons with communicable diseases, particularly if the women are known to be seronegative (e.g., for CMV) or have no prior history of the disease (e.g., with VZV). In some cases, specific measures can be taken. The pregnant woman should avoid intercourse with her sexual partner if he has a vesicular lesion on the penis that may be due to HSV or if he is known or suspected to be infected with HIV. Pregnant women should avoid eating raw or undercooked lamb, pork, and beef, because such products sometimes contain *T. gondii*. They also should avoid contact with cat feces, or objects or materials contaminated with cat feces, because these are highly infectious if they harbor oocysts of *T. gondii* (see Chapter 31). Pregnant women should not eat unpasteurized

dairy products (including all soft cheeses), prepared meats (hot dogs, deli meat, and paté), and undercooked poultry, because such foods often contain *Listeria monocytogenes* (see Chapter 14).

### Immunization

Routine immunization schedules for infants and children with currently available live vaccines, including measles, poliomyelitis, mumps, and rubella, should confer protection against these infections throughout the childbearing years.

Public health authorities and obstetricians generally agree that immunization during pregnancy poses only theoretical risks to the developing fetus. Nevertheless, pregnant women should receive a vaccine only when the vaccine is unlikely to cause harm, the risk for disease exposure is high, and the infection would pose a significant risk to the mother (e.g., influenza) or fetus (e.g., tetanus).<sup>107</sup> The following considerations are of importance with regard to immunization of the pregnant woman.

- The only vaccines routinely recommended for administration during pregnancy in the United States, when indicated for either primary or booster immunization, are those for tetanus, diphtheria, and influenza.<sup>108</sup> Such vaccines are inactivated. Inactivated vaccines, including typhoid fever vaccine, are not considered hazardous to the pregnant woman or her fetus and often can be of major benefit when indicated. An example is the use of tetanus toxoid vaccines in areas of the world in which infection in the newborn from unsterile delivery and cord care carries a significant risk of fatal outcome. In the United States, pregnant women are at increased risk for influenza-like illness that requires hospitalization when compared with nonpregnant women of similar age. For this reason, routine immunization of pregnant women at the onset of the influenza season is recommended by the Advisory Committee on Infectious Diseases of the CDC.<sup>108</sup> In women at increased risk for certain serious bacterial infections, such as invasive pneumococcal or meningococcal disease (e.g., those with sickle cell disease or HIV infection), immunization should precede pregnancy if at all possible. If immunization has not occurred before pregnancy and the risk is significant (e.g., with a meningococcal outbreak in the community), the women should be vaccinated.
- Pregnancy is a contraindication to administration of all live vaccines, except when susceptibility and exposure are highly probable and the disease to be prevented constitutes a greater threat to the woman and her fetus than a possible adverse effect of the vaccine. For example, yellow fever vaccine is indicated for pregnant women who are at substantial risk for imminent exposure to infection (such as with international travel). A report of IgM antibodies to yellow fever in the infant of a woman immunized during pregnancy suggests that transplacental transmission of the yellow fever vaccine virus does occur, although the incidence of congenital infection is unknown.<sup>109</sup>
- Varicella vaccine should not be administered to pregnant women, because the possible effects on fetal development are unknown. When postpubertal females are immunized, pregnancy should be avoided for at least 2 months following immunization.
- Because several weeks can elapse before pregnancy is evident, caution and selectivity are indicated in administering a live virus vaccine to any woman of child-bearing age. The demonstration of prolonged virus shedding after immunization with live virus vaccine suggests that pregnancy should be avoided when possible for 2 to 3 months subsequent to the administration of any live immunizing agent.
- The risk to the mother or fetus from immunization of members of her immediate family or other intimate contacts is uncertain. The use of attenuated measles, rubella, mumps, and varicella vaccines rarely results in dissemination of these viruses to susceptible subjects in the immediate environment, but household spread of attenuated polioviruses through contact with recently vaccinated, susceptible individuals in the family is common. From March 1995 through March 2003, 509 pregnant women whose pregnancy outcomes are known were inadvertently given varicella vaccine (VARIVAX Pregnancy Registry). No offspring had congenital varicella, and the rate of congenital anomalies was no greater than that in the general population. Furthermore, presence of a pregnant woman in the household is not a contraindication to varicella immunization of a child in that household, and varicella-susceptible women should be vaccinated post partum.

### Use of Immune Globulin

Human immune serum globulin administered after exposure to rubella, varicella, measles, or hepatitis A virus may modify clinical signs and symptoms of the disease but has not proved to be consistently effective in preventing disease, and presumably viremia, in susceptible persons. Human immune serum globulin is of undetermined value in protecting the fetus of a susceptible woman against infection with these viruses. Its use after maternal exposure to rubella virus should be limited to women to whom therapeutic abortion is unacceptable, in the event of documented infection during pregnancy.

### Antimicrobial Therapy

Almost without exception, antimicrobial agents administered systemically to the mother pass to the fetus. Management of pregnant women with acute infections amenable to therapy should be the same as that of nonpregnant patients but with attention paid to the possible effects on the fetus of the antimicrobial drug. Pregnant women with recently acquired acute toxoplasmosis, Lyme disease, and syphilis should undergo treatment as outlined in the specific chapters devoted to those topics. Women who are colonized with *C. trachomatis* or group B streptococci may receive treatment under selected circumstances, considered in the next section.

The landmark study of Connor and colleagues demonstrated reduction of maternal-infant transmission of HIV from 25.5% to 8.3% using zidovudine in women who had peripheral CD4<sup>+</sup> T lymphocyte counts of more than 200 cells per  $\mu\text{L}$  and were mildly symptomatic.<sup>110</sup> The currently recommended treatment regimen in the United States is oral zidovudine administered to pregnant women beginning at

14 to 34 weeks of gestation and continuing throughout pregnancy, intravenous zidovudine during labor and delivery, and oral zidovudine to the newborn for the first 6 weeks of life (see Chapter 21). This complex and costly regimen is not feasible for resource-limited countries, but recent studies in Uganda using one dose of nevirapine administered to the mother in labor and a single dose to the neonate before discharge provide a model.<sup>111</sup>

## INFECTIONS ACQUIRED BY THE NEWBORN INFANT DURING BIRTH

### Pathogenesis

The developing fetus is protected from the microbial flora of the maternal genital tract. Initial colonization of the newborn and of the placenta usually occurs after rupture of maternal membranes. If delivery is delayed after membranes rupture, the vaginal microflora can ascend and in some cases produce inflammation of fetal membranes, umbilical cord, and placenta. Fetal infection also can result from aspiration of infected amniotic fluid. Some viruses are present in the genital secretions (HSV, CMV, hepatitis B virus, or HIV) or blood (hepatitis B or C virus or HIV). If delivery follows shortly after rupture of the membranes, the infant can be colonized during passage through the birth canal. A variety of microorganisms may be present in the maternal birth canal, as summarized in Table 1-8; included are gram-positive cocci (staphylococci and streptococci), gram-negative cocci (*Neisseria meningitidis* [rarely] and *Neisseria gonorrhoeae*), gram-negative enteric bacilli (*Escherichia coli*, *Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Salmonella*, and *Shigella*), anaerobic bacteria, viruses (CMV, HSV, rubella virus, and HIV), fungi (predominantly *Candida albicans*), *C. trachomatis*, mycoplasmas, and protozoa (*Trichomonas vaginalis* and *T. gondii*). As indicated in Table 1-8, some of these organisms are significantly associated with disease in the newborn infant, whereas others affect the neonate rarely, if at all.

The newborn initially is colonized on the skin, mucosal surfaces, including the nasopharynx, oropharynx, conjunctivae, umbilical cord, and external genitalia, and the gastrointestinal tract (from swallowing of infected amniotic fluid or vaginal secretions). In most infants, the organisms proliferate at these sites without causing illness. A few infants become infected by direct extension from the sites of colonization (e.g., otitis media from nasopharyngeal colonization). Alternatively, invasion of the bloodstream can ensue, with subsequent dissemination of infection. The umbilical cord was a particularly common portal of entry for systemic infection before local disinfection methods became routine. This site was common because the devitalized tissues are an excellent medium for bacterial growth and because the thrombosed umbilical vessels provide direct access to the bloodstream. Microorganisms also can infect abrasions or skin wounds. Today the most frequent sources for bloodstream invasion are the lung from aspirated infected amniotic fluid or vaginal contents and the gastrointestinal tract from transmigration of microbial flora across the gut wall.

Infants in whom bacterial sepsis develops often have certain risk factors not evident in infants in whom significant infections do not develop. Among these factors are pre-

term delivery at a gestational age less than 37 weeks, low birth weight, prolonged rupture of maternal membranes, maternal intra-amniotic infection, traumatic delivery, and fetal anoxia. Relative immaturity of the immune system is considered to be one factor in increased risk of infection during the neonatal period. The role of host defenses in neonatal infection is discussed in detail in Chapter 4.

Preterm birth is the single most significant risk factor for infections acquired just before or during delivery of the infant or in the nursery. The increasing number of extremely and very low birth weight infants has continued to heighten concern for infection as a cause of morbidity and mortality. Furthermore, various modalities for treatment of infertility have continued to increase the number of multiple-birth pregnancies, and a gestational age of less than 28 weeks is not uncommon following various modalities for treatment of infertility. A recent summary of 6215 very low birth weight neonates (birth weight of 401 to 1500 g) from the National Institute of Child Health and Human Development Neonatal Research Network reported that 21% had one or more episodes of blood culture-proven late-onset sepsis.<sup>112</sup> Infection rate was inversely correlated with birth weight and gestational age, and infected infants had a significantly prolonged mean hospital stay (79 days) compared with uninfected infants (60 days). Also, infants with late-onset sepsis were significantly more likely to die than uninfected infants (18% versus 7%), especially if they were infected with gram-negative organisms (36%) or fungi (32%).<sup>112</sup>

The value of certain defense mechanisms remains controversial. Vernix caseosa has no specific antibacterial properties, but retention of vernix probably is of value because it provides a protective barrier to the skin. Breast milk influences the composition of the fecal flora by suppression of *E. coli* and other gram-negative enteric bacilli and encouragement of growth of lactobacilli. In addition, breast milk contains secretory IgA, lysozymes, white blood cells, and lactoferrin (an iron-binding protein that significantly inhibits the growth of *E. coli* and other microorganisms); however, the importance of these constituents for colonization and systemic infection in the neonate acquired at or shortly after birth is uncertain (see Chapter 5).

The virulence of the invading microorganism also must be considered as a factor in the pathogenesis of neonatal sepsis. Certain phage types of *S. aureus* (types 80 and 81) were responsible for most cases of disease in the staphylococcal pandemic of the 1950s. Phage group 2 *S. aureus* strains have been responsible for the staphylococcal scalded skin syndrome sometimes seen in neonates (toxic epidermal necrolysis). Other evidence suggests that the K1 capsular antigens of *E. coli* and type III strains of group B *Streptococcus* possess virulence properties that account for their propensity to cause invasion of the blood-brain barrier during bacteremia when compared with non-K1 and non-type III strains.

### Microbiology

The agents responsible for early-onset (before 72 hours) neonatal sepsis are those found in the maternal birth canal.<sup>113,114</sup> Most of these organisms are considered to be saprophytic, but on occasion they can be responsible for maternal infection and its sequelae, including endometritis and puerperal fever. A review of the microbial flora of the adult female genital

tract and its association with neonatal infection and disease is presented in Table 1-9.

Before the introduction of the sulfonamides and penicillin in the 1940s, gram-positive cocci, particularly group A streptococci, were responsible for most cases of neonatal sepsis. After the introduction of antimicrobial agents, gram-negative enterics, in particular *E. coli*, were the predominant

causes of serious bacterial infections of the newborn. An increase in serious neonatal infection caused by group B streptococci was noted in the early 1970s, and currently, group B streptococci and *E. coli* continue to be the most frequent causative agents for early-onset neonatal sepsis and for late-onset sepsis in term infants. By contrast, late-onset (after 7 days) sepsis in preterm neonates remaining in the

neonatal intensive care unit for weeks or months have sepsis caused by commensal organisms (e.g., coagulase-negative staphylococci and *Enterococcus*) as well as by organisms acquired from the mother and from the nursery environment. The bacteria responsible for neonatal sepsis are discussed in Chapter 6.

Mycoplasmas, anaerobic bacteria, and viruses (including HSV, hepatitis B virus, CMV, and HIV) that colonize the maternal genital tract also are acquired during birth.

## Diagnosis

Review of the maternal record provides important clues for diagnosis of infection in the neonate. Signs of illness during pregnancy, exposure to sexual partners with transmissible infections, and results of cultures (e.g., for *C. trachomatis*, *N. gonorrhoeae*, or group B streptococci), serologic tests (e.g., for HIV infection, rubella, hepatitis B and C, or syphilis), and tuberculin skin tests or chest radiographs should be identified in the pregnancy record. The delivery chart should be checked for peripartum events that indicate risk of sepsis in the neonate, including premature rupture of membranes, prolonged duration (longer than 18 hours) of rupture of membranes, evidence of fetal distress and fever or other signs of maternal infection such as bloody diarrhea, respiratory or gastrointestinal signs (i.e., enterovirus), indications of large concentrations of pathogens in the genitalia (as reflected in bacteriuria due to group B streptococci), and evidence of invasive bacterial infections in prior pregnancies.

The clinical diagnosis of systemic infection in the newborn can be difficult. The initial signs of infection may be subtle and nonspecific. Not only are the signs of infectious and noninfectious processes similar, but also the signs of in utero infection are indistinguishable from those of infections acquired either during the birth process or subsequently, during the first few days of life. Respiratory distress, lethargy, irritability, poor feeding, jaundice, emesis, and diarrhea are associated with a variety of infectious and noninfectious causes.

Some clinical manifestations of neonatal sepsis, such as hepatomegaly, jaundice, pneumonitis, purpura, and meningitis, are common to many of the infections that are acquired in utero or during delivery. Certain signs, however, are related to specific infections (see Tables 1-6 and 1-7). Many signs of congenital infection are not evident at birth: hepatitis B infection should be considered in the infant with onset of jaundice and hepatosplenomegaly between 1 and 6 months of age; CMV infection acquired at or soon after delivery is associated with an afebrile protracted pneumonitis; enterovirus infection should be considered in the infant with acute cerebrospinal fluid pleocytosis in the first months of life. Most infants with congenital HIV infection do not have signs of disease during the first months of life. Uncommonly, signs may be present at birth. Srugo and colleagues<sup>115</sup> described an infant with signs of meningoencephalitis at 6 hours of life; HIV was isolated from cerebrospinal fluid.

Most early-onset bacterial infections are nonfocal except in the circumstance of respiratory distress at or shortly after birth, in which the chest radiograph reveals pneumonia. Focal infections are frequent with late-onset neonatal sepsis and include otitis media, pneumonia, soft tissue infections, urinary tract infections, septic arthritis, osteomyelitis, and

peritonitis. Bacterial meningitis is of particular concern because of the substantial mortality rate and the significant morbidity in survivors. Few infants have overt meningeal signs, and a high index of suspicion and examination of the cerebrospinal fluid are required for early diagnosis.

Routine laboratory methods now available are of limited assistance in the diagnosis of systemic infections in the newborn infant. In bacterial sepsis, the total white blood cell count is variable and supports a diagnosis of bacterial sepsis only if it is high (more than 30,000 cells per mm<sup>3</sup>) or very low (fewer than 5000 cells per mm<sup>3</sup>). Immunoglobulin is produced by the fetus and newborn infant in response to infection. Increased levels of IgM have been measured in the serum of newborns with infections (i.e., syphilis, rubella, cytomegalic inclusion disease, toxoplasmosis, and malaria) acquired transplacentally. Increased levels of IgM also result from postnatally acquired bacterial infections. Not all infected infants, however, have increased levels of serum IgM, and some infants who do have elevated concentrations of total IgM are apparently uninfected. Thus, identification of increased levels of total IgM in the newborn is suggestive of an infectious process acquired before or shortly after birth, but this finding is not specific and is of limited assistance in diagnosis and management.

Because inflammation of the placenta and umbilical cord may accompany peripartum sepsis, pathologic examination of sections of these tissues may assist in the diagnosis of infection in the newborn. Of note, however, histologic evidence of inflammation also is noted in the absence of evidence of neonatal sepsis. In the immediate postnatal period, gastric aspirate, pharyngeal mucus, or fluid from the external ear canal has been used to delineate exposure to potential pathogens but are not useful in the diagnosis of neonatal sepsis.

Isolation of microorganisms from a usually sterile site, such as blood, cerebrospinal fluid, or skin vesicle fluid, or from a suppurative lesion or a sterilely obtained sample of urine, remains the only valid method of diagnosing systemic infection. Aspiration of any focus of infection in a critically ill infant (e.g., needle aspiration of middle ear fluid in an infant with otitis media or from the joint or metaphysis of an infant with osteoarthritis) should be performed to determine the etiologic agent. In very low birth weight infants, commensal microorganisms, such as coagulase-negative staphylococci, *Enterococcus*, or *Candida*, isolated from a usually sterile body site should be considered pathogens until proven otherwise. Culture of infectious agents from the nose, throat, skin, umbilicus, or stool indicates colonization; these agents may include the pathogens that are responsible for the disease but in themselves do not establish the presence of active systemic infection.

PCR assay to detect the nucleic acid of a variety of important pathogens including viruses and *Pneumocystis jiroveci*, enzyme immunoassay for *T. gondii*, and electron microscopy to identify CMV and rotaviruses are useful new tests available for diagnosis. When appropriate, serologic studies should be performed to ascertain the presence of in utero or postnatal infection. Serologic tests are available through local or state laboratories for HIV, rubella, parvovirus B19, *T. gondii*, and *T. pallidum*. For some of these infections (e.g., rubella), the serologic assay measures IgG. To distinguish passively transferred maternal antibody from antibody derived from infection in the neonate, it is

necessary to obtain two blood specimens from the infant. Because the half-life of IgG is estimated to be 23 days, the first sample is obtained soon after birth, and the second sample should be obtained at least two half-lives or approximately 6 weeks after the first specimen. Measurement of IgM antibody provides evidence of current infection in the neonate, but none of these assays has proven reliability at present.

## Management

Successful management of neonatal bacterial sepsis depends on a high index of suspicion based on maternal history and infant signs, prompt initiation of appropriate antimicrobial therapy while diagnostic tests are performed, and meticulous supportive measures. If the physician considers that a newborn may have bacterial infection, culture specimens should be obtained and treatment with antimicrobial agents active against the probable pathogens should be initiated immediately. In general, initial therapy must include agents active against gram-positive cocci, particularly group B and other streptococci, and gram-negative enteric bacilli. Ampicillin is the preferred agent with effectiveness against gram-positive cocci and *L. monocytogenes*. The choice of therapy for gram-negative infections depends on the current pattern of antimicrobial susceptibility in the local community. Most experts prefer ampicillin and gentamicin as agents for therapy for early-onset presumptive sepsis, with the addition of cefotaxime for presumptive bacterial meningitis.<sup>116</sup> Intrapartum antimicrobial therapy results in concentrations of drug in the blood of the newborn infant that can suppress growth of group B streptococci and possibly other susceptible organisms in blood obtained for culture. The requirement for more than one blood specimen for the microbiologic diagnosis of early-onset sepsis places a substantial burden on the clinician.

An algorithm has been prepared to guide empirical management of neonates born to mothers who received intrapartum antimicrobial prophylaxis for prevention of early-onset group B streptococcal infection.<sup>117</sup> These infants may be divided into three management groups:

1. Neonates who have signs of sepsis or those whose mothers are colonized with group B streptococci and have chorioamnionitis should receive a full diagnostic evaluation with institution of empirical treatment.
2. Term neonates who appear healthy and whose mothers received penicillin, ampicillin, or cefazolin 4 or more hours before delivery do not require further evaluation or treatment.
3. Healthy-appearing term neonates whose mothers received prophylaxis less than 4 hours before delivery and neonates born at less than 35 weeks of gestation whose mothers received prophylaxis of any duration before delivery should be observed for 48 hours or longer and should receive a limited evaluation, including white blood cell count and differential and culture of blood.<sup>117</sup>

Infants in the first two categories are readily identified, but assignment of infants to the third category often is problematic because of the vague end points. Recent recommendations for prevention and treatment of early-onset group B streptococcal infection are discussed in Chapter 13.

The choice of antibacterial drugs should be reviewed when results of cultures and susceptibility tests become

available. The clinician should be sure to select drugs that have been studied for appropriate dose, interval of dosing, and safety in neonates, especially very low birth weight infants, and that have the narrowest antimicrobial spectrum that would be effective (see Chapter 37). The duration of therapy depends on the initial response to the appropriate antibiotics but should be 10 days in most infants with sepsis, pneumonia, or minimal or absent focal infection; the *minimal* duration of therapy for uncomplicated meningitis caused by group B streptococci or *L. monocytogenes* is 14 days and for gram-negative enteric bacilli is 21 days.<sup>117</sup>

The clinical pharmacology of antibiotics administered to the newborn infant is unique and cannot be extrapolated from the data on absorption, excretion, and toxicity in the adult. The safety of new antimicrobial agents is a particular concern because toxic effects may not be detected until several years later (see Chapter 37).

Development of resistance of microbial pathogens to antimicrobial agents is a constant concern. Group B streptococci remain uniformly susceptible to penicillins and cephalosporins, but many isolates now are resistant to erythromycin and clindamycin.<sup>118,119</sup> The one or two doses of a penicillin or cephalosporin administered as part of a peripartum prophylactic regimen for prevention of group B streptococcal infection in the neonate would not be expected to significantly affect the genital flora, but surveillance for alteration in the flora and antibiotic susceptibility should be maintained. Because the nursery is a small, closed community, development of resistance is a greater concern with nosocomial infections than with infections acquired in utero or at delivery.

Despite the use of appropriate antimicrobial agents and optimal supportive therapy, mortality from neonatal sepsis remains substantial. With the hope of improving survival and decreasing the severity of sequelae in survivors, investigators have turned their attention to studies of adjunctive modes of treatment that provide supplements for the demonstrated deficits in the host defenses of the infected neonate. These therapies include use of standard hyperimmune immunoglobulins, leukocyte growth factors, and monoclonal antibody preparations that are pathogen specific.

Antiviral therapies are available for treatment for newborns infected with HSV (acyclovir), VZV (acyclovir), and HIV. Acyclovir and zidovudine are well tolerated in the pregnant woman. Because early use of acyclovir for herpes simplex infections in neonates has been associated with improved outcome, physicians may choose to begin therapy for presumptive disease due to HSV and reevaluate therapy when results of cultures and PCR assay are known and more information is available about the clinical course.

The results of phase II and III trials examining safety, pharmacodynamics, and efficacy of ganciclovir treatment of symptomatic congenital CMV infection have been reported.<sup>120,121</sup> The phase II trial established the safe dose of ganciclovir in infants and demonstrated an antiviral effect with suppression of viremia.<sup>120</sup> Neutropenia (63%), thrombocytopenia, and altered hepatic enzymes were noted in a majority of the infants. Nearly half of the infants required dosage adjustments because of severe neutropenia. The phase III randomized, controlled trial of intravenous ganciclovir for 6 weeks in 100 infants with central nervous system CMV involvement at birth demonstrated hearing

improvement or maintained hearing in 84% of infants who received ganciclovir, compared with 41% of control infants (see Chapter 23).<sup>121</sup>

## Prevention

### **Immunoprophylaxis**

Immune globulins may be valuable for prevention of certain infections that occur during the neonatal period. Zoster immune globulin is effective in the prevention or the attenuation of neonatal varicella, but its manufacture has been discontinued (as of 2005). Hepatitis B immune globulin is effective for the interruption of perinatal transmission of hepatitis B virus carrier state, especially when combined with immunization with hepatitis B vaccine. Intravenous immune globulin (IGIV) reduced the number of late-onset infections, particularly those caused by coagulase-negative staphylococci, in low-birth-weight premature infants in one multicenter, randomized controlled study<sup>121</sup> but not in another.<sup>122</sup> Currently, pathogen-specific hyperimmune globulins or monoclonal antibody preparations for staphylococci (see Chapter 17) are under investigation.

Universal immunization of infants with hepatitis B vaccine has been recommended by the American Academy of Pediatrics since 1992.<sup>123</sup> Prior selective strategies of vaccination in high-risk populations and serologic screening of all pregnant women for HB<sub>s</sub>Ag had little impact on control of hepatitis B infections or their sequelae, and public health authorities believe that infant immunization offers the most feasible approach to protection of all persons and eventual elimination of the disease. Infants born to HB<sub>s</sub>Ag-positive women should receive hepatitis B immune globulin at or shortly after birth and should be immunized at birth. Further improvement in this prevention strategy may be achieved if a universal birth dose of hepatitis B vaccine is recommended, thereby allowing intervention for those infants whose maternal records are incorrect or not available before hospital discharge.

### **Chemoprophylaxis**

Antimicrobial agents capable of crossing biologic membranes can achieve concentrations of drug in the fetus comparable with concentrations in other well-vascularized tissues after administration to the mother. Prevention of group B streptococcal infection in the newborn by administration of ampicillin to the mother was demonstrated by Boyer and colleagues<sup>124</sup> and other investigators as early as 1983 (see Chapter 13). A prevention strategy was recommended for use by the American Academy of Pediatrics in 1992.<sup>125</sup> These guidelines were revised in 1997, and current recommendations from the CDC are endorsed by the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the American Academy of Family Physicians. Current recommendations are for universal culture screening of all pregnant women at 35 to 37 weeks of gestation and for administration of intravenous penicillin during labor.<sup>3</sup> Concentrations of drug are achieved in the fetus that are more than 30% of the concentrations in the blood of the mother,<sup>126</sup> and bactericidal concentrations against group B streptococci are achieved in amniotic fluid 3 hours after a maternal dose (see Chapters 13 and 37). Parenteral antimicrobial therapy administered to the mother in labor is

essentially treating the fetus earlier in the course of the intrapartum infection. If the fetus has been infected, the regimen is treatment, not prophylaxis, and for some infected fetuses the treatment administered in utero will be insufficient to prevent early-onset group B streptococcal disease.<sup>128</sup> Although the prophylactic regimen has decreased the incidence of early-onset group B streptococcal disease (by more than 80% in a Pittsburgh survey<sup>127</sup>), the regimen has had no impact on the incidence of late-onset disease.<sup>3</sup>

Other modes of chemoprophylaxis administered to the neonate are the use of ophthalmic drops or ointments for prevention of gonococcal ophthalmia and the administration of zidovudine to infants born to HIV-infected mothers. Administration of antibacterial agents to infants with minimal or ambiguous clinical signs is therapy for presumed sepsis and should not be considered prophylaxis.

## **INFECTIONS OF THE NEWBORN INFANT IN THE FIRST MONTH OF LIFE**

When fever or other signs of systemic infection occur in the first weeks or months of life, appropriate management requires consideration of the various sources of infection. Five types of such infection based on source can be recognized: (1) congenital infections with onset in utero; (2) infections acquired during the birth process from the maternal genital tract; (3) infections acquired in the nursery; (4) infections acquired in the household after discharge from the nursery; and (5) infection that suggests an anatomic defect, underlying immunologic disease or metabolic abnormality.

## **Pathogenesis and Microbiology**

### **Congenital Infections**

Signs of congenital infection may not appear for weeks, months, or years following birth. Diagnosis and management are discussed in the disease chapters.

### **Infections Acquired during Delivery**

Although maternal intrapartum prophylaxis has reduced the incidence of early-onset group B streptococcal disease, the regimen has not altered the incidence of late-onset disease,<sup>3</sup> with signs occurring from 6 to 89 days of life, and in very low birth weight infants up to 6 months of age. The pathogenesis of late-onset group B streptococcal disease remains obscure, but it is likely that even when vertical transmission from the mother at birth is prevented, exposure to either the mother (in whom colonization resumes after delivery) and other colonized family members or caregivers can serve as a source for colonization through direct contact. Why sepsis develops without warning in an infant who has no risk factors for sepsis and was well for days to weeks remains a mystery. This concern also is relevant in infants who acquire late-onset disease due to *E. coli* and *L. monocytogenes*.

### **Nursery-Acquired Infections**

After arrival in the nursery, the newborn may become infected by various pathways involving either human carriers or contaminated materials and equipment.

Human sources in the hospital include personnel, mothers, and other infants. The methods of transmission may include the following:

- *Droplet spread* from the respiratory tract of adults or other newborn infants. Outbreaks of respiratory virus infections in prolonged-stay nurseries are frequent; viruses present include influenza, respiratory syncytial, and parainfluenza viruses.<sup>128</sup> Methods for identification and control are provided in Chapter 35.
- *Carriage* of the microorganism on the hands of hospital personnel. A study has suggested that the hands may be not only a means of transmission but also a significant reservoir of bacteria.<sup>129</sup>
- *Suppurative lesions*. Although spread of staphylococcal and streptococcal infections to infants or mothers may be associated with asymptomatic carriers, the most serious outbreaks have been caused by a member of the medical or nursing staff with a significant lesion.
- *Human milk*. CMV, HIV, HSV, human T cell lymphotropic virus type I (HTLV-I),<sup>130</sup> HTLV-II,<sup>131</sup> and HB<sub>s</sub>Ag have been identified in mother's milk and may be transmitted to the neonate by this route. CMV-infected milk from banks can be dangerous for infants without passively transferred maternal antibody.

The role of breast milk in transmission of HIV is of concern because of the importance of breast-feeding in providing nutrition and immunologic protection in the first year of life. Breast milk has been documented to be the likely source of HIV infection in neonates whose mothers were transfused with HIV-infected blood after delivery or in whom disease developed post partum through sexual contact.<sup>132</sup> These acute infections need to be differentiated from the usual event in which the mother is infected throughout pregnancy. Infection during the acute period occurs before development of antibody and may be a time when breast milk has a high titer of transmissible virus. Because of the importance of breast-feeding in the nutrition of infants in developing countries, the World Health Organization (WHO) first recommended that women in developing countries be encouraged to breast-feed even if they were known to be infected with HIV.<sup>133</sup> By contrast, in the United States and Western Europe, HIV-infected mothers were discouraged from breast-feeding because other forms of nutrition were available.<sup>134</sup> In July 1998, the United Nations changed its position and issued recommendations to discourage women infected with HIV from breast-feeding. The statement recognized that many infants were infected by the breast milk of HIV-infected mothers. The recommendation also noted that in some cultures, women may become stigmatized for not breast-feeding, and that in some places, alternatives such as formula are unaffordable or unsafe. The number of congenitally infected infants in developing countries that have no resources for prevention in pregnancy has reached alarming proportions: 70% of women at a prenatal clinic in Zimbabwe and 30% of women in urban areas in six African countries were infected. The United Nations survey indicated that by the year 2000, breast-feeding

would be responsible for more than one third (greater than 200,000) of children newly infected with HIV unless some attempts were made to limit this route of transmission.<sup>135</sup>

Infection of breast milk by bacterial pathogens such as *S. aureus*, group B streptococci, *L. monocytogenes*,<sup>136</sup> and *Salmonella* species can result in neonatal disease. Bacteria that are components of skin flora, including *Staphylococcus epidermidis* and  $\alpha$ -hemolytic streptococci, frequently are cultured from freshly expressed human milk and are unlikely to be of importance in the breast-fed infant. If these bacteria are allowed to multiply in banked breast milk, infection of the neonate is possible in theory, but no substantive data have been presented to suggest that this is an important problem.

Other possible sources of infection in the nursery include the following:

- *Blood products*. Blood used for replacement or exchange transfusion in neonates should be determined to be safe by techniques of proven efficacy, including tests for hepatitis B antigen, hepatitis C, HIV antibody, CMV antibody, and *Plasmodium* species in malaria-endemic areas.
- *Equipment* has been implicated in common-source nursery outbreaks. The most frequent factors in transmission of infection in such instances have been contaminated solutions used in nebulization equipment, room humidifiers, and bathing solutions. Several gram-negative bacteria, including *Pseudomonas aeruginosa*, *Serratia marcescens*, and *Flavobacterium*, have been so troublesome in the past that they have been termed "water bugs" because of their ability to multiply in aqueous environments at room temperature. In the past decade, few solution- or equipment-related outbreaks due to these organisms have been reported, because of the scrupulous infection control practices that are enforced in most intensive care nurseries.
- *Catheterization* of the umbilical vein and artery has been associated with sepsis, umbilical cellulitis, and abscess formation, but again, careful hygienic practices with insertion of these devices make these complications rare. Intravenous alimentation using central venous catheters has been lifesaving for some infants but also is associated with increased risk for catheter-related bacteremia or fungemia.
- *Parenteral feeding* with lipid emulsions has been associated with neonatal sepsis due to coagulase-negative staphylococci and *Candida* species. Strains of staphylococci isolated from infected ventricular shunts or intravascular catheters produce a slime or glycocalyx that promotes adherence and growth of colonies on the surfaces and into the walls of synthetic polymers used in the manufacture of catheters. The slime layer also protects the bacteria against the action of antibiotics and phagocytosis. The introduction of lipid emulsion through the venous catheter provides nutrients for growth of the bacteria and fungi.<sup>137</sup>

Hand hygiene remains the single most important element in the control of the spread of infectious diseases in the nursery. Hand hygiene measures should be implemented

before and after every patient contact. Surveys of hospital employees indicate that rigorous adherence to hand hygiene, although the most simple of infection control techniques, is still lacking in most institutions. A study by Brown and colleagues in a Denver neonatal intensive care unit indicated that compliance with appropriate hand-washing techniques was low for both medical and nursing personnel.<sup>138</sup> Compliance was monitored using a direct observation technique; of 252 observed encounters of nurses, physicians, and respiratory therapists with babies, 25% of the personnel broke contact with the infant by touching self (69%) or touching another baby (4%), and 25% did not wash before patient contact.

Waterless, alcohol-based hand hygiene products have been introduced into nurseries recently. Their ease of application and requirement for less time than hand washing in achieving reduction of microorganisms should increase adherence with hand hygiene recommendations. According to recent surveys, waterless soap products have gained rapid acceptance by nursery personnel including physicians.

Early discharge at 24 or 48 hours was a common practice several years ago as hospitals and third-party payers have attempted to reduce costs of health care. Study of a cohort of more than 300,000 births in Washington documented that newborns discharged home early (before 30 hours after birth) were at increased risk for rehospitalization during the first month of life; the leading causes were jaundice, dehydration, and sepsis, with onset within 7 days after discharge. Among 1253 infants who were rehospitalized within the first month of life, sepsis was the cause in 55 cases (4.4%) who were discharged early, contrasted with 42 (3.4%) who were discharged late.<sup>139</sup> These and other reports, combined with corrective legislation in a number of states, have led to recommendations that newborns remain hospitalized at least 48 hours after vaginal birth and 72 hours after cesarean section delivery.

Prevention of disease in the first months of life may be accomplished by immunization of the mother with passive transfer of protective antibody to the neonate. Immunization of women in the childbearing years or during pregnancy is of proven value in prevention of neonatal tetanus but also has been considered for prevention of invasive disease in the first months of life. Maternal immunization with polysaccharide and conjugate *Haemophilus influenzae* type b vaccines has provided protective levels of antibody to the infant<sup>140</sup> and therefore may be considered for prevention of invasive pneumococcal infection in young infants, especially in resource-limited countries, where disease often occurs during the first few months of life.<sup>141</sup> Immunization of the mother during pregnancy is likely to be protective for other diseases in the neonate due to encapsulated organisms, including group B streptococci,<sup>142</sup> pneumococci, and meningococci, and has been considered for prevention of infection due to respiratory syncytial virus<sup>143</sup> and *Bordetella pertussis*.<sup>144</sup>

### Community-Acquired Infections

The newborn infant is susceptible to many of the infectious agents that colonize other members of the household and caregivers. The physician should consider illnesses in these contacts before discharging the infant from the hospital. If signs of an infectious disease develop after 15 to 30 days of

life in an infant who was well when discharged from the nursery and whose gestation and delivery did not involve significant risk factors, the infection probably was acquired from a household or community contact. A careful history of illness in family members can suggest the source of the infant's disease (e.g., respiratory viruses, skin infections, a prolonged illness with coughing).

An infant also can be a source of infection for household contacts. The infant with congenital rubella syndrome can shed virus for many months and is a significant source of infection for susceptible close contacts. The same is true for the infant with the vesicular lesions of herpes simplex or the syphilitic infant with rhinitis or skin rash. Suppurative lesions related to *S. aureus* in a household member can expose an infant to a virulent strain that causes disseminated infection.

### Infections That Indicate Underlying Abnormalities

Infection may serve as the first clue for identification of an underlying anatomic, metabolic, or immune system abnormality. Infants with galactosemia, iron overload, chronic granulomatous disease, and leukocyte adhesion defects are susceptible to certain invasive gram-negative infections. Genitourinary infection in the first months of life can point to an anatomic or a physiologic defect of the urinary tract. Similarly, otitis media in the first month of life may be an indication of a midline defect of the palate or of a eustachian tube dysfunction. Meningitis caused by non-neonatal pathogens (e.g., coagulase-negative staphylococci) can be a clue to the presence of a dermoid sinus tract to the intradural space. In infants with underlying humoral immune defects, systemic infections may not develop until passively acquired maternal antibody has dissipated. Because the half-life of IgG is about 3 weeks, such infections are likely to occur after 3 months of age.

### Epidemiology

Nursery-acquired nosocomial infections can become epidemic, and a common source may be identified by simple epidemiologic investigation. Organisms that frequently are the cause of nursery epidemics include *S. aureus*, group A streptococci, enteroviruses, respiratory viruses, rotavirus, and gram-negative bacilli. Infections attributed to gram-negative bacilli often are caused by multiple antimicrobial drug-resistant strains, especially extended-spectrum  $\beta$ -lactamase (ESBL)-producing *E. coli* and *Klebsiella* species in nurseries where use of third-generation cephalosporins is extensive.

The most complete documentation of nursery-acquired infection was developed during the worldwide pandemic of *S. aureus* disease in the 1950s. A variety of preventive measures were attempted, including environmental manipulations, hexachlorophene bathing, and systemic antibiotics. For unknown reasons, the pandemic began to subside about 1963. These factors are discussed further in Chapter 17.

Epidemic diarrhea in the newborn infant that is associated with infection with *E. coli*, *Salmonella*, and other agents is discussed in Chapter 20. In addition, several viruses have been implicated in nursery outbreaks of gastrointestinal and respiratory diseases. They include rotaviruses, various enteroviruses (see Chapters 20 and 30), respiratory syncytial virus, parainfluenza virus, influenza virus, and adenoviruses.

Health care workers can expose neonates to or acquire an infection from neonates. Studies of the carriage of staphylococci and streptococci usually note a significant incidence in personnel. In some cases, the infections are acquired from the infants. Studies of the shedding of rubella virus and CMV in the urine and saliva of infants with congenital infections indicate that these materials are infectious for susceptible adults working in the nursery, but appropriate hand hygiene prevents transmission. Infection control is discussed in Chapter 35.

Each hospital should have an infection control program for personnel. Serologic screening of female hospital personnel for rubella antibodies should be performed at the time of employment. Vaccination is advised for nonpregnant women who are seronegative. Health care workers in nurseries should undergo serologic testing for varicella if they have no history of prior infection and should be vaccinated if they are seronegative. All hospital employees should receive the hepatitis B vaccine series and should be tested annually with a tuberculin skin test.

## Diagnosis and Management

The diagnosis and management of infection acquired by the infant in the nursery or at home are similar to those of infection acquired during delivery. The management of late-onset bacterial infections is discussed in Chapters 6, 13, 14, and 17.

## Conclusion 50

One of the greatest challenges to global public health is to eliminate the gaps between rich and poor countries in health care resources, in access to preventive and curative services, and in health outcomes. Although infant mortality has declined by more than 50% since 1955,<sup>1</sup> neonatal mortality has changed little in some of the world's poorest countries. Worldwide, neonatal mortality accounts for a substantial proportion of deaths of both infants and children younger than 5 years.<sup>1-3</sup> The World Health Organization (WHO) estimates that more than 4 million neonates die each year and that 98% of these deaths occur in developing countries.<sup>2,3</sup> Causes of neonatal mortality, especially in developing countries, are difficult to ascertain, partly because many of these deaths occur at home, unattended by medical personnel, and partly because critically ill neonates often present with nondiagnostic signs and symptoms of disease. Infectious diseases, birth asphyxia, and complications of prematurity are thought to be the major causes of neonatal death worldwide.<sup>2-5</sup>

Although access to sophisticated technology is limited in developing countries, neonatal mortality related to infection could be substantially reduced by simple, known interventions before and during pregnancy, labor, and delivery; in the immediate postpartum period; and in the early days of life.<sup>2,3,5,6</sup> The global burden of infectious diseases in the newborn, direct and indirect causes of neonatal mortality attributed to infection, specific infections of relevance in developing countries, and strategies to reduce both the incidence of neonatal infection and morbidity and mortality in infants who do become infected are reviewed in this chapter.

## BACKGROUND AND GENERAL CONSIDERATIONS

### Infection as a Cause of Neonatal Death: Hospital- and Community-Based Studies

In developing countries, where most births and neonatal deaths occur at home and are not attended by doctors or other trained health care workers, deaths are underreported and information on cause of death is often incomplete. Accurate data on causes of death are useful for many reasons. Such data are important for providers of primary care, for investigators as they design interventions for prevention and treatment, for local and national health administrators, and for decision makers who implement and evaluate health care programs.

To evaluate the impact of infection as a cause of neonatal death, hospital- and community-based studies from developing countries (in Africa, Asia, the Indian subcontinent, the Pacific, the Middle East, and the Americas) that report neonatal mortality rates and present data on infection as a cause of death were reviewed. Neonatal deaths are defined as deaths among liveborn infants during the first 28 days of life, and the neonatal mortality rate (NMR) is reported per 1000 livebirths.<sup>7</sup> Early neonatal deaths are those that occur in the first week of life, and late neonatal deaths are those that occur between 8 and 28 days of life. Infections associated with neonatal death in these studies included bacterial sepsis and meningitis, respiratory infection, neonatal tetanus, omphalitis, and diarrhea.

Twenty-nine hospital-based studies published from 1980 onward were reviewed.<sup>5,8-36</sup> Epidemiologic studies varied in size, ranging from approximately 1000 to more than 100,000 livebirths and approximately 50 to 800 neonatal deaths. Data on infection as a cause of early neonatal death were presented in 17 of 29 studies; infection was associated with 7% to 54% of early neonatal deaths in these studies. Five studies reported data on infection as a cause of late neonatal death: 30% to 73% of these late deaths were associated with infection. Eighteen of the 29 studies presented data on infection as a cause of neonatal deaths overall (birth to 28 days). In these studies, infection was associated with 4% to 56% of all neonatal deaths.

Thirty-six community-based studies were reviewed.<sup>37-74</sup> Total population in each study ranged from several thousand to 60 million people, number of births ranged from under 1000 to more than 1 million, and number of neonatal deaths ranged from 7 to approximately 7000. Thirteen of the 36 studies presented data on infection as a cause of early neonatal death: 0% to 45% of early neonatal deaths were associated with infection. Seven community studies reported numbers of infections responsible for late neonatal deaths: 44% to 100% of late neonatal deaths were associated with infection. Thirty-one of the 36 studies presented data on infection as a cause of all neonatal deaths. Infection was associated with 8% to 85% of all deaths in these studies.

It is well known that neonatal deaths in developing countries are underreported and that infection as a cause of death is underestimated because of imprecision in diagnosis. Remarkably few published studies worldwide present detailed surveillance data on numbers of births and neonatal deaths and on probable causes of death. Although hospital-based studies are important for accurately determining causes of morbidity and mortality, they do not always reflect what is

happening in the community. Carefully conducted community studies are needed. Furthermore, in many parts of the developing world, neonatal deaths are underestimated owing to inadequate vital registration, especially of home births. If a child dies before the birth has been reported, there is a good chance that neither the birth nor the death will be recorded. If we estimate that 30% to 40% of neonatal deaths are associated with infections and use the WHO 2001 estimate of 4,035,000 neonatal deaths per year in the less developed regions of the world,<sup>3</sup> we can estimate that infection is responsible for between 1.2 and 1.6 million neonatal deaths per year, or between 3300 and 4500 deaths per day in the less developed countries of the world.

### Incidence of Neonatal Sepsis and Meningitis and Associated Mortality

Hospital-based studies from developing countries were reviewed to determine the incidence of neonatal sepsis and meningitis, the case-fatality rates (CFRs) associated with these infections, and the spectrum of bacterial pathogens in different regions of the world. Cases reported occurred among infants born in hospitals, as well as those referred from home or other health facilities. Fifty-three studies<sup>11,75-126</sup> from developing countries, published between 1980 and 2000, were reviewed to evaluate neonatal sepsis and meningitis in different geographic regions. Forty of these studies are primarily reports of neonatal sepsis, and 16 studies present data on bacterial meningitis. The vast majority of studies do not distinguish among maternally acquired, community-acquired, and nosocomial infections. Table 2-1 summarizes data by region.

In all regions, sepsis was responsible for a substantial burden of disease, with high CFRs reported in the vast majority of studies. Overall, incidence of neonatal sepsis ranged from 2 to 21 per 1000 livebirths (average 6 per 1000 livebirths), with CFRs of 1% to 69%. Of note, only two studies reported CFRs under 10%, whereas a majority of the studies reported sepsis CFRs above 30%. Fewer studies on neonatal meningitis were available from which to present incidence and CFRs by region. The incidence of neonatal meningitis ranged from 0.33 to 2.8 per 1000 livebirths (average 1 per 1000 livebirths), with CFRs ranging from 13% to 59% in these reports. Using these hospital-based rates and recent United Nations estimates of approximately 132,787,000 births per year in the less developed countries of the world,<sup>127</sup> we estimate that approximately 800,000 cases of neonatal sepsis and 130,000 cases of neonatal meningitis occur in developing

**Table 2-1 Incidence and Case Fatality Rate (CFR) for Sepsis and Meningitis from Hospital-Based Studies in Developing Countries**

Region	Incidence of Sepsis (case[s] per 1000 live births)	CFR (%)	Incidence of meningitis (case[s] per 1000 live births)	CFR (%)
India/Pakistan/Southeast Asia/Pacific	2.4-16	2-69	—	45
Sub-Saharan Africa	6-21	27-56	0.7-1.9	18-59

countries each year. Because the vast majority of neonates in developing countries are born at home and because many lack access to medical care if they become ill, these numbers are undoubtedly a gross underestimate of the true numbers of these infections. The high CFRs for both sepsis and meningitis (compared with those in developed countries) suggest that early detection and improved management of infected neonates would reduce mortality.

### Bacterial Pathogens Associated with Infections in Different Geographic Regions

Historical reviews from developed countries have demonstrated that the predominant organisms responsible for neonatal infections change over time.<sup>128,129</sup> Prospective microbiologic surveillance is therefore important to guide empirical therapy, to identify new agents of importance for neonates, to recognize epidemics, and to monitor changes over time. Moreover, the organisms associated with neonatal infection are different in different geographic areas, reinforcing the need for local microbiologic surveillance. In areas where blood cultures in sick neonates cannot be performed, knowledge of the bacterial flora of the maternal genital tract may serve as a surrogate marker for organisms causing early-onset neonatal sepsis, meningitis, and pneumonia. The vast majority of studies on the causes of neonatal sepsis and meningitis are hospital reviews that include data on infants born in hospitals as well as those transferred from home or other facilities. Sixty-five studies published between 1980 and 2003 were reviewed to determine the spectrum of bacterial pathogens responsible for neonatal sepsis and meningitis in developing countries and to compare these pathogens with the organisms prevalent in the developed world.\* In most of these studies, it is difficult to determine whether infections were of maternal origin or were hospital or community acquired. Also, the infants' ages at the time of infection are not always specified. The studies vary in the detail with which culture methods are presented. It is therefore difficult to judge the quality and reliability of the microbiologic data presented.

Fifty-four studies present data on bacterial sepsis.<sup>†</sup> The spectrum of organisms presented in these studies does indeed differ from what is known from developed countries. Although the group B streptococcus (GBS) remains the

most important bacterial pathogen associated with early-onset neonatal sepsis in many developed countries,<sup>150</sup> studies from developing countries present a different picture (Table 2-2). The most striking finding from the 23 studies from India, Pakistan, Asia, and the Pacific is the low rate of GBS sepsis.\* Half of these studies, summarizing data from more than 1000 patients with positive blood cultures, report no isolates of GBS, and the other studies report 67 cases among 4525 infected neonates (1.5%). Gram-negative organisms were isolated significantly more frequently than gram-positive organisms, with *Klebsiella* being the most frequently isolated pathogen in half of the studies. Fourteen studies present data from sub-Saharan Africa.<sup>†</sup> Again, group B streptococci were uncommon, isolated in only 8% of the 1529 patients with bacteremia. However, in three studies, group B streptococci were the most common agents found.<sup>9,11,90</sup> In half of the studies, *Staphylococcus aureus* was the most frequently isolated agent.

Overall, there was an almost equal distribution of gram-negative and gram-positive infections. Among 11 of 12 studies from the Middle East or North Africa,<sup>‡</sup> GBS infection also was uncommon (48 of 1216 [4%]), with only one study reporting group B streptococci in a substantial number of infected neonates (25 of 106 [24%]).<sup>93</sup> Gram-negative organisms were somewhat more likely to be associated with sepsis in these studies. The five studies from the Americas<sup>98,118,135,138,139</sup> present a varying range of gram-negative and gram-positive pathogens. The two largest of these studies, from Mexico<sup>138</sup> and Panama,<sup>98</sup> identified only 18 of 804 (2%) infants with GBS, whereas a study from the French West Indies reported 40 of 107 (37%) septic neonates infected with GBS.<sup>106</sup>

Table 2-2 summarizes data from 19 studies of bacterial meningitis in developing countries.<sup>§</sup> Among 721 culture-confirmed cases, 470 (65%) were caused by gram-negative pathogens. Group B streptococci were uncommon in a majority of the studies.

### World Health Organization Young Infant Study

A multicenter project to determine the bacterial etiology and clinical signs of serious infections in infants younger than 90

days was sponsored by WHO and conducted between 1990 and 1992 in four developing countries: Ethiopia, The Gambia, Papua New Guinea, and the Philippines.<sup>115,143,144,151-155</sup> This is the largest prospective study to date of early infant infections in developing countries. In the four different countries, 2453 sick young infants had blood cultures performed and 507 had lumbar punctures. Seven percent (167 of 2453 cases) of all blood cultures were positive: 10% in The Gambia, 9% in Ethiopia, 5% in Papua New Guinea, and 4% in the Philippines. Eight percent (40 of 507) of all cerebrospinal fluid cultures were positive. As might have been predicted, clinical symptoms were not helpful in distinguishing among infections caused by different pathogens. Overall, 30% of infants with positive blood cultures died. Serious infection was most common in the first week of life, with a majority of the deaths occurring in infants younger than 1 week of age.

A total of 1673 infants were evaluated in the first 4 weeks of life. Of these patients, 5% had positive blood cultures; 57% had gram-positive organisms, and 43% had gram-negative organisms. The most frequently isolated organisms were *S. aureus* (23%), *Streptococcus pyogenes* (20%), *Escherichia coli* (18%), and *Streptococcus pneumoniae* (10%). The virtual absence of GBS in this large study in four countries is striking (present in only 2 of 84 positive blood cultures). Nineteen patients had neonatal meningitis (11 had bacteremia as well); 63% of these were due to gram-negative organisms and 37% to gram-positive organisms. The most frequent isolates were *S. pneumoniae* (in 5 of 19 [26%]) and *E. coli* (in 4 of 19 [21%]). Only one neonate had GBS meningitis. Of interest, *S. pneumoniae* was the most frequent organism isolated in the second and third months of life, accounting for 30% (25 of 83) of all positive blood cultures and 55% (12 of 22) of all positive cerebrospinal fluid cultures. An important conclusion of this study is that the pneumococcus must be considered in any case of serious infection in a young infant in a developing country, particularly if signs of meningitis are present.

### Group B Streptococcal Infections

It is unclear why neonates in some developing countries are rarely infected with GBS. The most important risk factor for invasive GBS disease in the neonate is exposure to the organism via the mother's genital tract. Other known risk factors include young maternal age, preterm birth, prolonged rupture of the membranes, maternal chorioamnionitis, exposure to a high inoculum of a virulent GBS strain, and a low maternal serum concentration of antibody to the capsular polysaccharide of the colonizing GBS strain.<sup>156</sup> In the United States, differences in GBS colonization rates have been identified among women of different ethnic groups that appear to correlate with infection in newborns. In an attempt to understand the low rates of invasive GBS disease reported among neonates in many developing countries, Stoll and Schuchat<sup>157</sup> reviewed 34 studies published between 1980 and 1998 that evaluated GBS colonization rates in women. These studies reported culture results from 7730 women, with an overall colonization rate of 12.7%. Studies that used culture methods that were judged to be appropriate found significantly higher colonization rates than those that used inadequate methods (675 of 3801 women

[17.8%] versus 308 of 3929 [7.8%]). When analyses were restricted to studies with adequate methods, the prevalence of colonization by region was Middle East/North Africa, 22%; Asia/Pacific, 19%; sub-Saharan Africa, 19%; India/Pakistan, 12%; and Americas, 14%.

The distribution of GBS serotypes varied among studies. GBS serotype III, the most frequently identified invasive serotype in the West, was identified in all studies reviewed and was the most frequently identified serotype in one half of the studies. Serotype V, which has only recently been recognized as a cause of invasive disease in developed countries,<sup>158</sup> was identified in studies from Peru<sup>159</sup> and The Gambia.<sup>160</sup> Monitoring serotype distribution is important because candidate GBS vaccines are considered for areas with high rates of disease.

With estimated colonization rates among women in developing countries as high as 18%, higher rates of invasive neonatal disease than have been reported would be expected. Low rates of invasive GBS disease in some developing countries may be explained by less virulent strains, by genetic differences in susceptibility to disease, by as-yet unidentified beneficial cultural practices, or by high concentrations of transplacentally acquired protective antibody in serum (i.e., a mother may be colonized yet have protective concentrations of type-specific GBS antibody).

Hospital-based surveillance in developing countries may be insensitive at detecting sepsis in very young infants. In developing countries, where most deliveries occur at home, infants with early-onset sepsis often get sick and die at home or are taken to local health care facilities, where a diagnosis of possible sepsis may be missed, or where blood cultures cannot be performed. In this setting there may be underdiagnosis of infection by early-onset pathogens, including GBS. In the WHO Young Infant Study,<sup>151</sup> 1673 infants were evaluated in the first month of life; only 2 had cultures positive for GBS. The absence of GBS in this study cannot be explained by the evaluation of insufficient numbers of sick neonates (360 of the 1673 infants were younger than 1 week of age).

Increasing evidence suggests that heavy colonization with GBS increases the risk of delivering a preterm low-birth-weight (LBW) infant.<sup>161</sup> Population differences in the prevalence of heavy GBS colonization have been reported in the United States, where African Americans have a significantly higher risk of heavy colonization. If heavy colonization is more prevalent among women in developing countries and results in an increase in numbers of preterm LBW infants, GBS-related morbidity may appear as illness and death related to prematurity. By contrast, heavy colonization could increase maternal type-specific GBS antibody concentrations, resulting in lower risk of neonatal disease. Further studies in developing countries are needed to explore these important issues.

### Antibiotic Therapy

Studies of bacterial etiology have implications for presumptive antibiotic therapy of bacterial infection in neonates. Currently, the drugs most frequently used to treat suspected severe neonatal infections, in both developed and developing countries, are a combination of penicillin or ampicillin and an aminoglycoside (usually gentamicin).<sup>162</sup> Antibiotic therapy must be tailored to the specific microbiologic needs of a

particular geographic region based on local surveillance data, especially if blood cultures are not performed and cannot be used to guide therapy. In addition, issues related to drug supply, availability, quality, and cost must be addressed. The problem of antibiotic resistance is now recognized to be a global problem, and the emergence of antibiotic-resistant pathogens is particularly alarming in developing countries. Although the extent of the problem is unknown, hospital-based studies on the bacterial etiology of neonatal sepsis and reports of nosocomial outbreaks from a variety of countries demonstrate that antibiotic resistance is a problem among neonates in developing countries.<sup>122,145,163-165</sup> The widespread availability of antibiotics and their indiscriminate and inappropriate use contribute to this problem. The possibility of resistance must be considered in infants who deteriorate despite recommended antibiotic therapy.

## ACUTE RESPIRATORY INFECTIONS

The WHO estimated in 1994 that almost 800,000 deaths due to acute respiratory infections (ARIs) occur in neonates in developing countries each year.<sup>4,166</sup> Among young infants, most of these deaths are due to pneumonia, bronchiolitis, or laryngotracheitis. Pneumonia in neonates, like neonatal sepsis, may be of early or late onset (either acquired during birth from organisms that colonize or infect the maternal genital tract or acquired later from organisms in the hospital, home, or community). Although only a few studies of the bacteriology of neonatal pneumonia have been performed, the findings suggest that organisms causing disease are similar to those that cause neonatal sepsis.<sup>167,168</sup> The role of viruses in neonatal pneumonia, especially in developing countries, remains unclear. Recent studies from developed countries suggest that viruses, including respiratory syncytial virus, parainfluenza viruses, adenoviruses, and influenza viruses, contribute to respiratory morbidity and mortality, especially during epidemic periods.<sup>169,170</sup>

In a review of the magnitude of ARI mortality in developing countries, Garenne and co-workers<sup>166</sup> estimated that 21% of all ARI deaths in children younger than age 5 years occur in the neonatal period (1254 of 6041 ARI deaths in 12 countries). In a carefully conducted community study published in 1993, Bang and associates<sup>171</sup> determined that 66% of ARI deaths in the first year of life occurred in the neonatal period.

It is difficult to determine the incidence of neonatal ARI in developing countries because many sick neonates are never referred for medical care. In a large community study of ARI in Bangladeshi children, the highest incidence of ARI was in children younger than 5 months of age.<sup>172</sup> In the study by Bang and associates,<sup>171</sup> there were 64 cases of pneumonia among 3100 children (incidence of 21 per 1000), but this finding underestimates the true incidence because it was known that many neonates were never brought for care. The risk of pneumonia and of ARI-related death increases in infants who are of low birth weight and/or malnourished and in those who are not breast-fed.<sup>173,174</sup> In a study of LBW infants in India,<sup>175</sup> in which infants were visited weekly and mothers queried about disease, there were 61 episodes of moderate to severe ARI among 211 LBW infants and 125 episodes among 448 normal-weight infants. Although 33%

episodes occurred in LBW infants, 79% of the deaths occurred in this weight group.

## Tuberculosis

Tuberculosis (TB) remains a major global public health threat and has become the biggest killer of young women worldwide, with an estimated 1 million deaths occurring annually among women of childbearing age (15 to 44 years). The vast majority of infections and deaths due to TB occur in developing countries. TB during pregnancy may have adverse consequences for mother and baby, including increased risk of miscarriage, prematurity, low birth weight, and neonatal death.<sup>176-179</sup> Adverse perinatal outcomes are increased in mothers who have late diagnosis or incomplete or irregular therapy.<sup>177</sup> Ideally, diagnosis and treatment of TB in women should occur before pregnancy. The lung remains the most common site of infection; however, the prevalence of extrapulmonary TB is increasing. A 1999 study from India reviewed the outcomes of 33 pregnancies complicated by extrapulmonary TB.<sup>180</sup> Extrapulmonary TB confined to the lymph nodes had no adverse effect on maternal or fetal outcome. Disease at other sites (skeleton, intestines, kidney, meninges, endometrium), however, was associated with increased maternal disability and reduced fetal growth. Although congenital TB is rare, the fetus may become infected by hematogenous spread in a woman with placentitis, by swallowing or aspirating infected amniotic fluid, or by direct contact with an infected cervix at the time of delivery.<sup>173</sup> The most common route of infection of the neonate, however, is through airborne transmission of *Mycobacterium tuberculosis* from an infected untreated mother to her infant. Infected newborns are at particularly high risk of developing severe disease, including fulminant septic shock with disseminated intravascular coagulation and respiratory failure.<sup>176,181</sup>

The resurgence of TB and the increased risk of TB among those who are infected with the human immunodeficiency virus (HIV) are well known. In areas where HIV is endemic, TB rates are rising. In a 1999 study from Zambia, TB was the major nonobstetric cause of maternal death, and 92% of women with TB-related deaths were co-infected with HIV.<sup>182</sup> In a 1997 report from South Africa,<sup>183</sup> 11 neonates with culture-confirmed perinatal TB were described, 6 of whom had congenital TB. Six mothers were HIV positive, and three of their infants also were HIV infected; one infant died. Pregnant women who are co-infected with HIV may be at increased risk for placental or genital TB, resulting in an increased risk of transmission to the fetus.<sup>183,184</sup> In areas of the world where both TB and HIV are endemic, there must be a high index of suspicion for both diseases in the mother and the neonate.

## Home-Based Neonatal Care

Several studies have evaluated community-based care for acute respiratory illness to identify sick neonates in a timely fashion and to provide treatment in their own homes. Datta and colleagues<sup>175</sup> implemented a program of ARI control at the primary health care level and demonstrated that improved detection and treatment could reduce mortality among LBW infants (weighing less than 2500 g). Interventions involved

training primary health care workers and treating moderate to severe ARI with oral penicillin (125 mg twice a day for 5 days) using a “decision and action” classification. They compared numbers of episodes of ARI and CFRs among LBW infants in intervention and control villages. The ARI-specific mortality rate was 30 deaths per 1000 livebirths in the intervention area, versus 71 per 1000 livebirths in the control area (6/199 versus 15/211, respectively).

In a similar study of the feasibility of managing neonatal pneumonia in the community, Bang and colleagues<sup>171</sup> demonstrated reduction in ARI mortality in 1993 with a primary health care program. Community interventions used by this group included extensive health education of possible caregivers (traditional birth attendants, paramedics, and village health workers) and specific case management—continued breast-feeding and oral co-trimoxazole syrup for 7 days. Community-based management of pneumonia had a significant impact in reducing pneumonia-associated mortality. In the intervention area, the neonatal mortality rate from all causes was 64 per 1000 children and the pneumonia-specific mortality rate was 17 per 1000 versus 84 per 1000 and 29 per 1000, respectively, in control villages, representing a 24% reduction in mortality overall and a 40% reduction in pneumonia-specific mortality in the intervention villages. The CFR for neonatal pneumonia in the Bang study was 15% (10 of 65 died) in the intervention area, lower than what has been reported from hospital-based studies in India,<sup>167</sup> suggesting that cases managed in the community are diagnosed and treated earlier than are hospitalized cases.

Both of these intervention studies identified cultural barriers to care, including noncompliance with referral and medication use. Bhandari and associates<sup>185</sup> studied 2007 infants (aged 0 to 2 months) at two urban slum clinics in Delhi, India. Because of severe illness, hospital admission was advised for 273 (14%) of these infants, including 104 patients with ARI. Only 24% of families of sick infants and 20% of families of those with ARI complied with recommendations for hospitalization. The other infants were treated as outpatients and at home (with no deaths in the ARI group). These data suggest that improved community or domiciliary management of sick newborns may be the only way to improve outcome in some settings.

In a 1999 study, Bang and colleagues<sup>39</sup> implemented a comprehensive program of home-based neonatal care in a remote rural area of India. Trained female village health care workers identified pregnant women, visited them in their homes during the pregnancy, attended the delivery (along with traditional birth attendants), observed the neonate at birth and resuscitated the infant if necessary (using a simple resuscitation device), and visited the mother and baby in the home on days 1, 3, 5, 7, 14, 21, and 28 and any other time if called by the family. These health care workers were specifically trained to encourage mothers to breast-feed in the first hour after birth, to maintain a normal body temperature in the newborn by keeping the home warm and using clothing appropriately, and to identify severe illnesses including clinical sepsis, pneumonia, or meningitis. Criteria used to diagnose presumed sepsis, pneumonia, or meningitis in the infant included presence of normal crying at birth followed by development of a weak or abnormal cry; initial presence of normal sucking followed by cessation of sucking; onset of drowsiness or unconsciousness; skin temperature

above 99° F or below 95° F; pus on the skin or umbilicus; diarrhea, persistent vomiting, or abdominal distention; grunting or severe retractions; and a respiratory rate of 60 or more per minute in a quiet baby. If the presumptive diagnosis was sepsis, pneumonia, or meningitis, the parents were advised to take the infant to the clinic or hospital. If parents were unwilling to have the child hospitalized, home-based care was offered. This care included antibiotics (intramuscular gentamicin [5 mg twice daily for 10 days for preterm newborns or those with birth weights less than 2500 g or 7.5 mg twice daily for 7 days for term newborns or those with birth weights greater than 2500 g] and oral co-trimoxazole [sulfamethoxazole 200 mg and trimethoprim 40 mg/5 mL] 1.25 mL twice daily for 7 days), support to maintain a normal temperature and to promote breast-feeding, and very close follow-up with home visits twice a day for 7 to 10 days. Investigators compared health outcomes in 39 intervention and 47 control villages that had similar population characteristics and baseline mortality rates (1993 to 1995). Specific home-based neonatal care was studied in the intervention villages in 1995 to 1998. The vast majority of births in the intervention villages occurred at home (95%), and 43% of the neonates had low birth weights (less than 2500 g). Very few neonates in the intervention villages were hospitalized for a severe illness (less than 1% during study period). In this study, the CFR for severe neonatal illness declined from 16.6% before the intervention to 2.8% after the intervention ( $P < .05$ ). Moreover, early neonatal mortality, overall neonatal mortality, and infant mortality rates all declined significantly in the intervention villages (50% reduction, 62% reduction, and 46% reduction, respectively). Of interest, mortality was reduced at all birth weights (less than 1500 g, 1500 to 1999 g, 2000 to 2499 g, and 2500 g or greater). This comprehensive home-based system for neonatal care was accepted by families and was successful in reducing mortality.

The strategy of home-based neonatal care currently is being studied in other settings and other areas of the world, where referral to hospital for the sick neonate may not be acceptable to families or even possible.

## SEXUALLY TRANSMITTED DISEASES

It is estimated that over 333 million new cases of the four major curable sexually transmitted diseases (STDs)—syphilis, gonorrhea, chlamydial infection, and *Trichomonas* infection—occur worldwide each year, the vast majority in developing countries.<sup>186</sup> The largest number of new infections occur in South and Southeast Asia, followed by sub-Saharan Africa and then Latin America and the Caribbean. STDs rank among the leading causes of morbidity worldwide, a burden borne disproportionately by women of reproductive age. Because STDs in pregnant women often are asymptomatic, women may receive delayed or no treatment.<sup>187</sup> Most STDs are easily transmitted from mother to child during pregnancy or delivery.<sup>188</sup> The burden of neonatal disease in developing countries is difficult to estimate. Adverse pregnancy outcomes associated with untreated STDs include miscarriage, preterm delivery, intrauterine growth restriction, congenital infections, and maternal, fetal, and neonatal mortality.<sup>188,189</sup> Neonatal HIV infection is discussed later.

Worldwide there are approximately 7 million new cases of syphilis per year among women of childbearing age.<sup>186</sup> Rates of congenital syphilis parallel rates in women of reproductive age. Studies from developing countries published between 1993 and 2000 have found seroprevalence rates of syphilis that are significantly higher than those found in developed countries.<sup>190-192</sup> Untreated syphilis during pregnancy increases the risk of late fetal death, low birth weight, preterm delivery, and severe neonatal disease.<sup>190,193</sup> Data from a demonstration project in Zambia indicated that syphilis was the most significant cause of adverse pregnancy outcome among women attending antenatal clinics.<sup>194</sup> A prospective study of congenital syphilis in a Papua New Guinea hospital published in 2000 found that the infection was responsible for 6% of admissions and 22% of all neonatal deaths.<sup>195</sup>

Syphilis is transmitted from an infected mother to the fetus largely via transplacental infection, and rarely by contact with an infectious genital lesion during delivery. Active infection with syphilis in pregnant women is estimated to result in fetal or infant death or disability for 50% to 80% percent of affected pregnancies.<sup>196</sup> A majority of the infants born to mothers with untreated syphilis are asymptomatic at birth, but without treatment, clinical manifestations of disease may develop months to years after birth. Symptoms of early congenital syphilis include intrauterine growth restriction, anemia, thrombocytopenia, jaundice, and hepatosplenomegaly.<sup>197</sup> The most devastating complications of untreated or late congenital syphilis are neurologic manifestations that include mental retardation, hydrocephalus, cranial nerve palsies, and seizures. With adequate treatment for infected mothers, syphilis is a preventable cause of neonatal morbidity and death.

Neonates delivered vaginally to mothers with untreated gonorrhea are at great risk of developing gonococcal conjunctivitis, which, if left untreated, can lead to blindness. Rarely, disseminated gonococcal infection develops in neonates. Similarly, chlamydial infections occur in approximately two thirds of infants born by vaginal delivery to infected mothers.<sup>188</sup> *Chlamydia* can cause conjunctivitis and/or pneumonia, which may not be evident until the infant is several weeks old. (See later section on ophthalmia neonatorum.)

The control of STDs in pregnancy is a public health priority, especially in developing countries where rates of infection are high. Because STDs and chorioamnionitis have been associated with increased rates of mother-to-infant transmission of HIV, a community randomized trial of STD control for HIV infection prevention (antibiotics once in pregnancy) was conducted in the Rakai district of Uganda between 1994 and 1998.<sup>198</sup> Although antibiotic treatment did not reduce maternal HIV acquisition or perinatal HIV transmission, pregnancy outcome was improved, with decreased rates of neonatal death, low birth weight, and preterm delivery. Before presumptive therapy can be undertaken on a large scale, it must be studied further. Several countries have initiated STD control programs. The goals are to reduce STD transmission rates; to promote early diagnosis and appropriate treatment to prevent complications; and to reduce the risk of HIV infection. A special emphasis on women is needed.<sup>199</sup>

## HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The Joint United Nations Programme on HIV/AIDS (UNAIDS) and the WHO estimate that in 2003 more than 40 million people worldwide are infected with HIV and that approximately 5 million new infections occur each year.<sup>200</sup> Most HIV infections occur in the developing world; more than 90% of those infected live in sub-Saharan Africa, Asia, Latin America, or the Caribbean. Women are particularly vulnerable to HIV infection. Worldwide approximately 50% of cases occur in women and more than 600,000 children are infected with HIV each year, mostly by maternal-to-child transmission either in utero, at the time of delivery, or through breast-feeding.<sup>200,201</sup>

Because HIV increases deaths among young adults—both male and female—the acquired immunodeficiency syndrome (AIDS) epidemic has resulted in a generation of AIDS orphans. It is estimated that by the year 2010, more than 20 million children younger than 15 years of age will have been orphaned by AIDS, the vast majority in sub-Saharan Africa.<sup>202</sup> It is well known that maternal mortality increases neonatal and infant deaths, independent of HIV infection. Global estimates for the number of people living with HIV infection/AIDS, the number newly infected in 2003, and total AIDS deaths in 2003 are presented in Table 2-3.

### Transmission

There is great disparity between developed and developing countries in mother-to-child transmission of HIV.<sup>200,201,203</sup> In the era of antiretroviral therapy and obstetric interventions, including increased rates of scheduled cesarean section, transmission rates as low as 2% have been reported for Europe and North America.<sup>204-209</sup> By contrast, rates remain high (21% to 48%) among breast-feeding infants born to HIV-infected mothers in developing countries, in the absence of antiretroviral therapy.<sup>210-213</sup> This disparity is due primarily to differences in access to antiretroviral drugs (to reduce transmission) and to differences in breast-feeding practices. Other factors that may influence transmission rates in developing countries include co-infection with other STDs<sup>214</sup>; poor nutritional and/or immunologic status of the mother<sup>215</sup>; micronutrient deficiencies, particularly vitamin A deficiency<sup>216</sup>; maternal anemia<sup>212,213</sup>; specific obstetric factors including placental abruption, premature or prolonged rupture of the membranes, chorioamnionitis, obstetrical procedures, and mode of delivery<sup>212,213,217-222</sup>; virulence of the infecting HIV strain; viral phenotype and genotype; antiviral drug resistance<sup>223</sup>; viral load; and advanced maternal disease.<sup>224</sup>

### Breast-Feeding and Human Immunodeficiency Virus

HIV is present in breast milk, and postnatal transmission by means of breast-feeding is an important mode of transmission in developing countries.<sup>225-233</sup> A review of published studies evaluated transmission risk among mothers who were infected prenatally and postnatally.<sup>227</sup> Based on five studies in which the mother had been infected prenatally (as is most often the case), the additional risk of HIV trans-

Table 2-3 Regional HIV/AIDS Statistics and Features, End of 2003<sup>a</sup>

Region	Adults and Children Living with HIV/AIDS	Adults and Children Newly Infected with HIV	Adult Prevalence (%) <sup>b</sup>	Adult and Child Deaths Due to AIDS
Sub-Saharan Africa	25.0-28.2 million	3.0-3.4 million	7.5-8.5	2.2-2.4 million
North Africa and Middle East	470,000-730,000	43,000-67,000	0.2-0.4	35,000-50,000
South and South-east Asia	4.6-8.2 million	610,000-1.1 million	0.4-0.8	330,000-590,000
East Asia and Pacific	700,000-1.3 million	150,000-270,000	0.1-0.1	32,000-58,000
Latin America	1.3-1.9 million	120,000-180,000	0.5-0.7	49,000-70,000
Caribbean	350,000-590,000	45,000-80,000	1.9-3.1	30,000-50,000
Eastern Europe and Central Asia	1.2-1.8 million	180,000-280,000	0.5-0.9	23,000-37,000
Western Europe	520,000-680,000	30,000-40,000	0.3-0.3	2,600-3,400
North America	790,000-1.2 million	36,000-54,000	0.5-0.7	12,000-18,000
Australia and New Zealand	12,000-18,000	700-1,000	0.1-0.1	<100
Total	40 million (34-46 million)	5 million (4.2-5.8 million)	1.1 (0.9-1.3)	3 million (2.5-3.5 million)

<sup>a</sup>The ranges around the estimates in this table define the boundaries within which the actual numbers lie, based on the best available information. These ranges are more precise than those of previous years, and work is under way to increase even further the precision of the estimates that will be published mid-2004.

<sup>b</sup>The proportion of adults (15 to 49 years of age) living with HIV/AIDS in 2003, using 2003 population numbers.

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus [infection].

Data from AIDS Epidemic Update 2003, Geneva, WHO, UNAIDS, 2003.

mission with breast-feeding (above the in utero and delivery risks) was estimated to be 14% (95% confidence interval [CI] 7% to 22%). By contrast, when the mother developed her primary infection after birth of her infant, transmission risk increased substantially—estimated from four studies to be 29% (95% CI 16% to 42%). Worldwide, WHO estimated in 1998 that between one third and one half of all HIV-infected infants acquire infection postnatally from breast-feeding.<sup>233</sup>

Gaps remain in the understanding of how HIV is transmitted to the infant through breast-feeding. Although extended breast-feeding accounts for approximately 40% of infant HIV infections worldwide, most breast-fed infants remain uninfected despite prolonged breast-feeding and repeated exposure to HIV.<sup>225</sup> Mechanisms associated with transmission through breast milk or by breast-feeding, as well as factors related to protection, remain unclear. The risk of postnatal transmission increases as duration of breast-feeding increases.<sup>233,234-239</sup> Therefore, prolonged breast-feeding may be an important risk factor for transmission. A 2001 study from South Africa<sup>240</sup> compared HIV transmission rates in exclusively breast-fed, mixed-fed, and never-breast-fed (formula-fed) infants to assess whether the pattern of breast-feeding has an impact on early mother-to-infant transmission of HIV. Of 529 infants followed prospectively, 150 never breast-fed, 118 were exclusively breast-fed, and 261 received breast milk and other foods in the first 3 months of life. Transmission rates by day 1, which reflect in utero transmission, did not differ among groups (approximately 6%). Excluding those who were HIV positive on day 1, the proportion of infants infected at 3, 6, and 15 months of age did not differ significantly in those who never received breast milk (18%, 19%, 19%) versus those who were exclusively breast-fed (6%, 19%, 25%). The infection rate was significantly higher, however, in the group of infants who were partially breast-fed and received mixed feedings (24%, 26%, 36%;  $P = .01$ ). This study suggests that exclusive breast-feeding and early weaning may reduce postnatal HIV transmission.

Other factors that might influence the infectivity of breast milk and breast-feeding include the concentration of cell-free or cell-associated HIV in breast milk; viral strain; the presence or absence of HIV-specific antibodies, particularly secretory immunoglobulin A (IgA) or IgM, or cytotoxic T cells in breast milk, lactoferrin, lysozymes, and other factors with specific antiviral activity; and the presence of mastitis with or without overt nipple cracks and bleeding.<sup>225,226,241,242</sup> Furthermore, infant susceptibility to infection through breast-feeding might be affected by stomach pH, oral ulceration, gastroenteritis, prematurity or low birth weight, nutritional status, and the presence of mucosal (salivary, gastrointestinal) or serum anti-HIV antibodies or cytotoxic T lymphocytes.<sup>225,230,241</sup> Further studies are needed to better define risk factors for HIV transmission by breast-feeding and interventions to reduce risk.

Although breast-feeding by HIV-positive mothers is discouraged in Europe and North America, where safe and affordable alternatives to breast milk are available, the issue of breast-feeding and HIV is much more complicated in developing countries, where breast-feeding has proven benefits and where artificial feeding has known risks. Benefits of breast-feeding include decreased risk of diarrhea and other infectious diseases, improved nutritional status, and decreased infant mortality<sup>243</sup> (see later section on breast-feeding).

In 1998, UNAIDS, WHO, and the United Nations Children's Fund (UNICEF) issued a joint policy statement on HIV and infant feeding to help decision makers in different countries develop their own policies regarding feeding practices in the context of HIV infection.<sup>233</sup> The statement addresses several issues: the human rights perspective, prevention of HIV infection in women, the health of mothers and children, and elements for establishing a policy on HIV status and infant feeding. As a general principle, the document supports breast-feeding. Furthermore, the statement encourages access to voluntary and confidential HIV testing for both women and men of reproductive age, as well as education regarding the implications of their HIV status for the health

and welfare of their children. Because mothers may wish to keep their HIV status confidential, the statement acknowledges that women must be empowered to make decisions regarding infant feeding and supported to carry out their decision:

This should include efforts to promote a hygienic environment, essentially clean water and sanitation, that will minimize health risks when a breast milk substitute is used. When children born to women living with HIV can be ensured uninterrupted access to nutritionally adequate breast milk substitutes that are safely prepared and fed to them, they are at less risk of illness and death if they are not breast-fed. However, when these conditions are not fulfilled, in particular in an environment where infectious diseases and malnutrition are the primary causes of death during infancy, artificial feeding substantially increases children's risk of illness and death.<sup>233</sup>

Several issues are implicit in this document. Breast-feeding has been actively promoted for many years to improve child survival. Discouraging breast-feeding is contrary to these policies, and alternatives to breast-feeding may be socially unacceptable in certain settings as well as potentially unsafe. The risks of breast-feeding in the context of maternal HIV infection must be explained in a clear, supportive, and non-judgmental manner. Moreover, universal access to voluntary HIV testing, although a clear human right, has broad social as well as financial implications.<sup>244</sup> Women may feel coerced into being tested, rather than undertaking a truly voluntary decision. There is a stigma to being infected with HIV, which in some settings may lead to spousal rejection or abuse, loss of friends and family support networks, and loss of jobs or livelihood. Programs to reduce breast-feeding or limit its duration among HIV-infected women (thereby decreasing transmission to their infants) must not reduce breast-feeding among women who are uninfected as well and must ensure that safe and affordable (maybe even free) breast milk substitutes are readily available. Although scientists have attempted, through mathematical modeling, to define levels of HIV seroprevalence and non-HIV-related child mortality at which breast-feeding might be either discouraged or promoted, there are no simple solutions to this very complicated issue.<sup>245,246</sup> A possible decline in breast-feeding in developing countries could have grave consequences. Exclusive breastfeeding for 6 months followed by rapid weaning has been proposed to reduce postnatal transmission of HIV. Other proposed strategies include antiretroviral prophylaxis of mother and infant throughout the period of breast-feeding, caloric and micronutrient supplements for the breast-feeding mother, and measures to reduce breast milk stasis and mastitis.<sup>225</sup>

### Prevention of Human Immunodeficiency Virus Infection in Developing Countries

Primary prevention of HIV infection among women of childbearing age is the most successful but most difficult way to prevent the infection of infants. Improving the social status of women, education of both men and women, ensuring access to information about HIV infection and its prevention, promotion of safer sex through condom use, social marketing of condoms, and treatment of other STDs that increase the risk of HIV transmission are potential strategies that have been successful at reducing infection.<sup>199,201</sup>

### Prevention of Transmission from an Infected Mother to Her Infant

#### *Antiretroviral Strategies*

With over 600,000 infants infected perinatally each year worldwide, prevention strategies are urgently needed. In 1994, a clinical trial performed in the United States and France (Pediatric AIDS Clinical Trials Group [ACTG] Protocol 076)<sup>204</sup> demonstrated that zidovudine (AZT) (100 mg five times per day) administered orally to HIV-infected pregnant women with no prior treatment with antiretroviral drugs during pregnancy, beginning at 14 to 34 weeks of gestation and continuing throughout pregnancy, and then intravenously during labor (2 mg/kg over 1 hour followed by 1 mg/kg per hour until delivery), and orally to the newborn for the first 6 weeks of life (2 mg/kg every 6 hours) reduced perinatal transmission by 67.5%, from 25.5% (95% CI 18.4% to 32.5%) to 8.3% (95% CI 3.9% to 12.8%). The regimen was recommended as standard care in the United States and quickly became common practice.<sup>247</sup> However, because of feasibility issues and high costs, this regimen is unavailable to the vast majority of HIV-infected pregnant women in developing countries. In many such countries, women receive limited or no prenatal care; intravenous dosing may be unsafe, impractical, or impossible; and women either give birth at home or come to a hospital or clinic only when they are already in labor. Thus, newer, simpler, less expensive methods to reduce mother-to-infant transmission of HIV are needed for the majority of women and children in the world.

A number of modified AZT trials were published between 1999 and 2000.<sup>248-251</sup> These trials evaluated a shorter prenatal course, oral rather than intravenous dosing in labor, a shorter newborn course, or no AZT to the neonate. In a joint U.S. Centers for Disease Control and Prevention (CDC) and Thai Ministry of Public Health trial, 397 asymptomatic Thai women were randomized to receive either placebo or AZT in the last month of pregnancy (300-mg tablets; one tablet orally twice daily from 36 weeks until labor, one tablet at the onset of labor, and one tablet every 3 hours until delivery). Infants did not receive AZT and were not breast-fed (infant formula was provided free for 18 months). Transmission was reduced 50%, from 18.9% (95% CI 13.2% to 24.2%) in the placebo group to 9.4% (95% CI 5.2% to 13.5%) in the AZT group.<sup>248</sup>

The Thai trial, although highly effective, did not address the issue of whether short-course AZT would be effective in a more symptomatic population, and one in which breast-feeding is the norm. In Côte d'Ivoire, as in the rest of Africa, most HIV-infected women are counseled to breast-feed their infants because of high infant mortality without breast-feeding, the cost of infant formula, and the stigma associated with alternative feeding regimens. A trial using the Thai treatment regimen was performed in Côte d'Ivoire among a cohort of pregnant women who breast-fed their infants from birth.<sup>249</sup> In the Côte d'Ivoire trial, transmission was reduced from 21.7% in the placebo group ( $n = 140$ ) to 12.2% in the treatment group ( $n = 140$ ) at 1 month (44% reduction) and from 24.9% to 15.7% at 3 months (37% reduction). To further investigate the efficacy of this regimen in breast-feeding women, the results of similar studies performed in Burkina Faso and Côte d'Ivoire were combined.<sup>250</sup> At 6 months of age, the probability of HIV infection was 18.0% in the AZT group ( $n = 192$ ) versus 27.5% in the placebo group

( $n = 197$ ), a 38% reduction of early vertical transmission of HIV, despite breast-feeding. The Perinatal HIV Prevention Trial (PHPT) compared several different AZT regimens using the same doses as in the Thai trial just described.<sup>251</sup> They compared a “long-long regimen” started at 28 weeks of gestation, with 6 weeks of treatment for the infant; a “short-short regimen” started at 35 weeks of gestation, with 3 days of treatment for the infant; a “long-short regimen”; and a “short-long regimen.” Transmission rates for the short-short group were significantly higher, and that regimen was stopped. The regimens in the other arms had equivalent efficacy (6.5%, 4.7%, 8.6%), although in utero transmission rates were lower in the groups with longer maternal therapy.

With the introduction of two- and three-drug combination therapy to reduce viral load in people with AIDS, investigators began to study AZT in combination with other drugs for use in pregnancy in developing countries (in the late 1990s). The PETRA (*Perinatal Transmission*) trial performed in South Africa, Uganda, and Tanzania studied four regimens: regimen A, AZT plus lamivudine (3TC) starting at 36 weeks of gestation followed by oral intrapartum dosing and 7 days of postpartum dosing of mother and infant; regimen B, without the postpartum dosing; regimen C, intrapartum AZT alone; and regimen D, placebo. At 6 weeks, regimens A and B were effective at reducing transmission (5.7% and 8.9% versus 14.2% and 15.3%, for the four regimens, respectively). Benefits diminished considerably by 18 months, however, when transmission rates were 15%, 18%, 20%, and 22%.<sup>252</sup>

Nevirapine is a non-nucleoside reverse transcriptase inhibitor that has potent antiviral activity, is rapidly absorbed orally, and passes quickly through the placenta. The safety and efficacy of short-course nevirapine versus AZT given to women during labor and to neonates in the first week of life were evaluated in the HIV Network for Prevention (HIVNET) 012 trial conducted in Uganda between 1997 and 1999.<sup>253</sup> Six hundred twenty-six HIV-infected women (313 in each group) were randomly assigned to receive single-dose nevirapine (200 mg orally at onset of labor and 2 mg/kg to their babies within 72 hours of birth) or AZT (600 mg orally at onset of labor and 300 mg every 3 hours until delivery; and 4 mg/kg orally twice a day to babies for 7 days after birth). Almost all infants were breast-fed from birth (98.8%), and 95.6% were still breast-feeding at 14 to 16 weeks. The HIV transmission rates in the nevirapine and the AZT groups were 8.2% and 10.4%, respectively, at birth ( $P =$  not significant [NS]), 11.9% and 21.3% at 6 to 8 weeks ( $P = .0027$ ), and 13.1% and 25.1% at 14 to 16 weeks of age ( $P = .0006$ ). When nevirapine and AZT were both started at the onset of labor, nevirapine reduced HIV transmission by almost 50% in a breast-feeding population. Of note, the 25.1% transmission rate in the AZT group was higher than that reported in the AZT trials from Côte d'Ivoire,<sup>249,250</sup> but the drug was started at 36 weeks (not at the onset of labor) in those studies. Although nevirapine appeared to be safe, long-term follow-up evaluation of infants is needed. A study at 11 public hospitals in Saharan Africa (1999 to 2000) compared single-dose nevirapine with a combination of AZT and 3TC (SAINT).<sup>254</sup> New HIV infections were detected in 5.7% (95% CI 3.7 to 7.8) and 3.6% (95% CI 2.0 to 5.3) in the nevirapine and the AZT/3TC groups, respectively (Table 2-4). Concerns have been raised about the possible emergence of resistance mutations following the use of intrapartum regimens of nevirapine.<sup>254a</sup>

In many areas of the developing world, women present late in labor with unknown HIV status. A study from Malawi published in 2003 demonstrated that postexposure prophylaxis can offer protection against HIV infection to babies who missed opportunities for prenatal and intrapartum prophylaxis.<sup>255</sup> Combination therapy with single-dose nevirapine plus AZT for 1 week was superior to nevirapine alone (rate of new infections at 6 to 8 weeks was 7.7% versus 12.1%;  $P = .03$ ). A pilot public health program in the Cameroon confirmed the efficacy of single-dose nevirapine given to HIV-infected women during labor and to the child within 72 hours of birth for reducing mother-to-child transmission.<sup>256</sup> This study demonstrated that antiretroviral therapy can be used outside of clinical trials, in real-life settings in developing countries, to successfully lower the rate of mother-to-child transmission.

Antiretroviral therapy requires the identification of HIV-infected women early enough in pregnancy to allow them access to therapy; therefore, a system for voluntary, confidential HIV counseling and testing must be in place. Furthermore, women must understand the implications of HIV infection, the drug intervention, and the possibility that even with antiviral therapy they might transmit infection to their infants. Interventions to reduce mother-to-child transmission of HIV, especially the administration of antiretroviral drugs and the avoidance of breast-feeding, make it difficult for HIV-positive women to keep their infection status private. If women fear stigmatization, discrimination, and even violence if they are identified as HIV infected, they will be unable or reluctant to take advantage of strategies to reduce transmission to their infants. Providing voluntary counseling and testing, antiviral drugs, and alternatives to breast-feeding to reduce maternal-to-child HIV transmission has potential wider benefits for society, including improvement in the quality of health care services for mothers and children, and opportunities to address primary prevention of HIV; care for HIV-infected men, women, and children; support for HIV orphans; and discriminatory societal attitudes.

Several demonstration projects to reduce mother-to-child transmission of HIV were initiated in the late 1990s in selected low-income countries, including Botswana, Burkina Faso, Cambodia, Côte d'Ivoire, Honduras, Rwanda, Tanzania, Thailand, Uganda, Zambia, and Zimbabwe.<sup>257</sup> These projects provide early access to adequate antenatal care; voluntary and confidential counseling and HIV testing for women and their partners; antiretroviral drugs during pregnancy and delivery for HIV-positive women; improved care during labor and delivery; counseling for HIV-positive women explaining a range of choices for infant feeding; and support for HIV-positive women who choose not to breast-feed. UNICEF is working with governments and infant formula companies to identify ways of providing safe and affordable alternatives to breast milk. At the same time, UNICEF, WHO, and UNAIDS continue to promote breast-feeding as the best feeding method for mothers who are HIV negative or who do not know their HIV status.

### Other Strategies

**Cesarean Section.** Meta-analyses of North American and European studies performed in the late 1990s found that elective cesarean section reduced the risk of mother-to-child transmission of HIV by more than 50%.<sup>218,219</sup> However

<sup>a</sup>Treatment was given to the mother for 1 week post partum.

<sup>b</sup>A, B, and C refer to the three arms of the PETRA study.

<sup>c</sup>The PHPT was a four-arm study of long (starting at 28 weeks) and short (starting at 35 weeks) maternal treatment, and long (continuing until week 6) and short (continuing until 3 days)

neonatal treatment. The short-short arm of the PHPT study was found in an interim analysis to result in higher transmission rates compared with the long-long arm, and this regimen was dropped from the study.

PACTG, Pediatric AIDS Clinical Trials Group; PETRA, Perinatal Transmission study; PHPT, Perinatal HIV Prevention Trial; SAINT, South African Intrapartum Nevirapine Trial.

Data updated from Kourtis A, Bulterys M, Nesheim S, et al. Understanding the timing of HIV transmission from mother to infant. *JAMA* 285:709, 2001.

Table 2-5 Actions to Reduce Mother-to-Child Transmission of HIV

**Pre- and Perinatal Transmission**

Expand access to PMCT interventions while improving the quality/efficacy of the strategy  
 Develop strategies to lower the cost of new diagnostic tools for HIV infection in infancy in the appropriate settings  
 Trials to answer questions concerning nevirapine resistance—alternative agents? novel strategies?  
 Study innovative strategies to deliver interventions to women who do not have access to HIV testing or antenatal care

**Postnatal Transmission**

Integration of basic science studies on postnatal transmission within clinical research (collection of samples)  
 Define standardized and agreed-upon methodologic tools for postnatal transmission studies  
 Investigate new approaches to make implementation easier—e.g., early diagnosis of HIV infection in infants

**Pediatric Infection**

Development of affordable and reliable tests/repository of samples for evaluation of new technologies for early HIV diagnosis of children in resource-limited settings  
 Development and evaluation of pediatric HIV/AIDS diagnostic algorithms  
 Surveillance of ARV resistance (development of affordable and reliable tests) and adherence

**Cross-Cutting Actions**

Better coordination of funding sources  
 Optimize partnerships between researchers  
 Link HIV prevention programmes with PMTCT  
 Increase number of providers of PMTCT, taking into account regional context  
 Early communication with all stakeholders  
 Social and cultural studies including studies on culturally appropriate counseling should be part of clinical research protocols  
 Implementation of PMTCT programs should be in the context of household care/treatment and of sustainability by countries; care of children should be linked with that of the mother/family (prevention and care), and continuity of this care and coordination is critical  
 Research should support the foregoing principles and be relevant to the host country

AIDS, acquired immunodeficiency syndrome; ARV, AIDS-related virus; HIV, human immunodeficiency virus; PMCT, xxxxx; PMTCT, xxxxx.  
 From Menu E, Scarlatti G, Barré-Sinoussi F, et al. Mother-to-child transmission of HIV: developing integration of healthcare programmes with clinical, social and basic research studies. Report of the International Workshop held at Cobe Marina Lodge, Kasane, Botswana, 21-25 January 2003. *Acta Paediatr* 92:1343, 2003.

cesarean section is appropriate for reducing perinatal transmission of HIV only if it can be performed in a well-staffed and well-equipped facility in which risks to mother and baby are low.<sup>258</sup>

**Vaginal Lavage.** Use of vaginal microbicides during labor and delivery to reduce the amount of HIV the neonate comes in contact with during delivery, and cleaning the infant's skin immediately after delivery, have been studied. To date, efficacy has not been demonstrated, but additional research is under way.<sup>259</sup>

**Additional Interventions.** It has been suggested that a package of interventions to reduce mother-to-child transmission of HIV should be implemented, including the following<sup>260</sup>:

- Expansion and strengthening of family planning and information and services, as well as HIV prevention activities
- Early access to quality antenatal care from trained health workers
- Voluntary counseling and HIV testing for women and their partners
- Provision of antiretroviral medication to prevent HIV transmission from seropositive women to their babies
- Improved care during labor, delivery, and the postpartum period
- Counseling for HIV-positive women on infant feeding choices, with replacement feeding made available when needed and support for women in all of their feeding practices

An international workshop identified specific actions that need to be taken by the global community to reduce mother-to-child HIV transmission (Table 2-5).<sup>261</sup>

### Human Immunodeficiency Virus and Child Survival

Although there have been tremendous gains in child survival over the past 3 decades, with reductions worldwide in deaths due to diarrhea, pneumonia, and vaccine-preventable diseases, the AIDS epidemic threatens to undermine this dramatic trend.<sup>262</sup> In parts of the developing world, AIDS has already had a negative impact on child survival; in sub-Saharan Africa, AIDS has become a leading cause of death among infants and children (Table 2-6). Moreover, there is a complex link between increasing mortality of children under 5 years old and high rates of HIV prevalence in adults, related to both mother-to-child transmission of HIV and the compromised ability of parents who are ill themselves to care for young children.<sup>263</sup>

### NEONATAL TETANUS

More is known about neonatal tetanus than about any other newborn infection occurring in developing countries. There is a vast published literature on neonatal tetanus. Neonatal tetanus traditionally has been an underreported “silent” illness. Because it attacks newborns in the poorest countries of the world in the first few days of life while they are still confined to home, because of a high and rapid CFR (85%

AIDS, acquired immunodeficiency syndrome.

untreated),<sup>264</sup> and because of poor access to medical care, the disease may go unrecognized.<sup>265-267</sup> Retrospective community surveys of neonatal tetanus have been conducted since the late 1970s to determine burden of disease and mortality rates.<sup>268</sup> The surveillance case definition of neonatal tetanus is relatively straightforward—that is, the ability of a newborn to suck at birth and for the first few days of life, followed by inability to suck starting between 3 and 10 days of age, spasms, stiffness, convulsions, and death. Using this definition and the verbal autopsy technique, country surveys have estimated the magnitude of the problem worldwide.

In 2000, WHO estimated that approximately 200,000 deaths per year are still caused by neonatal tetanus.<sup>267</sup> The vast majority of cases and deaths occur in a limited number of countries. Eighty percent deaths worldwide occur in only eight countries—India, Nigeria, Pakistan, Ethiopia, Bangladesh, the Democratic Republic of Congo, Somalia, and China (Table 2-7).<sup>265,266</sup> In view of the significant disease burden, WHO and UNICEF have called for the elimination (defined as fewer than 1 case per 1000 livebirths) of neonatal tetanus by the year 2005. To date, 104 of 161 developing countries have achieved elimination of neonatal tetanus.<sup>266</sup>

Neonatal tetanus is a completely preventable disease. It can be prevented by immunizing the mother before or during pregnancy and/or by ensuring a clean delivery, clean cutting of the umbilical cord, and proper care of the cord in the days after birth. Clean delivery practices have additional benefits—prevention of other maternal and neonatal infections, in addition to tetanus. Tetanus threatens mothers as well as babies, and tetanus-related mortality is a complication of both induced abortion and childbirth in unimmunized women.<sup>269</sup> Immunization of women with at

<sup>a</sup>The numbers of deaths in the table are estimated, as most neonatal deaths occur at home, before the baby reaches 2 weeks of age, and neither the birth nor the death is reported.

Data from The Progress of Nations 2000. New York, UNICEF, 2000.

least three doses of tetanus toxoid vaccine provides complete prevention against both maternal and neonatal tetanus. The global elimination of maternal tetanus has recently been added to the elimination goals.

## OMPHALITIS

In developed countries, aseptic delivery techniques and cord care have decreased the occurrence of umbilical infection, or omphalitis. Furthermore, prompt diagnosis and antimicrobial therapy have decreased morbidity and mortality if omphalitis develops. Omphalitis continues to be a problem, however, in developing countries, where hygienic cord care practices are not universal.<sup>270</sup> The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. The umbilical stump is rapidly colonized by bacteria from the maternal genital tract and from the environment. This colonized necrotic tissue, in close proximity to umbilical vessels, provides microbial pathogens with direct access to the bloodstream. It is not surprising that umbilical infection is common in developing countries, with the triad of home births, unsterile cutting of the cord, and unhygienic cord care after birth. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, or the liver. Infants who present with abdominal wall cellulitis or necrotizing fasciitis have a high incidence of associated bacteremia (often polymicrobial) and a high mortality rate.<sup>270-272</sup>

There are only a limited number of recent studies on umbilical infection from developing countries.<sup>45,68,273-276</sup> Overall, incidence of omphalitis in these studies ranged from 2 to 54 per 1000 livebirths, with the CFR ranging from 0% to 15%. Guvenç and associates<sup>275</sup> identified 88 newborns with omphalitis at a university hospital in eastern Turkey over a 2-year period. These included 54 patients with local symptoms only and 34 with systemic symptoms. The overall CFR was 15%, but all deaths occurred among patients with systemic signs, with a CFR of 38% in this group. Gram-positive organisms were isolated from 68% of umbilical cultures, gram-negative organisms were isolated from 60%, and multiple organisms were cultured in 28% of patients. Airede<sup>273</sup> studied 33 Nigerian neonates with omphalitis. The incidence of omphalitis was 2 per 1000 livebirths, and the prevalence was 16 per 1000 hospital admissions. There were no deaths in this series. Aerobic bacteria were isolated from 70%, and anaerobic bacteria were isolated from 30%. Sixty percent of the aerobic isolates were gram-positive organisms, and polymicrobial isolates were common. Three studies from India were identified that present data on omphalitis or umbilical sepsis. Singhal and associates<sup>68</sup> reported that umbilical sepsis developed in 28 of 920 live-born infants (30 per 1000), and two of these infants died (CFR 7%). Four percent of all neonatal deaths in this study were attributed to umbilical sepsis. Bhardwaj and Hasan<sup>45</sup> reported that developed umbilical sepsis developed in 11 of 204 live-born infants (54 per 1000); there were no deaths in this group. Faridi and colleagues<sup>274</sup> studied 182 Indian neonates with omphalitis, including 104 hospital-born and 78 home-delivered infants. The incidence of omphalitis in the hospital-born group was 24 per 1000 livebirths. Overall, gram-negative organisms were isolated more frequently than gram-positive organisms (57% versus 43%), but *S. aureus* was the single most frequent isolate (28%). In one report from Turkey, 85 neonates with bacteriologically proven omphalitis were evaluated.<sup>276</sup> *S. aureus* and *E. coli* were the most frequent organisms isolated. Overall CFR was 13%, with no difference between term and preterm infants. In a study from Papua New Guinea published in 1999, umbilical cultures were performed in 116 young infants with signs suggestive of omphalitis. The most frequently isolated organisms were group A  $\beta$ -hemolytic streptococci (44%), *S. aureus* (39%), *Klebsiella* (17%), *E. coli* (17%), and *Proteus mirabilis* (16%).<sup>143</sup> In infants with both omphalitis and bacteremia, the same organism may be cultured from both umbilicus and blood. In the Papua New Guinea study cited earlier, newborns with sepsis and omphalitis had *S. aureus*, group A  $\beta$ -hemolytic streptococci, and *Klebsiella pneumoniae* each isolated from both sites.

The method of caring for the umbilical cord after birth affects both bacterial colonization and time to cord separation.<sup>277,278</sup> It is generally agreed that application of antimicrobial agents to the umbilical cord reduces bacterial colonization. The effect of such agents on reducing infection is less clear.<sup>278</sup> During a study of pregnancy in a rural area of Papua New Guinea, Garner and colleagues<sup>279</sup> detected a high prevalence of neonatal fever and umbilical infection, which were associated with the subsequent development of neonatal sepsis. They designed an intervention program for umbilical cord care that included maternal health education and umbilical care packs containing acriflavine spirit and

new razor blades. Neonatal sepsis was significantly less frequent in the intervention group (1 case per 67 versus 8 of 64;  $P = .02$ ). This study, published in 1994, documented the importance of umbilical infection in the etiology of neonatal sepsis in the setting of a rural developing country and demonstrated that a simple cord care intervention could reduce infectious morbidity.

## DIARRHEA

It is generally agreed that diarrheal episodes are more common in infants older than 6 months than in those who are younger.<sup>280,281</sup> It is thought that the high prevalence of breast-feeding in the first month of life, the fact that most of the world's children are born at home rather than in the hospital, and the relative segregation of infants for a period of time after birth are factors that protect the newborn from diarrhea. Mortality from diarrhea is thought to be greatest in the first year of life.

Numerous studies published in the 1980s and 1990s have investigated the epidemiology of diarrhea in hospital and community settings and the role of breast milk and breast-feeding in protection against disease.<sup>282-288</sup> Clemens and colleagues followed a cohort of 198 breast-fed Egyptian neonates for the first 6 months of life.<sup>288</sup> Neonates for whom breast-feeding was initiated within the first 3 days of life, when breast milk contains colostrum (early group;  $n = 151$ ), had a 26% lower rate of diarrhea during the first 6 months of life than that in infants who started breast-feeding later (late group;  $n = 47$ ) (early versus late: 6.4 episodes versus 9.0 episodes per child-year;  $P < .05$ ). Huilan and associates<sup>282</sup> studied the agents associated with diarrhea in children from birth to 35 months of age from five hospitals in China, India, Mexico, Myanmar, and Pakistan. A total of 3640 cases of diarrhea were studied, 28% of which occurred in infants younger than 6 months of age. Data on the detection of rotavirus, enterotoxigenic *E. coli*, and *Campylobacter* were provided by age. Five percent of isolates of these agents (17 of 323) were from neonates (birth to 29 days). Black and colleagues<sup>284</sup> performed community studies of diarrheal epidemiology and etiology in a periurban community in Peru. The incidence of diarrhea was 9.8 episodes per child in the first year of life and did not differ significantly by month of age (0.64 to 1.0 episode per child-month) from that in infants having diarrhea from birth. Mahmud and colleagues<sup>285</sup> prospectively followed a cohort of 1476 Pakistani newborns from four different communities. Eighteen percent of infants evaluated in the first month of life (180 of 1028) had diarrhea.

Although most infants in developing countries are born at home, those born in hospitals are at risk for nosocomial diarrheal infections. Aye and co-workers<sup>287</sup> studied diarrheal morbidity in neonates born at the largest maternity hospital in Rangoon, Myanmar. Diarrhea was a significant problem, with rates of 7 cases per 1000 livebirths for infants born vaginally and 50 per 1000 for infants delivered by cesarean section. These differences were attributed to the following: infants born by cesarean section remain hospitalized longer, are handled more by staff and less by their own mothers, and are less likely to be exclusively breast-fed.

Rotavirus is one of the most important causes of diarrhea among infants and children worldwide, occurring most

commonly in infants aged 3 months to 2 years. In developing countries, an estimated 800,000 children die of rotavirus diarrhea each year, and infections occur earlier in infancy.<sup>289,290</sup> There are few reports of rotavirus infection in newborns.<sup>291</sup> It appears that in most cases, neonatal infection is asymptomatic, and that neonatal infection may protect against severe diarrhea in subsequent infections.<sup>292,293</sup> Neonates are generally infected with unusual rotavirus strains that may be less virulent and may serve as natural immunogens.<sup>294</sup> The rate of infection among neonates may be more common than was previously thought. Cicirello and associates<sup>294</sup> screened 169 newborns at six hospitals in Delhi, India, and found a rotavirus prevalence of 26%. Prevalence increased directly with length of hospital stay. The high prevalence of neonatal infections in Delhi (and perhaps in other developing country settings) could lead to priming of the immune system and have implications for vaccine efficacy.

Several of the community-based studies reviewed earlier present data on diarrhea as a cause of neonatal death.<sup>46,49,52,54,56-59,68,69</sup> In these studies, diarrhea was responsible for 1% to 12% of all neonatal deaths. In 9 of the 10 studies, 70 of 2673 neonatal deaths (3%) were attributed to diarrhea. Whereas diarrhea is more common in infants after 6 months of age, it is clearly a problem, in terms of both morbidity and mortality, for neonates in developing countries. The WHO estimates that there are 4,035,000 neonatal deaths per year in the less developed regions of the world.<sup>3</sup> If 3% of all neonatal deaths are due to diarrhea, approximately 120,000 neonatal deaths per year are associated with diarrhea.

## OPHTHALMIA NEONATORUM

Ophthalmia neonatorum, defined as purulent conjunctivitis in the first 28 days of life, remains a common problem in many developing countries. The risk of infection in the neonate is directly related to the prevalence of maternal infection and the frequency of ocular prophylaxis. Infants born in areas of the world with high rates of STDs are at greatest risk. Data on incidence and bacteriologic spectrum from specific countries are limited. Although a wide array of agents are cultured from infants with ophthalmia neonatorum,<sup>293-298</sup> *Neisseria gonorrhoeae* (the gonococcus) and *Chlamydia trachomatis* are the most important etiologic agents from a global perspective.<sup>298-303</sup> The pathogenesis of infection is similar for these two agents: Infection is acquired from an infected mother during passage through the birth canal or through an ascending route. Infection due to one etiologic agent cannot be distinguished from infection due to the other by clinical examination; both produce a purulent conjunctivitis. However, gonococcal ophthalmia may appear earlier and is more severe than chlamydial conjunctivitis. Untreated gonococcal conjunctivitis may lead to corneal scarring and blindness, whereas the risk of severe ocular damage is low with chlamydial infection. Without ocular prophylaxis, ophthalmia neonatorum will develop in 30% to 42% of infants born to mothers with untreated *N. gonorrhoeae* infection,<sup>299,300,302</sup> and in approximately 30% of infants exposed to *Chlamydia*.<sup>300</sup>

Strategies to prevent or ameliorate ocular morbidity related to ophthalmia neonatorum include (1) primary prevention of STDs; (2) antenatal screening for and treatment

of STDs (particularly gonorrhea and *Chlamydia* infection); (3) eye prophylaxis at birth; and (4) early diagnosis and treatment of ophthalmia neonatorum.<sup>302</sup> For developing countries, eye prophylaxis soon after birth is the most cost-effective and feasible strategy. Eye prophylaxis is used primarily to prevent gonococcal ophthalmia. Primary prevention of STDs in developing countries is limited, although promotion of condom use has been successful in reducing STDs in some countries.<sup>304,305</sup> Screening women at prenatal and STD clinics and treatment based on a syndromic approach (i.e., treat for possible infections in all women with vaginal discharge without laboratory confirmation) is cost-effective but may lead to overtreatment of uninfected women and missed cases. Because primary infection with both *N. gonorrhoeae* and *Chlamydia* is usually asymptomatic, pregnant women need to be specifically screened for STDs to ensure early diagnosis and treatment of the mother before delivery of her neonate.

Eye prophylaxis consists of cleaning the eyelids and instilling an antimicrobial agent into the eyes as soon after birth as possible. The agent should be placed directly into the conjunctival sac (using clean hands), and the eyes should not be flushed after instillation. Infants born both vaginally and by cesarean section should receive prophylaxis. Although no agent is 100% effective at preventing disease, the use of 1% silver nitrate solution (introduced by Credé in 1881)<sup>306</sup> dramatically reduced the incidence of ophthalmia neonatorum. This inexpensive agent is still widely used in many parts of the world and is the most successful prophylactic antimicrobial agent in history. The major problems with silver nitrate are that it may cause chemical conjunctivitis in up to 50% of infants and that it has limited antimicrobial activity against *Chlamydia*.<sup>301,307,308</sup> In developing countries in which heat and improper storage may be a problem, evaporation and concentration are particular concerns. Although 1% tetracycline and 0.5% erythromycin ointments are commonly used in developed countries, and are as effective as silver nitrate for the prevention of gonococcal conjunctivitis, these agents are more expensive and unavailable in many parts of the world. Moreover, silver nitrate appears to be a better prophylactic agent in areas where penicillinase-producing *N. gonorrhoeae* (PPNG) is a problem.<sup>309</sup>

The ideal prophylactic agent for developing countries would have a broad antimicrobial spectrum and also be available and affordable. Povidone-iodine is an inexpensive, nontoxic topical agent that is potentially widely available in developing countries. Preliminary studies suggest that it may be useful in preventing ophthalmia neonatorum. A prospective masked, controlled trial of ocular prophylaxis using 2.5% povidone-iodine solution, 1% silver nitrate solution, or 0.5% erythromycin ointment was conducted in Kenya.<sup>310</sup> Of 3117 neonates randomized to receive a study drug, 13.1% in the povidone-iodine group versus 15.2% of those who received erythromycin and 17.5% in the silver nitrate group developed infectious conjunctivitis ( $P < .01$ ). The high rates of infection in this group despite ocular prophylaxis are striking. Although there was no significant difference among agents in prevention of gonococcal ophthalmia (1% or less for each agent), povidone-iodine was more effective than either other agent in preventing chlamydial conjunctivitis. A 2003 study by the same group compared prophylaxis with one drop and with two drops of the povidone-iodine solution instilled in

both eyes at birth in 719 Kenyan neonates. No cases of *N. gonorrhoeae* infection were identified. Double application did not change the rates of infection with *C. trachomatis* (4.2% and 3.9%).<sup>311</sup> Although the antimicrobial spectrum of povidone-iodine is wider than that of other topical agents<sup>312</sup> and antibacterial resistance has not been demonstrated,<sup>313</sup> published data on the efficacy of povidone-iodine against PPNG are not yet available. Of note, 2.5% povidone-iodine might also be useful as an antimicrobial agent for cord care—of relevance in the prevention of omphalitis (see earlier). Further studies of the safety and efficacy of this agent are particularly important for its use in developing countries.

The frequency of ocular prophylaxis in developing countries is unknown. In consideration of the high rates of STDs among pregnant women in many developing countries, eye prophylaxis is an important blindness prevention strategy. For infants born at home, a single dose of antimicrobial agent for ocular prophylaxis could be added to traditional birth attendant or home delivery kits. The strategy of ocular prophylaxis is more cost-effective than early diagnosis and appropriate treatment. Furthermore, in areas of the world in which access to medical care is limited and effective drugs are scarce or unavailable, it may be the only viable strategy.

No prevention strategy is 100% effective. Even with prophylaxis, 5% to 10% of infants will develop ophthalmia. All infants with ophthalmia must be given appropriate treatment—even if they received prophylaxis at birth. A single dose of either ceftriaxone (25 to 50 mg/kg intravenously [IV] or intramuscularly [IM], not to exceed 125 mg) or cefotaxime (100 mg/kg, IV or IM) is effective therapy for gonococcal ophthalmia caused by both PPNG and non-PPNG strains.<sup>309</sup> Gentamicin and kanamycin also have been shown to be effective therapeutic agents and may be more readily available in some settings. Rarely, gonococcal infection acquired at birth may become disseminated, resulting in arthritis, septicemia, and even meningitis. Neonates with disseminated gonococcal disease require systemic therapy with ceftriaxone (25 to 50 mg/kg once daily) or cefotaxime (25 mg/kg IM or IV twice daily) for 7 days (arthritis, sepsis) or 10 to 14 days (meningitis). If a lumbar puncture cannot be performed (and meningitis cannot be ruled out) in an infant with evidence of dissemination, the longer period of therapy should be chosen.<sup>309</sup> Infants with chlamydial conjunctivitis should receive a 2-week course of oral erythromycin (50 mg/kg per day in four divided doses). After the immediate neonatal period, oral sulfonamides may be used.<sup>309</sup>

Intraocular instillation of human milk or colostrum has been used as a traditional remedy for ophthalmia neonatorum in some developing countries. An interesting 1996 study from Nigeria demonstrated that colostrum (but not mature milk) resulted in *in vitro* inhibition of growth of *S. aureus* and a variety of coliform organisms.<sup>314</sup> A similar study compared *in vitro* activity of colostrum to that of povidone-iodine and confirmed that colostrum inhibited growth of *N. gonorrhoeae* as well as *S. aureus*.<sup>315</sup> Although an unorthodox prophylactic or therapeutic agent, colostrum or human milk deserves further study, especially for rural areas with limited access to health care facilities.

## MALARIA

From a global perspective, malaria is one of the most important infectious diseases. More than 40% of the world's population live in areas with malaria risk. The WHO estimates that 300 to 500 million cases occur annually, with 1.5 to 3 million deaths. More than half of all malaria deaths occur in children younger than 5 years of age.<sup>316</sup> The disease is mainly confined to poorer tropical areas of Africa, Asia, and Latin America. Countries in sub-Saharan Africa account for more than 90% of malaria cases. Each year approximately 24 million African women become pregnant in malaria-endemic areas and are at risk for malaria during pregnancy.<sup>317</sup> Four species of the malaria parasite infect humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. *P. falciparum* is responsible for the most severe form of disease and is the predominant parasite in tropical Africa, Southeast Asia, the Amazon area, and the Pacific. Groups at greatest risk for severe disease and death are young nonimmune children, pregnant women (especially primigravidas), and nonimmune adults.<sup>318</sup>

### Malaria in Pregnancy

Preexisting levels of immunity determine susceptibility to infection and severity of disease.<sup>317-321</sup> In areas of high endemicity or high stable transmission, where there are high levels of protective immunity, the effects of malaria on the mother and fetus are less severe than in areas where malaria transmission is low or unstable (i.e., sporadic, periodic). It is unclear why pregnant women (even with preexisting immunity) are at increased risk for malaria. Severe maternal complications (cerebral malaria, pulmonary edema, renal failure) occur most commonly in women with little or no immunity and are most frequent with infections due to *P. falciparum*. Severe malaria may result in pregnancy-related maternal death.

Maternal parasitemia is more common, and the parasite burden is higher in pregnant than in nonpregnant women.<sup>319,320</sup> This increase in both prevalence and density of parasitemia is highest in primiparous women and decreases with increasing parity.<sup>320</sup> The parasite burden is highest in the second trimester and decreases with increasing gestation.<sup>321-323</sup> The most important effects of malaria on pregnant women are severe anemia<sup>319</sup> and placental infection.<sup>317-321,324,325</sup> The prevalence of anemia can be as high as 78%, and anemia is more common and more severe in primigravidas.<sup>325</sup> A 1999 study highlighted the importance of *P. vivax* infection (as well as the much more studied *P. falciparum*) as a cause of pregnancy-related morbidity, including anemia.<sup>326</sup>

### Perinatal Outcome

Perinatal outcome is directly related to placental malaria. Malaria is associated with an increase in spontaneous abortions, stillbirths, preterm delivery, and intrauterine growth restriction, particularly in areas where malaria is acquired by nonimmune women.<sup>321,327,328</sup> Reported rates of fetal loss range from 9% to 50%.<sup>320</sup> The uteroplacental vascular space is thought to be a relatively protected site for parasite sequestration and replication.<sup>324,329</sup> Placental malaria is

Data from World Health Organization. International Travel and Health—Vaccination Requirements and Health Advice. Geneva, World Health Organization, 1997; and from The Progress of Nations 1997. New York, UNICEF, 1997.

characterized by the presence of parasites and leukocytes in the intervillous space, pigment within macrophages, proliferation of cytotrophoblasts, and thickening of the trophoblastic basement membrane.<sup>325</sup> Placental infection may alter the function of the placenta, reducing oxygen and nutrient transport and resulting in intrauterine growth retardation, and may allow the passage of infected red blood cells to the fetus, resulting in congenital infection. In primigravidas living in endemic areas, placental malaria occurs in 16% to 63% of women, whereas in multigravidas, the prevalence is much lower at 12% to 33%.<sup>319,320</sup>

The most profound effect of placental malaria is the reduction of birth weight.<sup>321,330,331</sup> Both *P. falciparum* and *P. vivax* infection during pregnancy are associated with a reduction in birth weight.<sup>326</sup> Steketee and associates<sup>330</sup> have estimated that in highly endemic settings, placental malaria may account for approximately 13% of cases of low birth weight secondary to intrauterine growth retardation. In Africa, malaria is thought to be an important contributor to low birth weight in the almost 3.5 million LBW infants born annually.<sup>332</sup> Of importance, malaria is one of the few preventable causes of low birth weight. Because low birth weight is a major determinant of neonatal and infant mortality in developing countries, malaria may indirectly increase mortality by increasing low birth weight.<sup>333</sup> An important benefit of malaria prevention programs will be a reduction of low birth weight and low birth weight-associated infant mortality.<sup>334</sup>

### Congenital Malaria

Transplacental infection of the fetus also may occur. It is relatively rare in populations with prior immunity (0.1% to 1.5%)<sup>319</sup> but more common in nonimmune mothers. It is thought that the low rate of fetal infection concomitant with a high incidence of placental infection is due in part to protection from transplacental maternal antibodies.<sup>335,336</sup>

The clinical characteristics of neonates with congenital malaria (i.e., malaria parasitemia on peripheral blood smear) include fever, respiratory distress, pallor, anemia, hepatomegaly, jaundice, and diarrhea. There is a high mortality rate with congenital infection.<sup>337</sup> The global burden of disease related to congenital malaria is unknown.

### Prevention and Treatment of Malaria

Pregnant women living in malaria-endemic areas need access to services that can provide prompt, safe, and effective treatment for malaria. Chloroquine, the safest, cheapest, most widely available antimalarial drug, has been the agent of choice for the prevention and treatment of malaria in pregnancy.<sup>338</sup> However, in all areas where *P. falciparum* is prevalent, the parasite is at least partially resistant to chloroquine (Table 2-8).<sup>316</sup> There are a limited number of safe and effective antimalarials available for use in pregnancy. For a drug to be considered safe, it must be safe for the mother, safe for the fetus, and ideally also safe for the breast-feeding infant.<sup>339</sup> New drug development has been impeded by the fact that pregnant women have been excluded from drug development programs because of the justified fear of risks to the fetus.<sup>340</sup>

A 2002 systematic review of prevention versus therapy in pregnant women examined studies on the effectiveness of prompt therapy for malaria infection, prophylaxis with antimalarial drugs to prevent infection, and reduced exposure to mosquito-borne infection by using insecticide-treated bednets.<sup>341</sup> Chemoprophylaxis is associated with reduced maternal disease, including anemia and placental infection. One study found that the incidence of placental malaria is reduced by prophylaxis, even when chloroquine is used in areas with chloroquine-resistant malaria.<sup>342</sup> In addition, prophylaxis has been found to have a positive effect on birth weight and risk of preterm delivery.<sup>343</sup>

Table 2-9 Estimated Global Burden of Disease—Major Neonatal Infections

Infection	Estimated No. of Cases	Estimated Case-Fatality Rate (%)	Estimated No. of Deaths

<sup>a</sup>Data unavailable: Most HIV-related deaths occur after the neonatal period.  
Data updated from Stoll BJ. The global impact of neonatal infection. Clin Perinatol 24:1997.

A major problem with both chemoprophylaxis and prompt therapy for known or suspected infection is that it is often difficult to deliver services to pregnant women, especially those who live in areas remote from health centers. Intermittent presumptive therapy involves two or three doses of a safe and effective antimalarial given to women in malaria-endemic areas with the presumption that they are at high risk to be infected. Recent studies from Africa have demonstrated that intermittent preventive treatment (IPT) can reduce the incidence of malaria and its adverse consequences.<sup>344,345</sup> These interventions are particularly important and cost-effective in pregnancy.<sup>343,346</sup> In 2000, the WHO recommended IPT with sulfadoxine-pyrimethamine in malaria-endemic areas where *P. falciparum* is resistant to chloroquine and sensitive to sulfadoxine-pyrimethamine.<sup>347</sup> This drug is effective in a single dose, is not bitter, and is relatively well tolerated. In areas where malaria transmission is lower and *P. vivax* as well as *P. falciparum* is a problem, finding an appropriate drug regimen is more difficult.<sup>348</sup>

### Other Malaria Control Measures

Although the benefits of antimalarial chemoprophylaxis have been established, poor compliance<sup>349</sup> and increasing drug resistance have led to trials of alternative prevention strategies. Use of insecticide-treated bed nets has been successful in reducing childhood morbidity and mortality in malaria-endemic areas.<sup>350-352</sup> The effects of bed nets on malaria in pregnancy have been inconsistent, however. A study in Tanzania found a significant reduction in parasitemia and anemia.<sup>353</sup> A study from the Thai-Myanmar border found a significant reduction in maternal anemia, with only a marginal effect on peripheral parasitemia<sup>354</sup>; a study from The Gambia found a reduction in severe anemia in the dry season and fewer preterm deliveries in the rainy season,<sup>355</sup> but studies from Ghana<sup>356</sup> and Kenya<sup>357</sup> showed no significant impact of insecticide-impregnated bed nets on malaria-associated morbidity in pregnant women, including anemia and low birth weight. Given the number of pregnant women living in malarious areas, research on non-drug control strategies are needed for this high-risk group. The use of social marketing has increased bed net use. An additional benefit of bed net use is protection of the neonate, who almost always sleeps with the mother in this setting.<sup>355</sup>

Studies published in 2003 have shown an association between malaria and HIV in pregnancy with an increase in the risk of maternal malaria and of placental malaria in HIV-positive mothers.<sup>358-360</sup> Furthermore, co-infection with malaria and HIV infection in pregnancy has been shown to increase mother-to-child transmission of HIV<sup>360</sup> and both perinatal and early infant mortality.<sup>361</sup>

### GLOBAL BURDEN OF INFECTIOUS DISEASES AMONG NEWBORNS

Table 2-9 summarizes estimates of the global burden for the most important neonatal infections. These estimates are based on the review of studies presented earlier and selected WHO and United Nations documents.<sup>5,7,127,266</sup> In summary, of the estimated 132,787,000 children born in developing countries each year, more than 20% (or almost 30 million children) develop a neonatal infection and more than 1,500,000 infants die of infection in the neonatal period each year.

### DIRECT AND INDIRECT CAUSES OF NEONATAL DEATH RELATED TO INFECTION

The immediate or direct medical causes of neonatal death related to infection include sepsis, meningitis, omphalitis, neonatal tetanus, pneumonia, TB, diarrhea, malaria, and HIV infection/AIDS. There are, however, a vast array of indirect causes for many of the infectious deaths in developing countries (Table 2-10). These contributory factors have social as well as medical roots. Sociocultural factors include poverty (not just of individuals but of governments as well), illiteracy, low social status of women, lack of political power (for women and children) and lack of will in those who have power, gender discrimination (for both mother and neonate), harmful traditional or cultural practices, poor hygiene, lack of clean water and sanitation, the cultural belief that a sick newborn is doomed to die (and is, moreover, replaceable), the family's inability to recognize danger signs in the newborn, inadequate access to high-quality medical care (either because it is unavailable or because of the lack of transport for emergency care) or the lack of supplies or appropriate

Table 2–10 Direct and Indirect Causes of Neonatal Death Related to Infections in Less Developed Countries

Direct Causes of Death	Indirect Causes of Death
<b>Medical</b>	<b>Sociocultural</b>
Sepsis	Poverty
Meningitis	Illiteracy
Omphalitis with sepsis	Low social status of women
Tetanus	Lack of potential power
Pneumonia	Gender discrimination (for mother and newborn)
Tuberculosis	Harmful traditional practices
Diarrhea	Poor hygiene
Malaria	Lack of clean water and sanitation
HIV infection/AIDS	Cultural belief that a sick newborn is doomed to die
	Inability to recognize danger signs in sick newborn
	Poor care-seeking behavior
	Inadequate access to high-quality medical care
	Lack of transport for emergency care
	Lack of appropriate drugs
	Maternal death
	<b>Medical</b>
	Poor maternal health
	Untreated maternal infections including sexually transmitted diseases, urinary tract infection, chorioamnionitis
	Failure to fully immunize mother against tetanus
	Inappropriate management of labor and delivery
	Unsanitary cutting and care of umbilical cord
	Failure to promote early and exclusive breast-feeding (HIV dilemma noted)
	Prematurity/low birth weight

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Data updated from Stoll BJ. The global impact of neonatal infection. *Clin Perinatol* 24:1, 1997.

drugs, and maternal death.<sup>2,3,362,363</sup> Medical factors that may also contribute to an infectious neonatal death include poor maternal health, untreated maternal infections (including STDs, urinary tract infection, and chorioamnionitis), failure to fully immunize the mother against tetanus, inappropriate management of labor and delivery, unsanitary cutting and care of the umbilical cord, failure to promote early and exclusive breast-feeding, and prematurity and/or low birth weight.<sup>2-4,364,365</sup> To promote change, families must know enough to identify illness and must want and be able to seek care. Health care workers (of all levels) must know what to do and must have the resources to support needed therapy. Moreover, better maternal care—both preventive and curative—is preventive medicine for the newborn.

With the scientific knowledge currently available, it is possible to address the medical causes of infectious death and to make a significant impact on mortality. It is far harder to address the sociocultural factors that, in some settings, make a medical approach to preventing and treating these diseases impossible. Coordinated activities are needed to bring about change that is sustainable by countries on their own, over the long haul. This will involve a multidisciplinary approach—bringing together people with different interests, from different backgrounds, different agencies, different government ministries—to seek solutions to problems and to implement change at the local level. Finally, it will involve the global acknowledgment that this is the right thing to do (i.e., a moral imperative) and, therefore, the long-term commitment of substantial funding to help provide needed services to poor countries. The challenge for the next decade is to link science and medicine with social solutions through

a global commitment to long-term, long-lasting change so that improvements in both maternal and newborn health can be achieved and sustained.

### STRATEGIES TO LIMIT INFECTION IN THE NEONATE AND TO REDUCE INFECTION-ASSOCIATED MORTALITY

Strategies to prevent or reduce neonatal infections, and to reduce morbidity and mortality in those newborns in whom infection develops, involve putting into practice what is known and inventing creative ways to make these interventions workable in a developing country context. Use of simple, cost-effective technologies that are potentially available at the village or district hospital level could have a major impact in reducing morbidity and mortality related to neonatal infection. Moreover, public health, medical, and social interventions all have a role to play in reducing the global burden of neonatal infection. Several potential interventions are reviewed here (Table 2-11).

#### Maternal Immunization to Prevent Neonatal Disease

There is growing interest in the possibility of using maternal immunization to protect neonates and very young infants from infection through passively acquired transplacental or breast milk antibodies, or both.<sup>366,367</sup> Immunization of pregnant women with tetanus toxoid has dramatically reduced cases of neonatal tetanus and is the classic example of maternal

**Table 2-11 Interventions to Reduce Neonatal Infections or to Reduce Infection-Associated Mortality in Developing Countries****Antenatal Care**

Tetanus immunization

Maternal immunization with new vaccines in the future (e.g., group B streptococci, *Haemophilus influenzae* type b, pneumococcus)

Primary prevention of sexually transmitted disease, including HIV infection, through maternal education and safer sex using condoms

Diagnosis and treatment of sexually transmitted diseases, urinary tract infection, malaria, tuberculosis, other infections

Plan clean and safe delivery

**Intrapartum/Delivery Care**

Prevent prolonged labor

Optimal management of complications, including fever, premature rupture of membranes, puerperal sepsis

Clean delivery

Clean cutting of umbilical cord/optimal cord care

**Breast-feeding**

Promote early and exclusive breast-feeding (HIV dilemma noted)

**Gender Issues**

Promote gender equality

Encourage education of girls

**Interventions to Decrease Low Birth Weight and/or Prematurity**

Delay childbearing in young adolescents

Promote maternal education

Improve maternal nutrition: caloric supplementation before and during pregnancy

Reduce tobacco use

Diagnose and treat sexually transmitted diseases

Malaria prophylaxis and treatment

Limit maternal work load during pregnancy

Maternal support to decrease stress/anxiety

**Community-Based Interventions**

Train birth attendants to identify problems in the newborn, treat simple problems, refer newborns with serious illness

Promote and support breast-feeding (HIV dilemma noted)

Maternal education regarding personal and domestic hygiene, newborn care, childhood immunization

Home-based diagnosis and treatment of newborn infections

**Early Identification and Improved Treatment of Neonates with Infection**

Integrated approach to the sick young infant (WHO/UNICEF)

Improve newborn care at all levels: home, village, health center, district hospital, referral hospital

**Neonatal Immunization**

Bacillus Calmette-Guérin, hepatitis B, other new vaccines (e.g., rotavirus)

HIV, human immunodeficiency virus; UNICEF, United Nations Children's Fund; WHO, World Health Organization.  
Data updated from Stoll BJ. The global impact of neonatal infection. *Clin Perinatol* 24:1, 1997.

immunization and subsequent passive immunization to protect the newborn. Because most IgG antibody is transported across the placenta in the last 4 to 6 weeks of pregnancy, maternal immunization to prevent neonatal disease through transplacental antibodies is most promising for term newborns, who will have adequate antibody levels at birth. By contrast, this strategy will be less successful for preterm infants because of insufficient passage of maternal antibodies. Boosting breast milk antibodies by immunizing the mother is a potential strategy for reducing infection in both term and preterm infants. Vaccines being currently developed or field tested to reduce or prevent neonatal infection by passive immunization include vaccines against GBS, *S. pneumoniae*, and *Haemophilus influenzae*.<sup>368-377</sup>

Because most neonatal GBS disease—especially the most severe—occurs in the first hours of life, maternal immunization to provide passive protection to the neonate is a potentially important strategy. A problem with GBS vaccines has been poor immunogenicity. Studies performed in the last decade have focused on the immunogenicity of polysaccharide-protein conjugate vaccines and suggest that

conjugate vaccines may be highly effective in pregnant women.<sup>369</sup> Published data suggest that candidate GBS polysaccharide-tetanus toxoid conjugates are safe in adults and elicit antibody levels above what is likely to be passively protective for neonates.<sup>370,371</sup> Multivalent vaccines, which could provide protection against multiple GBS serotypes, are particularly promising.<sup>372</sup>

Pneumococcal polysaccharide vaccines have been administered safely to pregnant women.<sup>373,374</sup> One study from Bangladesh reported that pneumococcal vaccination during pregnancy increased type-specific IgG serum antibody in both mother and infant.<sup>373</sup> Cord blood levels of antibody were about half those of the mother, with IgG1 subclass antibodies preferentially transferred to the infant. The estimated antibody half-life in the infant was 35 days. Immunization increased breast milk antibody as well. However, in a study of the 23-valent pneumococcal vaccine given to women before pregnancy, neither mothers nor infants had significantly elevated pneumococcus-specific antibody at delivery.<sup>375</sup> If passive immunization does not interfere with active immunization of young infants, vaccination of

pregnant women could potentially be used to prevent pneumococcal disease in early infancy. The recent finding from the WHO Young Infant Study that *S. pneumoniae* is an important cause of sepsis and meningitis in young infants<sup>151</sup> supports the continued investigation of maternal immunization with pneumococcal vaccines as a prevention strategy for developing countries.

In developed countries, invasive disease resulting from *H. influenzae* type b (HIB) has been almost completely eliminated by the use of HIB conjugate vaccines.<sup>378</sup> However, in many parts of the world, HIB remains an important cause of life-threatening infections in infancy, particularly pneumonia and meningitis. Although HIB infection is rare in the neonatal period, approximately 40% of cases of HIB disease in developing countries occur in infants younger than 6 months of age.<sup>379,380</sup> Both neonatal and maternal immunization strategies are being explored to target populations in which HIB infections occur in young infants.<sup>367,376,377</sup> A study from The Gambia<sup>376</sup> showed that maternal immunization with HIB polysaccharide–tetanus protein conjugate vaccine increased both maternal and neonatal antibody concentrations. At 2 months of age, 60% of infants of vaccinated mothers had antibody concentrations considered to be protective. Similar results were found in a study of native American women immunized with HIB conjugate vaccines before pregnancy. Significant antibody elevations were detected at birth in infants born to these women.<sup>375</sup>

Additional studies of the safety, efficacy, and effectiveness of immunizing pregnant women with specific vaccines are needed. They must address issues of safety to the mother, fetus, and young infant. Furthermore, they must assess protection against specific diseases (e.g., sepsis, pneumonia, meningitis) as well as protection against all causes of neonatal and infant mortality. The subsequent response of the infant to active immunization also must be evaluated, to ensure that passive immunization does not interfere with the infant's ability to mount an immune response. Therefore, in developing countries, studies must be carried out in settings in which it is possible to maintain surveillance throughout infancy.

## Neonatal Immunization

Protection of young infants against vaccine-preventable diseases requires vaccines that are immunogenic in early life.<sup>381</sup> A number of vaccines are currently given to newborns or young infants: bacillus Calmette–Guérin (BCG), hepatitis B, polio, diphtheria, tetanus, pertussis, and HIB. The BCG vaccine, developed early in this century, is a live attenuated strain of *Mycobacterium bovis*. The WHO promotes the use of BCG in newborns to prevent TB, and this vaccine is widely used in developing countries in which TB is a common and potentially lethal disease. Although approximately 3 billion doses have been given, the efficacy of this vaccine is still debated. Vaccine efficacy in many prospective trials and case-control studies of vaccine use at all ages ranges from possibly harmful to 90% protective.<sup>382</sup> One meta-analysis of BCG studies in newborns and infants concluded that the vaccine was effective and reduced infection in children by more than 50%.<sup>383</sup> BCG reduced the risk of pulmonary TB, TB meningitis, disseminated TB, and death from TB. Factors that may explain the variability of responses to BCG vac-

nation in different studies and populations include use of a wide variety of vaccine preparations, regional differences in environmental flora that may alter vaccine response, and population differences.<sup>367</sup> The safety of BCG in immunocompromised patients (e.g., those with HIV infection) is unclear.

Hepatitis B vaccination of newborns has proved that neonatal immunization can prevent neonatal infections and their sequelae.<sup>384</sup> Studies from both developed and developing countries have shown that hepatitis B vaccine administered in the immediate newborn period can significantly reduce the rate of neonatal infection and the development of a chronic hepatitis B surface antigen (HB<sub>s</sub>Ag) carrier state.<sup>385</sup> The efficacy of vaccine alone (without hepatitis B immune globulin [H-BIG]) has allowed developing countries that cannot screen pregnant women and do not have H-BIG to make a major impact in reducing the infection of newborns. Recently, the WHO recommended that all countries add hepatitis B vaccine to their routine childhood immunization programs.<sup>386</sup> In addition, studies of neonatal immunization with polio vaccine, HIB conjugate vaccines, and pneumococcal conjugate vaccines suggest some protection with neonatal vaccination that might reduce but not eliminate disease.<sup>367</sup>

Rotavirus diarrhea is a major killer of young infants in developing countries, causing approximately 800,000 childhood deaths per year. The development of a live oral quadrivalent rhesus rotavirus vaccine, which has been shown to be highly effective in young infants, particularly at preventing severe disease, is exciting and potentially very important.<sup>387</sup> Additional studies in developing countries are needed before rotavirus vaccines can be added to routine childhood vaccination programs. The quadrivalent rhesus rotavirus vaccine, highly effective in preventing severe disease in Venezuelan children,<sup>388</sup> has never been tested in African or Asian children. Factors that might influence efficacy in developing countries include younger age at infection, potentially larger viral inoculum, presence of different or unusual strains of rotavirus, and poorer nutritional status.<sup>289</sup> Unlike children in developed countries, those in developing countries experience most severe episodes of rotavirus diarrhea in the first year of life. Vaccines will need to be delivered early—perhaps at birth. Further studies on the safety and efficacy of rotavirus vaccine in neonates are needed.<sup>294,387</sup>

With the global problem of increasing antibiotic resistance, maternal and neonatal immunization have become even more important strategies to pursue. In developing countries, issues of vaccine cost, availability, and efficacy in the field are particularly pressing and are major barriers to the use of vaccines that are known to be safe and effective in developed countries. Efforts to reduce vaccine cost by studying lower doses of vaccine and use of single-dose vials for multiple-dose use are promising.<sup>389</sup> Ultimately, the reduction of vaccine cost is in the hands of vaccine manufacturers.

## Antenatal Care and Prevention of Neonatal Infection

The care and general well-being of the mother are inextricably linked to the health of her newborn. Antenatal care can play an important role in the prevention or reduction of neonatal infections.<sup>390</sup> Both preventive and curative interventions directed toward the mother can have

beneficial effects on the fetus or newborn or both. Tetanus immunization of the pregnant woman is an essential component of any developing country's antenatal care program and, as discussed earlier, will prevent neonatal tetanus.<sup>365,391</sup> The diagnosis and treatment of STDs—especially syphilis, gonorrhea, and chlamydial infection—can have a significant impact on neonatal morbidity and mortality.<sup>186,188</sup> In areas of the world in which syphilis is endemic, congenital syphilis may be a major cause of neonatal morbidity and mortality.<sup>392</sup> Antenatal treatment of gonorrhea and chlamydial infection can prevent neonatal infection with these agents—ophthalmia neonatorum (for gonorrhea and chlamydial infection), disseminated gonorrhea, and neonatal respiratory disease (for chlamydial infection).<sup>186,188</sup> Moreover, STDs and maternal urinary tract infection increase the mother's risk of puerperal sepsis, with its associated increased risk of neonatal sepsis. In malaria-endemic areas, treatment of maternal malaria can have an impact on newborn health, particularly through a reduction in the incidence of low birth weight.<sup>393</sup>

Antenatal care also is an important setting for maternal education regarding danger signs during pregnancy, labor, and delivery—especially maternal fever, prolonged or premature rupture of the membranes, and prolonged labor—and danger signs to watch for in the newborn. Moreover, it is the time and place for the mother to plan where and by whom she will be delivered and for the health care worker to stress the importance of a clean delivery, preferably with a trained skilled birth attendant.

### Intrapartum and Delivery Care and Prevention of Neonatal Infection

It is universally recognized that poor aseptic techniques during labor and delivery, including performing procedures with unclean hands and unclean instruments and unhygienic cutting of the umbilical cord, are major risk factors for both maternal and neonatal infections.<sup>390</sup> It is essential to promote safe and hygienic practices at every level of the health care system where women deliver (i.e., home, health center, district or referral hospital). Proper management of labor and delivery can have a significant impact on the prevention of neonatal infection. It is important to emphasize the need for clean hands, clean perineum, clean delivery surface, clean instruments, clean cord care, use of an appropriate clean delivery kit, avoidance of harmful traditional practices, prevention of unnecessary vaginal examinations, prevention of prolonged labor, and optimal management of pregnancy complications including prolonged rupture of the membranes, maternal fever, and chorioamnionitis/puerperal sepsis.<sup>5</sup>

If the mother does develop a puerperal infection, the newborn requires special attention and should be treated for presumed sepsis.<sup>390</sup> Prolonged rupture of the membranes, maternal fever during labor, and chorioamnionitis are particular risk factors for early-onset neonatal sepsis and pneumonia in both developed and developing countries.<sup>394-396</sup> Ideally, high-risk infants who are born at home should be referred to the nearest health care facility for observation and antibiotic therapy. In practice, this may be either impossible or unacceptable to the family, and ways to deliver care to the mother and the newborn in the home must be

developed and evaluated. The traditional birth attendant or other health care worker who attends the birth has a critical role to play in the early health of the newborn.

### Breast-Feeding

The promotion of early and exclusive breast-feeding is one of the most important interventions for the maintenance of newborn health and the promotion of optimal growth and development.<sup>5</sup> Breast-feeding is especially important in developing countries, where safe alternatives to breast milk are often unavailable or too expensive. Moreover, poor hygiene and a lack of clean water and clean feeding utensils make artificial formula an important vehicle for the transmission of infection. Breast milk has many unique anti-infective factors, including secretory IgA antibodies, lysozyme, and lactoferrin. In addition, breast milk is rich in receptor analogues for certain epithelial structures that microorganisms need for attachment to host tissues, an initial step in infection.<sup>397</sup> Many studies performed in the 1980s and 1990s have shown that breast-feeding reduces the risk of infectious diseases, including neonatal sepsis, diarrhea, and possibly respiratory tract infection.<sup>283,398-402</sup> Moreover, there is evidence that breast-feeding protects against infection-related neonatal and infant mortality.<sup>403-406</sup>

The HIV epidemic has raised questions about the safety of breast-feeding in areas in which there is a high prevalence of HIV infection among lactating women.<sup>225-233,241,407</sup> HIV may be transmitted through breast-feeding. A major question for any setting is whether the benefits of breast-feeding outweigh the risk of postnatal transmission of HIV through breast milk.<sup>407</sup> For many areas of the world, where infectious diseases, especially diarrheal diseases, are a primary cause of infant death, breast-feeding, even when the mother is HIV infected, remains the safest mode of infant feeding. Countries with high and low reported rates of exclusive breast-feeding are listed in Table 2-12.<sup>316</sup>

Table 2-12 Breast-Feeding Rates in Developing Countries<sup>a,b</sup>

Exclusive Breast-Feeding Rates of 10% or Less		Exclusive Breast-Feeding Rates of 50% or More	
Country	%	Country	%
Niger	1	Rwanda	90
Nigeria	2	Burundi	89
Angola	3	Ethiopia	74
Côte d'Ivoire	3	Tanzania	73

### Maternal Education and Socioeconomic Status

Maternal education, literacy, and overall socioeconomic status are powerful influences on the health of both mother and newborn.<sup>408-411</sup> Education of girls must be promoted and expanded so that women of reproductive age know enough to seek preventive services, understand the implications of danger signs during labor and delivery and in their newborns, and recognize that they must obtain referral care for obstetric or newborn complications, or both. Improvements in education and socioeconomic status are obviously linked. They may affect child health by allowing the mother a greater voice in the family with greater decision-making power, making her better informed about domestic hygiene, disease prevention, or disease recognition, or enhancing her ability to seek medical attention outside the home and to comply with medical advice.

### Low Birth Weight and Prematurity

Low birth weight (2500 g or less) constitutes a major public health problem. Worldwide, approximately 90% of LBW infants are born in developing countries.<sup>412</sup> Low birth weight is caused by impaired fetal growth, shortened gestation, or a combination of both. In developing countries, low birth weight is caused more frequently by intrauterine growth retardation than by prematurity.<sup>332,412</sup> Data suggest that both preterm and LBW infants are at increased risk for infection and infection-related mortality.<sup>413-415</sup> Therefore, strategies to reduce the frequency of low birth weight and prematurity could have a measurable impact on neonatal infection. Potential interventions to improve intrauterine growth or to lengthen gestation, or both, include delaying childbearing in adolescents, improved maternal education, caloric supplementation before and during pregnancy, general improvements in nutrition, malaria prophylaxis or treatment, treatment of STDs and other maternal infections, efforts to reduce tobacco use, improved water and sanitation, limitation of maternal work during pregnancy, and general improvement in socioeconomic conditions.<sup>332</sup>

### Community-Based Interventions

In parts of the world in which a majority of births occur at home, primary health care at the village level will need to put added emphasis on care of the newborn. The birth attendant is responsible for observation of the newborn at and after birth and deciding that the newborn is healthy and ready to be “discharged” to the care of the mother. It is important to link postpartum care of the mother with surveillance and care of the newborn. The postpartum visit should be used to detect and treat the sick newborn as well as to evaluate the mother. Birth attendants need to be trained to identify problems in the newborn, to treat simple problems (e.g., skin infections), and to refer those that are potentially life-threatening (e.g., suspected sepsis). Moreover, they should provide all new mothers with breast-feeding support and give advice regarding personal hygiene/cleanliness and other prevention strategies such as immunization. Improvement in domestic hygiene should be encouraged, including sanitary disposal of wastes, use of clean water, and hand washing, so that the newborn enters a clean home and is less likely to encounter pathogenic organisms. In some settings,

families will refuse to take even a sick newborn to a hospital, and care will need to be brought into the village or home. Community interventions need to be designed and modified to meet the needs of mothers and newborns in different settings in different countries and need further evaluation.

### Early Identification and Improved Treatment of Neonates with Infection

If untreated, infections in newborns can rapidly become severe and life-threatening. Therefore, early identification and appropriate treatment of newborns with infection are critical to survival. In developing countries, where access to care may be limited, diagnosis and treatment are particularly difficult. It is important to recognize maternal and neonatal factors that increase risk of infection in the newborn. These include maternal infections during pregnancy (STDs, urinary tract infection, others), premature or prolonged rupture of membranes, prolonged labor, fever during labor, unhygienic obstetric practices or cord care, poor hand-washing practices, low birth weight/prematurity, artificial feeding, and generally unhygienic living conditions.<sup>2-4</sup>

In areas without sophisticated technology and the diagnostic help of laboratory tests and x-ray studies, treatment decisions must be made on the basis of the history and findings on physical examination. In the WHO Young Infant Study, clinical predictors of neonatal sepsis were studied in more than 3000 sick infants younger than 2 months of age in Ethiopia, The Gambia, Papua New Guinea, and the Philippines.<sup>416</sup> In multivariable analysis, 14 signs were independent predictors of severe disease: reduced feeding ability, absence of spontaneous movement, temperature greater than 38°C, drowsiness or unconsciousness, a history of a feeding problem or change in activity, state of agitation, the presence of lower chest indrawing (retractions), respiratory rate greater than 60, grunting, cyanosis, a history of convulsions, a bulging fontanel, and slow digital capillary refill. The presence of any one of these signs had a sensitivity for severe disease (sepsis, meningitis, hypoxemia, or radiologically proven pneumonia) of 87% and a specificity of 54%.

Mothers, birth attendants, and other health care workers and family members must be educated so that they can identify danger signs in the newborn and understand that prompt and appropriate therapy may make the difference between life and death. The positive deviance (PD) approach involves investigating children (in this case newborns) with healthy outcomes despite adverse conditions, identifying model practices among successful families, and designing an intervention to transfer these behaviors to other mothers and families. Save the Children has studied the PD approach in newborns in Pakistan. In-depth interviews were conducted to identify common behaviors among parents of surviving asphyxiated newborns, thriving LBW babies, surviving newborns who demonstrated danger signs, and normal newborns. PD families had better maternal care, better routine and special newborn care, and better care-seeking behavior.<sup>417</sup> A study from Sri Lanka, a developing country with relatively low neonatal and infant mortality rates, identified a high level of care-seeking behavior among mothers, particularly for illnesses with acute, high-risk danger signs.<sup>418</sup>

An integrated approach to the sick child, including the young infant, has been developed by the WHO and

UNICEF.<sup>419</sup> This strategy promotes prompt recognition of disease, appropriate therapy using standardized case management, referral of serious cases, and prevention through improved nutrition (breast-feeding of the neonate), and immunization. This approach stresses diagnosis using simple clinical signs that can be taught to health care workers at all levels. The health care worker assesses the child by questioning the mother and examining the child, classifies the illness as serious or not, and determines if the infant needs urgent treatment and referral, specific treatment and advice, or only simple advice and home management. Importance of breast-feeding is stressed, and follow-up instructions are given. All young infants are checked for specific danger signs that equate with need for emergency care and urgent referral. Because the signs of serious bacterial infection in the newborn are not easily recognized, every young infant with danger signs is given treatment for a possible bacterial infection. All newborns with suspected severe infection receive antibiotics as soon as possible and are then referred for hospitalization. In situations where referral is impossible or unacceptable to the family, community-based interventions must be designed, implemented, and evaluated.

## CONCLUSION

The 1996 World Health Report<sup>420</sup> highlights the global importance of infectious diseases, especially among young children, and stresses the impact of new or emerging diseases. Neonatal infections are old diseases. Furthermore, each infection-related death should be considered a potentially preventable death. What is needed is a new recognition that they are important causes of morbidity and mortality and that simple interventions are available that can have a significant impact on reducing the incidence of both infection and death related to infection in developing countries.

Special Situations  
Treatment of Term Premature Rupture of Membranes

Early-onset neonatal infection often has its origin in utero. Thus, risk factors for neonatal sepsis include prematurity, premature rupture of the membranes (PROM), and maternal fever during labor (which may be caused by clinical intra-amniotic infection). This chapter focuses on these major obstetric conditions. Included in addition to these three “classic” topics is a discussion of new information indicating that intrauterine exposure to bacteria is linked to major neonatal sequelae, including cerebral palsy, bronchopulmonary dysplasia (BPD), and respiratory distress syndrome (RDS).

## INTRA-AMNIOTIC INFECTION

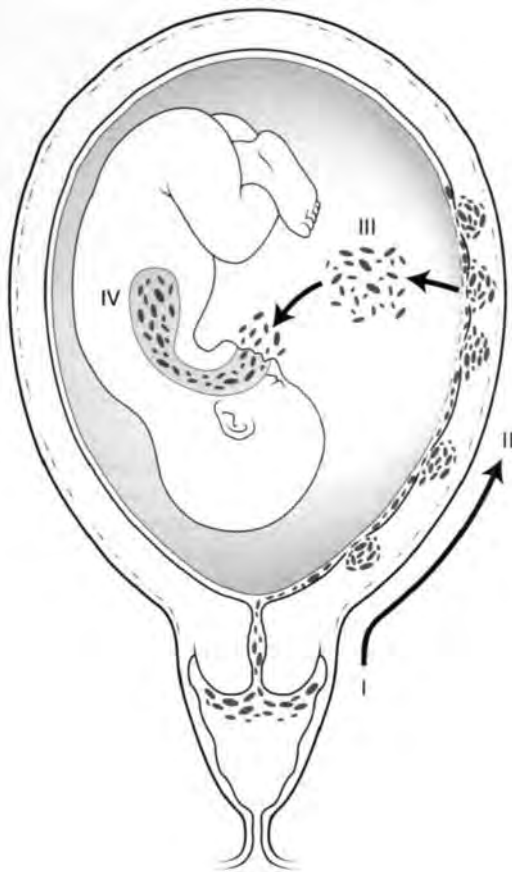

Clinically evident intrauterine infection during the latter half of pregnancy develops in 1% to 10% of pregnant women

and leads to increased maternal morbidity as well as perinatal mortality and morbidity. In general, the diagnosis is clinically based on the presence of fever and other signs and symptoms, such as maternal or fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, and maternal leukocytosis. Although not invariably present, rupture of the membranes or labor also occurs in most cases. Some prospective reports have noted higher rates (4.2% to 10.5%)<sup>1-3</sup> than in older retrospective studies (1% to 2%).<sup>4</sup> A number of terms have been applied to this infection, including *chorioamnionitis*, *intrapartum infection*, *amniotic fluid infection*, and *intra-amniotic infection* (IAI). We use the last designation to distinguish this clinical syndrome from bacterial colonization of amniotic fluid (also referred to as “microbial invasion of the amniotic cavity”) and from histologic inflammation of the placenta (i.e., histologic chorioamnionitis).

## Pathogenesis

Before labor and membrane rupture, amniotic fluid is nearly always sterile. With the onset of labor or with membrane rupture, bacteria from the lower genital tract usually enter the amniotic cavity. This ascending route is the most common pathway for development of IAI.<sup>4</sup> In 1988, Romero and co-workers described four stages of ascending intra-uterine infection (Fig. 3-1). Shifts in vaginal or cervical flora and the presence of pathologic bacteria in the cervix represent stage I. Bacterial vaginosis may also be classified as stage I. In stage II, bacteria ascend from the vagina/cervix into the decidua, the specialized endometrium of pregnancy. The inflammatory response here allows organisms to invade the amnion and chorion leading to chorioamnionitis. In stage III, bacteria invade chorionic vessels (choriovasculitis) and migrate through to the amnion into the amniotic cavity to cause IAI. Once in the amniotic cavity, bacteria may gain access to the fetus through several potential mechanisms, culminating in stage IV; fetal bacteremia, sepsis, and pneumonia may result.<sup>5</sup>

Occasional instances of documented IAI in the absence of rupture of membranes or labor support a presumed hematogenous or transplacental route of infection. Fulminant IAI without labor and without rupture of membranes may be caused by *Listeria monocytogenes*.<sup>6-10</sup> Maternal sepsis due to this organism often manifests as maternal flulike illness and may result in death of the fetus. In an outbreak caused by “Mexican-style” cheese contaminated with *Listeria*, several maternal deaths occurred.<sup>11</sup> Other virulent organisms, such

**Figure 3-1** The stages of ascending infection. (From Romero R, Mazor M. Infection and preterm labor: pathways for intrauterine infections. *Clin Obstet Gynecol* 31:558, 1988.)

as group A streptococci, also have been the cause of transplacental infection.<sup>12</sup> IAI may develop less commonly as a consequence of obstetric procedures such as cervical cerclage, diagnostic amniocentesis, cordocentesis (percutaneous umbilical cord blood sampling), or intrauterine transfusion. The absolute risk is small with all of these procedures: IAI develops in 2% to 8% of patients after cerclage,<sup>13-16</sup> in less than 1% of patients after amniocentesis,<sup>17</sup> and in 5% of patients after intrauterine transfusion.<sup>18</sup> Higher risks are encountered, however, when cerclage is performed when the cervix is dilated and effaced.

Two large studies of risk factors for IAI identified characteristics of labor as the major risk factors by logistic regression analysis. These features included low parity, increased number of vaginal examinations in labor, as well as increased duration of labor, membrane rupture, and internal fetal monitoring.<sup>3,4</sup> More recently, risk factors for IAI have been stratified for term versus preterm pregnancies.<sup>19</sup> For patients at term with IAI, the study investigators observed, by logistic regression analysis, that the independent risk factors were membrane rupture for longer than 12 hours (odds ratio [OR] 5.81), internal fetal monitoring (OR 2.01), and more than four vaginal examinations in labor (OR 3.07). For preterm pregnancies, these three risk factors were again identified as being independently associated with IAI, but with differing ORs. Specifically, in the preterm pregnancies, membrane rupture for longer than 12 hours was associated

with an OR of 2.49; for internal fetal monitoring, the OR was 1.42; and for more than four examinations, the OR was 1.59. One interpretation of these data regarding risk factors among preterm pregnancies is that there was some other risk factor not detected in this survey. Additionally, meconium staining of the amniotic fluid has been associated with an increased risk of chorioamnionitis (4.3% versus 2.1%).<sup>20</sup> Prior spontaneous and elective abortion (at less than 20 weeks) in the immediately preceding pregnancy has also been associated with development of IAI in the subsequent pregnancy (OR 4.3 and 4.0, respectively).<sup>21</sup>

In 1996, a multivariable analysis demonstrated quantitatively the importance of chorioamnionitis in neonatal sepsis.<sup>22</sup> The OR for neonatal sepsis accompanying clinical chorioamnionitis was 25, whereas for preterm delivery, membrane rupture for longer than 12 hours, endometritis, and group B streptococcal colonization, the ORs all were less than 5. Epidural anesthesia has been associated with fever in labor (independent of infection).<sup>23</sup> This knowledge must be considered in determining the etiology of fever in a patient who has an epidural anesthetic in place.

Although Naeye had reported an association between recent coitus and development of chorioamnionitis defined by histologic study,<sup>24</sup> further analysis of the same population refuted this association.<sup>25</sup> Other studies have not demonstrated any relationship between coitus and PROM, premature birth, or perinatal death.<sup>26</sup>

## Microbiology

The cause of IAI is often polymicrobial. Gibbs and colleagues reported a microbiologic case-control study of amniotic fluid from 52 patients with clinical IAI.<sup>27</sup> The following organisms were found in the amniotic fluid from patients with IAI: *Bacteroides* species, 25%; group B streptococci, 12%; other aerobic streptococci, 13%; *Escherichia coli*, 10%; other aerobic gram-negative rods, 10%; *Clostridium* species, 9%; *Peptococcus* species, 7%; and *Fusobacterium* species, 6%. The mean number of bacterial isolates in patients with IAI was 2.2. For the 52 patients with clinical IAI, aerobes and anaerobes were isolated from 48%; aerobes only from 38%; anaerobes alone from 8%; and no aerobes or anaerobes from 6%. Cultures of amniotic fluid from patients with IAI were more likely to have more than 10<sup>2</sup> colony-forming units (CFUs) of any isolate per milliliter, any number of high-virulence isolates, and more than 10<sup>2</sup> CFUs/mL of high-virulence isolates. Only 8% of these cultures from control patients had 10<sup>2</sup> CFUs/mL or more of high-virulence isolates. The isolation rate of low-virulence organisms, such as lactobacilli, diphtheroids, and *Staphylococcus epidermidis*, was similar in both the IAI and the control groups. In smaller studies, a similar spectrum of organisms was reported.<sup>13,28</sup> *Neisseria gonorrhoeae* was not isolated in any of these studies, but it appears to be an infrequent cause of amnionitis.<sup>29,30</sup>

A role for genital mycoplasmas has been suggested by case reports describing their isolation from amniotic fluid of clinically infected patients and by epidemiologic studies showing an association between the isolation of *Mycoplasma hominis* or *Ureaplasma* and placental inflammation.<sup>31,32</sup> Unfortunately, these latter studies did not demonstrate correlation of isolation of genital mycoplasmas with clinical infection in the mother or neonate. In a controlled study of

IAI, Blanco and co-workers reported that 35% of cultures of amniotic fluid from patients with IAI yielded *M. hominis*, whereas only 8% of matched control cultures showed *M. hominis* ( $P < .001$ ).<sup>33</sup> *Ureaplasma urealyticum* was isolated from amniotic fluid from 50% of the infected and uninfected patients. In a subsequent study, Gibbs and colleagues found *M. hominis* in the blood of 2% of women with IAI and reported a serologic response in 85% of women with IAI who also had *M. hominis* in the amniotic fluid.<sup>34</sup> This rate of serologic response was significantly higher than that in asymptomatic control women or in infected women without *M. hominis* in the amniotic fluid ( $P < .001$ ).<sup>34</sup> Cultures of blood and serologic results did not clarify the role of *U. urealyticum*. Thus, the pathogenic potential of *M. hominis* is high in IAI, but the pathogenic status of *U. urealyticum* is unclear in this infection.

Data related to the role of *Chlamydia trachomatis* in infections of amniotic fluid are in conflict. Martin and co-workers prospectively studied perinatal mortality in women whose pregnancies were complicated by antepartum maternal chlamydial infections.<sup>35</sup> Two of the six fetal deaths in the *Chlamydia*-positive group were associated with chorioamnionitis compared with one of eight in the control group. Wager and colleagues showed that the rate of occurrence of intrapartum fever was higher in patients with antepartum *C. trachomatis* infection (9%) than in patients without *C. trachomatis* isolated from the cervix (1%).<sup>36</sup> The data are interesting but must be interpreted with caution because of the limited number of patients and because the control group may not have been sufficiently similar to the infected group. Furthermore, *C. trachomatis* has not been isolated from amniotic cells or placental membranes of patients with IAI.<sup>37,38</sup> In a preliminary study, no difference was found in the rate of serologic response to *C. trachomatis* in women with IAI compared with that in asymptomatic women.<sup>39</sup>

In a large prospective study, Sperling and colleagues reported amniotic fluid culture results from 408 cases of IAI.

The most commonly isolated organisms were *U. urealyticum* (47%), *M. hominis* (31%), *Prevotella bivia* (29%), *Gardnerella vaginalis* (24%), group B streptococci (15%), anaerobic streptococci (9%), *E. coli* (8%), *Fusobacterium* species (6%), enterococci (5%), and other aerobic gram-negative rods (5%).<sup>40</sup> A summary of representative data for five microbiologic studies is given in Table 3-1. Because of differences among these studies in microbiologic and collection techniques and in reporting format for isolates, Table 3-2 is meant to show broad, overall results.

Evidence has shown that maternal bacterial vaginosis is causally linked to IAI.<sup>41</sup> The evidence may be categorized as follows: (1) the microorganisms in bacterial vaginosis and in chorioamnionitis are similar; (2) bacterial vaginosis is

**Table 3-1 Microbes Isolated in Amniotic Fluid from Cases of Intra-amniotic Infection: A Summary of Studies**

Microbe	Representative % Isolated
<b>Genital Mycoplasmas</b>	
<i>Ureaplasma urealyticum</i>	47-50
<i>Mycoplasma hominis</i>	31-35
<b>Anaerobes</b>	
<i>Prevotella bivia</i>	11-29

**Table 3-2 Comparative Studies of Intrapartum versus Postpartum Maternal Antibiotic Therapy in Treatment of Intra-amniotic Infection**

Author, Year	Design/Setting	No. of Patients	Maternal Intrapartum Antibiotic Regimen	Benefits of Intrapartum Treatment
Sperling et al, <sup>73</sup> 1987	Retrospective/public teaching hospital in San Antonio, Texas	257	Penicillin G plus gentamicin IV	NNS reduced from 19.6% in postpartum treatment group to 2.8% in intrapartum treatment group ( $P = .001$ )
Gilstrap et al, <sup>75</sup> 1988	Retrospective/public teaching hospital in Dallas, Texas	273	Varied <sup>a</sup>	NNS reduced from 5.7% in postpartum treatment group to 1.5% in intrapartum treatment group ( $P = .06$ ); group B streptococcal bacteremia reduced from 5.7% to 0% ( $P = .004$ )
Gibbs et al, <sup>74</sup> 1988	Randomized clinical trial/same as Sperling (1987)	45	Ampicillin plus gentamicin IV	NNS reduced from 21% to 0%; maternal morbidity also decreased ( $P = .05$ )

<sup>a</sup>Antibiotic regimens noted as 47% received ampicillin or penicillin in combination with gentamicin and clindamycin; 22%, ampicillin or penicillin with gentamicin; 20%, cefoxitin; and 11%, other antibiotics. IV, intravenously; NNS, neonatal sepsis confirmed by blood culture.

associated with the isolation of organisms in the chorioamnion; and (3) bacterial vaginosis is associated with development of clinical chorioamnionitis in selected populations.<sup>42-44</sup> It has been demonstrated that treatment of bacterial vaginosis in high risk populations prenatally decreases the risk of chorioamnionitis and other pregnancy outcomes.<sup>47</sup> However, in the large Maternal Fetal Medicine Units Network trial, screening and treatment did not lead to benefit either in the overall patient population or in the secondary analysis of women with prior preterm birth.<sup>48</sup> Subsequently, an American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin on assessment of risk factors for preterm birth advocated that screening and treating of either high- or low-risk women would not be expected to reduce the overall rate of preterm birth.<sup>49</sup> However, in select populations of high-risk women such as those with prior preterm birth and bacterial vaginosis early in pregnancy, we still recommend treatment of those women.

Amniotic fluid cultures from cases of intra-amniotic infection accompanying a low-birth-weight infant are more likely to contain the anaerobic organism *Fusobacterium* (21.6% versus only 3.8% in non-low-birth-weight cases,  $P < .001$ ) and *P. bivia* (46% versus 28%,  $P = .035$ ). There were no significant differences, however, in the isolation rates of group B streptococci, *E. coli*, other aerobes, or genital mycoplasmas between cases from low-birth-weight and non-low-birth-weight infants.<sup>40</sup>

Bloodstream isolates from newborns in 408 cases of IAI were reported as follows: *E. coli*, 5 cases; group B streptococci, 4 cases; *Staphylococcus aureus*, 2 cases; enterococci, 2 cases; other streptococci, 3 cases; and 1 case each for *Enterobacter* species, *Haemophilus influenzae*, *Haemophilus parainfluenzae*, and microaerophilic streptococci.<sup>40</sup> Thus, of 20 isolates, group B streptococci and *E. coli* accounted for 45% of isolates, even though these organisms were present in the amniotic fluid of just 20% of cases.

The role of viruses in causing IAI is less well delineated. Yankowitz and associates evaluated fluid from 77 mid-trimester genetic amniocentesis by polymerase chain reaction (PCR) assay for the presence of adenovirus, enterovirus, respiratory syncytial virus (RSV), Epstein-Barr virus (EBV), parvovirus, cytomegalovirus (CMV), and herpes simplex virus (HSV). Six samples were positive (three adenovirus, one parvovirus, one CMV, and one enterovirus), and two resulted in pregnancy loss, one at 21 weeks (adenovirus) and one at 26 weeks (CMV).<sup>50</sup>

## Diagnosis

Diagnosis of IAI requires a high index of suspicion because the clinical signs and symptoms may be subtle. Moreover, usual laboratory indicators of infection, such as positive stains for organisms or leukocytes and positive culture results, are found more frequently than is clinically evident infection. Microorganisms are easily grown in culture from the amniotic fluid or chorioamniotic membranes using standard techniques. Cassell and colleagues demonstrated positive cultures from the chorioamniotic space twice as frequently as from the intra-amniotic space (20% versus 9%), lending further support to the theory that microorganisms ascend from the vagina through the chorioamniotic space to gain access to the amniotic cavity and then the fetus.<sup>51</sup>

The rate of positive amniotic fluid cultures for microorganisms is higher with preterm PROM (32.4%) than with preterm labor with intact membranes (12.8%).<sup>52</sup>

Rates of IAI are probably underestimated with preterm PROM, because severe oligohydramnios may preclude sampling success. Additionally, women in labor on hospital admission generally are not sampled but have been shown to have higher rates of microbial invasion of the amniotic cavity at (39%) than those in women not in labor (25%). When they do enter labor, the risk of microbial invasion of the amniotic cavity is still higher at 75%.<sup>53</sup>

Clinical diagnosis of IAI usually is based on maternal fever, maternal or fetal tachycardia, uterine tenderness, foul odor of amniotic fluid, and leukocytosis. Other causes of fever in the parturient patient include epidural analgesia, concurrent infection of the urinary tract or other organ systems and perhaps dehydration, illicit drug use and other rare conditions. The differential diagnosis of fetal tachycardia consists of prematurity, medications, arrhythmias, and hypoxia, whereas for maternal tachycardia other possible causes are drugs, hypotension, dehydration, and anxiety as well as intrinsic cardiac conditions, hypothyroidism, as well as pulmonary embolism. In general, the most common clinical and laboratory criteria for diagnosis of IAI are fever, leukocytosis, and ruptured membranes; fetal tachycardia and maternal tachycardia are noted in a variable percentage of cases.<sup>1,45,46</sup> Foul-smelling amniotic fluid and uterine tenderness, although more specific signs, occur in a minority of the cases. Bacteremia occurs in less than 10% of cases. Because peripheral blood leukocytosis is common during normal labor, this result does not always indicate infection. As a predictor of IAI, leukocytosis (white blood cell counts greater than 12,000/mm<sup>3</sup>) had a sensitivity of 67%, specificity of 86%, positive predictive value of 82%, and negative predictive value of 72%.<sup>54</sup>

Direct examination of the amniotic fluid may provide important diagnostic information. Samples can be collected transvaginally by aspiration of an intrauterine pressure catheter, by needle aspiration of the forewaters, or by amniocentesis. Outside of research protocols, transabdominal amniocentesis is the most common technique.

There is a significant association between detecting white blood cells or bacteria in a stain of uncentrifuged amniotic fluid and clinical infection.<sup>27,55</sup> In a case-control study, white blood cells were seen on smear in 67% of cases of IAI and in only 12% of controls ( $P = .001$ ). Bacteria were seen on smear in 81% of cases of IAI and in 29% of controls ( $P < .001$ ).<sup>27</sup> With suspected IAI, detection of bacteria or white blood cells on a smear of uncentrifuged fluid supports the diagnosis, but there are frequent false-positive and false-negative results.

Several other recent tests of amniotic fluid have been evaluated as predictors of IAI. In a small case-control study, Hoskins and co-workers found that the leukocyte esterase test showed excellent performance (91% sensitivity, 95% specificity, and 95% positive and 91% negative predictive values) when the clinical diagnosis of chorioamnionitis was used as the gold standard.<sup>54</sup> Low concentrations of amniotic fluid glucose (variably reported at less than 10 to 20 mg/dL) are strongly associated with positive amniotic fluid culture and less strongly associated with clinical IAI.<sup>56-58</sup>

Recently, attention has been directed to proinflammatory cytokines as markers of IAI. During the course of intrauterine infection, bacteria reach the decidua, stimulating a maternal inflammatory response. Once bacteria gain access to the amniotic cavity and the fetus, the fetal inflammatory response can be activated.

Interleukin-6 (IL-6) is an immunostimulatory cytokine and a key mediator of fetal host response to infection. Several lines of investigation indicate that IL-6 may be the future diagnostic test of choice. For example, elevated levels of IL-6 in the amniotic fluid have been a more sensitive rapid test for the detection of microbial invasion of the amniotic cavity than amniotic fluid glucose, amniotic fluid Gram stain, or amniotic fluid white blood cell count. Amniotic fluid IL-6 levels have also been shown to be increased with positive cultures of either the amniotic fluid or the amniochorion.<sup>59</sup> Elevation of IL-6 levels in the amniotic fluid also is a very sensitive indicator of acute histologic chorioamnionitis and the identification of neonates at risk for significant morbidity and mortality.<sup>60</sup> Maternal serum IL-6 levels also have been reported to be elevated when preterm labor is associated with intrauterine infection.<sup>61</sup> Finally, fetal production of IL-6 (as determined by cordocentesis) is an independent risk factor for the occurrence of severe neonatal morbidity, including sepsis and pneumonia.<sup>62,63</sup> Additional areas of research currently include cervicovaginal production of cytokines.

PCR, a molecular biologic technique that amplifies the signal of small amounts of DNA, is likely to change the future of diagnosis of IAI. Several studies have evaluated amniotic fluid samples using PCR techniques. PCR assay has a higher sensitivity than that of culture for detection of microorganisms in the amniotic fluid, particularly in patients whose amniotic fluid is culture negative but other markers indicate evidence of an inflammatory response.<sup>59,64-67</sup>

### Chronic Intra-amniotic Infection

Increasing evidence is accumulating to suggest that IAI also may exist as a chronic condition. Several studies have performed microbiologic studies of midtrimester genetic amniocentesis fluid. Risk of adverse pregnancy outcome is increased when patients are asymptomatic but have positive results on such studies at midtrimester amniocentesis, compared with patients with culture-negative fluid.<sup>59</sup> Similarly, amniotic fluid IL-6 concentrations were found to be significantly higher in patients experiencing a loss following midtrimester amniocentesis than in those patients delivering at term.<sup>68,69</sup>

Emerging evidence also suggests that chronic inflammation may also be present in maternal serum. Goldenberg and colleagues recently showed elevated granulocyte colony-stimulating factor (G-CSF) at 24 and 28 weeks in women subsequently delivering prematurely.<sup>70</sup>

These data then beg the question of whether infection could be present before conception. The documented increased risk of recurrent preterm birth would lend credence to this hypothesis, but studies have not yet proved this hypothesis.<sup>71,72</sup>

### Management and Short-Term Outcome

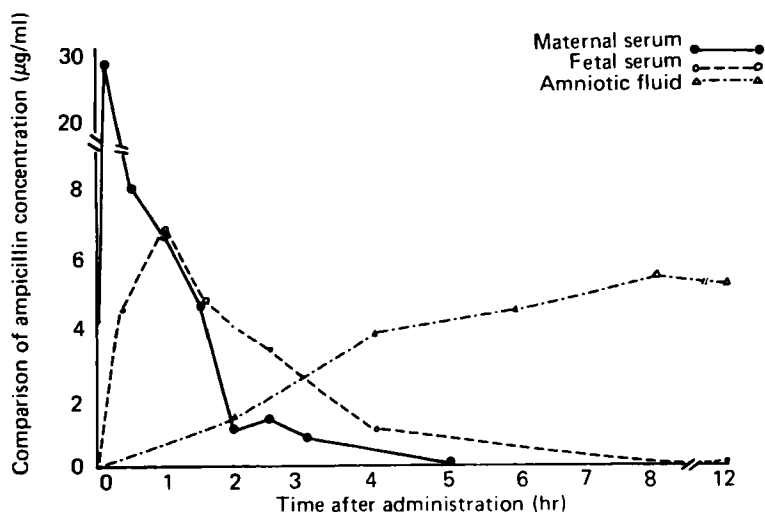

Traditionally, the effectiveness of management has been viewed in terms of short-term maternal and neonatal out-

comes, including maternal sepsis, neonatal sepsis, pneumonia, meningitis, and perinatal death. This section discusses the management principles of these short-term outcomes.

In the past, there was debate regarding timing of antibiotic administration, but it has now become standard to begin treatment during labor, as soon as possible after the maternal diagnosis of IAI is made. Three studies, including a randomized clinical trial, have demonstrated benefits from intrapartum antibiotic therapy compared with immediate postpartum treatment (see Table 3-2).<sup>73-75</sup> In a large, non-randomized allocation of intrapartum versus immediate postpartum treatment, the former treatment was associated with a significant decrease in neonatal bacteremia (2.8% versus 19.6%;  $P < .001$ ) and a reduction in neonatal death from sepsis (0.9% versus 4.3%;  $P = .07$ ).<sup>73</sup> Another large study showed an overall reduction in neonatal sepsis ( $P = .06$ ), especially bacteremia due to group B streptococci (0% versus 4.7%;  $P = .004$ ), with use of intrapartum treatment.<sup>75</sup> Then, in a randomized clinical trial, Gibbs and associates demonstrated that intrapartum treatment provided both maternal benefits (decreased hospital stay, lower mean temperature post partum) and neonatal benefits (decrease in sepsis: 0% versus 21%,  $P = .03$ , and decreased hospital stay). In this study, neonatal treatment was identical and consisted of intravenous ampicillin and gentamicin begun within 1 to 2 hours of birth and continued for at least 72 hours. If bacteremia or neonatal pneumonia was diagnosed, antibiotics were continued for 10 days.<sup>74</sup>

Pharmacokinetic studies<sup>76</sup> done during early pregnancy show that ampicillin concentrations in maternal and fetal sera are comparable 60 to 90 minutes after administration (Fig. 3-2). Penicillin G levels in fetal serum are one third of the maternal levels 120 minutes after administration.<sup>77</sup> In addition, ampicillin has some activity against *E. coli*. Accordingly, ampicillin is preferable to penicillin G for treatment of IAI. When used in combination with an aminoglycoside, ampicillin should be administered first, because it has the broader antimicrobial spectrum. In late pregnancy, gentamicin also crosses the placenta rapidly, but peak fetal levels may be low, especially if maternal levels are subtherapeutic.<sup>78</sup> An initial gentamicin dose of at least 1.5 to 2.0 mg/kg followed by 1.0 to 1.5 mg/kg every 8 hours is indicated because of the potential for unfavorable gentamicin kinetics. As an alternative, a newer penicillin or cephalosporin with excellent activity against aerobic gram-negative bacteria might be used. However, there is little published experience with these other antibiotics in IAI. Levels of ampicillin and aminoglycosides in amniotic fluid usually are below fetal serum levels, and peak concentrations in amniotic fluid may be attained only after 2 to 6 hours.<sup>76-78</sup> The kinetics of newer penicillin and cephalosporin antibiotics have not been studied extensively in pregnancy.

The duration of maternal treatment post partum in cases of chorioamnionitis is debatable. One randomized trial compared single-dose versus multidose postpartum treatment of mothers and reported that single-dose treatment was accompanied by a shorter time to discharge (33 hours in the single-dose group versus 57 hours in the multidose group;  $P = .001$ ).<sup>79</sup> However, the single-dose group had a nearly threefold increase in failure of therapy, but this did not achieve statistical significance (11% in the single-dose treatment group versus 3.7% in the multidose group;  $P = .27$ ).

**Figure 3-2** Ampicillin levels achieved with systemic administration to the mother. (From Bray RE, Boe RW, Johnson WL. Transfer of ampicillin into fetus and amniotic fluid from maternal plasma in late pregnancy. *Am J Obstet Gynecol* 96:938, 1966.)

Turnquist and associates also studied postpartum antibiotic therapy given when IAI was present, but only when cesarean section was performed. All patients received one dose of preoperative intravenous gentamicin and clindamycin. Patients were then randomized to receive no further antibiotics or to continue clindamycin plus gentamicin and had received ampicillin intravenously every 6 hours after a diagnosis of IAI was made. Our preference is to administer antibiotics for 24 hours or more after resolution of fever.

With regard to timing of delivery, short-term outcome is excellent without the use of arbitrary time limits.<sup>1,80,81</sup> Cesarean delivery usually is reserved for standard obstetric indications, not for IAI itself. In nearly all cases, delivery occurred within 8 hours after diagnosis of IAI (mean interval was 3 to 5 hours). No critical interval from diagnosis of amnionitis to delivery could be identified. Yet nearly in all of these cases the pregnancy was at or near term. Rates of cesarean section are two to three times higher among patients with IAI than in the general population, owing to patient selection (most cases occur in women with dystocia already diagnosed) and a poor response to oxytocin.<sup>82,83</sup> There is no demonstrated advantage of the extraperitoneal caesarean technique over the transperitoneal technique in decreasing maternal complications of IAI.<sup>84-87</sup>

In the past, we used a combination of an intravenous penicillin and intravenous gentamicin as soon as the diagnosis was made and cultures had been obtained.<sup>1,46</sup> Several studies have reported good results with similar regimens.<sup>80</sup> When a cesarean section is necessary, clindamycin should be added post partum to these antibiotics because of the importance of anaerobes in post-cesarean section infection and the high failure rate (20%) with therapy with penicillin-gentamicin after cesarean section for IAI.<sup>4</sup> Other initial regimens with cefoxitin alone or ampicillin plus a newer cephalosporin may be equally effective, but no comparative trials have been performed.

Since 1979, retrospective studies have shown a vastly improved perinatal outcome compared with that reported in earlier studies. Gibbs and colleagues reported a retrospective study of 171 patients with IAI in whom therapy (with penicillin G and kanamycin) usually was begun at the time of diagnosis.<sup>4</sup> The mean gestational age of the neonate was

37.7 weeks. There were no maternal deaths, and bacteremia was found in only 2.3% of mothers. Among women with IAI, the rate of cesarean delivery was increased approximately threefold to 35%, mainly because of dystocia. In all mothers the outcome was good. There was only one episode of septic shock, with no pelvic abscesses or maternal deaths. Similar results were reported from Los Angeles County Hospital.<sup>45</sup>

Gibbs and colleagues found that when IAI is present, the perinatal mortality rate (140 per 1000 births) was approximately seven times the overall perinatal mortality rate for infants weighing more than 499 g (which was 18.2 per 1000 births).<sup>4</sup> Yet none of the perinatal deaths was clearly attributable to infection; of live-born infants weighing more than 1000 g, none died of infection. In the study by Koh and co-workers, the perinatal mortality rate was lower (28.1 per 1000 births), which probably reflected the higher mean gestational age (39.3 weeks).<sup>45</sup> There were no intrapartum fetal deaths and only four neonatal deaths. Again, no deaths were due to infection. Neither perinatal nor maternal complications correlated with more prolonged diagnosis-to-delivery intervals. Because patients who underwent cesarean section had more complicated courses, it was concluded that cesarean section should be reserved for patients with standard obstetric indications for this procedure in addition to IAI.

Yoder and colleagues later provided a prospective, case-control study of 67 neonates with microbiologically confirmed IAI at term.<sup>46</sup> There was only one perinatal death, which was unrelated to infection. Cerebrospinal fluid culture results were negative for all 49 infants tested, and there was no clinical evidence of meningitis. Findings on chest radiographs were interpreted as possible pneumonia in 20% of patients and as unequivocal pneumonia in only 4%. Neonatal bacteremia was documented in 8%. There was no significant difference in the frequency of low Apgar scores between the IAI and control groups.

Two other retrospective studies have been confirmatory. In 1984, Loeff and Hager reported the outcomes of 104 pregnancies with clinical chorioamnionitis.<sup>80</sup> The mean gestational age was 36 weeks. The perinatal mortality rate was 123 per 1000 births. Nearly all of the excess mortality

Table 3-3 Perinatal Outcome in Preterm Amnionitis (Intra-amniotic Infection)

Measure (%)	Amnionitis <sup>a</sup>		Control <sup>a</sup>	
	Reference <sup>88</sup> (N = 47)	Reference <sup>89</sup> (N = 92)	Reference <sup>88</sup> (N = 204)	Reference <sup>89</sup> (N = 606)

<sup>a</sup>At centers reporting these results, there were active referral services. In these series of consecutive patients with preterm premature rupture of membranes, those with amnionitis are compared with those without.

<sup>b</sup>Rates are significantly lower than for amnionitis group in corresponding study.  
NR, not reported.

was attributed to prematurity rather than to sepsis. These authors also reported an increase in the cesarean delivery rate (26%). In 1985, Hauth and co-workers reviewed data for 103 pregnancies with clinical chorioamnionitis at term.<sup>81</sup> The mean interval from diagnosis of amnionitis to delivery was 3.1 hours, which confirmed the absence of a critical interval for delivery. In this study, the overall perinatal mortality rate was 9.7 per 1000 births and the cesarean delivery rate was 42%.

Neonates born prematurely have a higher frequency of complications if their mothers have IAI. Garite and Freeman noted that the perinatal death rate was significantly higher in 47 preterm neonates with IAI than in 204 neonates with similar birth weights but without IAI.<sup>88</sup> The group with IAI also had a significantly higher percentage (13% versus 3%;  $P < .05$ ) with RDS and total infection. A larger but similar comparative study of 92 patients with chorioamnionitis and 606 controls of similar gestational age also demonstrated significant increases in mortality, RDS, intraventricular hemorrhage (IVH), and clinically diagnosed sepsis in the group with chorioamnionitis (Table 3-3).<sup>89</sup> When Sperling and associates stratified outcomes in cases of IAI by birth weight, cases leading to low birth weight were associated with more frequent maternal bacteremia (13.5% versus 4.9%;  $P = .06$ ), early-onset neonatal sepsis (16.2% versus 4.1%;  $P = .005$ ), and neonatal death from sepsis (10.8% versus 0;  $P < .001$ ).<sup>40</sup>

In a retrospective, case-control study, Ferguson and co-workers reported neonatal outcome after chorioamnionitis.<sup>90</sup> Seventy percent of newborns weighed less than 2500 g. In 116 matched pairs, the authors found more deaths (20% versus 11%), more sepsis (6% versus 2%), and more asphyxia (27% versus 16%) in the group with chorioamnionitis. None of these differences, however, achieved statistical significance.

Chorioamnionitis has been previously a maternal infection. Increasing evidence indicates that the fetus is primarily involved in the inflammatory response leading to premature delivery. The fetal inflammatory response syndrome (FIRS), well described by Yoon and co-authors, characterizes preterm PROM and spontaneous preterm labor, with a systemic pro-inflammatory cytokine response resulting in earlier delivery and with an increased risk of complications.<sup>91</sup> Additionally, these investigators show an association between the fetal inflammatory cascade and fetal white matter damage.<sup>92</sup> It remains unclear, however, whether cytokines mediate this damage or directly cause the damage, or if infection itself is

responsible for the damage. Cytokines also can be stimulated by a number of noninfectious insults such as hypoxia, reperfusion injury, and toxins.<sup>93</sup>

### Long-Term Outcome

Hardt and colleagues studied long-term outcomes in preterm infants (weighing less than 2000 g) born after a pregnancy with chorioamnionitis and found a significantly lower mental development index (Bayley's score) for these infants than noted for preterm control infants ( $104 \pm 18$  versus  $112 \pm 14$ ;  $P = .017$ ).<sup>94</sup> Morales reported 1-year follow-up of preterm infants born after pregnancy with chorioamnionitis and of control infants. He did not observe differences in mental and physical development, but adjustments were made for IVH and RDS, both of which were more frequent in the amnionitis group.<sup>89</sup>

Intriguing new information strongly suggests that intrauterine exposure to bacteria is associated with long-term serious neonatal complications, including cerebral palsy or its histologic precursor, periventricular leukomalacia (PVL), as well as major pulmonary problems of bronchopulmonary dysplasia (BPD) and RDS. The unifying hypothesis states that intrauterine exposure of the fetus to infection leads to abnormal fetal production of proinflammatory cytokines. This leads in turn to fetal cellular damage in the brain, lung, and potentially other organs. This FIRS has been likened to the systemic inflammatory response syndrome (SIRS) in adults. The evidence linking infection to cerebral palsy may be summarized as follows:

1. Intrauterine exposure to maternal or placental infection is associated with an increased risk of cerebral palsy both in preterm and term infants.<sup>95,96</sup>
2. Clinical chorioamnionitis in very low birth weight infants is significantly associated with an increase in PVL ( $P = .001$ ).<sup>97</sup>
3. The levels of inflammatory cytokines are increased in the amniotic fluid of infants with white matter lesions (PVL), and there is overexpression of these cytokines in neonatal brain with PVL.<sup>98</sup>
4. Experimental intrauterine infection in rabbits leads to brain white matter lesions.<sup>99</sup>
5. Marked inflammation of the fetal side of the placenta is associated with adverse neurologic outcomes. Coexisting evidence of infection and thrombosis, particularly on the

fetal side of the placenta, is associated with a heightened risk of cerebral palsy or neurologic impairment in term and preterm infants. Additionally, histologic funisitis is associated with an increased risk of subsequent cerebral palsy (OR 5.5, 95% confidence interval [CI] 1.2 to 24.5).<sup>97,100,101</sup> This risk underscores the importance of sending placentas for gross and microscopic examination in the setting of IAI.

The association between IAI and cerebral palsy differs for the term infant and the preterm infant. A recent review article nicely outlines the controversies in this area, including the associations among microbiologic, clinical, and histologic chorioamnionitis.<sup>102</sup> Additionally, emerging evidence points to genetic predispositions to inflammation and thrombosis; cytokine polymorphisms also may be linked to cerebral palsy.<sup>93</sup>

In addition to cellular and tissue damage in the fetal brain, an overexuberant cytokine response induced by bacteria may damage other fetal tissues, such as the lung, contributing to RDS and BPD.<sup>103</sup> In support of this hypothesis, a case-control study of infants with and without RDS was conducted. Those with RDS were significantly more likely to have elevated levels of amniotic fluid tumor necrosis factor (TNF)- $\alpha$ , a positive culture of the amniotic fluid, and severe histologic chorioamnionitis ( $P < .05$  for each association). Elevated amniotic fluid IL-6 levels were also twice as common in the group with RDS, but this association did not achieve statistical significance. Furthermore, preterm fetuses with elevated cord blood IL-6 concentrations (greater than 11 pg/mL) were more likely to develop RDS (64% versus 24%;  $P < .005$ ) than were those without elevated cord IL-6 levels. Rates of occurrence of BPD also were increased (11% versus 5%), but the observed difference was not statistically significant.<sup>62</sup> Curley and associates found elevated matrix metalloproteinase-9 (MMP-9) concentration in bronchoalveolar lavage fluid in preterm neonates with pregnancies complicated by chorioamnionitis compared with age-matched uninfected controls. These investigators hypothesize that increased MMP levels in the lung cause destruction of the extracellular matrix, breaking down type IV collagen in the basement membrane and leading to the failure of alveolarization and to fibrosis components of chronic lung disease.<sup>104</sup>

More recently, genetic predisposition toward exuberant host response to tissue injury has been described. Proinflammatory cytokine polymorphisms such as TNF- $\alpha$  308 relate to bacterial endotoxin and an increased risk of preterm delivery.<sup>105-107</sup>

In summary, IAI has a significant adverse effect on mother and neonate, but vigorous antibiotic therapy and reasonably prompt delivery result in an excellent short-term prognosis, especially for the mother and the term neonate. With the combination of prematurity and amnionitis, serious sequelae are more likely for the neonate. Newly developing information suggests that intrauterine infection is linked to major neonatal long-term complications. A complex interplay of cytokine genotype may contribute to long-term complications as well.

### Conclusion

The unanswered question remains: Why does IAI develop in some patients and not in others? Investigations of maternal and fetal genotypes for pro-inflammatory markers, among

**Table 3-4 Proposed Prevention Strategies for Clinical Intra-amniotic Infection**

Prompt management of dystocia
Induction of labor with premature rupture of membranes at term
Antibiotic prophylaxis with preterm premature rupture of membranes
Antibiotic prophylaxis with preterm labor, but with intact membranes
Antibiotic prophylaxis for group B streptococcal infection
Prenatal treatment of bacterial vaginosis
Chlorhexidine vaginal irrigations in labor
Infection control measures

others, as well as study of mucosal immunity and host response, may help to answer this important question, as well as clarifying when neonatal damage will occur. It is not until we understand the answers to these questions that satisfactory therapeutic approaches can be developed.

### Prevention

As categorized in Table 3-4, numerous approaches have been proposed for the prevention of IAI. Among these, prompt management of dystocia has been shown to decrease chorioamnionitis, as well as to shorten labor and reduce the cesarean section rate.<sup>108</sup> Similarly, induction in women with PROM at term most likely results in fewer maternal infections than may occur with expectant management.<sup>109</sup> Antibiotic prophylaxis for patients with preterm PROM decreases chorioamnionitis as well as other complications.<sup>110,111</sup> Treatment for bacterial vaginosis in high-risk women decreases incidence of preterm birth. Antibiotic prophylaxis for patients in preterm labor (but with intact membranes) does not appear to decrease frequency of chorioamnionitis.<sup>112</sup> Intrapartum prophylaxis for the prevention of neonatal group B streptococcal sepsis is now a national standard in known group B streptococci-colonized parturients or those in at-risk categories. It is presumed that this approach also decreases chorioamnionitis, but there are no definitive data to support this. Prenatal treatment of bacterial vaginosis in low-risk women, chlorhexidine vaginal washes in labor, and specific infection control measures have not been demonstrated to be effective.<sup>19,113-115</sup>

### INFECTION AS A CAUSE OF PRETERM BIRTH

Preterm birth is the leading perinatal problem in the United States. Infants born before week 37 of gestation account for approximately 11% of births but for 60% to 80% of all perinatal deaths.<sup>116-118</sup> In most cases, the underlying cause of premature labor is not evident. Evidence from many sources points to a relationship between preterm birth and genitourinary tract infections (Table 3-5).<sup>119,120</sup> Infection leading to preterm birth may arise in the lower genital tract, the urinary tract, or a more remote site such as the lung or periodontal tissues.<sup>121</sup>

**Table 3-5 Evidence for Relationship between Preterm Births and Subclinical Genitourinary Tract Infection**

- The incidence of histologic chorioamnionitis is increased after preterm birth.
- The incidence of clinical infection is increased after preterm birth in both mother and neonate.
- Some lower genital tract microbes or infections are associated with an increased risk of preterm birth.
- There are biochemical mechanisms linking prematurity and infection.
- Infection and inflammation cause cytokine release and prostaglandin production.
- Bacteria and bacterial products induce preterm delivery in animal models.
- Amniotic fluid tests for bacteria are positive in some patients in premature labor.
- Some antibiotic trials have shown a decrease in numbers of preterm births.

### Histologic Chorioamnionitis and Prematurity

Over the past 3 decades, one of the most consistent observations is that placentas in premature births are more likely to demonstrate evidence of inflammation (i.e., histologic chorioamnionitis) (Fig. 3-3). In a series of 3500 consecutive placentas, Driscoll found infiltrates of polymorphonuclear cells in 11%.<sup>122</sup> Clinically evident infection developed in only a few of the women in this study, but the likelihood of neonatal sepsis and death was increased.<sup>123</sup>

An association has been established between histologic chorioamnionitis and chorioamnion infection (defined as a positive culture).<sup>123</sup> Odds ratios (ORs) have been reported from 2.8 to 14, this relationship being stronger among preterm deliveries than among term deliveries. Overall, the organisms found in the chorioamnion are similar to those found in the amniotic fluid in cases of clinical IAI. This array of organisms supports an ascending route for chorioamnion infection in most cases.

Although it is not certain how histologic chorioamnionitis and membrane infection cause preterm delivery or preterm PROM, studies suggest that they lead to weakening of the membranes (as evidenced by lower bursting tension, less work to rupture, and less elasticity<sup>124</sup> in vitro) and to production of prostaglandins by the amnion.<sup>125,126</sup>

### Clinical Infection and Prematurity

Both premature infants and women who previously gave birth to premature infants are more likely to develop clinically evident infection.<sup>127</sup> In a large study of more than 9500 deliveries, confirmatory evidence has shown that chorioamnionitis, endometritis, and neonatal infection all were significantly increased in preterm pregnancies, even after correcting for the presence of PROM.<sup>128</sup> These observations suggest that subclinical infection led to the labor and that infection became clinically evident after delivery. Some investigators argue that there is no causal relationship but that infection develops more frequently in premature infants because, for example, they are compromised hosts or because they have more invasive monitoring in the nursery.

**Figure 3-3** Infiltrates of polymorphonuclear cells are seen in the fetal membranes. Inflammation of the placenta and membranes has been consistently observed more often after preterm births than after term births.

### Association of Lower Genital Tract Organisms or Infections with Prematurity

Premature birth has been associated with isolation of several organisms from the maternal lower genital tract and with subclinical infections, as listed in Table 3-6. Lower genital tract colonization with *U. urealyticum* is not associated with preterm birth. Similarly, cervical infection with *C. trachomatis* is not associated with preterm birth. However, other lower genital tract or urinary infections, including those due to *N. gonorrhoeae* and *Trichomonas vaginalis* and bacteriuria, are associated with preterm birth. Bacterial vaginosis, characterized by high concentrations of anaerobes, *Gardnerella vaginalis*, and genital mycoplasmas, with a corresponding decrease in the normal vaginal lactobacilli, has been consistently associated with premature birth.

Maternal genital tract colonization with group B streptococci may lead to neonatal sepsis, especially when birth occurs prematurely or when the membranes have been ruptured for prolonged intervals. In addition, an association between colonization of the cervix with these organisms and premature birth has been found by Regan and co-workers.<sup>129</sup> These investigators noted delivery at less than 32 weeks in 1.8% of the total population but in 5.4% of women colonized with group B streptococci ( $P < .005$ ). PROM also occurred significantly more often in the colonized group

**Table 3–6 Association of Lower Genitourinary Tract Infections with Preterm Birth**

Infection	Odds Ratio for Preterm Birth (95% confidence Interval)
<i>Ureaplasma urealyticum</i>	1.0 (0.8-1.2) <sup>a</sup>
<i>Chlamydia trachomatis</i>	0.7 (0.36-1.37) <sup>b,c</sup>
<i>Neisseria gonorrhoeae</i>	5.31 (1.57-17.9) <sup>d</sup>
<i>Trichomonas vaginalis</i>	1.3 (1.1-1.4) <sup>e</sup>
Bacterial vaginosis	2.19 (1.54-3.12) <sup>f</sup>
Bacteriuria	1.64 (1.35-1.78) <sup>g</sup>

<sup>a</sup>Data from Carey JC, Blackwelder WC, Nugent RP, et al. Antepartum cultures for *Ureaplasma urealyticum* are not useful in predicting pregnancy outcome. *Am J Obstet Gynecol* 1991; 164:728.

(15.3% versus 8.1%;  $P < .005$ ). Of six studies evaluating the association between group B streptococci genital colonization and preterm labor or delivery, five found no association.<sup>120</sup> In contrast with the conflicting data regarding group B streptococcal genital colonization, group B streptococcal bacteriuria has been consistently associated with preterm delivery, and treatment of this bacteriuria resulted in a marked reduction in prematurity (37.5% in the placebo group versus 5.4% in the treatment group).<sup>130-132</sup> Current recommendations for prevention of perinatal group B streptococcal infection from the Centers for Disease Control and Prevention (CDC) are for intrapartum treatment only, with the exception of group B streptococcal bacteriuria, which should be treated antepartum. The CDC recommend adoption of universal screening. The *universal screening approach* involves screening women at 35 to 37 weeks of gestation with proper collection and culture techniques, followed by intrapartum treatment for all women with positive cultures.<sup>133</sup>

Untreated acute pyelonephritis has been found to be consistently associated with a 30% risk of preterm labor and delivery. A meta-analysis<sup>134</sup> showed that women with asymptomatic bacteriuria had a 60% higher rate of low birth weight (95% CI 1.4 to 1.9) and a 90% higher rate of preterm delivery (95% CI 1.3 to 1.9).

### Amniotic Fluid Cultures in Preterm Labor

Among patients with signs and symptoms of preterm labor, the probability of finding a positive result on tests for bacteria

depends on several factors. These factors are the specimen tested, the population under investigation, and the technique used for microbial detection. Thus, when standard culture techniques have been used for the amniotic fluid of patients clinically defined as being in preterm labor, the likelihood of positive cultures ranges from 0% to 25%. Yet with culture of the amniotic fluid of patients in preterm labor who deliver a preterm infant within 72 hours of the amniocentesis, the likelihood of a positive result has been 22%. With use of more sensitive assays such as PCR assay, the probability of finding bacteria in the amniotic fluid of patients in preterm labor has been as high as 30% to 55%.<sup>135-139</sup> Because bacteria are likely to be present in the amniotic membranes before appearing in the amniotic fluid, the rate of positive cultures of the membranes for patients in preterm labor has been 32% to 61%. Histologic evidence of chorioamnion infection is extremely common, being found in approximately 80% of placentas after the birth of an infant weighing 1000 g or less.

### Biochemical Links of Prematurity and Infection

The widely accepted working hypothesis is that bacteria ascending into the uterine cavity are able to directly stimulate cytokine activity. IL-1, IL-6, and TNF- $\alpha$ , the proinflammatory cytokines, have been shown to be produced by the fetal membranes, decidua, and myometrium. Patients with elevated levels of these cytokines in the amniotic fluid have shorter amniocentesis-to-delivery intervals than those for patients without elevated cytokine levels. Levels also are elevated when preterm labor is associated with IAI.<sup>140</sup> In addition, elevated amniotic fluid IL-6 levels have been found to prospectively identify those fetuses destined for significant neonatal morbidity and mortality.<sup>141</sup> Similarly, Gomez and associates demonstrated that elevated fetal plasma levels of IL-6 in patients with preterm PROM, but not in labor, had a higher rate of delivery within 48 hours compared with those who delivered more than 48 hours after cordocentesis. These important findings suggest a fetal inflammatory cytokine response triggers spontaneous preterm delivery.<sup>142</sup>

Immunomodulatory cytokines such as IL-1 receptor antagonist (IL-1ra), IL-10, and transforming growth factor (TGF)- $\beta$  play a regulatory role in the cytokine response, allowing for a downregulation of this response. IL-1ra has been shown in humans to increase in response to IAI.<sup>143</sup> Similarly, IL-10 inhibits IL-1 $\beta$ -induced preterm labor in a rhesus model.<sup>144</sup>

Animal models have been used to evaluate cytokine-mediated initiation of preterm birth. Romero and colleagues demonstrated that systemic administration of IL-1 induced preterm birth in a murine model.<sup>145</sup> Similarly, Kaga and co-workers gave low-dose lipopolysaccharide (LPS) intraperitoneally to preterm mice, causing preterm delivery.<sup>146</sup> Again in the murine model, others demonstrated preterm birth after intrauterine inoculation of *E. coli*.

Other investigators have used inoculation of live bacteria to study the infection-cytokine-preterm birth pathway. For example, in rabbits, we found that intrauterine inoculation of *E. coli*, *Fusobacterium* species, or group B streptococci led to rapid induction of labor at 70% gestation with an accompanying increase in histologic infiltrate and elaboration of TNF- $\alpha$  into the amniotic fluid. More recently, using our rabbit model, we demonstrated that intrauterine inoculation

**Table 3-7 Randomized Trial of Erythromycin for Treatment of Vaginal *Ureaplasma urealyticum* Infection in Pregnancy**

Outcome	Treatment Group		P Value
	Erythromycin (N = 605)	Placebo (N = 576)	
Birth weight (g, mean ± SD)	3302 ± 557	3326 ± 558	NS
Birth weight <2500 g (%)	7	6	NS
Gestational age at delivery ≥36 wk (%)	8.6	8.2	NS
Premature rupture of membranes at ≥36 wk (%)	2.5	2.5	NS
Stillbirth (%)	0.5	0.5	NS
Neonatal death (%)	0.2	0	NS

NS, not significant; SD, standard deviation.

of the anaerobe *P. bivia* at 70% gestation led to establishment of a “chronic” infection in 64% of animals, with preterm birth occurring in 33%.<sup>147</sup> Also using a rhesus monkey model, Gravett and colleagues inoculated group B streptococci at 78% gestation and found resulting increases in amniotic fluid cytokines and prostaglandins followed by a progressive cervical dilatation.<sup>148</sup>

### Antibiotic Trials

These treatment trials may be categorized into three general types as follows: (1) antibiotics given during prenatal care to patients at increased risk of preterm delivery; (2) antibiotics given adjunctively with tocolytics to women in preterm labor; and (3) antibiotics given to women with preterm PROM but not yet in labor.

In the prototype of the first category of antibiotic trial, Kass and colleagues<sup>149</sup> and McCormack and associates<sup>150</sup> noted a reduction in the percentage of low-birth-weight infants delivered of women who received oral erythromycin for 6 weeks in the third trimester, compared with those delivered of women who were given a placebo. Of note, these results were not confirmed in a National Institutes of Health-sponsored, multi-institutional study. More than 1100 women with genital *U. urealyticum* were randomized to receive placebo or erythromycin beginning at 26 to 28 weeks of gestation and continuing until 35 weeks. Here, no improvement was detected in any outcome measure (Table 3-7). Two retrospective, nonrandomized studies have reported reductions in PROM, low birth weight, and preterm labor through antenatal treatment of *C. trachomatis* infection.<sup>151,152</sup> However, the only randomized treatment trial for *C. trachomatis* infection in pregnancy led to conflicting results.<sup>152a</sup>

Treatment with metronidazole should be offered to women who have symptomatic *T. vaginalis* infection in pregnancy in order to relieve maternal symptoms.<sup>153</sup> Metronidazole is safe for use in the first trimester of pregnancy.<sup>154</sup> Yet when pregnant women with asymptomatic *T. vaginalis* infection at 24 to 29 weeks of gestation were randomized to receive treatment with either metronidazole or placebo, rates of delivery at less than 37 weeks and at less than 37 weeks due to preterm labor were both increased in the group given metronidazole (relative risk 1.8 [95% CI 1.2 to 2.7] for delivery at less than 37 weeks and relative risk 3.0 [95% CI 1.5 to 5.9] for delivery at less than 37 weeks due to preterm labor).<sup>155</sup>

**Table 3-8 Risk of Selected Adverse Outcomes with Use of Antibiotics in Preterm Labor with Intact Membranes**

Outcome	Relative Risk <sup>a</sup> (95% CI)
Preterm birth	0.99 (0.92-1.05)
Delivery within 48 hours	1.04 (0.89-1.23)
Perinatal mortality	1.22 (0.88-1.70)
Neonatal death	1.52 (0.99-2.34)

<sup>a</sup>A relative risk (RR) less than 1.0 favors antibiotics, and an RR greater than 1.0 favors controls. The RR is statistically significant if the 95% CI (confidence interval) excludes 1.0.

From King J, Flenady V. Prophylactic antibiotics for inhibiting preterm labour with intact membranes. Cochrane Database Syst Rev (1), 2003.

Because of the consistent association of bacterial vaginosis with preterm birth, several treatment trials have been carried out in pregnancy. A recent meta-analysis reported no significant reduction in preterm delivery when women with bacterial vaginosis were given antibiotic therapy as part of their prenatal care. Similarly, there is no significant reduction in preterm labor with treatment for bacterial vaginosis in women with previous preterm birth or in women at low risk for preterm birth. Of major importance, however, in the subset of women with both previous preterm birth and treatment for at least 7 days with an oral regimen, there was a significant reduction in preterm delivery (OR 0.42, 95% CI 0.27 to 0.67). Whether vaginal treatment of bacterial vaginosis is effective in preventing preterm birth is unclear. In the meta-analysis, no benefit was obtained by vaginal treatment.<sup>156</sup> Yet, in a recent trial of a 3-day course of clindamycin cream beginning at less than 20 weeks, a decreased incidence of preterm birth was observed (4% preterm birth in the antibiotic group versus 10% in the placebo group;  $P < .03$ ).<sup>157</sup>

Among women in preterm labor with intact membranes, there have been several studies and recent meta-analyses. For example, the ORACLE II study demonstrated no delay in delivery or no improvement in a composite outcome that included neonatal death, chronic lung disease, or cerebral anomaly.<sup>158</sup> In the Cochrane meta-analysis, a total of 7428 women in 11 trials were assessed. As shown in Table 3-8, the use of antibiotics did not decrease preterm birth delivery within 48 hours or perinatal mortality. Of interest, the relative

risk for neonatal death in the antibiotic treatment group was 1.52 (95% CI 0.99 to 2.34). There was a significant reduction in postpartum intrauterine infection with use of antibiotics, but this reduction was not seen as sufficient justification for widespread use of antibiotics in preterm labor. In a sub-analysis, the reviewers looked at trials employing antibiotics that were active against anaerobes (i.e., metronidazole or clindamycin). Here there were significant benefits in delivery within 7 days and in neonatal intensive care unit (NICU) admissions. However, these benefits were not accompanied by significant reductions in major end points such as preterm birth, perinatal mortality, or neonatal sepsis.

Among patients with preterm PROM, again there have been several large trials. In 2003, the Cochrane Library up-

dated its meta-analysis of these trials. In 13 trials comprising 6000 patients, antibiotics in this clinical setting had consistent benefits. Among women exposed to antibiotics, delivery within 48 hours, or within 7 days, or development of chorioamnionitis was less likely. Their neonates were less likely to have infection or sepsis. See Table 3-9.

Lack of consistent findings in these antibiotic trials raises the question of why antibiotics have been effective in so few clinical situations. One likely explanation is that a true effective antibiotic may be “diluted out” by inclusion in the trials of patients in whom premature labor is not due to infection, for example, patients in preterm labor at 34 to 37 weeks. Another likely explanation is that once clinical signs and symptoms of preterm labor begin, the complex biochemical reactions have progressed too far to be stopped by antibiotic therapy alone.

Widespread use of antibiotics for the purpose of prolonging a premature pregnancy raises concerns regarding selection of resistant organisms and masking of infection. To date, evidence of selection pressure has been limited mainly to very low birth weight infants.<sup>159</sup> Concerns over masking infection is now of great concern, especially in view of recent evidence that intrauterine exposure to bacteria is associated with long-term adverse neonatal outcomes including cerebral palsy and PVL.<sup>160,161</sup>

For reasons other than prevention of preterm birth, detection and treatment of *N. gonorrhoeae*, *C. trachomatis*, and bacteriuria are appropriate. Our recommendations for use of antibiotics to prevent preterm birth are summarized in Table 3-10. However, future research is urgently needed to identify markers in women who are in preterm labor as a

**Table 3-9 Risk of Selected Adverse Outcomes with Use of Antibiotics for Preterm Premature Rupture of Membranes**

Outcome	Relative Risk <sup>a</sup> (95% CI)
Delivery within 48 hours	0.71 (0.58-0.87)
Delivery within 7 days	0.8 (0.71-0.9)
Chorioamnionitis	0.57 (0.37-0.86)
Neonatal infection	0.68 (0.53-0.87)
Abnormalities on cerebral ultrasound examination	0.82 (0.68-0.98)

<sup>a</sup>A relative risk (RR) less than 1.0 favors antibiotics, and an RR greater than 1.0 favors controls. The RR is statistically significant if the 95% CI (confidence interval) excludes 1.0. Data from reference 27.

**Table 3-10 Consensus on Use of Antibiotics to Prevent Preterm Birth**

Opinion	Comment
<b>During Prenatal Care</b>	
1. Treat <i>Neisseria gonorrhoeae</i> and <i>Chlamydia trachomatis</i> infection.	Screening and treatment of these two sexually transmitted organisms should follow standard recommendations to prevent spread to sexual partner(s) and the newborn. Published nonrandomized trials show improved pregnancy outcome with treatment.
2. Treat bacteriuria, including group B streptococcal bacteriuria.	Screening and treatment for bacteriuria is a standard practice to prevent pyelonephritis. A meta-analysis concluded that bacteriuria is directly associated with preterm birth.
3. Screen for and treat bacterial vaginosis in patients at high risk for preterm birth. In these high-risk women, treat with an oral metronidazole for 1 week or more.	A meta-analysis has shown benefit in women with high-risk pregnancies with this treatment.
4. Treat symptomatic <i>Trichomonas vaginalis</i> infection to relieve maternal symptoms, but do not screen for or treat asymptomatic trichomoniasis.	This opinion is based on randomized trials in asymptomatic infected women.
5. Do not treat <i>Ureaplasma urealyticum</i> genital colonization.	One double-blind treatment trial that corrected for confounding infections showed no benefit.
6. Do not treat group B streptococcal genital colonization.	One double-blind treatment trial showed no benefit.
<b>With Preterm Labor and Intact Membranes</b>	
1. Give group B streptococcal prophylaxis to prevent neonatal sepsis.	As recommended by the Centers for Disease Control and Prevention and the American College of Obstetricians and Gynecologists.
2. Do not give antibiotics routinely to prolong pregnancy.	Meta-analyses concluded that antibiotics gave no neonatal benefit, overall.
<b>With Preterm Premature Rupture of Membranes</b>	
1. Give group B streptococcal prophylaxis to prevent neonatal sepsis.	As recommended by the Centers for Disease Control and Prevention and the American College of Obstetricians and Gynecologists.
2. Give additional antibiotics in pregnancies at 24 to 32 weeks.	Meta-analyses concluded that there was substantial benefit to the neonate.

result of infection, in whom intervention with antibiotics or other novel therapies is most likely to be of benefit. In addition, detection of women genetically predisposed to infection-induced preterm birth is important. For example, some investigators have identified associations between polymorphisms in the cytokine gene complexes, including that for TNF- $\alpha$ , and preterm PROM or spontaneous preterm birth.<sup>162-165</sup>

## PREMATURE RUPTURE OF MEMBRANES

PROM is a common but poorly understood problem. Because there is little understanding of its etiology, management has been largely empirical, and obstetricians have been sharply divided over what constitutes the best approach to care. Indeed, the problem is complex. Gestational age and demographic factors influence the outcome with PROM. Therapeutic modalities added within the past 2 decades include corticosteroids, tocolytics, and more potent antibiotics, but their place in therapy remains controversial. Of major importance is the marked improvement in survival of low-birth-weight infants. This chapter emphasizes developments since 1970. The literature has been reviewed periodically.<sup>166-169</sup>

### Definition

Lack of standard, clear terminology has hindered understanding of PROM. Most authors define PROM as rupture at any time before the onset of contractions, but *premature* also carries the connotation of preterm pregnancy. To avoid confusion, we reserve *preterm* to refer to rupture occurring at a gestational age less than 37 weeks. Others using the expression "prolonged rupture of the membranes" have used the same acronym, PROM.

The *latent period* is defined as the time from membrane rupture to onset of contractions. It is to be distinguished from the *latent phase*, which designates the phase of labor that precedes the active phase. "Conservative" or "expectant" management refers to the period of watchful waiting when IAI has been at least clinically excluded in the setting of PROM.

In addition to IAI, terms used to describe maternal or perinatal infections during labor include *fever in labor*, *intrapartum fever*, *chorioamnionitis*, *amnionitis*, and *intrauterine infection*. In most reports, clinical criteria used for these diagnoses include fever, uterine irritability or tenderness, leukocytosis, and purulent cervical discharge. After delivery, maternal uterine infection is referred to as *endometritis*, *endomyometritis*, or *metritis*. These clinical diagnoses usually are based on fever and uterine tenderness. In few studies, however, were presumed maternal infections confirmed by blood or genital tract cultures.

For neonates, the most common term used to report infection is *neonatal sepsis*, but some authors use a positive blood or cerebrospinal fluid culture result, whereas others use clinical signs of sepsis without bacteriologic confirmation.

### Incidence

In several reports, the incidence of PROM has ranged from 3% to 7% of total deliveries,<sup>170,171</sup> whereas PROM related to preterm birth has occurred in approximately 1% of all

pregnancies.<sup>7-9</sup> In some referral centers, however, preterm PROM accounted for 30% of all preterm births.<sup>175</sup>

### Etiology

Several clinical variables have been associated with PROM,<sup>173,176</sup> including cervical incompetence, cervical operations and lacerations, multiple pregnancies, polyhydramnios, antepartum hemorrhage, and heavy smoking. In most instances, however, none of these clinical variables are present. No association has been found between the frequency of PROM and maternal age, parity, maternal weight, fetal weight and position, maternal trauma, or type of work.<sup>166,178</sup>

Physical properties of membranes that rupture prematurely also have been investigated. Studies of the collagen content of amnion in patients with PROM have led to conflicting results, perhaps because of important differences in methodology. Of interest, patients with Ehlers-Danlos syndrome, a hereditary defect in collagen synthesis, are at increased risk of preterm PROM. Other reports have shown that membranes from women with PROM are thinner than membranes from women without PROM.<sup>178</sup> Using *in vitro* techniques to measure rupturing pressure, investigators have found that the membranes from patients with PROM withstand either the same or higher pressure before bursting than do membranes from women without PROM.<sup>179-181</sup> Such observations have suggested a local defect at the site of rupture, rather than a diffuse weakening, in membranes that rupture before labor. These studies of physical properties should be interpreted with caution because of differences in measuring techniques, possible deterioration of membrane preparations, and need for proper controls. In addition to being a possible cause of premature labor, subclinical infection may be a cause of PROM (see previous section). Acute inflammation of the placental membranes is twice as common when membranes rupture within 4 hours before labor than when they rupture after the onset of labor, which suggests that this "infection" may be the cause of PROM.<sup>177</sup> Supporting this hypothesis, increases in amniotic fluid matrix metalloproteases (MMP-1, -8, and -9) as well as decreases in matrix metalloprotease (MMP-1 and -2) inhibitors have been demonstrated in women experiencing preterm PROM.<sup>182,183</sup>

Several reports have suggested a relationship among coitus, histologic inflammation, and PROM. In additional analyses, two successive singleton pregnancies in each of 5230 women (10,460 pregnancies) were considered.<sup>184</sup> Preterm PROM occurred in only 2% of 773 pregnancies when there was no recent coitus and histologic chorioamnionitis, but it occurred in 23% of 96 pregnancies when both of these features were present. However, a causal role of coitus or infection was not established, because there may have been other factors that were not considered. Evaluation of successive pregnancies would not necessarily have eliminated these confounding variables. In the South African black population, the rates of histologic chorioamnionitis and PROM were increased when coitus had occurred within the last 7 days. Use of a condom during coitus resulted in less placental inflammation. In addition, PROM occurred more often ( $P < .01$ ) when there had been male orgasm during coitus.<sup>185</sup> Because organisms may attach to sperm, it has been hypothesized that sperm carry organisms into the endocervix or uterus.

Further evidence is provided by bacteriologic studies. Patients with PROM before term or with prolonged membrane rupture are more likely to have anaerobes in the endocervical cultures than are women without PROM at term.<sup>186,187</sup> These observations may be interpreted as showing that subclinical anaerobic “infection” leads to PROM. The increased presence of anaerobes in cervical cultures, however, may reflect hormonal or other influences at different stages of gestation.

Investigations of risk factors for preterm PROM are likely to provide insight into the etiology of this condition. In the largest case-control study, Harger and colleagues reported 341 cases and 253 controls.<sup>188</sup> Only three independent variables were associated with preterm PROM in a logistic regression analysis. These were previous preterm delivery (OR 2.5, 95% CI 1.4 to 2.5), uterine bleeding in pregnancy, and cigarette smoking. The OR accompanying bleeding increased with bleeding in late pregnancy and with the number of trimesters in which bleeding occurred (OR for first-trimester bleeding 2.4, 95% CI 1.5 to 3.9; OR for third-trimester bleeding 6.5, 95% CI 1.9 to 23; OR for bleeding in more than one trimester 7.4, 95% CI 2.2 to 26). For cigarette smoking, the OR was higher for those who continued smoking (2.1, 95% CI 1.4 to 3.1) than for those who stopped (1.6, 95% CI 0.8 to 3.3). Because previous preterm pregnancy is a historical feature and little can be done to prevent bleeding in pregnancy, this study provides additional reason to encourage all patients, especially women of reproductive age, to stop smoking.

In the vast majority of cases, the specific etiology of preterm PROM remains unknown.

## Diagnosis

In most cases, PROM is readily diagnosed by history, physical findings, and simple laboratory tests such as determination of pH (Nitrazine [phenaphthazine] test [Bristol-Myers Squibb, Princeton, NJ]) or detection of ferning. Although these tests are accurate in approximately 90% of cases, they yield false-positive and false-negative results, especially in women with small amounts of amniotic fluid in the vagina. Other biochemical and histochemical tests and intra-amniotic injection of various dyes have been suggested, but they have not gained wide acceptance. Ultrasound examination also has been used as a diagnostic technique, because finding oligohydramnios suggests PROM. Oligohydramnios, however, has many additional causes.

## Natural History

The onset of regular uterine contractions occurs within 24 hours after membrane rupture in 80% to 90% of term patients.<sup>1</sup> The latent period exceeds 24 hours in 19% of patients at term and exceeds 48 hours in 12.5%.<sup>188,189</sup> Only 3.6% of term patients do not begin labor within 7 days.<sup>188</sup>

Before term, latent periods are longer among patients with PROM. Confirming earlier studies, more recent investigations have shown latent periods of 24 hours in 57% to 83%,<sup>189,190</sup> of 72 hours in 15% to 26%,<sup>172,191,192</sup> and of 7 days in 19% to 41% of patients.<sup>172,189</sup> There is an inverse relationship between gestational age and the proportion of patients with latent periods of 3 days.<sup>191</sup> There is also an inverse

relationship between advancing gestation and a decreased risk of chorioamnionitis. One third of women with pregnancies between 25 and 32 weeks of gestation had latent periods of 3 days, whereas for pregnancies between 33 and 34 and between 35 and 36 weeks, the values were 16% and 4.5%, respectively. In 53 cases of PROM at 16 to 25 weeks (mean, 22.6 weeks), the median length of time from PROM to delivery was 6 days (range, 1 to 87 days; mean, 17 days).<sup>193</sup> In a population-based study of 267 cases of PROM before 34 weeks, fully 76% of women were already in labor at the time of admission, and an additional 5% had an indicated delivery. Only 19% were candidates for expectant management, and of these women, 60% went into labor within 48 hours.<sup>194</sup> Thus, the natural history of PROM reveals that labor usually develops within a few days.

In a minority of the cases of PROM, the membranes can “reseat,” especially with rupture of membranes after amniocentesis. With expectant management, 2.8% to 13% may anticipate the cessation of leakage of amniotic fluid.<sup>195,196</sup>

## Complications

Analysis of complications described in recent studies is complex because of differences in study design. Table 3-11, however, attempts to summarize complications observed in studies with more than 100 infants. Direct comparisons of data from one study to another require extreme caution. The wide-ranging differences are attributable to major differences in populations at risk, gestational age, definitions, and management.

The most common complication among cases with PROM before 37 weeks is RDS, which is found in 10% to 40% of neonates. (A small number of studies have reported RDS in as many as 60% to 80% of newborns.) Neonatal sepsis was documented in less than 10%, whereas amnionitis (based on clinical criteria only) occurred in 4% to 60%.<sup>197</sup> Endometritis developed in 3% to 29% of patients in most reports, but it is not clear whether patients with amnionitis are included in the endometritis category. In selected groups,

**Table 3-11 Complications in Newborns after Premature Rupture of Membranes<sup>a</sup>**

Complication	Rate (%)
Perinatal mortality, overall	0-43
Term	0-2.5
All preterm	2-43
1000-1500 g	29
1501-2500 g	7
RDS, all preterm	10-42
1000-1500 g	42
1501-2500 g	7
Infection	
Amnionitis	4-33
Maternal (overall)	3-29
Endometritis	3-29
Neonatal sepsis	0-7
Neonatal overall (including clinically diagnosed sepsis)	3-281

<sup>a</sup>Studies with more than 100 infants. RDS, respiratory distress syndrome.

such as women who undergo cesarean section after PROM, endometritis occurs in up to 70% of patients.

When latent periods in preterm pregnancies are prolonged, pulmonary hypoplasia is an additional neonatal complication. When rupture of membranes occurs before 19 weeks, the incidence of pulmonary hypoplasia has been reported as 60%.<sup>198</sup> In cases where PROM occurred before 26 weeks and with long intervals (e.g., more than 5 weeks) between rupture and delivery, Nimrod and colleagues noted a 27% incidence of pulmonary hypoplasia.<sup>200</sup> Other studies demonstrate a lower incidence of pulmonary hypoplasia.<sup>199</sup> Pulmonary hypoplasia is rare if PROM occurs after 26 weeks of gestation.<sup>201</sup> In addition, pulmonary hypoplasia is poorly predicted antenatally by ultrasound examination.<sup>202</sup> Ultrasound estimates of interval fetal lung growth include lung length, chest circumference, chest circumference–abdominal circumference ratio, or chest circumference–femur length ratio. An additional 20% of neonates had fetal skeletal deformities as a result of compression. Nonskeletal restriction deformities of prolonged intrauterine crowding similar to features of Potter's syndrome include abnormal facies with low-set ears and epicanthal folds. Limbs may be malpositioned and flattened.<sup>203</sup>

Low Apgar scores, less than 7 at 5 minutes of life, are noted in 15% to 64% of live-born infants.<sup>204-207</sup> This complication is most common among very low birth weight infants. Other complications of PROM, especially in the preterm pregnancy, include malpresentation, cord prolapse, and congenital anomalies. In view of the long list of potential hazards, it is not surprising that premature infants surviving after PROM often are subject to prolonged hospitalization.

Perinatal mortality depends mainly on gestational age. The wide variation in results in Table 3-11 for preterm infants reflects different groupings of gestational ages. It is not certain whether infants with PROM have higher mortality than that for infants of the same gestational age without PROM.

Causes of perinatal death may be determined by examining data from four large series (Table 3-12).<sup>208-210</sup> Two of these studies included stillbirths; two studies excluded them. Overall, RDS was the leading cause of death. Deaths were presumed to be due to hypoxia when there was an ante-

partum or intrapartum death of a very small infant. In both frequency and severity, RDS was a greater threat than infection to the preterm fetus.

Maternal mortality as a complication of PROM is rare. Studies document only one maternal death (related to chorioamnionitis, severe toxemia, and cardiorespiratory arrest) in more than 3000 women with PROM.<sup>211</sup> Case reports of maternal death from sepsis complicating PROM appear sporadically.<sup>212</sup>

### Approach to Diagnosis of Infection

Because of the frequency and potential severity of maternal and fetal infections after PROM, various tests have been studied as predictors of infection. One review critically appraised eight tests and found no test to be ideal.<sup>213</sup> Several authors have evaluated the use of amniocentesis and microscopic examination of amniotic fluid for the presence of bacteria. This approach is limited, however, because amniotic fluid is available in only half of the patients. Clinical infection is more common in women with positive smears or cultures, but 20% to 30% of these women or their newborns had no clinical evidence of infection.<sup>214-217</sup> In addition, amniocentesis may potentially be accompanied by trauma, bleeding, initiation of labor, or introduction of infection, although Yeast and co-authors reported no increase in onset of labor and no trauma in their retrospective series.<sup>218</sup> Table 3-13 summarizes the diagnostic and prognostic value of several tests of amniotic fluid.<sup>219</sup>

Because the value of amniocentesis in patients with preterm PROM has not been determined precisely, most practitioners do not employ this test routinely for several reasons. Most patients with PROM and positive amniotic fluid culture results are in labor within 48 hours, and culture results often are delayed and available after the fact. Because at least some patients have positive culture results with no clinical evidence of infection, there is concern regarding unnecessary delivery of preterm infants. Finally, it has not been demonstrated that clinical decisions based on data from amniocentesis lead to an improved perinatal outcome. Feinstein and colleagues evaluated 73 patients with preterm PROM who underwent amniocentesis.<sup>220</sup> When the Gram stain or culture result was positive, delivery was accomplished. Results were compared with those of 73 matched patients from a historical group. Compared with controls, patients managed by amniocentesis had less clinically diagnosed amnionitis (7% versus 20%;  $P < .05$ ) and fewer low Apgar scores for their infants at 5 minutes (3% versus 12%;  $P < .05$ ). There were, however, no significant differences in rates of overall infection (22% versus 30%), "possible neonatal sepsis" (12% versus 14%), or perinatal deaths (1% versus 3%). Although there were apparent advantages to management by amniocentesis, historically controlled studies have serious limitations, and no significant decreases in overall infection or perinatal mortality were found. In a small comparative study of expectant management versus the use of amniocentesis, Cotton and colleagues reported a significantly shorter neonatal hospital stay in the amniocentesis group ( $P < .01$ ), but more than 25% of patients were excluded because no amniotic fluid pocket was seen.<sup>221</sup> Also, there were no significant differences in rates of maternal infection, neonatal sepsis, or neonatal death. Ohlsson and Wang found Gram

**Table 3-12 Primary Causes of Death among Preterm Infants Born with Premature Rupture of Membranes**

Cause	% of Perinatal Deaths <sup>a</sup>
RDS	29-70
Infection	3-19
Congenital anomaly	9-27
Asphyxia-anoxia	5-46 <sup>b</sup>
Others <sup>c</sup>	9-27

<sup>a</sup>Overall perinatal mortality was 13% to 24%.

<sup>b</sup>Includes stillbirths with birth weight between 500 and 1000 g.

<sup>c</sup>Includes atelectasis, erythroblastosis fetalis, intracranial hemorrhage, and necrotizing enterocolitis.

RDS, respiratory distress syndrome.

Gram stain plus WBC count ( $\geq 50$ cells/mm <sup>3</sup> )	10/11 (90.91%)	102/109 (93.58%)	10/17 (58.82%)	102/103 (99.03%)
Gram stain plus glucose ( $\leq 14$ mg/dL)	10/11 (90.91%)	88/109 (80.73%)	10/31 (32.26%)	88/89 (98.88%)
Gram stain plus IL-6 ( $> 11.30$ ng/mL)	11/11 (100.0%)	89/109 (81.65%)	11/31 (35.48%)	89/89 (100.0%)
Gram stain plus glucose ( $\leq 14$ mg/dL) plus WBC count ( $\geq 50$ cells/mm <sup>3</sup> )	10/11 (90.91%)	85/109 (77.98%)	10/34 (29.41%)	85/86 (98.84%)
Gram stain plus WBC count ( $\geq 50$ cells/mm <sup>3</sup> ) plus IL-6 ( $\geq 11.30$ ng/mL)	11/11 (100.0%)	87/109 (79.82%)	11/33 (33.33%)	87/87 (100.0%)
Gram stain plus glucose ( $\leq 14$ mg/dL) plus IL-6 ( $\geq 11.30$ ng/mL)	11/11 (100.0%)	78/109 (71.56%)	11/42 (26.19%)	78/78 (100.0%)
Gram stain plus WBC count ( $\geq 50$ cells/mm <sup>3</sup> ) plus IL-6 ( $\geq 11.30$ ng/ml) plus glucose ( $\leq 14$ mg/dL)	11/11 (100.0%)	76/109 (69.72%)	11/44 (25.00%)	76/76 (100.0%)

IL-6, interleukin-6; WBC, white blood cell.

Data from Romero R, Yoon BH, Mazor M, Gomez R, et al. The diagnostic and prognostic value of amniotic fluid white blood cell count, glucose, interleukin-6, and Gram stain in patients with preterm labor and intact membranes. *Am J Obstet Gynecol* 169:805, 1993.

stain and culture of amniotic fluid to have a modest positive predictive value for clinical chorioamnionitis.<sup>214</sup> Thus, clear evidence for the widespread use of amniocentesis in PROM is not available. In view of the more recent information regarding the association of cerebral palsy and infection, these issues should be reinvestigated in a controlled fashion.

Noninvasive procedures such as measuring the level of maternal serum C-reactive protein and amniotic fluid volume have also been suggested as predictors of infection. Several groups have evaluated C-reactive protein as such a predictor.<sup>222-226</sup> An elevated level of C-reactive protein in serum from patients with PROM has a modest positive predictive value for histologic amnionitis (40% to 96%), but its predictive value for clinically evident infection is poor (10% to 45%). The value of a normal level of C-reactive protein for predicting absence of clinical chorioamnionitis is better (80% to 97%). In view of the low predictive value of a positive test, a decision to attempt delivery based solely on an elevated C-reactive protein level does not appear wise.

Women who have PROM with oligohydramnios appear to be at increased risk for clinically evident infection, but the positive predictive value is modest (33% to 47%). In 1985, Gonik and co-workers noted that "amnionitis" developed in 8 (47%) of 17 patients with no pocket of amniotic fluid larger than 1 by 1 cm on ultrasound examination, whereas amnionitis developed in 3 (14%) of 22 patients with adequate pockets (i.e., larger than 1 by 1 cm) ( $P < .05$ ).<sup>227</sup> To improve the predictability of these tests, Vintzileos and colleagues used a biophysical profile that included amniotic fluid volume, fetal movement and tone, fetal respirations, and a nonstress test.<sup>228</sup> However, positive predictive value of the biophysical profile has been variable (31% to 60% for clinical chorioamnionitis and 31% to 47% for neonatal sepsis).<sup>214</sup>

### Treatment of Preterm Premature Rupture of Membranes before Fetal Viability

Because fetal viability is nil throughout nearly all of the second trimester, the traditionally recommended approach to PROM in this period of gestation has been to induce labor. However, retrospective reports have provided pertinent data on expectant management for PROM before fetal viability.<sup>229-233</sup> As expected, the latent period is relatively long (mean, 12 to 19 days; median, 6 to 7 days). Although in these reports, maternal clinically evident infections were common (amnionitis in 35% to 59% and endometritis in 13% to 17%), none of these infections were serious, but maternal death from sepsis has been reported.<sup>234</sup> Of note, there was an appreciable neonatal survival rate of 13% to 50%, depending on gestational age at membrane rupture and duration of the latent period. In cases with PROM at less than 23 weeks, the perinatal survival rate was 13% to 47%; whereas with PROM at 24 to 26 weeks, it was 50%.<sup>232,233</sup> The incidence of stillbirths is higher (15%) with midtrimester preterm PROM than with later preterm PROM (1%). The incidence of lethal pulmonary hypoplasia is 50% when membrane rupture occurs before 19 weeks.<sup>235</sup> Accordingly, with appropriate counseling, expectant management may be offered even in the second trimester for selected cases of PROM (Table 3-14). As neonatal survival in the periviable periods continues to improve, the numbers of infants afflicted by moderate to severe disabilities remains substantial.<sup>236</sup> These concerns should be clearly communicated to the mother before delivery. As discussed subsequently, a plan for group B streptococcal surveillance and treatment also would be indicated.

### Investigational Treatment Measures

Highly experimental protocols are investigating the possibility of extrinsic materials to promote resealing of the amniotic membranes.<sup>237</sup> This idea stems from the use of a blood patch

**Table 3-14 Summary of Management Plans for Premature Rupture of Membranes**

Management	
<b>In Second Trimester (&lt;26-28 wk)</b>	
A. Induction	
B. Expectant management	Retrospective works show high maternal infection rate but 13% to 50% neonatal survival
<b>In Early Third Trimester (26-34 wk)</b>	
A. Tocolytics to delay delivery	Randomized trials show no important benefits
B. Corticosteroids to accelerate lung maturity	CDC consensus statement recommends use between 24 and 32 wk
C. Antibiotics for prophylaxis of neonatal group B streptococcal infection	Efficiency established in randomized trial
D. Antibiotics to prolong latent period	Risk-benefit ratio unresolved; limit to randomized trials; optimal duration of antibiotics unresolved
E. Expectant management	Approach followed most commonly; if premature rupture of membranes occurs >32 wk, randomized trials show no neonatal benefit to expectant management
<b>At or Near Term (&gt;35 wk)</b>	
A. Early induction, within 12-24 hr	
B. Late induction, after approximately 24 hr	
C. Expectant management until labor or infection develop	Recent evidence supports both option A and option C
D. Prostaglandin E <sub>1</sub> and E <sub>2</sub> preparations to ripen cervix/ induce labor	Randomized trials and historical data support safety and efficacy

CDC, Centers for Disease Control and Prevention.

for treatment of spinal headache.<sup>238</sup> An aggressive interventional protocol for early midtrimester PROM using gelatin sponge for cervical plugging in patients with spontaneous or iatrogenic preterm PROM at less than 22 weeks with significant oligohydramnios (maximal vertical pocket less than 1.5 cm) evaluated transabdominal or transcervical placement of the gelatin sponge. This measure was in addition to broad-spectrum antibiotic therapy and cervical cerclage. Eight of 15 women undergoing the procedure reached a late enough stage in gestation to allow fetal viability, and 30% of infants survived to hospital discharge. Three of the surviving infants had talipes equinovarus, and two had bilateral hip dysplasia and torticollis. Quintero and colleagues<sup>239</sup> introduced an “amniopatch” consisting of autologous or heterologous platelets and cryoprecipitate through a 22-gauge needle intra-amniotically into seven patients with preterm PROM 16 to 24 weeks following fetoscopy or genetic amniocentesis and reported a fetal survival rate of 42.8% (three of seven). Of the remaining patients, two had unexplained fetal death, one miscarried, and a fourth had an underlying bladder outlet obstruction that prevented resealing of membranes. With spontaneous rupture of membranes, 0 of 12 patients have had resealing of their membranes.<sup>238</sup> The investigators speculate that with spontaneous rupture of membranes, rupture sites are larger, are located over the internal cervical os, are less amenable to patching, and are more susceptible to ascending infection and weakening of the lower portion of the membranes by proinflammatory agents.

To address the larger defect with spontaneous preterm PROM, Quintero and colleagues have investigated the use of an “amnio graft,” achieved by laser-welding the amniotic membranes using Gore-Tex materials and a collagen-based graft material (Biosis), as well as combined use with a fibrin glue, with variable success in both animal models and selected patients.<sup>238-240</sup> Use of a fibrin sealant was associated with a 53.8% survival rate when the sealant was placed

transcervically. In their study, mean gestational age at rupture of membranes was 19 weeks 4 days; at treatment, 20 weeks 5 days; and at delivery, 27 weeks 4 days, with a mean latency of 48 days from initial rupture to delivery. Additional research in this area is necessary to establish the safety and efficacy of this modality.

### Treatment of Preterm Premature Rupture of Membranes in Early Third Trimester

It is at the gestational age interval of 24 to 34 weeks that management is most controversial. Yet new information has become available, and sophisticated meta-analyses have been performed. Controversial components of therapy, including corticosteroids, tocolytics, and antibiotics, are reviewed here. Specific situations such as HSV and HIV infection and cerclage coexisting with PROM are reviewed later in the chapter (see Table 3-14).

#### Corticosteroids

Many investigators have used corticosteroids in at least some patients with PROM.<sup>241-243</sup> In some studies, the investigators found evidence for an increased rate of maternal postpartum infection after administration of corticosteroids. The infections occurred mainly after vaginal delivery and were mild. Of still greater concern is the observation of some investigators that the rate of neonatal sepsis was increased when corticosteroids were used. However, most studies have not found this association.

Some studies reported significant (or nearly significant) decreases in the occurrence of RDS, but others found no significant decrease when corticosteroids were used in patients with PROM.<sup>244-253</sup> There are major difficulties in interpreting these studies. In some of the more rigorously designed studies of corticosteroid use, the numbers of patients with PROM were small. Thus, real differences may have been

missed (a beta error). In most studies, there were at least small decreases in the incidence of RDS in the corticosteroid group. A relatively wide range of gestational ages was studied. The minimum number of weeks of gestation for entry into a study ranged from 25 to 32, and the maximum ranged from 32 to 37. Because an equal effect of corticosteroids on the rate of RDS is unlikely at all gestational age intervals, real differences may have been missed in some intervals, because data for these intervals were combined with data for other gestational ages. Finally, experiments measuring the surfactant-inducing potency of corticosteroids suggest differences in the efficacy of various corticosteroid preparations and various dosages.

Several studies, including three meta-analyses, have attempted to resolve the confusion.<sup>254-256</sup> Unfortunately, the authors reached differing conclusions. Ohlsson concluded that in preterm PROM, corticosteroid treatment “cannot presently be recommended to prevent RDS ... outside a randomized controlled trial.”<sup>254</sup> The reasons underlying this conclusion are that the evidence that it decreases RDS is weak and its use increases the incidence of endometritis and may increase neonatal infections.” On the other hand, Crowley and associates concluded that corticosteroids were effective in preventing RDS after preterm PROM (OR 0.44, 95% CI 0.32 to 0.60) and that they were not associated with a significant increase in perinatal infection (OR 0.84, 95% CI 0.57 to 1.23) or neonatal infection (OR 1.61, 95% CI 0.9 to 3.0).<sup>255</sup> Lovett and colleagues, in a prospective, double-blind trial of treatment for preterm PROM, did use corticosteroids in all patients. They also found significant decreases in mortality, sepsis, and RDS rates, as well as increased birth weight, when corticosteroids and antibiotics were given compared with use of corticosteroids alone. In addition, Lewis and co-workers investigated use of ampicillin-sulbactam in preterm PROM and then randomized patients to receive weekly corticosteroids versus placebo between 24 and 34 weeks. They found a decrease in RDS (44% versus 18%;  $P = .03$  or  $.29$ , 95% CI 0.10% to 0.82%) in the corticosteroid treatment group with no increase in maternal or neonatal infection complications.<sup>256</sup> Lee’s group also evaluated use of weekly steroids in a randomized double-blind trial in women at 24 to 32 weeks with preterm PROM, compared with only a single course of steroids. Although the investigators found no differences in the overall composite neonatal morbidity between the groups (34.2% versus 41.8%), they did find an increased rate of chorioamnionitis in the weekly-course group (49.4% versus 31.7%;  $P = .04$ ). Of note, in the group with gestational age at delivery of 24 to 27 weeks, there was a significant reduction in RDS from 100% in the single-course group to 26.5% ( $P = .001$ ) in the weekly-course group.<sup>257</sup>

Leitch and associates concluded that corticosteroids appear to diminish the beneficial effects of antibiotics in the treatment of preterm PROM. This was based on the results of their meta-analysis of five randomized trials of antibiotics and preterm PROM in which corticosteroids were used, which they compared with those of their previous meta-analysis of preterm PROM without corticosteroids. They found nonsignificant differences in mortality, sepsis, RDS, IVH, and necrotizing enterocolitis when both antibiotics and corticosteroids were used. By contrast, when antibiotics but not corticosteroids were used, they found a significant

decrease in chorioamnionitis (OR 0.37,  $P = .0001$ ), postpartum endometritis (OR 0.47,  $P = .03$ ), neonatal sepsis (OR 0.27,  $P = .002$ ), and IVH (OR 0.48,  $P = .02$ ).<sup>258</sup>

The National Institutes of Health (NIH) Consensus Development Panel in 1995 recommended that corticosteroids be given in the absence of IAI to women with preterm PROM at less than 30 to 32 weeks of gestation because the benefits of corticosteroids may outweigh the risk at this gestational age, particularly with IVH. Because the number of patients receiving corticosteroids with PROM at more than 32 weeks of gestation was small, the consensus panel chose to restrict its recommendation to less than 32 weeks of gestation. Recommended dosing includes betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg every 12 hours for four doses. The consensus panel reconvened in 2000 and reconfirmed their original recommendations. Repeat dosing of steroids was not recommended outside of randomized trials. Guinn and colleagues found no decrease in neonatal morbidity with serial weekly courses of betamethasone compared with single course therapy.<sup>259</sup>

### Antibiotics

Patients with preterm PROM are candidates for prophylaxis against group B streptococci.<sup>260-262</sup> In addition, one innovative report noted use of combination antibiotics in an asymptomatic patient with preterm PROM because of bacterial colonization of the amniotic fluid, which was detected by amniocentesis. A second amniocentesis 48 hours after therapy revealed a sterile culture.<sup>263</sup>

Some studies of preterm pregnancies have found an increased rate of amnionitis to be associated with an increasing length of the latent period,<sup>205,208,264</sup> whereas others<sup>207</sup> have not. In patients with preterm PROM, digital vaginal examination should be avoided until labor develops, although transvaginal or transperineal ultrasound can be safely used to assess cervical length without increasing the risk of infection.<sup>265</sup> Some studies noted that prolonged ROM decreased the incidence of RDS,<sup>210,211</sup> others noted no significant effect.<sup>207-209,242,245,266,267</sup> These discrepancies may be explained by differences in experimental design (such as grouping of various gestational ages and using different sample sizes) or in definitions of clinical complications.

Antibiotics of several classes have been found to prolong pregnancy in the setting of preterm PROM. Two large multicenter clinical trials with different approaches had adequate power to evaluate the utility of antibiotics in the setting of preterm PROM. Mercer and Arheart<sup>268</sup> evaluated the use of antibiotics in PROM with a meta-analysis. They evaluated such outcomes as length of latency, chorioamnionitis, postpartum infection, neonatal survival, neonatal sepsis, RDS, IVH, and necrotizing enterocolitis. Several classes of antibiotics were used, including penicillins and cephalosporins, although few studies used either tocolytics or corticosteroids. Benefits of antibiotics in this analysis included a significant reduction in chorioamnionitis, IVH, and confirmed neonatal sepsis. There was a significant decrease in the number of women delivering within 1 week of membrane rupture (OR 0.56, CI 0.41 to 0.76), but no significant differences were seen in necrotizing enterocolitis, RDS, or mortality. The evidence currently supports use of antibiotics in preterm PROM to prolong latency and to

decrease maternal and neonatal infectious complications, but further studies to select the preferred agent have yet to be performed.

The Maternal Fetal Medicine Units Network of the National Institutes of Child Health and Development (NICHD) conducted a large, multicenter trial of antibiotics after PROM but also did not use tocolytics or corticosteroids. Patients with preterm PROM at between 24 and 32 weeks were included. Patients were randomized to receive aggressive intravenous antibiotic therapy consisting of ampicillin (2 g intravenously [IV] every 6 hours) and erythromycin (250 mg IV every 6 hours) for the first 48 hours, followed by 5 days of oral therapy of amoxicillin (250 mg every 8 hours) and enteric coated erythromycin (333 mg orally every 8 hours) or placebo. Antibiotic treatment resulted in prolongation of pregnancy. Twice (50%) as many patients in the antibiotic treatment group remained pregnant after 7 days and 21 days composite neonatal morbidity was reduced in the antibiotic treatment group from 53% to 44% ( $P < .05$ ). In addition, individual neonatal comorbid conditions occurred less often in the antibiotic treatment group: RDS (40.5% versus 48.7%), stage 3/4 necrotizing enterocolitis (2.3% versus 5.8%), patent ductus arteriosus (PDA) (11.7% versus 20.2%), BPD (13.0% versus 20.5%) ( $P < .05$  for each). Occurrence rates for specific infections including neonatal group B streptococci-associated sepsis (0% versus 1.5%), overall neonatal sepsis (8.4% versus 15.6%), and pneumonia (2.9% versus 7.0%) all were significantly less ( $P < .05$ ) in the antibiotic treatment group.

The second large trial was the multicenter, multiarm ORACLE trial of oral antibiotics in women with preterm PROM at less than 37 weeks. Over 4000 patients were randomized to receive oral erythromycin, amoxicillin-clavulanic acid, both, or placebo for up to 10 days. All of the antibiotic regimens prolonged pregnancy compared with placebo. Amoxicillin-clavulanic acid, however, increased the risk for neonatal necrotizing enterocolitis (1.9% versus 0.5%;  $P = .001$ ), and this regimen is now advised against. The investigators demonstrated a significant decrease in perinatal morbidity, RDS, and necrotizing enterocolitis with use of ampicillin and erythromycin.<sup>269</sup>

Egarter and associates found in a meta-analysis of seven published studies a 68% reduction of neonatal sepsis and a 50% decreased risk of IVH in infants born to mothers receiving antibiotics after preterm PROM. They did not, however, find any significant differences in either RDS or neonatal mortality.<sup>270</sup>

The Cochrane Library has reviewed antibiotic use in preterm PROM in more than 6000 women in 19 trials. This meta-analysis also found that antibiotic use in preterm PROM was associated with an increased latent period at 48 hours and 7 days and reduction in major neonatal comorbid conditions or indicators such as neonatal infection, surfactant use, oxygen therapy, and abnormalities on head ultrasound examination prior to hospital discharge. Of interest, there was an increased risk of necrotizing enterocolitis in the two trials involving 2492 babies in which co-amoxiclav was administered to the mother (relative risk 4.6, 95% CI 1.98 to 10.72). Another included trial in the meta-analysis compared erythromycin to co-amoxiclav; the investigators found fewer deliveries at 48 hours in the co-amoxiclav group but no difference at 7 days. However,

they also found a decrease in necrotizing enterocolitis when erythromycin rather than co-amoxiclav was used (relative risk 0.46, 95% CI 0.23 to 0.94).<sup>271</sup> Thus, they recommended that co-amoxiclav should be avoided in the setting of preterm PROM.

Owing to concerns of emergence of resistant organisms, another question involves duration of antibiotic therapy in preterm PROM. Two recent small trials have evaluated this question. Segel and associates compared 3 days and 7 days of ampicillin in patients at 24 to 33 weeks with preterm PROM. In their 48 patients, there was no difference in 7-day latency as well as no difference in rates of chorioamnionitis, postpartum endometritis, and neonatal morbidity and mortality.<sup>272</sup> Lewis and colleagues studied 3 days versus 7 days of ampicillin-sulbactam (3 g IV every 8 hours) and similarly found no difference in outcomes between groups.<sup>273</sup> Both of these studies are small, so the final answer to this important question remains unanswered. We use 7 days of antibiotics, usually ampicillin and erythromycin, following the dosing from the NICHD trial.

### **Tocolytics and Development of Respiratory Distress Syndrome**

Older studies suggested a decrease in the rate of RDS with use of beta-adrenergic drugs, but in the National Collaborative Study, use of tocolytics in patients with ruptured membranes increased the likelihood of RDS by about 350%.<sup>274</sup> In addition, two small randomized controlled trials have assessed use of tocolytics in the presence of PROM.<sup>275,276</sup> Neither found any significant increase in time to delivery or in birth weight or any decrease in RDS or neonatal hospital stay. These studies, however, did not use antibiotics or corticosteroids. Tocolytics have been shown to prolong pregnancy by about 48 hours in patients with intact membranes, but their efficacy with preterm PROM remains debatable. In the patient with preterm PROM and no contractions, tocolytics need not be given. In the patient with preterm PROM and contractions, IAI should be ruled out before consideration of tocolytics. Tocolytics could be considered in the early third trimester to maximize impact of antenatal corticosteroids (48-hour delay) on neonatal morbidity and mortality. Interested readers are referred to a recent review of this subject.<sup>277</sup>

### **Determination of Fetal Lung Maturity**

Some clinicians determine the status of fetal pulmonary maturity and proceed with delivery if the lungs are mature. Amniotic fluid may be collected by amniocentesis or from the posterior vagina. Either presence of phosphatidylglycerol or a lecithin-to-sphingomyelin ratio higher than 2 in amniotic fluid has been reported to be a good predictor of pulmonary maturity. In a series of patients with PROM before 36 weeks, Brame and MacKenna determined whether phosphatidylglycerol was present in the vaginal pool and delivered patients when there was presence of phosphatidylglycerol, spontaneous labor, or evidence of sepsis.<sup>278</sup> Of 214 patients, 47 had phosphatidylglycerol present initially and were delivered. Of the remaining 167, 36 (21%) were subsequently found to have phosphatidylglycerol and were induced or delivered by cesarean section. Evidence of maternal infection developed in 8 (5%) and spontaneous labor developed in 123 (74%) of the 167 patients. Phosphatidylglycerol in

amniotic fluid from the vagina reliably predicted fetal lung maturity; however, its absence did not necessarily mean that RDS would develop. Of 131 patients who did not show phosphatidylglycerol in the vaginal pool in any sample, 82 (62%) were delivered of infants who had no RDS. Lewis and colleagues also showed the presence of a mature Amniostat-FLM (Hana Biologies, Irvine, Calif) in a vaginal pool sample from 18% of 201 patients, and none developed RDS.

### **Intentional Preterm Induction in the Mid-Third Trimester**

Even with PROM, delivery of a premature infant simply because the lungs show biochemical maturity may be questioned in view of other potential hazards of prematurity and the potential difficulties of the induction.

Two papers have examined this controversial issue. With respect to the new information regarding the association among preterm PROM, chorioamnionitis, and subsequent development of cerebral palsy, the use of intentional mid-third-trimester induction is receiving increased attention.

Mercer and colleagues compared expectant management and immediate induction in 93 pregnancies complicated by PROM between 32 and 36 weeks 6 days, when mature fetal lung profiles were documented. They found significant prolongation of latent period and of maternal hospitalization, as well as increased neonatal length of stay, and increased antimicrobial use in the expectant management group despite no increase in documented neonatal sepsis. Thus, they concluded that in women with preterm PROM at 32 through 36 weeks with a mature fetal lung profile, immediate induction of labor reduces the duration of hospitalization in both mother and neonates.<sup>279</sup> Cox and Leveno similarly studied pregnancies complicated by preterm PROM at 30 to 34 weeks of gestation. Consenting patients were randomly assigned to one of two groups: expectant management versus immediate induction. Corticosteroids, tocolytics, and antibiotics were not used in either group. Fetal lung profiles were not determined. The investigators found a significant increase in the incidence of chorioamnionitis and antepartum hospitalization in the expectant management group. In addition, they found no clinically significant differences in birth weight or frequency of IVH, necrotizing enterocolitis, neonatal sepsis, RDS, or perinatal death. They concluded that there were no clinically significant neonatal advantages to expectant management of ruptured membranes and decreased antepartum hospitalization in those women managed with immediate induction.<sup>280</sup>

### **Fetal Surveillance**

Owing to concerns regarding cord compression and cord prolapse as well as the development of intrauterine and fetal infection, daily fetal monitoring in the setting of preterm PROM has been studied. Vintzileos and colleagues demonstrated that infection developed when the nonstress test became nonreactive 78% of the time, compared with only 14% when the nonstress test remained reactive.<sup>281</sup> Similarly, the biophysical profile score of 6 or less also predicted perinatal infection.<sup>282</sup> As a result, we recommend daily monitoring with nonstress tests. If the nonstress test is nonreactive, further workup with biophysical profile should be performed. Because there are currently no large studies

evaluating outpatient management of preterm PROM, we recommend hospitalization until delivery.

### **Conclusion**

Despite availability of recent data and sophisticated meta-analyses, we believe the evidence supports the use of expectant management in the absence of LAI and in the absence of documented fetal lung maturity in the third trimester until 34 completed weeks. If expectant management is chosen, corticosteroids to enhance fetal organ maturation should be given until 32 weeks. In addition, broad-spectrum antibiotics consisting of ampicillin and erythromycin should be administered for 7 days. Bacterial vaginosis should also be treated if present. In general, tocolytics should be avoided. Daily fetal surveillance is also recommended. Appropriate group B streptococcal prophylaxis in this high-risk group is strongly encouraged during labor. From a cost-effectiveness standpoint, Grable and co-workers looked at PPRM between 32 and 36 weeks. Using their decision analysis based on 1996 cost data, they weighed the costs of maternal hospitalization, latency, infection, and minor/major neonatal morbidity versus that of immediate induction. They found that it is most effective to delay delivery by 1 week between 32 and 34 weeks and to induce at presentation at or after 35 weeks.<sup>283,284</sup>

### **Recurrence**

Recurrence of PPRM in a subsequent pregnancy following an index pregnancy complicated by PPRM has been estimated to be 13.5% to 44%. In Lee and colleagues' population-based case-control study, there was an odds ratio of 20.6 for recurrent PPRM and 3.6 for recurrent preterm birth. However, the estimated gestational age of index preterm PROM is poorly predictive of subsequent timing of recurrent events. The other two studies had higher recurrence of risks but probably included transferred patients, so that the study populations constituted a more select group.<sup>285-288</sup>

### **Prevention**

Because preterm PROM often is accompanied by both maternal and neonatal adverse events, prevention of preterm PROM is desirable. Prediction of preterm PROM was evaluated in a large prospective trial, the Preterm Prediction Study,<sup>288</sup> sponsored by the NICHD Maternal Fetal Medicine Units Network. Prior preterm birth and preterm birth secondary to preterm PROM were associated with subsequent preterm birth. In nulliparas, preterm PROM is associated with medical complications, work in pregnancy, symptomatic contractions, bacterial vaginosis, and low body mass index. In multiparas, associated risk factors included prior preterm PROM, prior preterm birth due to preterm labor, and low body mass index. In both nulliparas and multiparas, a cervix found to be shorter than 25 mm by endovaginal ultrasound examination was associated with preterm PROM. A positive fetal fibronectin also was predictive of preterm PROM in both nulliparas (16.7%) and multiparas (25%). Multiparas with a prior history of preterm birth, a short cervix, and a positive fetal fibronectin had a 31-fold higher risk of PROM and delivery before

35 weeks compared with women without these risk factors (25% versus 0.8%;  $P = .001$ ).<sup>289</sup>

## Special Situations

### ***Cerclage and Preterm Premature Rupture of Membranes***

Classic obstetric dogma has suggested immediate removal of the cervical cerclage stitch when preterm PROM occurs. Risks associated with the retained stitch include maternal infection from bacterial proliferation emanating from the foreign body and cervical lacerations consequent to progression of labor despite the retained stitch. Small retrospective studies have shown conflicting results.

Currently, there are not enough data in the literature to recommend removal or retention of the suture. If there is no evidence of IAI or preterm labor in very premature gestations, one could consider leaving the stitch in during corticosteroid administration while there is uterine quiescence. After corticosteroids are maximized after 48 hours, then the stitch might be removed.<sup>290-294</sup>

### ***Preterm Premature Rupture of Membranes and Herpes Simplex Virus***

In a retrospective review from 1986 to 1996 of 29 patients with preterm PROM and a history of recurrent genital herpes, there were no cases of neonatal herpes. However, the 95% CI suggests that the risk of vertical transmission could be as high as 10%. The mean estimated gestational age at membrane rupture was 27.7 weeks. Mean estimated gestational age at maternal herpetic lesion development was 28.7 weeks. With continued expected management, mean estimated gestational age at delivery was 30.6 weeks in the study group. Of the 29 patients, 13 (45%) were delivered by cesarean section. Additionally, although delivery was performed for obstetric indication only, 8 of 13 patients undergoing cesarean section had active lesions as the only or a secondary indication for cesarean section. In this study, risk of neonatal death from complications of prematurity was 10%. Risk of major neonatal morbidity was 41%. The risks of major morbidity and mortality would have been considerably higher had there been iatrogenic delivery at the time of development of their herpetic lesion. Thus, it appears prudent when there is a history of recurrent HSV infection to continue expectant management in the significantly preterm gestation. In the setting of primary herpes (or nonprimary first episode), with the higher viral loads that entails, early delivery theoretically may prevent vertical transmission, but this has not been specifically studied. Only 8 of the patients in this study received acyclovir treatment. Thus, use of acyclovir for symptomatic outbreaks would theoretically reduce the risk of transmission, as well as decreasing the number of cesarean sections performed for presence of active lesions at the time of delivery.<sup>295</sup> Additionally, Scott and associates have demonstrated a decreased cesarean section rate in term patients with a history of recurrent HSV infection.<sup>296</sup>

### ***Human Immunodeficiency Virus and Preterm Premature Rupture of Membranes***

There are no specific data regarding the subset of patients with preterm PROM who are seropositive for HIV. With

highly active antiretroviral therapy (HAART) and a low viral load, expectant management of preterm PROM after clinical exclusion of IAI might be considered, because the complications of prematurity with gestational age of less than 32 weeks, and certainly less than 28 weeks, are significant. With continued HAART, the risk of vertical transmission should remain low. The physician should discuss and document potential risks and benefits with the mother regarding the possibility of vertical transmission or neonatal morbidity and mortality. Intravenous infusion of zidovudine should be initiated at admission, if the antiretroviral regimen permits, because latency can be unpredictably short in many patients with preterm PROM.<sup>297</sup> If, after a period of observation and no evidence of spontaneous preterm labor, intravenous zidovudine may be discontinued and oral HAART continued.

### **Treatment of Term Premature Rupture of Membranes**

Approximately 8% of pregnant women at term experience PROM, although contractions commence spontaneously within 24 hours of membrane rupture in 80% to 90% of patients.<sup>197</sup> After greater than 24 hours elapses following membrane rupture at term, the incidence of neonatal infection is approximately 1%, but this risk increases to 3% to 5% when clinical chorioamnionitis is diagnosed.<sup>298</sup> For many years, the practice in most institutions had been to induce labor in term patients within approximately 12 hours of PROM, primarily because of concerns about development of chorioamnionitis and neonatal infectious complications. More recently, three studies have demonstrated that in most patients, expectant management can be safely applied (see Table 3-14). The designs of these three reports were different.

Kappy and associates reported a retrospective review in a private population.<sup>299</sup> Duff and colleagues performed a randomized study in indigent patients with unfavorable cervix characteristics (less than 2 cm dilated, less than 80% effaced) and with no complications of pregnancy (e.g., toxemia, diabetes, previous cesarean section, malpresentation, meconium-stained fluid).<sup>300</sup> In the patients assigned to the induction group, initiation of induction generally was at 12 hours after rupture of membranes. The excess cesarean deliveries in the induction group were for failed induction. In the induction group, there was a higher probability of IAI. In the study by Conway and colleagues, all patients were observed until the morning after admission.<sup>301</sup> Induction of labor was then undertaken if the patient was not in labor.

Wagner and co-workers provided yet another variant by comparing early induction (at 6 hours after PROM) to late induction (at 24 hours after PROM).<sup>302</sup> In their population at a Kaiser Permanente hospital, the results favored early induction by shortening maternal hospital stay and decreasing neonatal sepsis evaluations. Recent work also has evaluated use of oral and vaginal prostaglandin preparations (prostaglandins E<sub>1</sub> and E<sub>2</sub>) to ripen the cervix or induce labor after PROM at term. These preparations appear to be effective in shortening labor without increasing maternal or neonatal infection.<sup>303-305</sup>

Hannah and colleagues evaluated four management schemes in women with PROM at term: (1) immediate induction with oxytocin, (2) immediate induction with

vaginal prostaglandin E<sub>2</sub>, (3) expectant management for up to 4 days followed by oxytocin induction, and (4) expectant management followed by prostaglandin E<sub>2</sub> induction. Although no differences in cesarean section rates or frequency of neonatal sepsis were found, an increase in chorioamnionitis was noted in the expectant management groups, and all deaths not caused by congenital anomalies occurred in the expectant management group. Of note, patient satisfaction was higher in the immediate induction group. A secondary analysis demonstrated five variables as independent predictors of neonatal sepsis: clinical chorioamnionitis (OR 5.89), presence of group B streptococci (OR 3.08), seven to eight vaginal examinations (OR 2.37), duration of ruptured membranes 24 to 48 hours (OR 1.97), greater than 48 hours from membrane rupture to active labor (OR 2.25), and maternal antibiotics before delivery (OR 1.63).<sup>306</sup>

We endorse immediate induction with oxytocin in women with PROM at term if the condition of the cervix is favorable and the patient is willing. If the condition of the cervix is unfavorable, induction with appropriate doses of prostaglandins may be used before use of oxytocin. Intrapartum antibiotic prophylaxis against group B streptococci should be used according to the 2002 guidelines,<sup>260</sup> which emphasize universal screening of all gravidas at 35 to 37 weeks. All seropositive women should receive intravenous antibiotics in labor. Changes in the 2002 recommendations over the previous guidelines also include antibiotic guidelines for those with high- and low-risk penicillin allergy, as well as checking antibiotic sensitivities due to emerging antibiotic resistance, particularly resistance of erythromycin and clindamycin to group B streptococci.

# DEVELOPMENTAL IMMUNOLOGY AND ROLE OF HOST DEFENSES IN FETAL AND NEONATAL SUSCEPTIBILITY TO INFECTION

David B. Lewis • Christopher B. Wilson

## T Lymphocytes and Antigen Presentation 88

Overview

Basic Aspects of Antigen Presentation

Antigen Presentation in the Fetus and Neonate

Circulating Neonatal Dendritic Cells

Basic Aspects of T Cell Development and Function

T Cell Development and Function in the Fetus and Neonate

Gamma-Delta T Cells

Antigen-Specific T Cell Function in the Fetus and Neonate

Fetal T Cell Sensitization to Maternally Administered Vaccines and Maternally Derived Antigens

Summary

## B Cells and Immunoglobulin 127

Basic Aspects of B Cells and Immunoglobulin Production

Ontogeny of B Cells and Immunoglobulins

Immunoglobulin Synthesis by the Fetus and Neonate

Summary

## Natural Killer Cells 143

Basic Aspects of Natural Killer Cells and Their Function

Natural Killer Cell Development and Function in the Fetus and Neonate

Summary

## Phagocytes 149

Origin and Differentiation of Phagocytes

Neutrophilic Polymorphonuclear Leukocytes

Neutrophils in the Fetus and Neonate

Eosinophilic Granulocytes

Mononuclear Phagocytes

Mononuclear Phagocytes in the Fetus and Neonate

Summary

## Humoral Mediators of Inflammation and Opsonization 160

Complement

C-Reactive Protein

Mannan-Binding Lectin

Surfactant Apoproteins

Lipopolysaccharide-Binding Protein

Fibronectin

Opsonic Activity

Chemotactic Factor Generation

Summary

## Host Defense against Specific Classes of Neonatal Pathogens 164

Pyogenic Bacteria: Group B Streptococci

Viruses

Nonviral Intracellular Pathogens

## Immunoprophylaxis in the Neonate 180

Passive Immunization

Active Immunization

Recognition of Primary Immunodeficiency in the Neonate

The human fetus and neonate, particularly the premature neonate, are unduly susceptible to a wide variety of microbes. This susceptibility results from limitations of both innate and adaptive (antigen-specific) immunity, and from limitations in processes through which the innate immune system facilitates and directs the development of protective antigen-specific immunity. This chapter focuses on the ontogeny of the cellular and humoral components of the immune system and their function in the human fetus, neonate, and young infant. Antigen-specific immunity is discussed first, followed by innate mechanisms of host defense. The relationship between deficiencies in immune function in the neonate and fetus and their increased susceptibility to bacterial, viral, and protozoal infections are examined, followed by a brief review of current and potential applications of immunotherapy as therapeutic adjuncts or for the prevention of these infections.

The immune system is composed of hematopoietic cells, including lymphocytes, mononuclear phagocytes, myeloid and lymphoid dendritic cells (DCs), and granulocytes; certain nonhematopoietic cells, such as follicular DCs and thymic epithelial cells; and humoral factors, such as cytokines (Tables 4-1 and 4-2) and complement components. The mature hematopoietic cells of mammals are derived from pluripotent hematopoietic stem cells (HSCs). HSCs are generated during ontogeny from embryonic para-aortic tissue (the splanchnopleure), fetal liver, and bone marrow.<sup>1</sup> The yolk sac, which is extraembryonic, is a major site of nonlymphoid hematopoiesis starting at about the third week of embryonic development and is supplanted by the fetal liver at 8 weeks of gestation and, finally, by the bone marrow after 5 months of gestation. HSCs are found in the para-aortic tissue region by day 27 of human gestation, and cells with blood-forming potential in vitro have been identified in this region as early as day 19 of development.<sup>2</sup> Hematopoiesis by the fetal liver and bone marrow is established by seeding of these sites with circulating HSCs derived from para-aortic tissue.<sup>3</sup> All major lineages of hematopoietic cells that are part of the immune system are present in the human by the beginning of the second trimester. Their ontogeny from HSCs is discussed in separate sections of this chapter.

**Table 4-1 Major Human Cytokines and TNF Family Ligands: Structure, Cognate Receptors, and Receptor-Mediated Signal Transduction Pathways**

Cytokine Family	Members	Structure	Cognate Receptor Family	Proximal Signal Transduction Pathway(s)
IL-1	IL-1 $\alpha$ , IL-1 $\beta$ , IL-18 (IL-1 $\gamma$ ), and IL-1 receptor antagonist	$\beta$ -Trefoil, monomers; processed and secreted	IL-1 receptor	IRAK; JNK
Hematopoietin	IL-2-IL-7, IL-9-IL3, IL-15, IL-17, IL-19, IL-29, CSFs, oncostatin-M, and IFNs ( $\alpha$ , $\beta$ , $\gamma$ , and others); class II subfamily consists of IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, and IFNs	Four $\alpha$ -helical; monomers except for IL-5 and IFNs (homodimers) and IL-12, IL-23, and IL-27 (heterodimers); secreted	Hematopoietin receptors	JAK tyrosine kinases/ STAT, Src and Syk tyrosine kinases
TNF ligand	TNF- $\alpha$ , lymphotoxin- $\alpha$ , - $\beta$ , CD27L, CD30L, CD40L, OX40L, TRAIL, and others	$\beta$ -Jellyroll; homotrimers; type II membrane proteins and secreted	TNF receptor family	TRAFs and proteins mediating apoptosis
TGF- $\beta$	TGF- $\beta$ 1, - $\beta$ 2, - $\beta$ 3, bone morphogenetic proteins	Cysteine knot; processed and secreted	TGF- $\beta$ receptors type 1 and type 2 heterodimers (intrinsic serine threonine kinases)	Smad proteins
Chemokines		Three-stranded $\beta$ -sheet; all but fractalkine are secreted	Seven membrane-spanning domains	G protein-mediated
CXC ligand subfamily	CXCL1-14, CXCL16		CXCR1-CXCR6	
CC ligand subfamily	CCL1-5, CCL7, CCL8, CCL11, CCL13-CCL28		CCR1-CCR10	
C ligand subfamily	XCL1 (lymphotactin), XCL2 (SCM-1 $\beta$ )		XCR1	
CX3C ligand subfamily	CX3CL (fractalkine)		CX3CR1	

CSF, colony-stimulating factors; IFN, interferon; IL, interleukin; IRAK, IL-1 receptor-associated serine/threonine kinase; JNK, c-Jun N-terminal kinase; STAT, signal transducer and activator of transcription; TGF, transforming growth factor; TNF, tumor necrosis factor; TRAFs, TNF- $\alpha$  receptor-associated factors; TRAIL, TNF-related apoptosis-inducing ligand.

## T LYMPHOCYTES AND ANTIGEN PRESENTATION

### Overview

T lymphocytes, which are commonly referred to as T cells, are so named because the vast majority originate in the thymus. Along with B lymphocytes (B cells), which develop in the bone marrow, T cells comprise the adaptive or antigen-specific immune system. T lymphocytes play a central role in antigen-specific immunity because they directly mediate cellular immune responses and play a critical role in facilitating antigen-specific humoral immune responses by B cells.

Most T cells recognize antigen in the form of peptides bound to major histocompatibility complex (MHC) molecules on antigen-presenting cells (APCs). Antigen-specific T cell receptors (TCRs) are heterodimeric molecules composed of either  $\alpha$  and  $\beta$  chains ( $\alpha\beta$ -TCRs) (Fig. 4-1) or  $\gamma$  and  $\delta$  chains ( $\gamma\delta$ -TCRs).<sup>4</sup> The amino-terminal portion of each of these chains is variable and is involved in antigen recognition. As

discussed later, the highly variable nature of this portion of the TCR is generated, in large part, as a result of TCR gene rearrangement of variable (V), diversity (D), and joining (J) segments. By contrast, the carboxy-terminal region of each of the four TCR chains is monomorphic or constant. The TCR on the cell surface is invariably associated with the nonpolymorphic complex of CD3 proteins, which include CD3- $\gamma$ , - $\delta$ , - $\epsilon$ , and - $\zeta$  (see Fig. 4-1).<sup>5,6</sup> The cytoplasmic domains of proteins of the CD3 complex include 10 immunoreceptor tyrosine-based activation motifs (ITAMs), which serve as docking sites for intracellular tyrosine kinases that transduce activation signals to the interior of the cell after the TCR has been engaged by antigen.<sup>6</sup>

Nearly all T cells that bear an  $\alpha\beta$ -TCR, hereafter referred to as  $\alpha\beta$  T cells, also express on their surface the CD4 or CD8 co-receptors in a mutually exclusive manner. The CD4 co-receptor is expressed as a monomeric or homo-oligomeric complex.<sup>7</sup> The CD8 co-receptor may consist either of CD8- $\alpha$ /CD8- $\beta$  heterodimers or CD8- $\alpha$ /CD8- $\alpha$  homodimers.<sup>8</sup> The  $\alpha\beta$  T cells mainly express CD8- $\alpha$ /CD8- $\beta$  heterodimers; a subset of T cells with  $\gamma\delta$ -TCRs, hereafter referred to as  $\gamma\delta$

Table 4-2 Immunoregulatory Effects of Select Cytokines, Chemokines, and TNF Ligand Family Proteins and Their Production by Human Neonatal Cells

Cytokine	Principal Cell Source	Major Biologic Effects	Production by Neonatal versus Adult Cells	Reference(s)
IL-1 $\alpha$ , IL-1 $\beta$	Many cell types; M $\phi$ are a major source	Fever, inflammatory response, cofactor in T and B cell growth	MNCs: normal after LPS treatment; ?reduced in premature	1080, 1405
IL-2	T cells	T > B cell growth, increased cytotoxicity by T and NK cells, increased cytokine production and sensitivity to apoptosis by T cells, growth and survival of regulatory T cells	T cells: normal with most polyclonal stimuli; neonatal < adult after CD3 mAb treatment	326, 342, 343
IL-3	T cells	Growth of early hematopoietic precursors (also known as multi-CSF)	T cells: neonatal and adult naïve < adult memory	342, 1406, 1407
IL-4	T cells, mast cells, basophils, eosinophils	Required for IgE synthesis; enhances B cell growth and MHC class II expression; promotes T cell growth and T <sub>H</sub> 2 differentiation, mast cell growth factor; enhances endothelial VCAM-1 expression	MNCs: neonatal < adult T cells: Neonatal and adult naïve < adult memory	342, 343
IL-5	T cells, NK cells, mast cells, basophils, eosinophils	Eosinophil growth, differentiation, and survival	T cells: neonatal and adult naïve < adult memory	342
IL-6	M $\phi$ , fibroblasts, T cells	Hepatic acute-phase protein synthesis, fever, T and B cell growth and differentiation	T cells: neonatal < adult naïve < adult memory MNC: term normal to slightly reduced; premature ~25% of adult M $\phi$ : neonatal < adult after RSV infection Whole blood: neonatal = adult	1408-1412
IL-7	Stromal cells of bone marrow and thymus	Essential thymocyte growth factor	Not known	
IL-8 (CXCL8)	M $\phi$ , endothelial cells, fibroblasts, epithelial cells, T cells	Chemotaxis and activation of neutrophils	MNCs: neonatal < adult or normal in different studies using LPS stimulation; preterm < term M $\phi$ : decreased after GBS incubation Whole blood: neonatal = adult	1082, 1083, 1408, 1413
IL-9	T cells, mast cells	T cell and mast cell growth factor	Not known	
IL-10	M $\phi$ , T cells, B cells, NK cells, B cells, NK cells, keratinocytes, eosinophils	Inhibits cytokine production by T cells and mononuclear cell inflammatory function; promotes B cell growth and isotype switching, NK cell cytotoxicity	T cells: neonatal and adult naïve < adult memory MNC: neonatal < adult (lectin or LPS) M $\phi$ : neonatal < adult Whole blood: neonatal = adult	346, 731, 1088, 1408
IL-11	Marrow stromal cells, fibroblasts	Hematopoietic precursor growth, acute-phase reactants by hepatocytes	Fibroblasts: neonatal > adult	1414

**Table 4–2 Immunoregulatory Effects of Select Cytokines, Chemokines, and TNF Ligand Family Proteins and Their Production by Human Neonatal Cells—cont'd**

Cytokine	Principal Cell Source	Major Biologic Effects	Production by Neonatal versus Adult Cells	Reference(s)
IL-12	Dendritic cells, M $\phi$	Enhances T <sub>H</sub> 1 differentiation, T cell growth, T cell and NK cell cytotoxicity; induces IFN- $\gamma$ secretion by T cells and NK cells; enhances B cell response to TI antigens	MNCs: neonatal and young children < adult or normal after LPS in different studies; normal in response to <i>S. aureus</i> DC: neonatal < adult in response to LPS or pertussis toxin	69, 73, 85-88, 911, 1415, 1416
IL-13	T cells, mast cells, basophils, eosinophils	Very similar to those of IL-4, with possible exception of lacking direct T cell effects and greater effect on goblet cells of lung	T cells: neonatal and adult naïve CD4 <sup>+</sup> < adult memory CD4 <sup>+</sup> Neonatal CD8 <sup>+</sup> > adult CD8 <sup>+</sup>	358, 1417
IL-15	Epithelial cells, bone marrow stromal cells, activated monocytes	Enhances NK cell development, growth, survival, cytotoxicity, and cytokine production; T cell chemoattractant and growth factor	MNC: neonatal < adult after LPS stimulation	891
IL-17	T cells	Enhances T cell proliferation; proinflammatory cytokine release by macrophages	Not known	
IL-18	Macrophages, hepatic Kupffer cells, intestinal and skin epithelia	Promotes T <sub>H</sub> 1 differentiation; production of IL-2 and GM-CSF by T cells, and IFN- $\gamma$ by T cells, NK cells, and B cells; T cell- and NK cell-mediated cytotoxicity, DC recruitment	MNCs: neonatal 65% of adult in response to group B streptococci	1093
IL-21	T cells	Enhances proliferation of B cells, naïve T cells; NK cell differentiation and cytotoxicity	Not known	
IL-23	Dendritic cells, M $\phi$	Similar effects to those of IL-12	Not known	
IL-25	T <sub>H</sub> 2 cells, mast cells	Promotes T <sub>H</sub> 2 cytokine secretion by T cells and APCs (?M $\phi$ )	Not known	
IL-27	Dendritic cells, M $\phi$	Promotes responsiveness of T cells to IL-12; inhibits T <sub>H</sub> 2 differentiation	Not known	
IFN- $\alpha$	Dendritic cells, M $\phi$	Inhibits viral replication; increases MHC class I expression and NK cell cytotoxicity	MNCs: normal to some stimuli but reduced to most stimuli, including HSV, parainfluenza virus, unmethylated CpG DNA and poly (I:C), particularly in premature	69, 82, 83, 84, 1091, 1418
IFN- $\beta$	Fibroblasts, epithelial cells, dendritic cells	Same as for IFN- $\alpha$	MNC: normal	82
IFN- $\gamma$	T cells, NK cells, eosinophils (?), IL-18-stimulated B cells	Same as for IFN- $\alpha$ and - $\beta$ ; also activates M $\phi$ , increases MHC class II and antigen presentation molecules, inhibits IgE production, enhances B cell response to TI antigens, promotes T <sub>H</sub> 1 differentiation	T cells: neonatal and adult naïve < adult memory; neonatal < adult naïve with allostimulation NK cells: normal after HSV and IL-2 stimulation MNCs: neonatal < adult after IL-12 and IL-15 treatment	86, 326, 343, 356, 891, 924, 1415, 1419

**Table 4-2 Immunoregulatory Effects of Select Cytokines, Chemokines, and TNF Ligand Family Proteins and Their Production by Human Neonatal Cells—cont'd**

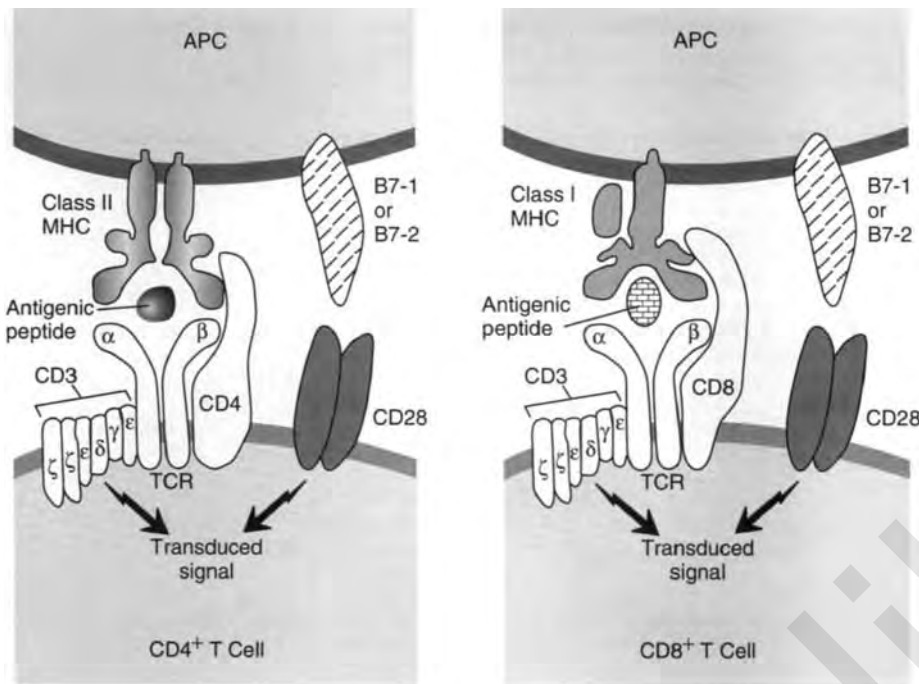

Cytokine	Principal Cell Source	Major Biologic Effects	Production by Neonatal versus Adult Cells	Reference(s)
TNF- $\alpha$	M $\phi$ , T cells, and NK cells	Fever and inflammatory response effects similar to IL-1, shock, hemorrhagic necrosis of tumors, and increased VCAM-1 expression on endothelium; induces catabolic state	T cells: neonatal < adult MNCs: neonatal < adult after IL-15 or LPS treatment M $\phi$ : neonatal < adult after RSV infection; preterm < adult after LPS treatment Whole blood: neonatal = adult	348, 891, 1080, 1408, 1412, 1420
CD40 ligand (CD154)	T cells, lower amounts by B cells and DCs	B cell growth factor; promotes isotype switching, promotes IL-12 production by dendritic cells, activates M $\phi$	T cells: neonatal < adult naive after calcium ionophore and phorbol ester; neonatal $\leq$ adult or adult naive after CD3 mAb and allostimulation	356, 362, 364, 376-379
Fas ligand	Activated T cells, NK cells retina, testicular epithelium	Induces apoptosis of cells expressing Fas, including effector B and T cells	T cells: neonatal < adult after CD3 and CD28 mAbs	362
Flt-3 ligand	Bone marrow stromal cells	Potent DC growth factor; promotes growth of myeloid and lymphoid progenitor cells in conjunction with other cytokines	Unknown	
G-CSF	M $\phi$ , fibroblasts, epithelial cells	Growth of granulocyte precursors	MNCs: neonate normal or slightly < than adults M $\phi$ : term similar and preterm < adult	344, 962, 1421
GM-CSF	M $\phi$ , endothelial cells, T cells	Growth of granulocyte-M $\phi$ precursors and dendritic cells, enhances granulocyte-M $\phi$ function and B cell antibody production	T cells: neonatal < adult MNC: neonatal < adult M $\phi$ : normal after LPS stimulation	342, 344, 1421, 1422
CCL3 (MIP-1 $\alpha$ )	M $\phi$ , T cells	M $\phi$ chemoattractant; T cell activator	MNCs: neonatal < adult	1083
CCL5 (RANTES)	M $\phi$ , T cells, fibroblasts, epithelial cells	M $\phi$ and memory T cell chemoattractant; enhances T cell activation; blocks HIV co-receptor	T cells: neonatal < adult	357
TGF- $\beta$	M $\phi$ , T cells, fibroblasts, epithelial cells, others	Inhibits M $\phi$ activation; inhibits T $_H$ 1 T cell responses	MNCs: neonate < adult	1083

APC, antigen-presenting cell; CSF, colony-stimulating factor; DC = dendritic cell; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GBS, group B streptococci; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IFN, interferon; IgE, immunoglobulin E; IL, interleukin; LPS, lipopolysaccharide; M $\phi$ , mononuclear phagocytes; mAb, monoclonal antibody; MHC, major histocompatibility complex; MIP-1 $\alpha$ , macrophage inflammatory protein-1 $\alpha$ ; MNCs, circulating mononuclear cells; NK, natural killer; RSV, respiratory syncytial virus; *S. aureus*, *Staphylococcus aureus*; TGF, transforming growth factor; TI, T cell-independent; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1.

T cells, express CD8- $\alpha$ /CD8- $\alpha$  homodimers. Those  $\alpha\beta$  T cells expressing CD4 or CD8 are commonly referred to as CD4<sup>+</sup> or CD8<sup>+</sup> T cells, respectively. Nearly all  $\alpha\beta$  T cells recognize protein antigens in the form of peptide fragments bound to classic MHC molecules—peptide-MHC class I complexes in the case of CD8<sup>+</sup> T cells and peptide-MHC class II molecules in the case of CD4<sup>+</sup> T cells. Thus, antigen processing—the generation of peptide fragments from protein antigens—and antigen presentation—the display of peptide-MHC

complexes on the surface of cells—play an essential role in enabling T cells to recognize and respond to microbes.

Certain types of cells express MHC class I molecules and also constitutively express MHC class II molecules, which endows them with enhanced capacity to present antigenic peptides to T cells. Such cells commonly are referred to as APCs and include DCs, mononuclear phagocytes, and B lymphocytes. DCs express particularly high amounts of MHC class I and class II molecules, as well as other proteins

**Figure 4-1** T cell recognition of antigen and activation. The  $\alpha\beta$  T cell receptor ( $\alpha\beta$ -TCR) recognizes antigen presented by the antigen-presenting cell (APC) in the form of antigenic peptides bound to major histocompatibility complex (MHC) molecules on the APC surface. Most  $CD4^+$  T cells recognize peptides bound to MHC class II, whereas most  $CD8^+$  T cells recognize peptides bound to MHC class I. This MHC restriction is the result of a thymic selection process, and is due in part to an intrinsic affinity of the CD4 and CD8 molecules for the MHC class II and class I molecules, respectively. Once antigen is recognized, the CD3 protein complex, which is invariably associated with the  $\alpha\beta$ -TCR, acts as a docking site for tyrosine kinases that transmit activating intracellular signals. Interaction of the T cell CD28 molecule with either CD80 (B7-1) or CD86 (B7-2) provides an important co-stimulatory signal to the T cell, leading to complete activation, rather than partial activation or functional inactivation (anergy).

that allow them to effectively take up and present antigen to naïve  $CD4^+$  and  $CD8^+$  T cells, allowing them to play a critical role in the initiation of primary antigen-specific T cell responses.<sup>9</sup> Thus, DCs, which are part of the innate immune system, are a critical link between innate immunity and the induction of antigen-specific T cell-mediated immunity.

In contrast with  $\alpha\beta$  T cells, a majority of  $\gamma\delta$  T cells appear to recognize either stress-induced, nonclassic MHC molecules themselves or nonpeptide antigens, such as host- or pathogen-derived lipid-containing molecules, bound to these nonclassic MHC molecules.

## Basic Aspects of Antigen Presentation

### Antigen Presentation by Class I Major Histocompatibility Complex Molecules

Three major types of MHC class I heavy chains exist in humans: the human leukocyte antigens HLA-A, -B, and -C, which are encoded by three genes clustered on chromosome 6, in a region known as the MHC locus. Classic MHC class I molecules consist of a polymorphic  $\alpha$  or heavy chain, which is associated with a monomorphic light chain,  $\beta_2$ -microglobulin. MHC molecules have a special cleft or groove for presenting antigenic peptides (Fig. 4-2; see also Fig. 4-1). In MHC class I molecules, this cleft is formed by the  $\alpha 1$  and  $\alpha 2$  domains of the heavy chain. Peptides bound to MHC class I are preferentially recognized by the  $CD8^+$  subset rather than the by  $CD4^+$  subset of  $\alpha\beta$  T cells. This specificity is due, at least in part, to an affinity of the CD8 molecule for the  $\alpha 3$  domain of the heavy chain, which is distinct from the portion of the heavy chain involved in binding peptide.

Most peptides bound to MHC class I molecules are derived from proteins synthesized de novo within host cells (see Fig. 4-2). The bulk of these peptides are derived from recently translated proteins rather than as a result of turn-

over of stable proteins, thereby minimizing any delay in detecting pathogen-derived peptides that may result from recent infection.<sup>10</sup> In uninfected cells, these peptides are derived from host proteins; that is, they are self-peptides. Recently synthesized host proteins that are targeted for degradation, for example, because of misfolding or defective post-translational modification, are a major source of self-peptides that bind to MHC class I. After intracellular infection, such as with a virus, peptides derived from viral proteins endogenously synthesized within the cell bind to and are presented by MHC class I. Antigenic peptides are derived predominantly by enzymatic cleavage of proteins in the cytoplasm by a specialized organelle called the proteasome. A specific peptide transporter or pump, the transporter associated with antigen processing (TAP), then shuttles peptides formed in the cytoplasm to the endoplasmic reticulum, where peptides are able to bind to recently synthesized MHC class I molecules. Peptide binding stabilizes the association of the heavy chain with  $\beta_2$ -microglobulin in this compartment and allows the complex to transit to the cell surface.

Peptides bound to MHC class I molecules in vivo typically are 8 to 10 amino acids in length. The peptide-binding groove is closed at both ends so that larger peptides cannot be accommodated. For a given MHC allele, certain positions (anchor residues) within the peptide can be encoded only by specific amino acids for effective binding to the cleft. Amino acid residues at other, more variable positions point out of the cleft and are recognized by the TCR (epitope residues). The antigen recognition process clearly imposes significant restrictions on the ability of peptides from a particular protein to be immunogenic, because the peptide must both bind to the MHC molecule and be recognized by the TCR.

These constraints on peptide immunogenicity are offset by the availability of the three different types of MHC class I molecules (HLA-A, -B, and -C), each of which is highly polymorphic. The human HLA-A, -B, and -C heavy chain genes

**Figure 4-2** Intracellular pathways of antigen presentation. **A**, Foreign peptides that bind to major histocompatibility complex (MHC) class I are derived predominantly from cytoplasmic proteins synthesized de novo within the cell. Viral proteins entering cells following fusion of an enveloped virus with the cell membrane may also enter this pathway. Dendritic cells are particularly efficient at taking up proteins for the MHC class I pathway by micro- or macropinocytosis. These cells also can transfer proteins taken up as part of necrotic or apoptotic debris into the MHC class I pathway, a process known as cross-presentation. Cytoplasmic proteins are degraded by proteasomes into peptides, which then enter into the endoplasmic reticulum via the TAP ("transporter associated with antigen processing") system. Peptide binding to de novo synthesized MHC class I takes place within the endoplasmic reticulum. **B**, Foreign peptides that bind to MHC class II are mainly derived from either internalization proteins found in the extracellular space or that are components of cell membrane. The invariant chain binds to recently synthesized MHC class II and prevents peptide binding until a specialized cellular compartment for MHC class II peptide loading is reached. In this compartment, the invariant chain is proteolytically cleaved and released and peptides derived from internalized proteins may now bind to MHC class II. The human leukocyte antigen (HLA)-DM molecule facilitates the loading of peptide within this compartment. In dendritic cells, proteins that enter into the MHC class II antigen presentation pathway can be transferred to the MHC class I pathway by cross-presentation.

have at least 303, 558, and 150 different molecularly defined alleles, respectively,<sup>11</sup> with the greatest degree of polymorphism found in the region encoding the antigenic cleft.<sup>12</sup> MHC polymorphism ensures that at the individual and population levels, MHC molecules are able to bind and present a wide variety of peptides to T cells. It has been proposed that populations in which the MHC alleles are less polymorphic, such as Native Americans, may be at greater risk for certain infections owing to limitations in the diversity of antigenic peptides that can be presented.<sup>13</sup>

MHC class I molecules and the cell components required for peptide generation, transport, and MHC class I binding are virtually ubiquitous in the cells of vertebrates. The advantage to the host is that cytotoxic CD8<sup>+</sup> T cells can then recognize and lyse cells infected with intracellular pathogens in most tissues. Adult neuronal cells are one of the few cell types that constitutively lack MHC class I.<sup>14</sup> Because neurons are predominantly postmitotic cells, lack of MHC class I molecules may help to limit immune-mediated destruction of a cell type with a limited capacity to be replaced. MHC class I molecules are expressed by some populations of fetal neuronal cells, however, and this expression appears to play a role in neuronal development that is distinct from antigen presentation.<sup>15</sup> MHC class I HLA-A, -B, and -C molecules also are absent from the trophoblast of the human placenta, which may serve to limit the recognition of fetal-derived

trophoblast cells as foreign by maternal T cells. The abundance of MHC class I molecules is increased by exposure to interferons (IFNs), which also can induce the expression of modest amounts of MHC class I molecules on cell types that normally lack expression, including neuronal cells.

DCs appear to be unique in their ability to present antigenic peptides on MHC class I molecules by an additional pathway, known as cross-presentation, in which extracellular proteins that are taken up as large particles (phagocytosis), as small particles (macropinocytosis), or in soluble form (micropinocytosis) are then transferred from endocytic vesicles to the cytoplasm and subsequently loaded onto MHC class I molecules through TAP.<sup>16</sup> Phagocytosis of apoptotic cells or blebs from apoptotic cells appears to be a particularly efficient source of antigens for cross-presentation.<sup>16</sup> Cross-presentation is enhanced by exposure of DCs to IFN- $\alpha$  and IFN- $\beta$ , which together constitute type I IFN, and are typically produced at high levels during viral infections.<sup>17</sup> Cross-presentation is essential for the induction of primary CD8<sup>+</sup> T cell responses directed toward antigens of pathogens that do not directly infect APCs (e.g., most viruses) and therefore cannot be directly loaded into the MHC class I pathway. Other viruses, such as those of the herpesvirus family, can directly infect APCs but also disrupt conventional MHC class I antigen presentation (discussed in more detail later on). In this situation, the cross-presentation pathway may allow peptides

derived from viral proteins taken up by the cell to reach the TAP transporter before the expression of virally encoded gene products that disrupt antigen presentation.<sup>18</sup>

### Antigen Presentation by Class II Major Histocompatibility Complex Molecules

In MHC class II molecules, an  $\alpha$  and a  $\beta$  chain each contribute to the formation of the groove in which antigenic peptides bind (see Fig. 4-2).<sup>19</sup> MHC class II-peptide complexes are recognized primarily by  $\alpha\beta$  T cells of the CD4<sup>+</sup> but not by the CD8<sup>+</sup> subset. This is due, at least in part, to an affinity of the CD4 molecule for a domain of the MHC class II  $\beta$  chain distinct from the region that forms part of the peptide-binding groove. In contrast with MHC class I, peptides that bind to MHC class II proteins are derived mostly from phagocytosis or endocytosis of soluble or membrane-bound proteins (see Fig. 4-2). In the absence of foreign proteins, a majority of peptides bound to MHC class II molecules are self-peptides derived from proteins found either on the cell surface or secreted by the cell. Newly synthesized MHC class II molecules associate in the endoplasmic reticulum with a protein called the invariant chain, which impedes their binding of endogenous peptides in this compartment. The loading of exogenously derived peptides and the removal of invariant chain from MHC class II are facilitated by HLA-DM (see Fig. 4-2), a nonpolymorphic heterodimeric protein that is encoded in the MHC locus.<sup>19</sup> Peptide loading appears to occur in a late endocytic compartment or compartments, which have been called CIIV or MIIC (class II vesicles or MHC class II compartment),<sup>20</sup> effectively separating peptide binding to MHC class I and to MHC class II into two separate pools. Unlike the MHC class I cleft, the MHC class II cleft is open at both ends, allowing the binding of larger peptides. Most MHC class II peptides are from 14 to 18 amino acids in length, although they can be substantially longer.

As with MHC class I molecules, the genes that encode the  $\alpha$  and  $\beta$  chains of the three major types of human MHC class II molecules—HLA-DR, -DP, and -DQ—are located on chromosome 6 and are highly polymorphic, particularly in the region encoding the peptide-binding cleft.<sup>21</sup> In humans and primates, HLA-DR allelic diversity is mediated solely by the HLA-DR  $\beta$  chain, because the HLA-DR  $\alpha$  chain is monomorphic. HLA-DR $\beta$  protein is encoded mainly at the *DRB1* locus, for which there are 362 known molecular alleles.<sup>11</sup> Some HLA-DR $\beta$  proteins may be encoded by less polymorphic loci, such as *DRB3*, that are closely linked to *DRB1*. The HLA-DP $\alpha$ , -DP $\beta$ , -DQ $\alpha$ , and -DQ $\beta$  gene loci are highly polymorphic, consisting of 20, 107, 25, and 56 known molecular alleles, respectively.<sup>11</sup> HLA-DR is expressed at substantially higher levels than HLA-DP or HLA-DQ, which probably accounts for its predominance as the restricting MHC class II type for many CD4<sup>+</sup> T cell immune responses.

The distribution of MHC class II in uninflamed tissues is much more restricted than MHC class I,<sup>22</sup> with constitutive MHC class II mainly limited to APCs, such as DCs, mononuclear phagocytes, and B cells. Limiting MHC class II expression in most situations to these cell types makes teleologic sense, because the major function of these professional APCs is to process foreign antigen for recognition by CD4<sup>+</sup> T cells. Other cell types can be induced to express MHC class II and, in some cases, present antigen to CD4<sup>+</sup> T cells, as a consequence of tissue inflammation or exposure to

cytokines, particularly IFN- $\gamma$  but also tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) or granulocyte-macrophage colony-stimulating factor (GM-CSF) (see Tables 4-1 and 4-2).

### Nonclassic Antigen-Presentation Molecules

**HLA-E.** HLA-E is a nonclassic and nonpolymorphic MHC molecule similar to conventional MHC class I in its dependency on the TAP transporter for peptide loading and in its obligate association with  $\beta_2$ -microglobulin.<sup>23</sup> In contrast with conventional MHC class I, HLA-E preferentially binds hydrophobic peptides derived from the amino-terminal leader sequences of most alleles of HLA-A, -B, and -C.<sup>24</sup> Low levels of HLA-E surface expression can be detected on most cell types,<sup>25</sup> consistent with the nearly ubiquitous distribution of HLA-A, -B, and -C and the TAP system. The principal role for HLA-E is to interact with the CD94-containing receptors on natural killer (NK) lymphocytes and to regulate their function (see later section on NK cell inhibitory receptors). HLA-E messenger RNA (mRNA) is detectable in human fetal liver early during the second trimester.<sup>26</sup>

**HLA-G.** HLA-G, which is expressed at high levels by human cytotrophoblasts and macrophages within the maternal uterine wall, has limited polymorphism but otherwise is quite similar to MHC class I in its association with  $\beta_2$ -microglobulin and structure. HLA-G occurs as either an integral membrane protein or a secreted isoform.<sup>27</sup> Cytolytic activity by NK cells normally is limited by engagement of inhibitory receptors, many of which recognize MHC class I. Because trophoblast cells lack expression of most conventional MHC class I molecules, the surface expression of HLA-G, which is particularly high during the first trimester of pregnancy, may limit their lysis by maternal or fetal NK cells.

HLA-G engages CD94-NKG2A, the same inhibitory receptor utilized by HLA-E for inhibiting NK cell-mediated cytotoxicity.<sup>28</sup> In addition, membrane-bound HLA-G engages inhibitory receptors expressed on T cells, including p49, immunoglobulin-like transcript (ILT)-2, and ILT-4; this may account for the ability of HLA-G to inhibit the proliferation of adult T cells in response to allogeneic stimuli.<sup>29</sup> Because HLA-G also is expressed by cells found outside the placenta (e.g., circulating adult monocytes after treatment with IFN- $\gamma$ ),<sup>30</sup> it also may regulate the later phases of the T cell immune response.

Soluble HLA-G is present at relatively high levels in the serum of pregnant women and in lower amounts in cord blood and in the peripheral blood of nonparous women and men.<sup>27</sup> The *in vivo* function of soluble HLA-G remains unclear, but it may inhibit immune responses. Consistent with this proposed function, soluble HLA-G can induce Fas (CD95)-dependent apoptosis of activated CD8<sup>+</sup> T cells, apparently by engaging CD8 and increasing surface expression of Fas ligand (CD95L).<sup>31</sup>

**MICA and MICB.** MHC class I-related chains A and B (MICA and MICB), the genes for which also are found at the MHC locus, have limited but clear homology with conventional MHC class I molecules.<sup>32,33</sup> In contrast with conventional MHC class I, however, they lack a binding site for CD8, are not associated with  $\beta_2$ -microglobulin, and do not appear to be involved with the presentation of peptide antigens. Instead, these molecules are expressed on stressed intestinal epithelial cells, such as those experiencing heat shock,

and are recognized by  $\gamma\delta$  T cells that bear V $\delta$ 1-containing  $\gamma\delta$ -TCR. MICA and MICB also may be induced on other cell types in response to infection with viruses, such as those of the herpesvirus group. MICA and MICB are ligands for NKG2D found on most NK cells, and on some CD8<sup>+</sup> T cells and  $\gamma\delta$  T cells, which can either activate or act in concert with TCR-mediated signals to activate these cells.<sup>34,35</sup>

**CD1.** The human CD1 locus includes four nonpolymorphic genes, CD1a through CD1d.<sup>36,37</sup> CD1 molecules associate with  $\beta_2$ -microglobulin but have limited structural homology with either MHC class I or MHC class II proteins. In humans, they are expressed mainly on APCs, including DCs.<sup>9</sup> CD1b efficiently binds and presents highly hydrophobic lipoglycan molecules of mycobacteria, such as lipoarabinomannans, mycolic acid, and glucose monomycolate, and some self-lipids, such as G<sub>M1</sub> ganglioside.<sup>36,37</sup>

Mycobacterial lipoglycans undergo processing and loading onto CD1b in an endosomal compartment that is similar or identical to the compartment where peptides are loaded onto MHC class II molecules. Subsets of CD8<sup>+</sup> T cells and of the rare CD4<sup>-</sup>CD8<sup>-</sup>  $\alpha\beta$  T cells respond to microbial lipids on CD1b and CD1c molecules, and a subset of  $\gamma\delta$  T cells recognizes as-yet uncharacterized antigens on CD1c molecules.<sup>36</sup>

CD1d, the only member of the human CD1 cluster that also is expressed in the mouse, appears to be specialized for the presentation of hydrophobic nonpeptide molecules, such as endogenous lipids or glycolipid molecules. As in the case of CD1b, loading of antigens onto CD1d is apparently accomplished in a "late" endosomal compartment similar or identical to the compartment where peptides are loaded onto MHC class II molecules. A unique subset of  $\alpha\beta$  T cells, which are autoreactive to CD1d *in vitro*, are commonly referred to as NK T cells (see later on); NK T cells are mainly CD4<sup>-</sup> and CD8<sup>-</sup> and express a canonical TCR  $\alpha$  chain (V $\alpha$ 24J $\alpha$ Q).

### Dendritic Cells

DCs, the sentinels of the immune system, are bone marrow-derived cells that in their mature form display characteristic cytoplasmic protrusions or dendrites. DCs in the circulation and tissues are heterogeneous with regard to their surface phenotype and functional attributes, and the precursor-product relationship of these subsets with each other and with other cell types remains controversial.<sup>9</sup> A common feature of DCs is the absence of most or all cell surface molecules that characterize other bone marrow-derived cell lineages (that is, they lack lineage markers), including molecules typically expressed on T cells (with the exception of a low level of expression of CD4), B cells, NK cells, and granulocytes. By contrast, DCs do express MHC class II, and mature DCs express much greater amounts of MHC class II (and MHC class I) than any other cell type. Thus, DCs are lineage marker-negative (Lin<sup>-</sup>), MHC class II-positive, mononuclear cells of hematopoietic origin.

As described later on, DCs are poised to respond rapidly to microbial invasion by secretion of cytokines and presentation of microbial antigens to T cells, which leads to T cell activation and functional differentiation. It also is clear that DCs modulate the function of B cells and NK cells and, in steady-state conditions that prevail in uninfected persons, play a central role in maintaining a state of tolerance to self-

antigens by presenting them to T cells in the absence of accessory signals required for T cell activation; these functions are not discussed further.<sup>38</sup>

**DC1 (Myeloid Subset of) Dendritic Cells.** In this chapter, CD11c<sup>+</sup> DCs are collectively referred to as DC1 cells or myeloid DCs.<sup>39</sup> DCs in the skin include Langerhans cells, which express CD1a and Birbeck granules but lack expression of the factor XIIIa coagulation factor, and interstitial cells of the dermis, which conversely lack Birbeck granules and are factor XIIIa positive. Both express CD11c and ILT-1.<sup>9,40</sup> Interstitial DC1 cells are found in essentially all tissues and are highly effective in uptake of antigen in soluble or particulate form.<sup>41</sup>

DC1 cells in uninflamed tissues are said to be immature because they express only moderate levels of MHC class I and class II molecules on their surface. Immature DC1 cells also are found in the blood—probably in transit to the tissues—but in small numbers (0.2% to 0.4% of peripheral blood mononuclear cells [PBMCs]) relative to monocytes (approximately 10% of PBMCs), a cell type from which DC1 cells can be derived.<sup>42</sup> After exposure of immature DC1 cells to inflammatory stimuli, further antigen uptake ceases, and maturation ensues in which antigenic peptides derived from previously internalized particles are displayed on their cell surface in the groove of MHC class I and class II molecules, which are now expressed in great abundance on the cell surface.

Exposure of immature DCs to inflammatory stimuli results in their migration from the tissues to the T cell-dependent areas of secondary lymphoid organs, such as the lymph nodes and spleen. The migration of leukocytes, including DCs, is mediated by a combinatorial and multistep process determined by the pattern of expression on the cell surface of adhesion molecules and chemokine receptors and by the local patterns and gradients of adhesion molecule and chemokine receptor ligands in tissues (see Tables 4-1 and 4-2). Chemokines constitute a cytokine superfamily with more than 50 members known at present, most of which are secreted and of relatively low molecular weight.<sup>43,44</sup> Chemokines are produced by a large number of cell types and selectively attract various leukocyte populations, which bear the appropriate G protein-linked chemokine receptors. They can be divided into four families according to their pattern of amino-terminal cysteine residues: CC, CXC, C, and CX3C (X represents a noncysteine amino acid between the cysteines). A nomenclature for the chemokines and their receptors has been adopted, in which the family is first given (e.g., CC), followed by L for ligand (the chemokine itself) and a number or followed by R (for receptor) and a number. Functionally, chemokines also can be defined by their principal function—in homeostatic or inflammatory cell migration—and by the subsets of cells on which they act.<sup>45</sup> Maturing DCs increase surface expression of the CCR7 chemokine receptor and decrease expression of most other chemokine receptors. This results in the migration of these cells through lymphatics to T cell-rich areas of secondary lymphoid organs that express the CCR7 ligands CCL19 and CCL21.<sup>46</sup>

DC1 cell maturation and migration can be triggered by a variety of stimuli, including pathogen-derived products that are recognized through Toll-like receptors (TLRs) (Table 4-3),<sup>47</sup>

**Table 4-3 Human Toll-like Receptors (TLRs)**

Toll-like Receptor	Ligand	Site of Interaction with Ligand	Signal Transduction/Effector Molecules
TLR-1	Heterodimerizes with TLR-2	Cell surface	MyD88-dependent induction of cytokines
TLR-2	Peptidoglycan and lipoteichoic acid of gram-positive bacteria, mycoplasmal and meningococcal lipopeptides, mycobacterial lipoarabinomannan, <i>Neisseria</i> porins, and others; recognition of some ligands is dependent on heterodimerization with TLR-1 or TLR-6	Cell surface	MyD88-dependent induction of cytokines
TLR-3	Double-stranded RNA (viruses)	Endosome	TRIF-dependent induction of type I IFN and cytokines
TLR-4	LPS, RSV (?fibronectin)	Cell surface	MyD88- and TRIF-dependent induction of cytokines; TRIF-dependent induction of type I IFN
TLR-5	Flagellin	Cell surface	MyD88-induced cytokines
TLR-6	Heterodimerizes with TLR-2	Cell surface	MyD88-dependent induction of cytokines
TLR-7	Imidazoquinoline drugs, single-stranded RNA molecules (viruses)	Endosome	MyD88-dependent induction of type I IFN and cytokines
TLR-8	Imidazoquinoline drugs, single-stranded RNA molecules (viruses)	Endosome	MyD88-dependent induction of type I IFN and cytokines
TLR-9	Unmethylated CpG DNA (bacteria and viruses)	Endosome	MyD88-dependent induction of cytokines and type I IFN
TLR-10	Unknown	Unknown	Unknown

IFN, interferon; LPS, lipopolysaccharide; RSV, respiratory syncytial virus.

by endogenous cytokines, such as interleukin (IL)-1, TNF- $\alpha$ , and GM-CSF (see Tables 4-1 and 4-2), and by engagement of CD40 on the DC surface by CD40 ligand (CD154), a molecule that is expressed at particularly high levels by activated CD4<sup>+</sup> T cells (Table 4-4). Thus, the function and localization of DC1 cells are highly plastic and rapidly modulated either by direct recognition of microbes or their products, by cytokines produced by neighboring DCs and other cells of the innate system, or by products of T cells to which they present antigens.

The TLR family of transmembrane proteins recognizes microbial structures that, for the most part, are essential for the proper function of microbes that express them. These microbial structures are relatively invariant and are not present in normal mammalian cells (see Table 4-3). For this reason, recognition of these “pathogen-associated molecular patterns” by TLRs provides infallible evidence for microbial invasion alerting the innate immune system to respond appropriately.<sup>48</sup> To date, 10 different TLRs have been identified in humans,<sup>47</sup> with distinct recognition specificities and patterns of expression, and both shared and unique downstream response pathways (see Table 4-3). For example, TLR-2, along with TLR-1 and TLR-6, recognizes bacterial lipopeptides, peptidoglycan and lipoteichoic acid on the surface of gram-positive bacteria, fungal surface structures, and cytomegalovirus (CMV); TLR-3 recognizes viral double-stranded RNA, a component of the life cycle of many viruses, and a synthetic mimic of double-stranded RNA, poly(I:C); TLR-4 recognizes lipopolysaccharide (LPS) from gram-negative bacteria and a protein encoded by respiratory syncytial virus (RSV); TLR-5 recognizes bacterial flagellin; TLR-7 and TLR-8 recognize single-stranded RNA, a characteristic of RNA viruses, such as influenza virus<sup>49,50</sup>; TLR-9 recognizes DNA from bacteria,

which contain unmethylated CpG dinucleotide residues (CpG DNA)<sup>47</sup> and from DNA viruses, such as herpes simplex virus (HSV), in which these CpG residues also are unmethylated.<sup>51,52</sup> Because TLR-9 does not recognize DNA containing methylated CpG residues, which predominate in human DNA, this receptor serves as a means to distinguish host from pathogen-related DNA. Signals from each of these TLRs induce maturation and migration of DCs, but the patterns of cytokine production induced vary both with the TLR that is being activated and with the cell type on which the TLR is expressed (see Table 4-3).<sup>39,53</sup> Notably, DC1 cells express TLRs that recognize bacterial, fungal, and protozoal cell surface structures but do not express TLR-9. Consequently, DC1 cells are not activated in response to unmethylated CpG DNA, a potent inducer of IFN- $\alpha$  production by another DC population, pre-DC2 cells. DC1 cells express TLR-3, however, and signal through TLR-3 to induce type I IFN.

Mature DC1 cells express high levels of peptide-MHC complexes and molecules that act as co-stimulatory signals for T cell activation, such as CD80 (B7-1) and CD86 (B7-2), and consequently are highly efficient for presenting antigen in a manner that leads to the activation of naïve CD4<sup>+</sup> and CD8<sup>+</sup> T cells (see Fig. 4-1 and Table 4-4).<sup>9</sup> DCs not only play a critical role in T cell activation but also influence the quality of the T cell response that ensues by directing the differentiation of naïve CD4<sup>+</sup> T cells into T helper I (T<sub>H</sub>1) (capable of producing IFN- $\gamma$  but not IL-4, IL-5, or IL-13) or T<sub>H</sub>2 (capable of producing IL-4, IL-5, or IL-13 but not IFN- $\gamma$ ) effector T cells (see later sections on differentiation and homeostasis of activated T cells). For example, the production by DCs of IL-12, a heterodimeric cytokine consisting of a p35 and a p40 chain, or of type I IFN skews differentiation toward the T<sub>H</sub>1 pathway.<sup>54-56</sup>

**Table 4–4 Selected Pairs of Surface Molecules Involved in T Cell–Antigen-Presenting Cell (APC) Interactions**

T Cell Surface Molecule	T Cell Distribution	Corresponding Ligand(s) on APCs	APC Distribution
CD2	Most T cells; higher on memory cells, lower on adult naïve and neonatal T cells	LFA-3 (CD58), CD59	Leukocytes
CD4	Subset of $\alpha\beta$ T cells with predominantly helper activity	MHC class II $\beta$ chain	Dendritic cells, M $\phi$ , B cells, others (see text)
CD5	All T cells	CD72	B cells, M $\phi$
CD8	Subset of $\alpha\beta$ T cells with predominantly cytotoxic activity	MHC class I heavy chain	Ubiquitous
LFA-1 (CD11a/CD18)	All T cells; higher on memory cells, lower on adult naïve and neonatal T cells	ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)	Leukocytes (ICAM-3 > ICAM-1,-2) and endothelium (ICAM-1, ICAM-2); most ICAM-1 expression requires activation
CD28	Most CD4 <sup>+</sup> T cells, subset of CD8 <sup>+</sup> T cells	CD80 (B7-1) CD86 (B7-2)	Dendritic cells, M $\phi$ , activated B cells
ICOS	Effector and memory T cells; not on resting naïve cells	B7RP-1 (B7h)	B cells, M $\phi$ , dendritic cells, endothelial cells
VLA-4 (CD49d/CD29)	All T cells; higher on memory cells, lower on adult naïve and neonatal T cells	VCAM-1 (CD106)	Activated or inflamed endothelium (increased by TNF, IL-1, IL-4)
ICAM-1 (CD54)	All T cells; higher on memory cells, lower on adult virgin and neonatal T cells	LFA-1 (CD11a/CD18)	Leukocytes
TLA-4 (CD152)	Activated T cells	CD80 CD86	Dendritic cells, M $\phi$ , activated B cells, activated T cells
CD40 ligand (CD154)	Activated CD4 <sup>+</sup> T cells; lower on neonatal CD4 <sup>+</sup> T cells	CD40	Dendritic cells, M $\phi$ , B cells, thymic epithelial cells
PD-1	Activated CD4 <sup>+</sup> and CD8 <sup>+</sup> T cells	PD-L1, PD-L2	Dendritic cells, M $\phi$ , B cells, regulatory T cells

CTLA-4, cytotoxic T lymphocyte antigen-4; ICAM, intercellular adhesion molecule; ICOS, inducible co-stimulator; IL, interleukin; LFA, leukocyte function antigen; M $\phi$ , mononuclear phagocytes; MHC, major histocompatibility complex; PD, programmed death [molecule]; VCAM, vascular cell adhesion molecule; VLA-4, very late antigen-4.

**DC2 (Plasmacytoid) Subset of Dendritic Cells.** DC2 cells and their immediate precursors, pre-DC2 cells, appear to constitute a cell lineage distinct from DC1-lineage cells. Human DC2-lineage cells have a characteristic surface phenotype with high expression of the IL-3 receptor (CD123), low expression of CD4, and lack of CD11c and ILT-1.<sup>40</sup> Pre-DC2 cells, also referred to as plasmacytoid DCs, are found in the blood and secondary lymphoid organs, particularly in inflamed lymph nodes.<sup>40,53</sup> The difference in their pattern of localization from that of immature DC1 cells is due to differences in expression of chemokine receptors.<sup>40</sup> In contrast with immature DC1 cells, pre-DC2 cells have a limited capacity for antigen uptake and presentation.<sup>40</sup> Pre-DC2 and DC2 cells also differ from DC1-lineage cells by a capacity to produce large amounts of IFN- $\alpha$  and IL-12 in response to unmethylated CpG DNA, such as is contained in the HSV genome, and to RNA viruses, such as influenza virus,<sup>40,57–59</sup> and by their lack of response to LPS or peptidoglycan. The difference in responsiveness of immature DC1 and DC2 cells to different microbes and microbial structures parallels differences in TLR expression—pre-DC2 and immature DC2 cells express TLR-7 and TLR-9, whereas immature DC1 cells express TLR-1, -2, -3, -4, -5, and -6 (see Table 4-3). Studies indicate that pre-DC2 cells use TLR-9 to recognize HSV through its unmethylated genomic CpG DNA.<sup>51,52</sup> Single-stranded RNA contained in RNA viruses, such as influenza virus, activates pre-DC2 cells through TLR-7 or TLR-8, or both.<sup>50</sup> Activated pre-DC2 cells secrete high levels of type I IFN, which probably plays an important role in

early innate antiviral immunity by inducing a systemic antiviral state.

As with immature DC1 cells, activation of pre-DC2 cells by TLR, cytokines, or CD40 ligand also results in their maturation, including acquisition of the cytoplasmic protrusions characteristic of DCs, upregulation of CCR7 and migration to T cell-rich areas of lymph nodes, and an increased capacity to present antigen to naïve T cells. Although pre-DC2 cells cultured in IL-3 alone (to maintain viability *in vitro*) induce naïve neonatal T cells to produce a mixture of IFN- $\gamma$  and IL-10, the addition of CD40 ligand or influenza virus leads to the differentiation of naïve neonatal T cells into T<sub>H</sub>1 cells that produce IFN- $\gamma$  but not IL-10 or IL-4.<sup>40</sup> The strong T<sub>H</sub>1 polarization requires the production by DC2 cells of IFN- $\alpha$  in response to influenza virus, and IFN- $\alpha$  and IL-12 in response to CD40 ligand<sup>40</sup>; the response to CD40 ligand may involve additional mediators because, in the absence of T cells, CD40 ligand induces little or no IL-12 and IFN- $\alpha$  production by pre-DC2 cells.<sup>60</sup> Nonetheless, pre-DC2 cells activated through TLR-7 and TLR-9 probably act locally in the lymphoid tissues to favor the development of T<sub>H</sub>1 cells and to enhance local adaptive immune responses,<sup>61</sup> in addition to their role in innate antiviral defense.

### Antigen Presentation in the Fetus and Neonate

As discussed later, antigen-specific T cell responses in the fetus, neonate, and young infant are reduced or delayed compared with responses in the adult. These reduced or

delayed responses may reflect differences intrinsic to neonatal T cells, limitations of neonatal APC function, or both. Because DCs appear to play an essential role in antigen presentation to naïve T cells as part of primary immune responses, and because virtually all T cells in the fetus and neonate are naïve (as discussed more fully in the section on T cell development and function in the fetus and neonate), differences in the numbers and functions of neonatal DCs would be expected to have important effects on T cell responses in the fetus and neonate. Accordingly, the following discussion first considers general aspects of MHC expression in the fetus and neonate and then focuses on DCs, followed by antigen presentation by other cell types.

### **Major Histocompatibility Complex Molecule Expression in the Fetus and Neonate**

The expression of MHC class I and class II molecules by fetal tissues is evident by 12 weeks of gestation,<sup>62,63</sup> and all of the major APCs, including mononuclear phagocytes, B cells, and DCs,<sup>64</sup> are present by this time. Fetal tissues are vigorously rejected after transplantation into non-MHC-matched hosts, indicating that surface MHC expression is sufficient to initiate an allogeneic response, probably by host cytotoxic CD8<sup>+</sup> T cells. This vigorous allogeneic response does not exclude subtle deficiencies in antigen presentation in the fetus and neonate, particularly under conditions that more stringently test APC function (e.g., during infection with herpesviruses that inhibit peptide loading of MHC class I).<sup>65</sup> MHC class I expression on neonatal lymphocytes is lower than on adult cells.<sup>66</sup> The amount of MHC class II expressed per cell by neonatal monocytes or B cells is similar to or greater than that expressed by adult cells,<sup>66</sup> but a greater fraction of neonatal monocytes lack HLA-DR surface expression.<sup>67</sup>

### **Circulating Neonatal Dendritic Cells**

Although most DCs are found in the tissues, small numbers, consisting of immature DC1 and pre-DC2 cells and representing approximately 0.5% of circulating blood mononuclear cells, are found in the blood. Information regarding blood DCs in the human neonate comes from phenotypic analyses and very limited functional studies, inferences regarding their function based on studies using mixed blood mononuclear cells or whole blood assays, and phenotypic and functional studies on DCs derived by culturing blood monocytes *in vitro*. In the neonatal circulation, DCs with a pre-DC2 surface phenotype (Lin<sup>-</sup>HLA-DR<sup>mid</sup>CD11c<sup>-</sup>CD33<sup>-</sup>CD123<sup>hi</sup>) predominate in cord blood and early infancy, constituting about 75% of the total Lin<sup>-</sup>HLA-DR<sup>+</sup> DCs,<sup>68</sup> and approximately 0.75% of total blood mononuclear cells.<sup>69</sup> The relative increase in pre-DC2 cells in neonates and infants<sup>70</sup> may reflect an increased proportion of less differentiated CD11c<sup>-</sup>CD123<sup>mid</sup> cells in cord blood.<sup>71</sup> The remaining 25% of DCs have an HLA-DR<sup>hi</sup>CD11c<sup>+</sup>CD33<sup>+</sup>CD123<sup>lo</sup> surface phenotype that is similar to the phenotype of circulating adult DC1 cells, except that CD83 expression is absent.<sup>68</sup> After the neonatal period, the numbers of DC2-lineage cells appear to decline with increasing postnatal age, whereas the numbers of DC1 cells do not. The biologic significance of the predominance of DC2-lineage cells in the neonatal circulation is uncertain, but this predominance may reflect a

high rate of the colonization of lymphoid tissue, which is undergoing rapid expansion at this age.

Expression of MHC class II (HLA-DR) and co-stimulatory molecules on neonatal and on adult blood DC1 and pre-DC2 cells is similar.<sup>69,72</sup> Stimulation with LPS (a TLR-4 ligand) and poly(I:C) (a TLR-3 ligand) was shown to increase the expression of HLA-DR and CD86 on DC1 cells to a similar extent, but CD40 and CD80 increased less in neonatal than in adult DC1 cells.<sup>72</sup> Stimulation with unmethylated CpG DNA (a TLR-9 ligand) increased the expression of HLA-DR on pre-DC2 cells to a similar extent, but CD40, CD80, and CD86 increased less in neonatal than in adult pre-DC2 cells. Also, stimulation with pertussis toxin enhanced HLA-DR, CD80, and CD86 expression on adult DC1 cells (pre-DC2 cells do not respond to pertussis toxin) but not on neonatal DCs.<sup>73</sup> It should be noted that each of the studies from which the findings described in this paragraph were derived originated from one group of investigators, and the results have not yet been confirmed by others.

The first studies to directly test the ability of cord blood DCs to activate T cells was done before the availability of markers that allow them to be isolated relatively rapidly and in high purity. In these studies, cells cultured overnight *in vitro* were substantially less effective than adult cells in activating allogeneic T cell proliferation.<sup>74,75</sup> This decreased activity was associated with reduced levels of expression of HLA-DR and the adhesion molecule ICAM-1<sup>74</sup> (see Table 4-4). In the more recent studies cited in the previous paragraph, however, in which expression of HLA-DR was evaluated on uncultured DCs, HLA-DR expression on neonatal and on adult DC1 and pre-DC2 cells did not differ significantly. The lower level of HLA-DR expression by neonatal DCs in the earlier studies by Hunt and colleagues probably reflects the overnight culture or the predominance of pre-DC2 cells in neonatal blood, which express lower levels of HLA-DR than do DC1 cells.<sup>40,68</sup> DC2-lineage cells are highly prone to die during culture *in vitro*, and the use of an overnight protocol for cell isolation may adversely affect cord blood DCs, in which pre-DC2 cells are predominant.

Although more recent studies found that circulating DCs from cord blood can allogeneically stimulate cord blood T cells *in vitro*,<sup>68,76,77</sup> their efficiency was not compared with that of adult DCs. Virtually all of the allostimulatory activity of cord blood DCs is mediated by the DC1 subset rather than by the pre-DC2 subset,<sup>68</sup> raising the possibility that neonatal DC1 cells are functionally normal on a cell-by-cell basis. It should be noted that activation of allogeneic T cells does not require uptake, processing, and presentation of exogenous antigens and is not as stringent a test of APC function as is activation of foreign antigen-specific T cells. A direct comparison of DC1 lineage cells from the neonate and the adult is necessary to define the adequacy of neonatal myeloid DC antigen presentation. Like pre-DC2 cells from the tonsils of older children,<sup>78,79</sup> cord blood pre-DC2 cells are ineffective at uptake of either protein or peptide antigens.<sup>77</sup> It is unclear whether maturation of pre-DC2 cells in the neonate (e.g., by exposure to viruses) results in a similar increase in capacity for antigen presentation that is observed with adult pre-DC2 cells.

DCs also can influence whether naïve CD4<sup>+</sup> T cells differentiate into producers of mainly T<sub>H</sub>2 cytokines, mainly T<sub>H</sub>1 cytokines, or a mixture of both (also referred to as a T<sub>H</sub>0

cytokine profile), with the outcome dependent on the type of DCs and the conditions used for activation.<sup>39,53,80,81</sup> For example, antigen presentation by pre-DC2 cells favors the differentiation of naïve T cells into T<sub>H</sub>2 cells, unless these cells have been activated by viruses or unmethylated CpG DNA, which causes them to release IFN- $\alpha$  or IL-12 and, in turn, drives potent T<sub>H</sub>1 polarization.<sup>81</sup> The predominance of pre-DC2 cells in the fetus and neonate may account for the tendency toward T<sub>H</sub>2 skewing of immune responses to environmental allergens and the limited response to intracellular pathogens in these age groups, the maintenance of fetal-maternal tolerance during pregnancy, and the lower risk of graft-versus-host disease following cord blood transplantation.

In addition to the predominance of pre-DC2 cells in the neonatal circulation, the ability of neonatal DCs to produce type I IFN and IL-12 also appears to be somewhat diminished compared with that of DCs from adults. With specific exceptions noted later on, the relevant studies have been done with total blood mononuclear cells or whole blood, rather than purified DCs. Because DCs are the dominant source of IFN- $\alpha$  and IL-12 produced in response to the stimuli employed, it is likely that the findings reflect production by DCs. In an early study, type I IFN production by neonatal blood mononuclear cells was equivalent to that of adult cells for a variety of inducers, including HSV and other viruses.<sup>82</sup> Other studies, however, have found that type I IFN production and the frequency of IFN- $\alpha$ -producing cells in response to HSV were diminished compared with those in adults, particularly for prematurely born infants.<sup>83</sup> Similar results were obtained for blood cells stimulated with parainfluenza viruses<sup>84</sup> and unmethylated DNA.<sup>69</sup> It is likely that the decreased production of type I IFN by neonatal blood cells in response to viruses or unmethylated CpG DNA reflects decreased production by DC2-lineage cells signaling through TLR-9, but this decrease has been shown directly only for the response to unmethylated CpG DNA.<sup>69</sup> Neonatal blood cells also produce less IFN- $\alpha$  in response to poly(I:C), which activates DC1 cells through TLR-3.<sup>72</sup> Overall, these more recent studies suggest that neonatal DC1- and DC2-type cells produce approximately 0% to 30% as much type I IFN as that produced by adult cells. The production of bioactive IL-12, a heterodimer of p35 and p40, also appears to be reduced in response to LPS but not to all stimuli. For example, neonatal and adult blood mononuclear cells stimulated with *Staphylococcus aureus*, or other gram-positive and gram-negative bacterial cells produce equivalent amounts of IL-12.<sup>85-88</sup>

### Neonatal Monocyte-Derived Dendritic Cells

Mature DCs can differentiate in vitro from a variety of precursor cells, including blood monocytes, pre-DC2 cells, CD34<sup>+</sup> myelomonocytic cells, and even granulocytes, depending on the cytokines and culture conditions employed. Although both adult peripheral and cord blood monocytes cultured with GM-CSF and IL-4 give rise to immature DCs similar to the DC1 lineage,<sup>89-91</sup> monocyte-derived DCs from cord blood express less HLA-DR, CD1a, and co-stimulatory molecules (CD40 and CD80) than are expressed by adult cells. Consistent with these reductions in HLA-DR and co-stimulatory molecule expression, monocyte-derived DCs from cord blood

have decreased allostimulatory activity for T cells compared with that of adult monocyte-derived DCs.<sup>90-93</sup>

Cord blood monocyte-derived DCs also have a low capacity to produce IL-12 in response to LPS, engagement of CD40, or treatment with double-stranded RNA [poly(I:C)]; this is apparently due to a selective decrease in mRNA expression of the IL-12 (p35) chain component.<sup>93</sup> Reduced IL-12 expression may account for decreased production of IFN- $\gamma$  by adult CD4<sup>+</sup> T cells after allogeneic stimulation by cord blood-derived DCs compared with production after stimulation by adult monocyte-derived DCs.

These findings using monocyte-derived DCs provide an explanation for limitations in T<sub>H</sub>1 immunity, such as delayed-type hypersensitivity skin reactions and antigen-specific CD4<sup>+</sup> T cell IFN- $\gamma$  production, which are discussed later on. The relevance of these findings obtained with monocyte-derived DCs is supported by observations in mice suggesting that myeloid DCs can directly differentiate from monocytes when these undergo transendothelial trafficking.<sup>94,95</sup> It remains unclear, however, if the differentiation of monocytes into DCs following high doses of exogenous cytokines faithfully mimics DC differentiation from less mature precursors in vivo. A rigorous comparison of the gene and protein expression profiles and function of monocyte-derived DCs with freshly isolated highly purified DC populations may help clarify this issue.

### Fetal Tissue Dendritic Cells

Our knowledge of tissue DCs in the human fetus and neonate is limited. Epidermal Langerhans cells and dermal DCs are found in fetal skin by 16 weeks of gestation,<sup>96</sup> and immature DC1-lineage cells are found in the interstitium of solid organs by this age. Cells with the features of pre-DC2 cells are found in fetal lymph nodes between 19 and 21 weeks of gestation<sup>78</sup>; they have an immature phenotype and are not recent emigrants from inflamed tissues.

### Antigen Presentation by Neonatal Monocytes and B Cells

APC function of monocytes and B cells from human neonates has not been characterized in great detail. MHC class II-mediated antigen presentation by monocytes appears to be intact, since neonatal and adult monocytes are similarly effective in presenting soluble protein antigens or alloantigens to induce T cell proliferation,<sup>97,98</sup> a response that is mainly MHC class II dependent. One report suggested that a substantial fraction of MHC class II molecules on neonatal but not adult B cells are “empty”—that is, they lack peptides in the binding groove.<sup>99</sup> Accordingly, neonatal B cells may be functionally limited as APCs.

## Basic Aspects of T Cell Development and Function

### Prothymocytes and Major Thymocyte Subsets

With the exception of a subset of the T cells found in the gut and perhaps the liver,<sup>100-102</sup> most  $\alpha\beta$  T cells develop from immature progenitor cells within the unique microenvironment of the thymus. The thymus arises from the ventral portions of the third and fourth pharyngeal pouches. Both

ectoderm and mesoderm contribute to the formation of this tissue. The human thymus does not have a population of self-replenishing stem cells and therefore probably requires a continual input of thymocyte progenitor cells (prothymocytes) to maintain thymocytopoiesis, as is true for the mouse.<sup>103</sup> The human prothymocyte probably is a lymphoid cell that lacks TCR  $\alpha$  or TCR  $\beta$  chains and expresses CD3 molecules in its cytoplasm and the CD7 protein on its surface, with little or no expression of CD4 or CD8. CD7 also is found on mature T cells and NK cells, suggesting a close relationship between these two cell types.<sup>104</sup>

The precursor-product relationship between the prothymocyte and other immature lymphocyte progenitor cells remains controversial, as does the extent to which the prothymocyte is committed to the T cell or NK cell lineages before thymic entry.<sup>105</sup> Prothymocytes may be derived from the common lymphocyte progenitor (CLP) cell, which is capable of giving rise to the T, B, and NK cell lineage when exposed to appropriate environmental cues. Cells with the properties suggestive of CLPs, based on *in vitro* differentiation assays, are found in cord blood and have a CD34<sup>+</sup>CD38<sup>-</sup>CD7<sup>+</sup> surface phenotype.<sup>106,107</sup> Nonetheless, a study in the mouse has found striking differences between bone marrow CLPs and the most immature lymphocyte populations found in the thymus, suggesting that prothymocytes could have a CLP-independent source.<sup>108</sup>

The prothymocyte probably enters the thymus through postcapillary venules located near the corticomedullary junction (Fig. 4-3).<sup>109</sup> This process may depend on expression of the CD44 and  $\alpha_6$  integrin molecules by the prothymocyte.<sup>105</sup> Human prothymocytes may retain the ability to differentiate into the NK cell lineage even after entering the thymus,<sup>104</sup> which is consistent with later occurrence of the split between T cell and the NK cell lineages than between the T cell and the B cell lineages. The engagement of Notch 1 on the prothymocyte cell surface by ligands expressed by thymic epithelial cells, such as Delta-1,<sup>110</sup> appears to be a key event in promoting T-lineage cell differentiation.

Intrathymic cellular progeny of the prothymocyte give rise to the three major subsets of thymocytes characteristic of the postnatal thymus. These subsets are named according to their pattern of surface expression of CD4 and CD8 and are further characterized by their surface expression of  $\alpha\beta$ -TCR-CD3 complexes. Thymocytes can be classified as double-negative (CD4<sup>-</sup>CD8<sup>-</sup>), which express little or no CD4 or CD8 (hence, double-negative) or  $\alpha\beta$ -TCR-CD3 and are direct products of the prothymocyte; double-positive (CD4<sup>hi</sup>CD8<sup>hi</sup>) which express medium levels of  $\alpha\beta$ -TCR-CD3 and are derived from double-negative cells; and single-positive (CD4<sup>hi</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>hi</sup>), which express high levels of  $\alpha\beta$ -TCR-CD3 and are derived from double-positive cells. In humans, there is also an intermediate stage between double-negative and double-positive thymocytes that is characterized by a CD4<sup>lo</sup>CD8<sup>-</sup>CD3<sup>-</sup> surface phenotype.<sup>111</sup> The double-negative progeny of the prothymocyte undergo cell division and progressive differentiation as they move outward in the cortex toward the subcapsular region. These cells then reverse course and move from the outer to the inner cortex as double-positive thymocytes. Finally, double-positive cells become single-positive thymocytes in the medulla, which probably exit the thymus through blood vessels located in the medulla.

### ***Intrathymic Generation of T Cell Receptor Diversity***

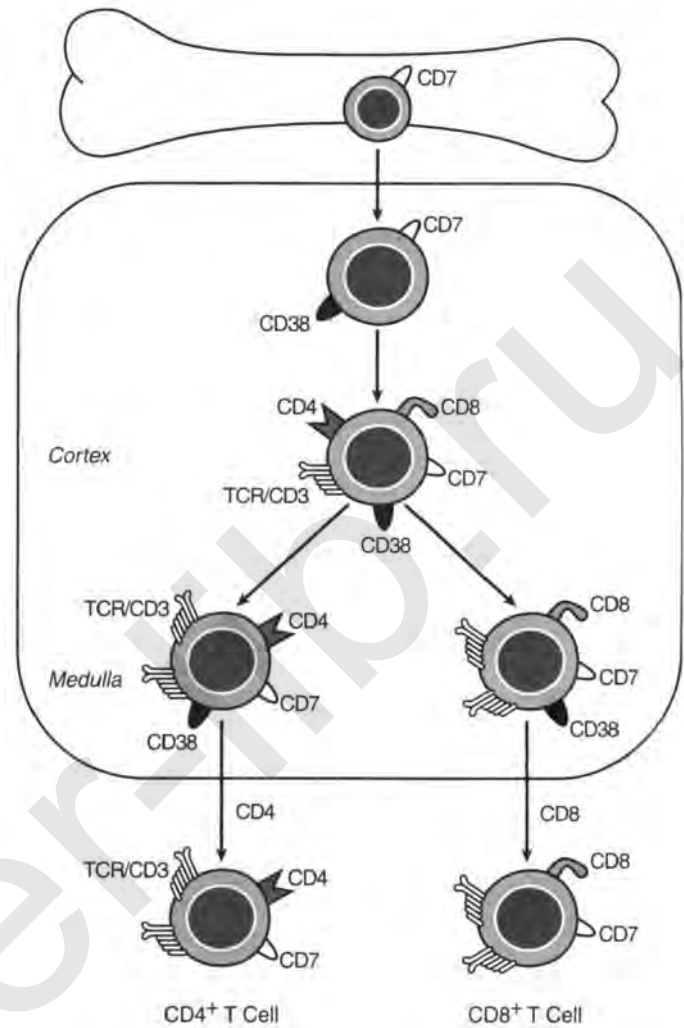

T (and B) lymphocytes undergo a unique developmental event, the generation of a highly diverse repertoire of antigen receptors through DNA recombination, a process referred to as V(D)J recombination. This diversity is generated through the random rearrangement and juxtaposition into a single exon of variable (V), diversity (D), and joining (J) segments to form in each cell a unique TCR  $\alpha$  and TCR  $\beta$  gene sequence.<sup>4</sup> The unrearranged human TCR  $\beta$  chain gene spans 685 kilobases of DNA on human chromosome 7 and contains 46 potentially functional V gene segments located upstream of two constant (C) regions, each associated with one D and six J segments (Fig. 4-4).<sup>112</sup> The human TCR  $\alpha$  chain gene locus on chromosome 14 contains 54 V segments and 61 J segments that can potentially be used for TCR  $\alpha$  gene rearrangement.<sup>112</sup>

V(D)J recombination is a highly ordered process and is controlled at multiple levels.<sup>113-115</sup> The restriction of the process of V(D)J recombination to cells of the T and B lymphocyte lineage results from the unique expression in their precursors of two recombination-activating genes, RAG1 and RAG2. Recombination of the TCR genes is further restricted to cells of the T lymphocyte rather than B lymphocyte lineage by mechanisms (e.g., histone acetylation) that allow RAG access to the TCR genes only in T cell progenitors. The RAG proteins are critically involved in the initiation of the recombination process—they recognize and cleave conserved sequences flanking each V, D, and J segment. Other proteins, including a high-molecular-weight DNA-dependent protein kinase and its associated Ku70 and Ku80 proteins, DNA ligase IV and its associated XRCC4 protein, and Artemis, then perform nonhomologous DNA end-joining of the cleaved V(D)J segments. Unlike RAG proteins, these other proteins involved in nonhomologous DNA end-joining are expressed in most cells and are involved in repair of double-stranded DNA breaks.<sup>116</sup> Genetic deficiency of any of the proteins involved in the rearrangement process results in a form of severe combined immunodeficiency (SCID), because T cell and B cell development depend on the surface expression of rearranged TCR and immunoglobulin genes, respectively. Human SCID due to genetic immunodeficiency of RAG-1, RAG-2, and Artemis is well documented.<sup>117</sup>

The complementarity-determining regions (CDRs) of the TCR and immunoglobulin molecules are those that are involved in forming the three-dimensional structure that binds with antigen. The V segments encode the CDR1 and CDR2 regions for both TCR chains. The CDR3 region, where the distal portion of the V segment joins the (D)J segment, is a particularly important source of  $\alpha\beta$ -TCR diversity for peptide-MHC recognition,<sup>118</sup> and is the center of the antigen-binding site for peptide-MHC complexes. CDR3 (also known as junctional) diversity is achieved by multiple mechanisms. These mechanisms include (1) the addition of one or two nucleotides that are palindromic to the end of the cut gene segment (termed P-nucleotides); these nucleotides are added as part of the process of asymmetrical repairing of “hairpin” ends (the two strands of DNA are joined at the ends) that are generated by RAG endonuclease activity<sup>119</sup>; (2) the activity of terminal deoxytransferase (TdT), which randomly adds nucleotides (called N-nucleotides) to the ends of segments undergoing rearrangement; TdT addition is a particularly

Cell Type	Major Developmental Events
Prothymocyte	Migration into thymus from bone marrow or fetal liver
Immature Thymocyte (CD4 <sup>lo</sup> CD8 <sup>lo</sup> CD38 <sup>lo</sup> )	Proliferation, TCR gene rearrangement
Cortical Thymocyte (CD4 <sup>hi</sup> CD8 <sup>hi</sup> CD38 <sup>hi</sup> )	Positive selection of the $\alpha\beta$ -TCR repertoire
Medullary Thymocyte (CD4 <sup>hi</sup> CD8 <sup>lo</sup> or CD4 <sup>lo</sup> CD8 <sup>hi</sup> CD38 <sup>hi</sup> )	Negative selection of the $\alpha\beta$ -TCR repertoire
Peripheral CD4 <sup>+</sup> and CD8 <sup>+</sup> T cells	Emigration to periphery

**Figure 4-3** Putative stages of human  $\alpha\beta$  T cell receptor-positive ( $\alpha\beta$ -TCR<sup>+</sup>) thymocyte development. Prothymocytes from the bone marrow or fetal liver, which express CD7, enter the thymus via vessels at the junction between the thymic cortex and medulla. They differentiate to progressively more mature  $\alpha\beta$ -TCR<sup>+</sup> thymocytes, defined by their pattern of expression of the  $\alpha\beta$ -TCR-CD3 complex, CD4, CD8, and CD38. TCR  $\alpha$  and TCR  $\beta$  chain genes are rearranged in the outer cortex. Positive selection occurs mainly in the central thymic cortex by interaction with thymic epithelial cells, and negative selection occurs mainly in the medulla by interaction with thymic dendritic cells. Following these selection processes, medullary thymocytes emigrate into the circulation and colonize the peripheral lymphoid organs as CD4<sup>+</sup> and CD8<sup>+</sup> T cells with high levels of the  $\alpha\beta$ -TCR-CD3 complex. These recent thymic emigrants (RTEs) also contain signal joint T cell receptor excision circles (TRECs), which are a circular product of TCR gene rearrangement. Most RTEs probably lack CD38 surface expression. By contrast, in neonates, most peripheral T cells retain surface expression of CD38 and have high amounts of TREC compared with adult peripheral T cells.

important mechanism for diversity generation because every three additional nucleotides encodes a potential codon, potentially increasing repertoire diversity by a factor of 20; and (3) exonuclease activity that results in a variable loss of nucleotide residues, as part of the DNA repair process.

Together, the mechanisms for generating diversity can theoretically result in as many as  $1 \times 10^{15}$  types of  $\alpha\beta$ -TCR. In reality, the final repertoire of naïve T cells in the adult human circulation is on average a total of  $1 \times 10^6$  different TCR  $\beta$  chains, each pairing on average with at least 25 different TCR  $\alpha$  chains.<sup>120</sup> This results in a maximum of about  $1 \times 10^8$  different combinations of TCR  $\alpha$  and TCR  $\beta$  chains for the naïve T cell  $\alpha\beta$ -TCR repertoire. Because in young adults the body has approximately  $2 \times 10^{11}$  CD4<sup>+</sup> T cells and  $1 \times 10^{11}$  CD8<sup>+</sup> T cells,<sup>121,122</sup> of which about 50% belong to the naïve

subset, the average clonal size for a naïve T cell is approximately 500 to 1000.<sup>120,123</sup>

RAG expression commences in double-negative thymocytes, and because the TCR  $\beta$  gene is the first to become accessible to RAG proteins, it is the first to undergo rearrangement (a small fraction of double-negative cells may undergo TCR  $\gamma$  and TCR  $\delta$  gene rearrangement, and this is discussed in more detail in the section on  $\gamma\delta$  T cells). The TCR  $\alpha$  gene is not accessible and does not rearrange at this stage. The TCR  $\beta$  chain D segment first rearranges to a downstream J segment, with the deletion of intervening DNA. This is followed by rearrangement of a V segment to the DJ segment, resulting in a contiguous (VDJ)  $\beta$  chain gene segment, which is joined to the constant (C) region segment by mRNA splicing. If a VDJ segment lacks premature translation stop

**Figure 4-4** The T cell receptor (TCR) and immunoglobulin genes are formed by rearrangement in immature lymphocytes. The TCR  $\beta$  chain gene and the immunoglobulin heavy chain genes are shown as examples. A similar process is involved with rearrangement of the TCR  $\alpha$ ,  $\gamma$ , and  $\delta$  chain genes, and with the immunoglobulin light chain genes. Rearrangement involves the joining of dispersed segments of variable (V), diversity (D), and joining (J) gene segments with the deletion of intervening DNA. This allows expression of a full-length mRNA transcript that can be translated into a functional protein, provided that there are no premature translational stop codons. Immunoglobulin heavy chain genes undergo an additional rearrangement called isotype switching, in which the constant (C) region segment is changed without alteration of the antigen combining site formed by the V, D, and J segments. The isotype switch from IgM to IgE is shown.

codons, the TCR  $\beta$  chain protein may be expressed on the thymocyte surface in association with a pre-TCR  $\alpha$  chain protein (pre-T $\alpha$ ) and some of the CD3 complex proteins. This pre-T $\alpha$  complex is capable of triggering many or most of the signals that are characteristic of engagement of the mature  $\alpha\beta$ -TCR<sup>124</sup> and instructs the thymocyte to increase its surface expression of CD4 and CD8, to start rearrangement of the TCR  $\alpha$  chain gene, and to stop rearrangement of the other TCR  $\beta$  chain allele. This inhibition of TCR  $\beta$  chain gene rearrangement results in allelic exclusion, so that greater than 99% of  $\alpha\beta$  T cells express only a single type of TCR  $\beta$  chain gene.<sup>125</sup>

Rearrangement of the TCR  $\alpha$  chain gene then occurs at the double-positive stage and involves the joining of V segments directly to J segments, without intervening D segments. If successful, this leads to the expression of a TCR  $\alpha\beta$  heterodimer on the cell surface in association with CD3 proteins to form the TCR-CD3 complex. Allelic exclusion is ineffective for the TCR  $\alpha$  chain gene, and it is estimated that as many as one third of peripheral human  $\alpha\beta$  T cells may express two types of TCR  $\alpha$  chains.<sup>126</sup> RAG protein expression normally ceases in cortical thymocytes, limiting gene rearrangement to early thymocyte development.

### Thymocyte Selection and Maturation of Double-Positive to Single-Positive Thymocytes

**Positive Selection.** Thymocytes that have successfully rearranged and express  $\alpha\beta$ -TCRs have a CD4<sup>hi</sup>CD8<sup>hi</sup> surface phenotype (see Fig. 4-3) undergo a selective process that tests the appropriateness of their TCR specificity, known as positive selection. Positive selection requires that the  $\alpha\beta$ -TCR recognize self-peptides bound to MHC molecules displayed on epithelial cells of the thymic cortex.<sup>127,128</sup> The  $\alpha\beta$ -TCR interacts not only with the MHC-associated peptide but also

with regions of the MHC that form the groove,<sup>129</sup> for which it has an intrinsic affinity.<sup>130</sup> This recognition of both portions of the MHC groove and peptide presumably applies to positive selection in the thymus as well as to the recognition of foreign antigen by peripheral  $\alpha\beta$  T cells. If the TCR has sufficient but not too high affinity for self-peptide-MHC complexes, the thymocyte receives a signal allowing its survival. If this signal is absent or weak, the thymocyte dies by apoptosis as a result of activation of caspases, a family of intracellular cysteine proteases. Too strong a signal also does not result in effective positive selection. Positive selection also is influenced by interactions between MHC molecules and the CD4 and CD8 molecules. As mentioned previously, MHC class I and class II molecules have constant domains located outside of their peptide-binding grooves that have affinity for CD8 and CD4, respectively. As a result of these interactions, most CD4<sup>hi</sup>CD8<sup>-</sup> thymocytes (and their peripheral CD4<sup>+</sup> T cell descendants) recognize peptides bound to MHC class II molecules, and most CD4<sup>-</sup>CD8<sup>hi</sup> T cells (and peripheral CD8<sup>+</sup> T cells) recognize peptides bound to MHC class I molecules (see Fig. 4-3). Positive selection also extinguishes RAG gene expression, terminating further TCR- $\alpha$  rearrangement.

**Negative Selection.** Positively selected CD4<sup>hi</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>hi</sup> thymocytes enter the medulla, where they undergo a second selection process called negative selection, in which they are eliminated by apoptosis if their TCR has too high an affinity for self-peptide-MHC complexes expressed on medullary DCs.<sup>128</sup> Negative selection helps eliminate  $\alpha\beta$  T cells with TCRs that could pose a risk of autoimmune reactions and is an important influence on the final TCR repertoire.<sup>131</sup> Thymic epithelial cells found in the medulla express a diverse array of self-antigens (e.g., insulin,

myelin basic protein) that help in this elimination.<sup>132</sup> A transcription factor encoded by the autoimmune regulator (*AIRE*) gene enhances the expression of self-antigen by thymic epithelial cells.<sup>133</sup> As a net result of either the failure to productively rearrange the TCR  $\alpha$  or TCR  $\beta$  chain gene, the lack of positive selection, or the occurrence of negative selection, only about 2% to 3% of the progeny of hematopoietic lymphoid precursors that enter the thymus emerge as mature single-positive thymocytes.<sup>134</sup>

**Impact of Thymocyte Selection on Self-MHC Restriction and MHC Alloreactivity.** Because the region forming the peptide-binding groove of MHC molecules is highly polymorphic in the human population (see section on basic aspects of antigen presentation), a result of positive selection is that T cells have a strong preference for recognizing a particular foreign peptide bound to self-MHC, rather than to the MHC of an unrelated person. On the other hand, the fact that TCR has intrinsic affinity for MHC molecules<sup>130</sup> accounts for the ability of an APC bearing foreign MHC molecules to activate a substantial proportion (up to several percent) of T cells—the allogeneic response. In the allogeneic response, T cells are activated by novel antigen specificities that are thought to result from the combination of a foreign MHC with multiple self-peptides.<sup>129,135</sup> Because these self-peptide–foreign MHC specificities are not expressed in the thymus, T cells capable of recognizing them have not been eliminated by the negative selection process in the medulla.

#### **Thymocyte Growth and Differentiation Factors**

The factors within the thymic microenvironment that are essential for thymocyte development include key cytokines produced by thymic epithelial cells, such as IL-7. Persons lacking a functional IL-7 receptor, owing to a genetic deficiency of either the IL-7 receptor  $\alpha$  chain<sup>136</sup> or the common  $\gamma$  chain ( $\gamma_c$ ) cytokine receptor (CD132) with which the  $\alpha$  chain associates,<sup>117</sup> have abortive thymocyte development and lack mature  $\alpha\beta$  T cells. A similar phenotype is observed with genetic deficiency of the JAK-3 tyrosine kinase, which is associated with the cytoplasmic domain of the  $\gamma_c$  cytokine receptor and delivers activation signals to the interior of the cell.<sup>137</sup> B cell development is spared in these human genetic immunodeficiencies.

#### **Thymocyte Postselection Maturation**

CD4<sup>hi</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>hi</sup> thymocytes are the most mature  $\alpha\beta$  T-lineage cell population in the thymus and predominate in the thymic medulla. Many of the functional differences between peripheral CD4<sup>+</sup> and CD8<sup>+</sup> T cells appear to be established during the later stages of thymic maturation, presumably as a result of differentiation induced by positive selection: Mature CD4<sup>hi</sup>CD8<sup>-</sup> thymocytes, like peripheral CD4<sup>+</sup> T cells, are enriched in cells that can secrete certain cytokines, such as IL-2, and in providing help for B cells in producing immunoglobulin.<sup>138</sup> CD4<sup>-</sup>CD8<sup>hi</sup> thymocytes, like peripheral CD8<sup>+</sup> T cells, are relatively limited in their ability to produce IL-2 but, once primed by antigen, are effective in mediating cytotoxic activity.<sup>139</sup>

#### **Thymocyte Emigration and Homing to Secondary Lymphoid Tissue**

Mature CD4<sup>hi</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>hi</sup> single-positive thymocytes enter into the circulation as antigenically naïve CD4<sup>+</sup> and

CD8<sup>+</sup>  $\alpha\beta$  T cells, respectively. These circulating T cells preferentially home to the secondary lymphoid tissue (see Fig. 4-3),<sup>140</sup> as antigenically naïve CD4<sup>+</sup> and CD8<sup>+</sup> T cells, respectively. Secondary lymphoid tissue consists of the lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT). Development of lymph nodes and Peyer's patches in mice is dependent on signaling by members of the TNF cytokine gene family through the lymphotoxin- $\beta$  (LT- $\beta$ ) receptor (see Table 4-1).<sup>141</sup>

As described for DCs, the migration of mature thymocytes into the circulation and their entry into the peripheral lymphoid organs are determined in part by the pattern of expression on the cell surface of chemokine receptors and by the local patterns and gradients of chemokine receptor ligands in tissues (see Table 4-1). Departure of naïve T cells from the thymus and entry into the secondary lymphoid tissues coincide with and are mediated in part by a change in the expression of chemokine receptors on their surface.<sup>43,45</sup> As they enter the medulla, mature single-positive thymocytes begin to lose expression of CCR9 and to gain expression of CCR7. As explained later on, this alteration allows them to leave the thymic medulla, where chemokines binding to CCR9 (TECK, CCL25) are found, and enter the secondary lymphoid tissues, where chemokines that bind to CCR7 are found.

Adhesion molecules and their ligands also play an important role in leukocyte trafficking, including thymic emigration and entry to peripheral lymphoid tissue. Two major families of adhesion molecules govern leukocyte migration: the selectins and the integrins. The three selectins are L-selectin (CD62L), which is constitutively expressed on many types of leukocytes, including naïve and certain subsets of memory T cells, and E-selectin (CD62E) and P-selectin (CD62P), both of which are expressed on activated vascular endothelium; P-selectin also is expressed on activated platelets.<sup>142,143</sup> Selectins bind to multivalent carbohydrate ligands, which are displayed on specific protein or lipid backbones on the cell surface.

The other major adhesion molecules are the integrins, which are heterodimers composed of different combinations of  $\alpha$  and  $\beta$  chains. All T cells express  $\alpha_1\beta_2$  integrin, also known as leukocyte function antigen (LFA)-1, and subsets of T cells express other integrins, including  $\alpha_4\beta_1$  (very late antigen-4 [VLA-4]) and  $\alpha_4\beta_7$ . Integrins bind to members of the immunoglobulin superfamily: LFA-1 binds to intercellular cell adhesion molecules ICAM-1, -2, and -3, and VLA-4 binds to vascular cell adhesion molecule-1 (VCAM-1), which is induced on activated endothelial cells. Mucosal addressin cell adhesion molecule-1 (MAdCAM-1), expressed on endothelial cells in the gut, is a ligand for L-selectin and for the  $\alpha_4\beta_7$  integrin. Many integrins also bind to components of the extracellular matrix, which is thought to contribute to leukocyte migration in the tissues after cells migrate across the vascular endothelium.

The initial interaction of leukocytes with the vascular endothelium is mediated by selectins and their ligands.<sup>142,143</sup> This low-affinity, high-valency interaction is facilitated by the display of selectins on the tips of microvilli, where they are positioned to sample the endothelial surface. If ligand is displayed, leukocytes are induced to roll along the endothelium, which allows them to survey for the presence of chemokines. In the case of naïve T cells, surface expression

**Figure 4-5** T cell–antigen-presenting cell (APC) interactions early during the immune response to peptide antigens. A major histocompatibility complex (MHC) class II–restricted response by CD4<sup>+</sup> T cells is shown as an example. Dendritic cells are probably the most important APCs for antigenically naïve T cells and constitutively express CD80 or CD86 (B7 molecules), CD40, and MHC class II molecules on their cell surface. Engagement of  $\alpha\beta$  T cell receptor ( $\alpha\beta$ -TCR) on the CD4<sup>+</sup> T cell by antigenic peptides bound to MHC molecules on the DC, in conjunction with co-stimulation by B7 (CD80/CD86) interactions with CD28 interactions, leads to T cell activation (Step 1). The activated T cell expresses CD40 ligand (CD154) on its surface, which engages CD40 on the dendritic cell; this increases B7 expression on the dendritic cell, enhancing T cell co-stimulation (Step 2). CD40 engagement also activates the dendritic cell to produce cytokines, such as interleukin (IL)-12. IL-12, in turn, promotes the proliferation and differentiation of T cells into T<sub>H</sub>1-type effector cells that produce high levels of interferon (IFN)- $\gamma$  and low or undetectable amounts of IL-4. Cytotoxic T lymphocyte antigen-4 (CTLA-4) (i.e., CD152) is expressed on the T cells during the later stages of T cell activation. Engagement of CTLA-4 by B7 molecules on the APC delivers negative signals that help terminate T cell activation (Step 3).

of L-selectin allows them to bind to the peripheral lymph node addressin, which is expressed on the surface of the specialized high endothelium of the postcapillary venules (HEV) in the peripheral lymph nodes, Peyer's patches, and tonsils.<sup>140</sup>

Tethered to the surface of the HEV is the chemokine, CCL21, which binds to CCR7 on the surface of naïve T cells. CCL21, and another CCR7 ligand, CCL19, are produced by stromal cells and perhaps some APCs in the lymph node. The engagement of CCR7 on naïve T cells by CCL21 triggers signals leading to an increase in the affinity of LFA-1, allowing the naïve T cells to bind avidly to the LFA-1 ligands ICAM-1 and ICAM-2 on the vascular endothelium. This stops T cell rolling, allowing the T cell to undergo diapedesis across the endothelium and to enter the T cell zones of the lymph node. There CCL19 is produced by DCs, resulting in the juxtaposition of naïve T cells and DCs.

#### Naïve T Cell Recirculation and Homeostasis

If naïve T cells encounter DCs presenting cognate peptide-MHC complexes, they stop migrating and remain in the lymph node. If they do not encounter such DCs, they migrate through the lymph node to the efferent lymph and thereby return to the bloodstream. Thus, naïve T cells continually circulate between the blood and secondary lymphoid tissues, allowing them the opportunity to continuously sample APCs for their cognate antigen. Because they regulate this homeostatic recirculation of naïve T cells, CCL19 and CCL21 are referred to as homeostatic chemokines.

Studies in mice indicate that the survival of naïve T cells in the periphery is dependent on two major exogenous factors. The first is continuous interaction with self-peptide-MHC complexes,<sup>144</sup> which appears to be particularly important for the survival of the antigenically naïve CD8<sup>+</sup>

T cell population.<sup>145,146</sup> Whether this survival signal is analogous to positive selection in the thymus in its requirements for a diverse self-peptide repertoire remains unclear. The second major factor appears to be signals provided through the  $\gamma\epsilon$  component of cytokine receptors—in the absence of  $\gamma\epsilon$ , naïve T cells appear to survive for fewer than 5 days.<sup>147</sup> It appears that the role of  $\gamma\epsilon$  in naïve T cell survival is primarily if not solely to transduce signals in response to IL-7 through the IL-7R $\alpha$ - $\gamma\epsilon$  receptor complex.<sup>148</sup> By contrast, once naïve T cells are activated in response to cognate peptide-MHC complexes, homeostasis is maintained by different mechanisms, which are discussed next.

#### T Cell Activation

The TCR-CD3 complex is linked to an intricate and highly interconnected complex of kinases, phosphatases, and adapter molecules that transduce signals in response to engagement of the TCR and, in  $\alpha\beta$  T cells, the appropriate CD4 or CD8 co-receptor by cognate peptide-MHC complexes (Fig. 4-5; see also Fig. 4-1). It is thought that lipid rafts play a critical role in facilitating the assembly of signaling complexes at specific regions of the plasma membrane; these complexes in turn recruit adapters and signal-transducing proteins.<sup>149</sup> A proximal event is activation of tyrosine kinases followed by events that lead to elevation of the T cell free intracellular calcium concentration ( $[Ca^{2+}]_i$ ). An increased calcium concentration in turn leads to the activation of calcineurin and the translocation of nuclear factor of activated T cells (NFAT) transcription factors from the cytosol to the nucleus. Concurrent activation of the extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) pathway enhances activation of other transcription factors, including activator protein-1/activating transcription factor (AP-1/ATF). Collectively, these trans-

cription factors induce the transcription of genes encoding key proteins for activation, such as cytokines, cell cycle regulators, and, in cytotoxic T cells, proteins involved in killing other cells, such as perforins. The expression of more than 100 genes is altered as a result of the activation process.<sup>150,151</sup>

**T Cell Activation versus Anergy.** For full T cell activation that leads to cytokine production and commitment of the cell to proliferate, signaling through the trimolecular  $\alpha\beta$ -TCR-peptide-MHC complex and through accessory or co-stimulatory signaling pathways must exceed a specific threshold. The nature and magnitude of the signal transmitted through the  $\alpha\beta$ -TCR-CD3 complex are a function of the affinity of the TCR for the peptide-MHC complex and the duration of their interaction.<sup>152,153</sup> Low-affinity interactions that do not trigger full T cell activation may lead to a state of long-term unresponsiveness to subsequent stimulation, which is referred to as anergy. Anergy is thought to contribute to the maintenance of tolerance by mature T cells to certain self-antigens—in particular, those that are not expressed in the thymus in sufficient abundance to induce negative selection.

From *in vitro* experiments, it has been estimated that naïve CD4<sup>+</sup> T cells require sustained  $\alpha\beta$ -TCR signaling for 20 to 24 hours to become activated. Surprisingly, studies suggest that a much shorter period of  $\alpha\beta$ -TCR-peptide-MHC interaction is required to activate naïve CD8<sup>+</sup> T cells—as little as 2 hours is sufficient for cells to commit to proliferation.<sup>154,155</sup> As with naïve CD4<sup>+</sup> T cells, however, cell division does not commence for approximately 24 hours after the initiation of signaling. The basis for this difference between naïve CD4<sup>+</sup> and CD8<sup>+</sup> T cells is not known. In any case, optimal signals provided through  $\alpha\beta$ -TCR-peptide-MHC interactions generally are not sufficient to fully activate either naïve CD4<sup>+</sup> or CD8<sup>+</sup> T cells—additional co-stimulatory signals play an important role in allowing naïve T cells to commit to cytokine production and proliferation. By contrast, memory T cells have a lower activation threshold, are less dependent on these co-stimulatory signals, and can commit to proliferate following engagement of their  $\alpha\beta$ -TCR for as little as 1 hour.<sup>152,156</sup>

**Facilitation of T Cell Activation by Co-stimulatory Interactions.** Although signals transmitted by the CD3 complex in response to engagement of the  $\alpha\beta$ -TCR by peptide-MHC complexes on APCs are necessary for T cell activation, many authorities argue that these signals, commonly referred to collectively as signal 1, rarely are sufficient for full activation of naïve T cells under most physiologic conditions. Rather, it appears that the immune system has evolved a strategy by which to “tune down” the response of naïve T cells relative to that of memory T cells, thereby rendering naïve T cells dependent on secondary co-stimulatory signals (signal 2) provided by other molecular interactions between APCs and T cells. Signal 2 alone does not lead to T cell activation but acts in concert with signal 1 provided through  $\alpha\beta$ -TCR-CD3 to facilitate full T cell activation rather than anergy. Co-stimulatory signals (signal 2) appear to be particularly important if the abundance and duration of antigenic peptide-MHC complexes are limiting.

The best-characterized co-stimulatory signal is provided by the engagement of CD28 on the T cell with CD80 (B7-1) or CD86 (B7-2) on APCs (see Table 4-4).<sup>157,158</sup> CD80 and

CD86 are related proteins belonging to the immunoglobulin superfamily, which are expressed at low levels on immature DCs, mononuclear phagocytes, and B cells. The expression of both CD80 and CD86 can be induced on APCs by a variety of factors such as LPS exposure, B cell receptor cross-linking, and CD40 signaling (see Fig. 4-5). Thus, APCs primed by these factors, and, in particular, mature DCs, express high levels of CD80 and CD86.

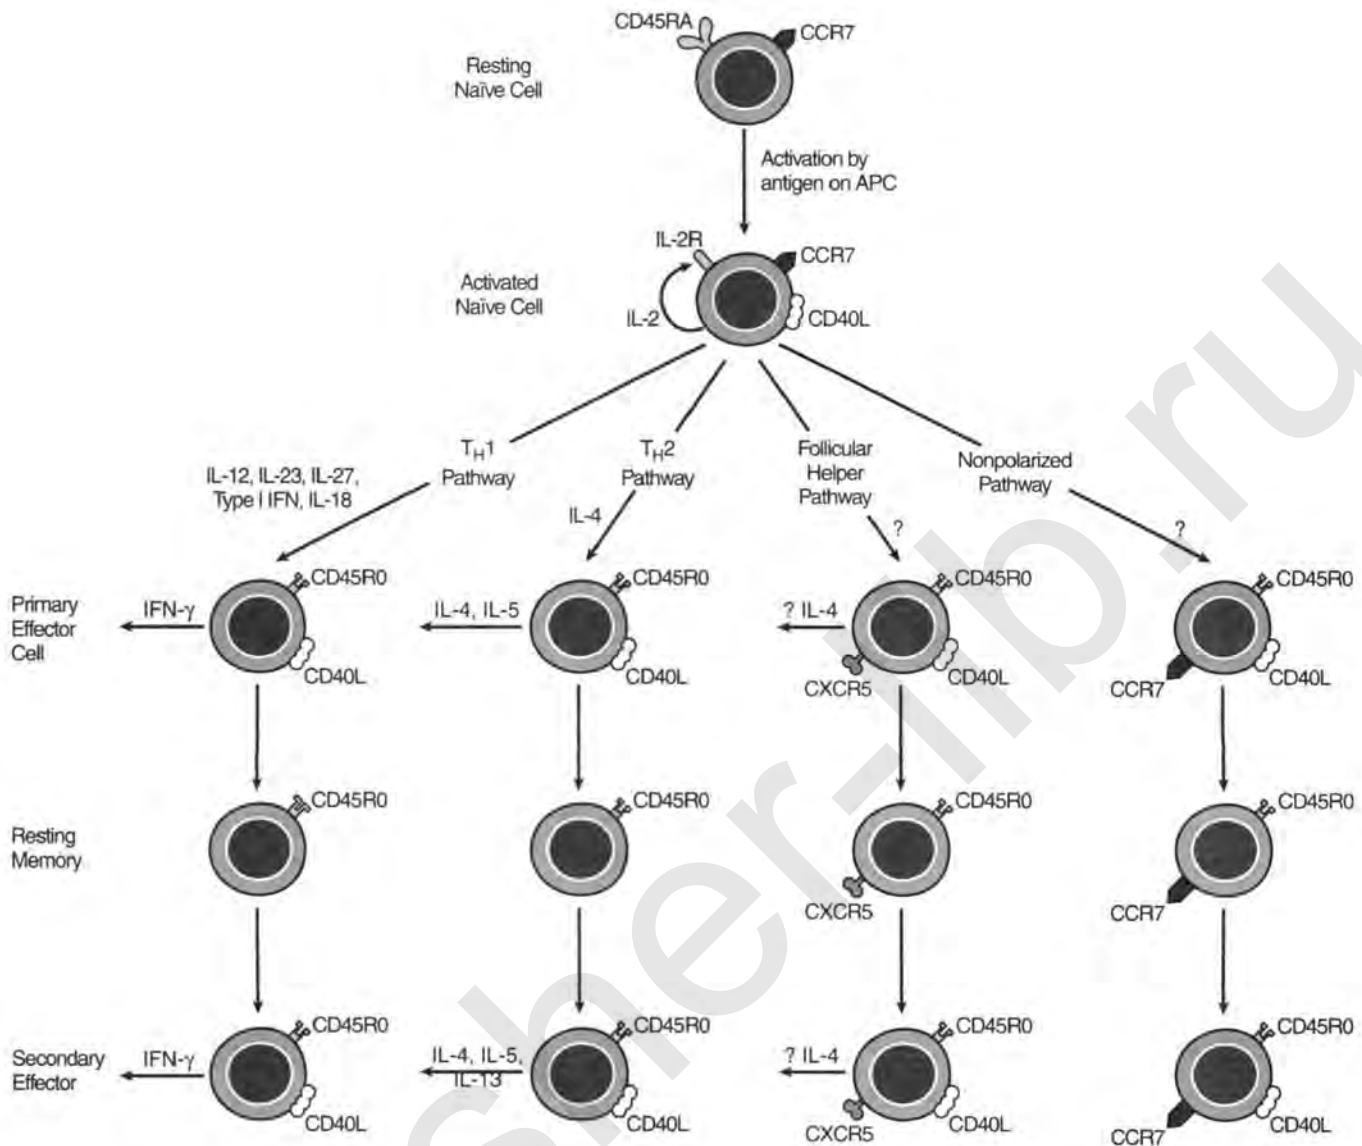

CD80 and CD86 both bind to CD28, which is constitutively expressed on T cells. Signaling through CD28 lowers the strength or duration of TCR signaling needed to fully activate T cells, which is particularly important for naïve T cells, in which the threshold for full activation is high compared with that for memory and effector T cells.<sup>156,159</sup> The Human Genome Project has contributed to the identification of a family of related co-stimulatory molecules that collectively constitute the B7 superfamily.<sup>158</sup> These co-stimulatory molecules may play a role in selective enhancement of certain types of T cell responses. For example, B7-H3 appears to favor the production of IFN- $\gamma$ , at least in humans, whereas B7-related protein-1 (B7RP-1) and its receptor on T cells (the inducible co-stimulator [ICOS]) favor the production of IL-4 and B cell help.<sup>158</sup> Other members of the family, such as PD-1 (“programmed death-1”), may act to dampen the T cell response by inducing T cell apoptosis.

Activated T cells express on their surface CD40 ligand, a member of the TNF ligand family (see Tables 4-1 and 4-4), which engages the CD40 molecule on B cells, DCs, and mononuclear phagocytes.<sup>160-162</sup> CD40 engagement by CD40 ligand induces the expression of CD80 and CD86 on these APCs. As mentioned previously, CD40 engagement also may induce DCs to produce IL-12, IL-23, and other cytokines (see Fig. 4-5) and to express increased levels of CD80 and CD86, which modulate the development and function of effector T cells, as described later on. Interactions between CD40 and CD40 ligand appear to play an important role *in vivo* in the expansion of CD4<sup>+</sup> T cells during a primary immune response but may be less critical for expansion of CD8<sup>+</sup> T cells.<sup>163,164</sup> TNF- $\alpha$  and TRANCE (also known as RANK ligand) are additional members of the TNF ligand family that are expressed on activated T cells and that also can stimulate APC function. Thus, activation-induced expression of TNF ligand family members on naïve T cells can amplify the primary immune responses by priming the function of APCs.

### **Differentiation and Homeostasis of Activated T Cells**

When naïve CD4<sup>+</sup> T cells first encounter foreign peptide-MHC complexes during a primary immune response, they extinguish expression of LKLF, a transcription factor that maintains naïve T cells in a resting state,<sup>165,166</sup> and produce a limited number of cytokines, including IL-2 in robust amounts and CD40 ligand in modest amounts (Fig. 4-6). They also are induced to express high-affinity IL-2 receptor complexes composed of the IL-2R  $\alpha$  and  $\beta$  chains and  $\gamma$ .

Engagement of the IL-2 receptor complex by IL-2, acting as both an autocrine and a paracrine growth factor, triggers T cells to undergo multiple rounds of proliferation, thereby expanding the numbers of antigen-specific T cells, and to differentiate into effector T cells (see Fig. 4-6).<sup>153,167,168</sup> They also express on their surface CD69 and Fas molecules<sup>169</sup> and downregulate expression of Bcl-2, an intracellular protein that protects against apoptosis.<sup>170</sup> Downregulation of Bcl-2

**Figure 4-6** Differentiation of antigenically naive  $CD4^+$  T cells into  $T_H1$ ,  $T_H2$ , unpolarized, and T follicular helper effector and memory T cells. Antigenically naive  $CD4^+$  T cells express high levels of the CD45RA isoform of the CD45 surface protein tyrosine phosphatase. They are activated by antigen presented by antigen-presenting cells (APCs) to express CD40 ligand and interleukin (IL)-2 and to undergo clonal expansion and differentiation, which is accompanied by expression of the CD45RO isoform and loss of the CD45RA isoform. Most effector cells die by apoptosis, but a small fraction of these cells persist as memory cells which express high levels of CD45RO. Exposure of expanding effector cells to IL-12 family cytokines, IL-18, and interferon (IFN)- $\gamma$  favors their differentiation into  $T_H1$  effector cells that secrete IFN- $\gamma$ , whereas exposure to IL-4 favors their differentiation into  $T_H2$  effector cells that secrete IL-4, IL-5, and IL-13. Many memory cells are nonpolarized and do not express either  $T_H1$  or  $T_H2$  cytokines. They may be enriched for cells that continue to express the CCR7 chemokine receptor, which favors their recirculation between the blood and the lymph nodes and spleen. T follicular helper cells, which express high levels of CXCR5, move into B cell follicle areas, where they express CD40 ligand and provide help for B cell responses. The signals that promote the accumulation of memory T follicular helper cells and their capacity to produce cytokines are poorly understood. Memory cells rechallenged with antigen undergo rapid clonal expansion into secondary effector cells that mediate the same functions as the initial memory population. Most secondary effector cells eventually die by apoptosis.

sensitizes these cells to apoptosis, which is countered by signals through the IL-2 receptor complex; this makes effector T cells dependent for their survival on IL-2 (or other cytokines that signal through the  $\gamma_c$  cytokine receptor) to induce the expression of Bcl-xL, which, like Bcl-2, inhibits apoptosis.<sup>171</sup> Thus, when concentrations of IL-2 become limiting, effector T cell attrition occurs, dampening the immune response. Conversely, IL-2 signals may sensitize T cells to Fas-mediated activation-induced cell death. Thus, the role of IL-2 in the expansion, survival, or death of effector

T cells is determined by a balance between prosurvival and proapoptotic effects of IL-2.

In this regard, it is notable that studies suggest that antigen-induced proliferation of murine  $CD4^+$  T cells in vivo, in striking contrast with findings in vitro, does not require signals through the IL-2 receptor or other receptor complexes that contain  $\gamma_c$ <sup>147</sup>; whether this also is true for  $CD8^+$  T cells and in humans is not known. Although these results do not exclude a role for IL-2 in antigen-induced proliferation of  $CD4^+$  T cells, they reinforce the observation

that the dominant effect observed in humans with IL-2 receptor  $\alpha$  chain deficiency is autoimmunity.<sup>171,172</sup> The basis for this effect is not certain, but it may reflect defects in activation-induced cell death mediated by Fas–Fas ligand interactions, and defects in regulatory T cells (see later section).<sup>173</sup>

Regardless of the role of IL-2 and IL-2 receptors in the initial proliferation of naïve T cells, proliferation leads to an expansion in the numbers of the responding T cell population. This increase is a key feature of antigen-specific immunity. In the absence of prior exposure, the frequency of T lymphocytes capable of recognizing and responding to that antigen is small, generally less than 1:100,000, but in response to infection can increase to greater than 1:20 for CD8<sup>+</sup> T cells and greater than 1:1000 for CD4<sup>+</sup> T cells in less than a week.<sup>174</sup> Furthermore, the phenotype and function of these cells are permanently changed from those characteristic of naïve T cells to those associated with memory or effector T cells.

**T<sub>H</sub>1 and T<sub>H</sub>2 CD4<sup>+</sup> T Cells.** The functions of effector T cells, particularly those of the CD4<sup>+</sup> subset, are mediated in large part by the multiple additional cytokines they produce that are not produced by naïve T cells. Most of these cytokines are secreted, although some (e.g., some members of the TNF ligand family) may be predominantly expressed on the T cell surface. These cytokines include IL-3, IL-4, IL-5, IL-9, IL-10, IL-13, IL-17, IL-21, interferon- $\gamma$  (IFN- $\gamma$ ), GM-CSF, CD40 ligand, TNF- $\alpha$ , and Fas ligand.<sup>175,176</sup> Table 4-2 summarizes the major immunomodulatory effects of T cell–derived cytokines and of cytokines produced by other cell types that act on T cells. Some key effects of cytokines in T cell proliferation, differentiation, and effector function, and in B cell, NK cell, and mononuclear phagocyte function, are discussed later on.

Two major types of CD4<sup>+</sup> effector T cells, T<sub>H</sub>1 and T<sub>H</sub>2, initially were described in mice, and similar profiles of polarized cytokine expression subsequently have been confirmed in other species, including humans.<sup>177–180</sup> IFN- $\gamma$  is the signature cytokine produced by T<sub>H</sub>1 effector cells, which also produce substantial amounts of IL-2, lymphotoxin- $\alpha$ , and TNF- $\alpha$ , but little or no IL-4, IL-5, and IL-13. By contrast, IL-4 is the signature cytokine of T<sub>H</sub>2 cells, which also produce IL-5, IL-9, and IL-13, but little or no IFN- $\gamma$  or IL-2.

More overlap or variability in patterns of cytokine production may be present in humans than in mice. Cells producing effector cytokines of both types are commonly referred to as T<sub>H</sub>0 cells, which often are seen following vaccination with protein antigens or following viral infections, such as influenza virus or CMV.<sup>181,182</sup> Generation of T<sub>H</sub>0 cells in vitro seems to be favored by the presence of large amounts of IL-2 in the absence of cytokines that polarize differentiation toward either T<sub>H</sub>1 or T<sub>H</sub>2 effector cells.<sup>179,183,184</sup> An alternative possibility is that T<sub>H</sub>0 cells have undergone less proliferation and differentiation and for this reason have not yet become committed T<sub>H</sub>1 or T<sub>H</sub>2 cells.<sup>46,156</sup> In addition to their differing cytokine profiles, T<sub>H</sub>1 and T<sub>H</sub>2 cells also differ in chemokine receptor and cell adhesion molecule expression.<sup>43,45,140,185,186</sup> This may allow T<sub>H</sub>1 and T<sub>H</sub>2 cells to differentially localize to particular tissues—for example, T<sub>H</sub>2 cells often are found in the mucosa.

**Regulation of T<sub>H</sub>1 versus T<sub>H</sub>2 Differentiation.** Factors contributing to the generation of T<sub>H</sub>1 versus T<sub>H</sub>2 cells include the strength of the activating signals, nature and abundance of co-stimulatory molecules on APCs, and the cytokine milieu, with the last playing the dominant role.<sup>177,179,183</sup>

T<sub>H</sub>1 effector development is favored by the exposure of CD4<sup>+</sup> T cells during their initial activation to high levels of IL-12, IL-18, IL-23, and IL-27 produced by APCs and to IFN- $\gamma$  produced by NK cells and other T cells (see Fig. 4-6). In humans but not in mice, IFN- $\alpha$  also is a potent inducer of T<sub>H</sub>1 cells.<sup>177,178</sup> Chemokines also may affect T<sub>H</sub>1 versus T<sub>H</sub>2 differentiation.<sup>187</sup> The importance of these cytokines in the development of robust T<sub>H</sub>1 responses and of IFN- $\gamma$  in human host defense is demonstrated by the increased susceptibility of patients with genetic defects in IL-12, IL-12 receptors, IFN- $\gamma$  receptors, or signal transducer and transcriptional activator-1 (STAT-1), which transduces IFN- $\gamma$  receptor–derived signals, to infection with intracellular pathogens, particularly mycobacteria and *Salmonella*.<sup>188</sup>

T<sub>H</sub>2 development is favored when CD4<sup>+</sup> T cells initially are activated in the presence of IL-4 or in the absence of IL-12, IL-18, IL-23, IL-27, IFN- $\alpha$ , or IFN- $\gamma$  (see Fig. 4-6), or both. The source of IL-4 in a primary CD4<sup>+</sup> T cell response leading to the generation of T<sub>H</sub>2 cells is uncertain. It is possible that in the absence of cytokines favoring T<sub>H</sub>1 development, the low levels of IL-4 produced by naïve T cells are sufficient,<sup>184</sup> but NK T cells, mast cells, basophils, and eosinophils also produce IL-4 and may contribute in some situations. High levels of co-stimulation through CD86<sup>189</sup> and the engagement of OX40 on the T cell by OX40 ligand, a member of the TNF ligand superfamily expressed by B cells, also may favor T<sub>H</sub>2 rather than T<sub>H</sub>1 CD4<sup>+</sup> T cell development.<sup>190</sup>

Evidence in the mouse suggests that the development and propagation of T<sub>H</sub>1 and T<sub>H</sub>2 T cells not only are influenced by these exogenous factors but are determined by the expression within CD4<sup>+</sup> T cells of opposing transcription factors that dictate T<sub>H</sub>1 versus T<sub>H</sub>2 development.<sup>177,178</sup> GATA-binding protein-3 appears to be a master regulator of T<sub>H</sub>2 T cell development.<sup>191</sup> The expression of GATA-3 is sufficient to override the other influences described earlier, and to reinforce its own expression through a positive feedback loop. Conversely, T-bet induces the development of T<sub>H</sub>1 cells, and many of the T<sub>H</sub>1-promoting cytokines, such as IFN- $\gamma$ , may induce T-bet expression in recently activated naïve CD4<sup>+</sup> T cells.<sup>192</sup>

### T Cell Help for Antibody Production

T cells play a crucial role in the regulation of B cell proliferation, immunoglobulin class switching, affinity maturation, and memory B cell generation in response to proteins or protein conjugates. The enhancement of B cell responses is commonly referred to as T cell help. This process is critically dependent on the recognition through the  $\alpha\beta$ -TCR of cognate peptide-MHC complexes on B cells, and on multiple contact-dependent interactions (see Fig. 4-5) between members of the TNF ligand–TNF receptor families (see Table 4-1) and the CD28-B7 families (see Table 4-4). Recently activated CD4<sup>+</sup> T cells that express CXCR5 migrate to B cell follicles and likely provide key help for antibody production (Table 4-5). CXCR5 is the receptor for CXCL13 (BCA-1), a chemokine produced by stromal cells of the B cell follicle. The function of these follicular CXCR5<sup>hi</sup> CD4<sup>+</sup> T cells, also

known as T follicular helper cells,<sup>193,194</sup> is discussed in more detail in the section on naive B cell activation, clonal expansion, immune selection, and T cell help.

The importance of cognate T cell help is clearly illustrated by the phenotype of patients with X-linked hyper-immunoglobulin M (hyper-IgM) syndrome, who have genetic defects in the expression of CD40 ligand.<sup>195</sup> In affected individuals, the marked paucity of immunoglobulin isotypes other than IgM and inability to generate memory B cell responses indicate that these responses critically depend on the engagement of CD40 on B cells by CD40 ligand on T cells. Engagement of CD40 on B cells in conjunction with other signals provided by cytokines, such as IL-4 and IL-21, markedly enhances immunoglobulin production and class switching and B cell survival. OX-40 ligand–OX40 and TNF- $\alpha$ –TNF- $\alpha$  receptor interactions also contribute.<sup>196</sup>

The interaction of CD28 on T cells with CD80 and CD86 on B cells also is important, because inhibition of this interaction markedly impedes T cell–dependent antibody responses, similar to the effects observed in the absence of CD40 signaling.<sup>87,157</sup> Activated and memory CD4<sup>+</sup> T cells also express ICOS, a ligand for B7RP-1, which is constitutively expressed on B cells and a variety of other cell types.<sup>158</sup> ICOS co-stimulates the T cell response, and inhibition of ICOS–B7RP-1 interactions impedes the production of IgG and the development of T<sub>H</sub>2 responses in mice. The identification of ICOS deficiency as a cause of hypogammaglobulinemia and poor antibody responses to vaccination<sup>197</sup> supports the importance of ICOS–B7RP interactions in humans. Other interactions, such as that between LFA-1 and CD54 (ICAM-1), may enhance T cell–dependent B cell responses,<sup>198</sup> an idea supported by the finding that humans with CD18 deficiency, which is a component of the LFA-1 integrin, have depressed antibody responses after immunization.<sup>199</sup>

Soluble cytokines produced by activated T cells influence the type of immunoglobulin produced by B cells. Experiments in mice in which the IL-2, IL-4, IL-5, or IFN- $\gamma$  gene or, in some cases, their specific receptors and associated STAT

signaling molecules have been disrupted by gene targeting suggest that these cytokines are important for the proper regulation of B cell immunoglobulin isotype expression. For example, inactivation of the IL-4 gene, components of the high-affinity IL-4 receptor, or the STAT-6 protein involved in IL-4 receptor signal transduction results in a greater than 90% decrease in IgE production, whereas the production of other antibody isotypes is largely unperturbed.<sup>200</sup>

### **Effector T Cell Migration to Relevant Tissues**

Once effector T cells have acquired the ability to mediate protective functions, they must migrate to the appropriate tissues for them to be useful. To do so, effector cells also acquire patterns of chemokine receptors and cell adhesion molecules that facilitate entry into inflamed or infected tissues (see Table 4-4).<sup>43,45,201,202</sup> Effector T cells no longer express CCR7, so they are no longer attracted by the homeostatic chemokines produced in the T cell zone of lymphoid tissues (CCL19 and CCL21). The T follicular helper subset of effector CD4<sup>+</sup> T cells, which expresses high levels of CXCR5, migrates to B cell follicles, which express CXCL13, the only ligand for this chemokine receptor. By contrast, most T<sub>H</sub>1, T<sub>H</sub>2, and CD8 effector T cells leave the lymphoid tissues and migrate to extralymphoid target organs. This migration results from the reduction in expression of the lymph node–homing receptor L-selectin and increased or de novo expression of other adhesion molecules that facilitate entry into other tissues, including LFA-1, VLA-4 and, in the case of cells that migrate to the skin, cutaneous lymphocyte antigen (CLA), or, in the case of cells that migrate to the gut, the  $\alpha_4\beta_7$  integrin.<sup>140,186</sup> T<sub>H</sub>1 cells (and effector CD8<sup>+</sup> cells that produce IFN- $\gamma$ ) express CCR5, the chemokine receptor for CCL3 (macrophage inflammatory protein-1 $\alpha$  [MIP-1 $\alpha$ ]), CCL4 (MIP-1 $\beta$ ), and CCL5 (RANTES), and CXCR3, the chemokine receptor for CXCL9 (monokine induced by gamma interferon [MIG]), CXCL10 (interferon- $\gamma$ -inducible protein 10 [IP-10]), and CXCL11 (interferon-inducible T-cell  $\alpha$  chemoattractant). The former chemokines (CCL3, CCL4,

and CCL5) characteristically are produced in inflamed tissues, and the last three (CCL9, CCL10, and CCL11) are specifically produced in response to IFN- $\gamma$ . These chemokines also are found at sites of effective cell-mediated immune responses, including delayed-type hypersensitivity (DTH) reactions, to which they attract not only T<sub>H</sub>1 CD4<sup>+</sup> T cells and effector CD8<sup>+</sup> T cells but also DCs and monocytes. Conversely, T<sub>H</sub>2 T cells uniquely express a receptor for prostaglandin D, CRTH2,<sup>203</sup> and preferentially express CCR2, CCR3, and CCR8, which are receptors for CCL13 (monocyte chemoattractant protein-4 [MCP-4], CCL11, CCL14, and CCL26 (eotaxins 1, 2, and 3), and CCL1 (inflammatory cytokine-309), respectively. These chemokines characteristically are found at sites of allergic responses. As some of their names suggest, these chemokines also attract eosinophils, thus helping to orchestrate concerted T<sub>H</sub>2-dependent responses.

### Termination of the T Cell Effector Response

To prevent excessive immune responses, active mechanisms for terminating the T cell response operate on multiple levels. CD45 is a protein tyrosine phosphatase that promotes T cell activation by counteracting the phosphorylation of tyrosine residues that inhibit the function of tyrosine kinases involved in T cell activation, such as Lck. Because dimerization of CD45 impedes its phosphatase activity, it is possible that the preferential expression of the low-molecular-weight CD45RO isoform on effector CD4<sup>+</sup> T cells may facilitate CD45 dimerization and thereby attenuate the immune response.<sup>204</sup> T cell activation is also limited by the engagement of cytotoxic T lymphocyte antigen-4 (CTLA-4) (i.e., CD152) on the T cell by CD80 and CD86 on the APC. CTLA-4 is expressed mainly on the T cell surface during the later stages of activation. In mice genetically deficient in CTLA-4, a fatal autoimmune syndrome develops that is mediated by CD4<sup>+</sup> T cells.<sup>205</sup> How CTLA-4 acts to terminate T cell activation is controversial. Engagement of this molecule has been variously reported to activate inhibitory signaling pathways in the T cell and to induce T cell anergy, apoptosis, and the secretion of antiproliferative cytokines, such as transforming growth factor (TGF)- $\beta$ .<sup>206</sup> It also is possible that CTLA-4 does not act primarily within conventional antigen-specific CD4<sup>+</sup> T cells, but acts mainly within the regulatory T cell subset to facilitate their ability to suppress the function of other T cells (see section on regulatory T cells). A controversial mechanism involves the engagement of CD80 and CD86 on the T cell by CTLA-4 of the regulatory T cell, generating a negative signal that suppresses T cell activation. Similarly, the engagement of the B7 family member PD-1 on activated T cells by its B7 family ligands PDL1 (B7-H1) and PDL2, expressed on APCs (see Table 4-4) and in certain tissues, dampens the effector T cell response.<sup>158</sup>

In addition to attenuating the generation of effector T cells, most effector T cells generated during a robust immune response to infection are eliminated by apoptosis. Evidently, such elimination is achieved by multiple mechanisms. A major mechanism is active induction of apoptosis through death receptors of the TNF ligand gene family and in particular, by Fas ligand. Fas ligand and its receptor, Fas, both are expressed by activated effector T cells (see Table 4-2). Furthermore, at the same time at which IL-2 transduces signals driving the proliferation of activated, effector T cells,

it sensitizes them to Fas-induced apoptosis by reducing the expression of molecules that block death signals downstream of Fas.<sup>7,207,208</sup> Other members of the TNF receptor and TNF ligand family also may participate in this process—for example, TNF- $\alpha$  may help to trigger apoptosis by effector CD8<sup>+</sup> T cells. Effector CD8<sup>+</sup> T cell expansion is limited by perforin and IFN- $\gamma$  produced by these cells, although the mechanism by which this is mediated is not known.<sup>209</sup>

In addition to these active mechanisms for the induction of apoptosis, T cell activation terminates the expression of the anti-apoptotic Bcl-2 protein. This renders effector T cells dependent on the expression of the related Bcl family member, Bcl-xL, expression of which is driven by cytokines, in particular, cytokines signaling through  $\gamma_c$ , such as IL-2, IL-7, and IL-15.<sup>171,210</sup> Thus, as the immune response evolves and the availability of these cytokines becomes limiting, apoptosis of effector T cells ensues, owing to a passive, death-by-neglect mechanism.

### Memory T Cells

**Characteristics and Origins of Memory T Cells.** Although greater than 90% of antigen-specific effector T cells generated during a robust primary immune response die, a fraction persist as memory T cells. Memory T cells account for the enhanced secondary T cell response to subsequent challenge—this reflects both the substantially greater frequency of antigen-specific memory T cells (approximately 1:100 to 1:10,000) than that of antigen-specific T cells in a naïve host (approximately 1:100,000 for most antigens), and the enhanced functions of memory compared with those of naïve T cells.<sup>164,211-213</sup> Memory T cells retain many of the functions of the effector T cells that characterized the immune response from which the memory T cells arose. These functions include a lowered threshold for activation and the ability to produce more rapidly the effector cytokines that characterized the effector T cell response from which they arose, that is, T<sub>H</sub>1 or T<sub>H</sub>2.<sup>156</sup> Turnover of memory T cells occurs slowly, but more rapidly than that of naïve T cells, and memory T cells appear to persist for decades in the absence of further contact with foreign antigenic peptide–MHC complexes.<sup>212</sup>

Our understanding of the key determinants of the genesis of memory T cells remains incomplete. It has been proposed that memory T cells are derived, perhaps stochastically, from a small subset of effector T cells that survive and persist.<sup>212,213</sup> This suggestion is consistent with the estimation that human memory T cells arise from naïve T cell precursors after an average of 14 cell divisions.<sup>214</sup> Alternatively, memory T cells may differentiate directly from naïve T cells rather than through an effector T cell intermediate,<sup>215</sup> or may arise from those T cells that do not proliferate or differentiate to the same extent as for cells that acquire full effector function, or effector T cells that subsequently undergo apoptosis.<sup>156,212</sup> Co-stimulatory interactions, including those between CD28 and CD80 (and CD86) and between CD40 ligand and CD40, seem to play a role in the generation of memory T cells,<sup>174</sup> and humans genetically deficient in CD40 ligand have reduced CD4<sup>+</sup> T cell recall responses to previously administered protein vaccines.<sup>216</sup>

Most human memory CD4<sup>+</sup> T cells can be distinguished from naïve cells by their surface expression of the CD45RO rather than the CD45RA isoform of CD45 (see Fig. 4-6). In

addition, memory and effector T cells typically express higher levels of adhesion molecules, such as the VLA-4  $\beta_1$  integrin, than levels observed on naïve T cells (see Table 4-4).<sup>217</sup> About 40% of circulating adult CD4<sup>+</sup> T cells have this CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> (VLA-4<sup>hi</sup>) memory/effector surface phenotype. Another 10% to 15% of circulating CD4<sup>+</sup> T cells have a CD45RA<sup>mid</sup>CD45RO<sup>mid</sup> surface phenotype and memory/effector-like function,<sup>218</sup> but their relationship to CD45RO<sup>hi</sup> T cells remains unclear. In contrast with memory/effector T cells, most naïve CD4<sup>+</sup> T cells have a CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> surface phenotype,<sup>219</sup> although a minority of these CD45RA<sup>hi</sup> T cells may be revertants from either CD45RO<sup>hi</sup> or CD45RO<sup>mid</sup> cells.<sup>217</sup> Such revertants may be more prominent in certain immunopathologic contexts, such as following allogeneic hematopoietic cell transplantation.<sup>220</sup>

Activation and propagation of CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> CD4<sup>+</sup> T cells in vitro result in their acquisition of memory/effector cell-like features, including a lower threshold for activation, a CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> phenotype, an enhanced ability to produce effector cytokines (e.g., IFN- $\gamma$ , IL-4), and an increased ability to provide help for B cell antibody production.<sup>217,221</sup> These findings support the notion that CD45RA<sup>hi</sup> T cells are precursors of CD45RO<sup>hi</sup> T cells, and that this differentiation occurs following T cell activation, and, in addition, are consistent with the observation that the CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> cell subset consists mainly of memory T cells that respond to recall antigens.

Memory CD8<sup>+</sup> T cells are similar to those of the CD4<sup>+</sup> subset in expressing a CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> surface phenotype and in possessing an enhanced capacity to produce multiple cytokines compared with that in their naïve precursors.<sup>218,222</sup> In addition, unlike with memory CD4<sup>+</sup> T cells, a substantial subset of these CD45RO<sup>hi</sup> CD8<sup>+</sup> T cells express CD11b, CD57, and killer inhibitory receptors (KIRs).<sup>223</sup> KIRs bind self-HLA-A, -B, or -C alleles and deliver an inhibitory signal into the cell. KIRs are expressed at high levels on most or all human NK lymphocytes. The importance of KIR expression by CD8<sup>+</sup> T cells remains unclear, but KIRs are hypothesized to regulate effector function, such as cytotoxicity, by raising the threshold for activation by antigenic peptide-MHC complexes. Human effector CD8<sup>+</sup> T cells also can be distinguished from circulating naïve CD8<sup>+</sup> T cells by surface phenotype: Most human CD8<sup>+</sup> effector cells have a CD45RA<sup>hi</sup>CD27<sup>lo</sup>CD28<sup>lo</sup> surface phenotype and a high capacity to mediate cytotoxicity and to produce T<sub>H</sub>1-type effector cytokines, including TNF- $\alpha$  and IFN- $\gamma$ .<sup>218,222,224</sup> By contrast, naïve CD8<sup>+</sup> T cells have a CD45RA<sup>hi</sup>CD27<sup>+</sup>CD28<sup>+</sup> surface phenotype and a limited ability to mediate cytotoxicity and to secrete these cytokines.

**Localization and Homeostasis of Memory T Cells.** The localization of memory T cells correlates with and probably is determined by differential expression of adhesion molecules and chemokine receptors. Studies suggest the existence of distinct central (lymphoid homing) and effector (tissue homing) memory T cell populations.<sup>43,156,201</sup> Central memory T cells express on their surface the CCR7 receptor and high levels of L-selectin, the lymph node homing receptor. By contrast, effector memory T cells lack CCR7 and express low levels of L-selectin. In humans, the generation of T<sub>H</sub>1 effector memory CD4<sup>+</sup> T cells appears to require intact receptor signaling for IL-12 and IL-23.<sup>225</sup> Central memory T cells

demonstrate delayed or limited production of effector cytokines, whereas effector memory T cells rapidly produce these cytokines, including in response to cognate antigen for the TCR.<sup>226</sup> Studies in the mouse also support this notion and suggest that a substantial subset of memory T cells are present in tissues, including the lung, liver, and gut, where they are poised to mediate rapid protection against rechallenge. The central memory subset, found in lymph nodes, is thought to provide a backup and potentially longer-lived reservoir of memory cells. The central memory pool may be a larger fraction of the memory pool for CD4<sup>+</sup> than for CD8<sup>+</sup> T cells.<sup>43</sup> The specific tissues to (or through) which memory T cells migrate also appear to be determined by the pattern of chemokine receptors and adhesion molecules they express. Those found in the skin express the CLA adhesion and chemokine receptors CCR4 and CCR10, whereas those in the small intestine express the  $\alpha_4\beta_7$  integrin and CCR9.<sup>43,45,140,186</sup>

The cellular and molecular interactions that are involved in the generation and maintenance of memory T cells remain incompletely understood. Turnover of memory T cells appears to be much more frequent than that of naïve T cells, suggesting that the process is a dynamic one.<sup>212</sup> Unlike with naïve T cells, the maintenance of memory T cells appears not to require continued contact with self-peptide-MHC complexes. For memory CD8<sup>+</sup> T cells, IL-7 and IL-15 appear to be critical for their maintenance.<sup>146,148,212</sup> IL-7 also may be required to promote the transition of effector CD4<sup>+</sup> T cells to memory cells.<sup>227</sup> What sustains established memory CD4<sup>+</sup> T cells is not known, but neither these nor other cytokines that signal through the  $\gamma_c$  cytokine receptor chain appear to be required.

**Activation of Memory T Cells.** When memory T cells re-encounter antigenic peptide-MHC complexes (“recall antigen”) as part of the secondary response, they are activated and undergo expansion and differentiation into a secondary effector population (see Fig. 4-6). The secondary immune response to recall antigen is typically more rapid and robust than the primary response to an antigen that has never been encountered previously. This difference is due both to the greater frequency of antigen-specific memory T cells than of naïve T cells with TCRs that recognize the same antigens and to the enhanced function of these memory T cells and their secondary effector progeny.<sup>156,212,213</sup> For example, individual secondary effectors generated from memory CD8<sup>+</sup> T cells may express both perforin and effector cytokines, whereas primary effectors generated from naïve CD8<sup>+</sup> T cells may express either perforin or cytokines, but not both.

### Regulatory T Cells

The phenomenon of T cell-mediated immune suppression—dominant inhibition of the response of one subset of T cells by another—was observed many years ago, and the cells mediating the inhibition were referred to as suppressor T cells.<sup>228</sup> Their nature and even existence remained uncertain, however, until the mid-1990s, when studies by Sakaguchi and colleagues in the mouse and Roncarolo and associates in humans provided evidence that a subset of CD4<sup>+</sup> T cells were involved in the active suppression of autoimmunity.<sup>229-231</sup> These regulatory or suppressor T cells are found within the

small fraction of circulating human CD4<sup>+</sup> T cells that are CD25<sup>+</sup>. Although not all cells of this phenotype mediate suppression, many do. CD25 is the IL-2 receptor  $\alpha$  chain, which, in conjunction with the IL-2 receptor  $\beta$  chain, and the  $\gamma$ c cytokine receptor, comprises the high-affinity IL-2 receptor. Regulatory CD4<sup>+</sup>CD25<sup>+</sup> T cells appear to depend on IL-2 and high-affinity IL-2 receptors for their generation and maintenance.

Regulatory T cells are generated in the thymus during the normal process of positive and negative selection and can also be induced by activation of naïve peripheral CD4<sup>+</sup> T cells in the presence of certain cytokines, including IL-10 and type I IFN.<sup>232</sup> Suppression requires activation through the  $\alpha\beta$ -TCR (e.g., antigenic peptide–MHC), but thereafter, regulatory T cell–mediated suppression is not antigen specific. Different mechanisms of inhibition have been described, including the production of IL-10, TGF- $\beta$ , or CTLA-4 (the last has been proposed to downregulate T cell responses by engaging their surface CD80 and CD86 molecules, resulting in a negative intracellular signal). In vitro studies suggest that contact-dependent inhibition of the activation of other T cells through an APC-independent process is a major mechanism by which regulatory T cells mediate suppression, although the molecular basis for this inhibition is not known.

### Natural Killer T Cells

A small population of circulating human T cells express  $\alpha\beta$ -TCR but lack expression of both CD4 and CD8 and also express NKR-P1A, the human orthologue of the mouse NK1.1 protein. These features, as well as others, such as CD56 and CD57 surface expression and a developmental dependence on the cytokine IL-15,<sup>233</sup> also are characteristic of NK cells, a non-T cell lymphocyte population. For this reason, these T cells frequently are referred to as NK T cells or natural T cells.

Similar to murine T cells expressing NK1.1, human NK T cells have a restricted repertoire of  $\alpha\beta$ -TCR (TCR  $\alpha$  chains containing the V $\alpha$ 24J $\alpha$ Q segments in association with TCR- $\beta$  chains containing V $\beta$ 11 segments)<sup>234–236</sup> and mainly recognize antigens presented by the nonclassic MHC molecule, CD1d, rather than by MHC class I or class II molecules. The CD1d-restricted antigens that can be recognized by NK T cells include certain lipid molecules, such as  $\alpha$ -galactosylceramide,<sup>203,237</sup> as well as certain hydrophobic peptides. Murine studies indicate that NK T cells may be derived from CD4<sup>hi</sup>CD8<sup>hi</sup> double-positive thymocytes by the interaction of their  $\alpha\beta$ -TCR with CD1d; the nature of CD1d-associated ligands in this selection process is unclear.<sup>105</sup>

NK T cells have the ability to secrete high levels of IL-4 and IFN- $\gamma$  and to express Fas ligand and the TNF-related apoptosis-inducing ligand (TRAIL) on their cell surface on primary stimulation, a capacity not observed with most antigenically naïve  $\alpha\beta$  T cells.<sup>203,238</sup> The physiologic role of NK T cells remains controversial. Although these cells may contribute to host defense against certain infections, murine studies suggest that NK T cells are negative regulators of certain T cell–mediated immune responses, particularly those involved in autoimmune disease<sup>239</sup> and in graft-versus-host disease following hematopoietic cell transplantation.<sup>240</sup> The regulatory function of NK T cells on autoimmune disease may be relevant in humans, because a decreased number of

NK T cells may predispose affected persons to the development of insulin-dependent diabetes mellitus.<sup>241</sup>

## T Cell Development and Function in the Fetus and Neonate

### Thymic Ontogeny

The fetal liver at 6 to 8 weeks of gestation contains CD34<sup>+</sup> lymphoid cells that appear to include prothymocytes, because these lymphoid cells can undergo in vitro differentiation into T-lineage cells.<sup>1,242</sup> Initial colonization of the fetal thymus by prothymocytes, which probably come from the fetal liver, occurs at approximately 8.5 weeks of gestation.<sup>243</sup> Thymocytes expressing proteins that are characteristic of T-lineage cells, including CD4, CD8, and the  $\alpha\beta$ -TCR–CD3 complex, are found shortly after the initial colonization at 8.5 weeks of gestation.<sup>243</sup> By 12 weeks of gestation, the pattern of expression of a number of other proteins expressed by thymocytes, such as CD2, CD5, CD38, and the CD45 isoforms, matches that in the postnatal thymus. Concurrently, a clear architectural separation between the thymic cortex and medulla is evident,<sup>244</sup> with Hassall's corpuscles observable in the thymic medulla shortly thereafter.<sup>245</sup> By 14 weeks of gestation, the three major human thymocyte subsets (double-negative, double-positive, and mature single-positive) characteristic of the postnatal thymus are found (see Fig. 4-3). Fetal thymocyte expression of the chemokine receptors CXCR4 and CCR5, which also are co-receptors for entry of human immunodeficiency virus (HIV)-1, has been found by 18 to 23 weeks of gestation<sup>246</sup> and is likely to be present earlier.

Medullary DCs in the fetus but not in the adult express high levels of CD80,<sup>247</sup> a ligand for CD28 and CTLA-4. CTLA-4 is expressed not only at the late stages of activation of mature T cells but also by thymocytes.<sup>248</sup> Murine experiments suggest that both CD80 and CD86 participate in negative selection by interaction with CD28; CTLA-4 engagement in this context appears to prevent negative selection. By contrast, some in vitro experiments using human cells suggest that a CD80–CTLA-4 interaction could enhance the process of negative selection,<sup>248</sup> but an in vivo role of CD80 in human fetal thymocyte development remains uncertain. The ICOS co-stimulatory molecule also is prominently expressed by the thymus as early as 17 weeks of gestation.<sup>249</sup> The role of ICOS in human thymocyte development is unclear, because it is not known if B7RP-1, the only identified ligand of ICOS,<sup>250</sup> also is expressed in this tissue. Studies in mice and humans with ICOS deficiency suggest that ICOS is not required for normal thymocyte development.<sup>197,251</sup>

Thymic cellularity increases dramatically during the second and third trimesters of fetal gestation. Transient thymic involution, mainly the loss of cortical double-positive (CD4<sup>hi</sup>CD8<sup>hi</sup>) thymocytes, which is evident within 1 day after birth, probably begins at the end of the third trimester.<sup>252</sup> This involution may be a consequence of the elevation in circulating levels of glucocorticoids that occurs during the third trimester before delivery. Thymic recovery is evident by 1 month following delivery and is paralleled by a sharp decline in glucocorticoid levels within hours after birth.<sup>252</sup> This transient involution is followed by a resumption of increased thymic cellularity, with peak thymus size attained at about age 10 years. When complete thymectomy is

performed during the first year of life, subsequent circulating numbers of CD4<sup>+</sup> and CD8<sup>+</sup> T cells are decreased, indicating the importance of postnatal production of thymocytes for maintenance of the peripheral T cell compartment.<sup>253</sup>

After puberty, the thymus involutes, with the gradual replacement of the cortex and medulla by fat. Single-positive thymocytes within the medulla are relatively spared during the involutionary process, in comparison with double-positive thymocytes in the cortex.<sup>254</sup> Nevertheless, the thymus of adults remains active<sup>255</sup> and is capable of increasing its output of antigenically naïve T cells in response to severe T cell lymphopenia (e.g., following intense cytotoxic chemotherapy<sup>256</sup> or treatment with highly active combination antiretroviral therapy for HIV infection<sup>257</sup>). The mechanisms by which increased thymocytopoiesis is triggered by severe lymphopenia is unclear but may include the increased production of IL-7.<sup>258</sup>

### **Fetal and Neonatal T Cell Receptor Repertoire**

The generation of the  $\alpha\beta$ -TCR repertoire by the process of V(D)J recombination of the TCR  $\alpha$  and TCR  $\beta$  genes probably occurs within a few days after colonization of the thymus by prothymocytes. The usage of D and J segments in rearrangement of the TCR  $\beta$  chain gene in the thymus at approximately 8 weeks of gestation is less diverse than at 11 to 13 weeks of gestation or subsequently.<sup>259,260</sup> This restriction is not explained by an effect of positive or negative selection in the thymus, because it applies to D-to-J rearrangements, which are not expressed on the immature thymocyte cell surface.<sup>259,261</sup> The CDR3 region of the TCR  $\beta$  chain transcripts is reduced in length and sequence diversity in the human fetal thymus between 8 and 15 weeks of gestation, probably owing to decreased amounts of the TdT enzyme, which performs N-nucleotide addition during V(D)J recombination.<sup>259-262</sup> TdT activity and CDR3 length both are increased by the second trimester,<sup>259-261</sup> and V $\beta$  and V $\alpha$  segment usage in the thymus and peripheral lymphoid organs is diverse.<sup>260,261,263,264</sup> The  $\alpha\beta$ -TCR repertoire of cord blood T cells that is expressed on the cell surface is characterized by a diversity of TCR  $\beta$  usage and CDR3 length that is similar to that of antigenically naïve T cells in adults and infants, indicating that the functional preimmune repertoire is fully formed by birth.<sup>265-267</sup>

Because the CDR3 region of the TCR chains is a major determinant of antigen specificity,<sup>118</sup> decreased CDR3 diversity, in conjunction with restricted usage of V(D)J segments, theoretically could limit recognition of foreign antigens by the fetal  $\alpha\beta$ -TCR repertoire, particularly during the first trimester. The effects of any potential “holes” in the  $\alpha\beta$ -TCR repertoire of the human fetus from limitations in CDR3 are likely to be subtle, however, particularly after the second trimester, when V segment usage is diverse. This is suggested by the fact that the T cell response to immunization and viral challenge generally is normal in mice that are completely deficient in TdT as a result of selective gene targeting.<sup>268</sup>

Repertoire analysis using CDR3 spectratyping suggests that there is greater oligoclonal expansion of  $\alpha\beta$  T cells during the third trimester, particularly after 28 weeks of gestation, than in adults, and that these oligoclonal expansions involve a variety of different V $\beta$  segment families.<sup>269</sup> Whether this oligoclonal expansion is antigen driven, such as by a response

to maternally derived immunoglobulins (e.g., immunoglobulin idiotypes),<sup>269</sup> or is a form of homeostatic proliferation is unknown.

Positive selection of thymocytes appears to be an important influence on the  $\alpha\beta$ -TCR repertoire during human fetal and neonatal development. This influence can be assessed by determining if the frequency of preimmune (antigenically naïve)  $\alpha\beta$  T cells, such as those predominantly found in the healthy neonate, expressing a particular V segment is skewed toward either CD4<sup>+</sup> or CD8<sup>+</sup> T cells. Such skewing suggests that these particular V segments have been positively selected primarily by MHC class II or class I molecules, respectively. Analysis of neonatal T cells found that V $\alpha$ 12.1 segments were expressed at a higher frequency by CD8<sup>+</sup> T cells, whereas V $\beta$ 6.7, V $\beta$ 8, and V $\beta$ 12 segments were expressed at a higher frequency by CD4<sup>+</sup> T cells.<sup>270-272</sup> This skewing also is evident in the frequency with which these V segments are expressed by CD4<sup>hi</sup>CD8<sup>-</sup> thymocytes versus CD4<sup>+</sup>CD8<sup>hi</sup> thymocytes in the infant.<sup>273</sup> Skewing also occurs when human fetal liver is used as a source of stem cells to reconstitute human fetal thymic development in SCID mice.<sup>264</sup>

### **T Cell Receptor Excision Circles**

T cell receptor excision circles (TRECs) are generated during TCR gene rearrangement of thymocytes. TRECs appear to persist for long periods in T-lineage cells that are not proliferating, and the TREC content of peripheral T cells has been used clinically to assess thymic output. Although TRECs are generated at each rearrangement step of the TCR  $\alpha$  and TCR  $\beta$  chain genes, those generated during V $\alpha$  to J $\alpha$  joining, and which contain TCR  $\delta$  gene locus, have been the most frequently employed for human studies. Among human thymocyte subsets, the highest levels of TCR  $\delta$  locus-containing TRECs are in CD4<sup>hi</sup>CD8<sup>hi</sup>CD3<sup>-</sup> double-positive thymocytes (approximately 150 TRECs per 100 cells), suggesting that both TCR  $\alpha$  chain gene alleles commonly undergo rearrangement.<sup>274</sup> TREC levels progressively decline as double-positive cells acquire high levels of the  $\alpha\beta$ -TCR-CD3 complex, in all likelihood reflecting mitosis that results from successful positive selection.<sup>274</sup>

Consistent with this model, the TREC content of adult antigenically naïve T cells is significantly higher than that of memory T cells, which have undergone marked clonal expansion. TREC levels in unfractionated T cells or purified naïve T cell populations have been used to monitor the recovery of thymic output and T cell reconstitution in various clinical situations. These studies, however, have generally assumed that naïve T cells have not undergone mitosis as a result of post-thymic, antigen-independent mechanisms, such as homeostatic proliferation.<sup>275</sup> In fact, such homeostatic proliferation of naïve peripheral T cells may occur in humans in cases of peripheral T cell destruction, such as HIV-1 infection, resulting in decreased TREC content and a potential underestimate of thymic output.<sup>276</sup>

### **Ontogeny of T Cell Surface Phenotype**

Circulating T cells are detectable as early as 12.5 weeks of gestation, demonstrating the emigration of mature T-lineage cells from the thymus.<sup>277</sup> By 14 weeks of gestation, CD4<sup>+</sup> and CD8<sup>+</sup> T cells are found in the fetal liver and spleen, and CD4<sup>+</sup> T cells are detectable in lymph nodes.<sup>278</sup> The percentage of T cells in the fetal or premature circulation gradually increases

during the second and third trimesters of pregnancy through approximately 6 months of age,<sup>279</sup> followed by a gradual decline to adult levels during childhood.<sup>280</sup> The ratio of CD4<sup>+</sup> to CD8<sup>+</sup> T cells in the circulation is relatively high during fetal life (about 3.5) and gradually declines with age.<sup>280</sup> The levels of expression of the  $\alpha\beta$ -TCR, CD3, CD4, CD5, CD8, and CD28 proteins on fetal and neonatal  $\alpha\beta$  T cells are similar to those in adult T cells (D. Lewis, unpublished data, 2000).<sup>98,281,282</sup>

**CD31.** CD31, also known as platelet endothelial cell adhesion molecule-1 (PECAM-1), is expressed in large amounts on most adult peripheral CD4<sup>+</sup> T cells that have a naïve (CD45RA<sup>hi</sup>) surface phenotype but is absent or decreased on most memory CD4<sup>+</sup> T cells. With aging, the fraction of adult CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells that are CD31<sup>lo</sup> gradually increases, and these cells have a very low TREC content relative to with that of the CD31<sup>hi</sup> CD45RA<sup>hi</sup> subset of CD4<sup>+</sup> T cells.<sup>283</sup> These CD31<sup>lo</sup> naïve CD4<sup>+</sup> T cells do not appear to contain CD45RO cells that have reverted to a CD45RA surface phenotype, because they lack the capacity to express cytokines characteristic of memory/effector cells, such as IFN- $\gamma$ , and do not share any cell surface phenotype markers with CD45RO<sup>hi</sup> memory CD4<sup>+</sup> T cells. These findings suggest that CD31<sup>lo</sup> naïve CD4<sup>+</sup> T cells are derived from CD31<sup>hi</sup> naïve CD4<sup>+</sup> T cells by a process of homeostatic proliferation in the periphery, and that CD31<sup>hi</sup> CD45RA<sup>hi</sup> T cells have more recently emigrated from the thymus than have CD31<sup>lo</sup> cells.

Most neonatal CD45RA<sup>hi</sup> T cells are CD31<sup>hi</sup>, but approximately 10% to 20% have been reported to be CD31<sup>lo</sup>.<sup>283,284</sup> Neonatal CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells tend to have a modestly higher TREC content than that of adult CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells, suggesting that TREC content may gradually decline in peripheral naïve CD4<sup>+</sup> T cells with time.<sup>283</sup> It is unclear if the neonatal CD31<sup>lo</sup> subset of naïve CD4<sup>+</sup> T cells has low levels of TREC similar to that found in adult CD31<sup>lo</sup> naïve CD4<sup>+</sup> T cells. Such low levels would suggest that these CD31<sup>lo</sup> naïve CD4<sup>+</sup> T cells in the fetal and neonatal circulation have proliferated or are currently in the process of proliferating, a possibility that is supported by one study<sup>123</sup> (see section on fetal and neonatal thymic output and peripheral T cell homeostasis). Alternatively, a finding of high TREC content in CD31<sup>lo</sup> naïve CD4<sup>+</sup> T cells of the neonate would suggest that this population may be an immature population that gives rise to CD31<sup>hi</sup> naïve CD4<sup>+</sup> T cells.

**CD38.** CD38 is an ectoenzyme that generates cyclic adenosine diphosphate (ADP)-ribose, a metabolite that induces intracellular calcium mobilization. It is expressed on most thymocytes, some activated peripheral blood T cells and B cells, plasma cells, and DCs. Unlike adult naïve T cells, virtually all peripheral fetal and neonatal T cells express the CD38 molecule,<sup>285-288</sup> suggesting that peripheral T cells in the fetus and neonate may represent a thymocyte-like immature transitional population. In contrast with circulating T cells, a significant fraction of T cells in the fetal spleen between 14 and 20 weeks of gestation lack CD38 expression,<sup>289</sup> indicating that CD38 may be downregulated on entry into secondary lymphoid tissue. Neonatal CD4<sup>+</sup> T cells lose expression of CD38 after in vitro culture with IL-7 for 10 days,<sup>290</sup> which implies that this cytokine promotes further maturation independently of engagement of the  $\alpha\beta$ -TCR-CD3 complex. The precursor-product relationship between CD38<sup>+</sup> and CD38<sup>-</sup> peripheral naïve T cells in humans is unclear.

The role of CD38 in the function of human T cells and other cell types also is unknown. In mice, CD38 is required for chemokine-mediated migration of mature DCs into secondary lymphoid tissue, and as a consequence, CD38 deficiency impairs humoral immunity to T cell-dependent antigens. Of interest, mice, in contrast with humans, have relatively low levels of thymocyte expression of CD38, and CD38 deficiency in these animals does not have a clear impact on thymocyte development or intrinsic T cell function.

**CD45 Isoforms.** Circulating T cells in the term and preterm (22 to 30 weeks of gestation) neonate and in the second- and third-trimester fetus predominantly express a CD45RA<sup>hi</sup>-CD45RO<sup>lo</sup> surface phenotype,<sup>288,291,292</sup> which also is found on antigenically naïve T cells of adults. About 30% of circulating T cells of the term neonate are CD45RA<sup>lo</sup>CD45RO<sup>lo</sup>,<sup>293</sup> a surface phenotype that is rare or absent in circulating adult T cells. Because these CD45RA<sup>lo</sup>CD45RO<sup>lo</sup> T cells are functionally similar to neonatal CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> T cells, and become CD45RA<sup>mid</sup>CD45RO<sup>lo</sup> T cells when incubated in vitro with fibroblasts,<sup>293</sup> they appear to be immature thymocyte-like cells rather than naïve cells that have been activated in vivo to express the CD45RO isoform.

Most studies have found that the healthy neonate and the late-gestation fetus lack circulating CD45RO<sup>hi</sup> T cells, consistent with their limited exposure to foreign antigens. A lack of surface expression of other memory/effector markers, such as  $\beta_1$  integrins (e.g., VLA-4), and, in the case of CD8<sup>+</sup> T cells, KIR<sup>294</sup> and CD11b,<sup>295,296</sup> also is consistent with an antigenically naïve population predominating in the healthy neonate.

A postnatal precursor-product relationship between CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> and CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> T cells is suggested by the fact that the proportion of  $\alpha\beta$  T cells with a memory/effector phenotype and the capacity of circulating T cells to produce cytokines, such as IFN- $\gamma$ , both gradually increase, whereas the proportion of antigenically naïve T cells decreases, with increasing postnatal age.<sup>280,297</sup> These increases in the ability to produce cytokines and expression of the CD45RO<sup>hi</sup> phenotype presumably are due to cumulative antigenic exposure and T cell activation, leading to the generation of memory T cells from antigenically naïve T cells.

In premature or term neonates who are stressed, a portion of circulating T-lineage cells are CD3<sup>lo</sup> and co-express CD1, CD4, and CD8,<sup>285</sup> a phenotype characteristic of immature thymocytes of the cortex.<sup>298</sup> It is likely that stress results in the premature release of cortical thymocytes into the circulation, but the immunologic consequences of this release are unclear.

### ***Fetal and Neonatal Thymic Output and Peripheral T Cell Homeostasis***

**Phenotype of Recent Thymic Emigrants.** Recent thymic emigrants (RTEs) have been variously defined as peripheral T cells that have emigrated from the thymus within 2 weeks to several months. Some authorities have even considered circulating naïve T cells in the term neonate to be synonymous with RTEs.<sup>290</sup> This population, however, is likely to contain substantial numbers of thymic emigrants (and their extrathymically generated descendants) that exited the thymus more than 6 months earlier. RTEs would be expected to be

enriched for TRECC compared with other naïve CD4<sup>+</sup> T cells that have been out in the periphery for longer periods of time, because these older cells would have had a greater opportunity to undergo antigen-independent (spontaneous) proliferation.

Based on the criterion of TREC enrichment, the expression of CD103 ( $\alpha_E\beta_7$  integrin) by circulating naïve CD45RA<sup>hi</sup> CD8<sup>+</sup> T cells<sup>299</sup> is a potential marker for CD8<sup>+</sup> T-lineage RTEs. Consistent with the high activity of thymus during the last trimester, between 6% and 20% of circulating neonatal naïve CD8<sup>+</sup> T cells are CD103<sup>+</sup>, whereas substantially lower numbers of these cells are found in the adult circulation.<sup>300</sup> As discussed earlier, CD31 also identifies adult naïve CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells that have higher levels of TREC than the CD31<sup>-</sup> fraction of this cell population. This finding suggests that CD31 loss may occur with some form of antigen-independent proliferation of naïve CD4<sup>+</sup> T cells, and that RTEs of the CD4<sup>+</sup> T lineage are likely to be CD31<sup>hi</sup>. However, because about 90% of neonatal and greater than 80% of adult naïve CD4<sup>+</sup> T cells are CD31<sup>hi</sup>, only a small fraction of these CD31<sup>hi</sup> cells are likely to be RTEs, if “recent” is defined as weeks to months. CCR9 expression also has recently been found to be greater on CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells in the newborn and infant than in older persons, suggesting that this could also enrich for CD4<sup>+</sup> T-lineage cell RTEs.<sup>301</sup> These circulating CCR9<sup>+</sup> cells have not been analyzed for their TREC content, however. The development of additional markers for RTEs, particularly of the CD4<sup>+</sup> T cell lineage, and additional studies of TREC content for naïve T cell populations identified using these markers may allow a more accurate assessment of thymic output at various ages of fetal and postnatal life.

**Spontaneous Naïve Peripheral T Cell Proliferation.** Naïve T cells may undergo proliferation by processes that are distinct from those of full activation by cognate antigen and appropriate co-stimulation, and such proliferative processes may make a significant contribution to expansion of the peripheral T cell pool during development. Based on flow cytometric analysis of expression of the Ki67 antigen, a significantly higher fraction of naïve (CD45RO<sup>lo</sup>) CD4<sup>+</sup> and CD8<sup>+</sup> T cells in the third-trimester fetus and the term neonate are spontaneously in cell cycle than the fraction of adult naïve T cells.<sup>123</sup> The highest levels are observed at 26 weeks of gestation, and these gradually decline with gestational age. Even at term, however, the frequencies reported for naïve CD4<sup>+</sup> and CD8<sup>+</sup> T cells—approximately 1.4% and 3.2%, respectively—are sevenfold those of adult naïve T cells and are substantially higher than those observed for adult CD45RO<sup>hi</sup> T cells.<sup>123</sup> These results are supported by other *in vitro* assays of mitosis, such as the incorporation of radioactive tritiated (<sup>3</sup>H)-thymidine or the loss of fluorescence after labeling cell membranes with carboxyfluorescein succinimidyl ester (CFSE) (D. Lewis, unpublished data, 2003).

Although the mechanism underlying this proliferation of human fetal and neonatal naïve T cells is unclear, it differs from that in rodent models of homeostatic proliferation, including in the neonatal mouse,<sup>302</sup> in that the proliferation occurs in the absence of peripheral lymphopenia. As discussed next, one potential explanation for this increased spontaneous proliferation is an increased sensitivity of fetal and neonatal T cells to cytokines, such as IL-7 and IL-15. It

will be of interest in future studies to determine if spontaneously proliferating naïve T cells in fetus and neonate have a diverse TCR repertoire (as would be predicted by a model of generalized increased sensitivity to cytokines) and whether they can be distinguished from noncycling cells by other markers, such as those that are induced during naïve T cell proliferation in the setting of peripheral lymphopenia, and by reduced TREC content.

**Antigen-Independent Naïve T Cell Proliferation in Response to IL-7 and IL-15.** Murine studies show that the homeostatic proliferation in the lymphopenic host and survival of naïve CD4<sup>+</sup> and CD8<sup>+</sup> T cells depends on IL-7.<sup>148,258,303,304</sup> Since human neonatal naïve CD4<sup>+</sup> T cells are capable of higher levels of polyclonal cell proliferation than adult naïve CD4<sup>+</sup> T cells in response to IL-7,<sup>123,305-307</sup> it is plausible that IL-7-dependent proliferation could account for the high rate of spontaneous CD4<sup>+</sup> T cell proliferation in the human fetus and neonate, and contribute to the normal and rapid expansion of the peripheral CD4<sup>+</sup> T cell compartment at this age. The increased IL-7 proliferative response is associated with increased expression of the IL-7 receptor  $\alpha$  chain component by neonatal naïve CD4<sup>+</sup> T cells compared with adult naïve CD4<sup>+</sup> T cells,<sup>305-307</sup> although surface expression of the other component of the IL-7 receptor, the  $\gamma_c$  cytokine receptor was actually decreased on neonatal naïve CD4<sup>+</sup> T cells compared with that on adult naïve cells in one study.<sup>307</sup>

Murine studies indicate that positive selection results in a dramatic upregulation of both the IL-7 receptor  $\alpha$  chain and the  $\gamma_c$  cytokine receptor on CD4<sup>-</sup> and CD8<sup>-</sup> single-positive thymocytes.<sup>308</sup> *In vitro* thymic organ culture experiments suggest that IL-7 plays a key role in the postselection expansion of the single-positive thymocyte population by a mechanism that does not involve  $\alpha\beta$ -TCR engagement.<sup>308</sup> Therefore, it is plausible that this increased ability to proliferate in response to IL-7 might particularly be a feature of RTEs, and that the naïve neonatal CD4<sup>+</sup> T cell compartment is enriched in cells with these properties.<sup>306</sup> Another possibility, not mutually exclusive, is that neonatal naïve CD4<sup>+</sup> T cells may retain thymocyte features, such as a proapoptotic tendency and high levels of IL-7 receptor expression, for substantially longer periods of time following thymic emigration than is the case with adult naïve CD4<sup>+</sup> T cells. In support of this “maturation” arrest model is the observation that virtually all neonatal T cells and thymocytes express high levels of CD38, whereas this marker is virtually absent from adult naïve T cells.

Whether IL-7 not only contributes to extrathymic expansion of naïve CD4<sup>+</sup> T cells but also influences their maturation remains unclear. IL-7 treatment of neonatal naïve CD4<sup>+</sup> T cells for relatively long periods (7 or 14 days) does not decrease expression of CD45RA or L-selectin and does not increase the expression of CD45RO.<sup>290,305,309,310</sup> The extent to which IL-7 treatment, alone, of neonatal naïve CD4<sup>+</sup> T cells results in acquisition of a phenotype with selective features of both naïve and memory/effector cells remains contentious: Results are conflicting regarding whether IL-7 treatment increases surface expression of CD11a, a memory/effector cell marker; the activation-dependent proteins CD25 and CD40 ligand; or the capacity of neonatal CD4<sup>+</sup> T cells to produce T<sub>H</sub>1 and T<sub>H</sub>2 cytokines.<sup>290,305</sup>

In contrast with IL-7, IL-15 is not required for naïve T cell survival and has its most important effects on the CD8<sup>+</sup>

rather than the CD4<sup>+</sup> subset of effector/memory T cells.<sup>311</sup> These findings do not, however, eliminate a possible role for IL-15 in naïve T cell expansion in certain contexts, such as in the fetus and neonate. Consistent with this possible role, neonatal naïve CD8<sup>+</sup> T cells are more responsive to treatment with a combination of IL-7 and IL-15 than is the analogous adult cell population, as indicated by loss of CFSE staining with culture after *in vitro* labeling.<sup>123</sup> Whether this enhanced effect is related to increased levels of IL-15 receptors on neonatal T cells is unknown. Also unclear are the effects of treatment with this combination of cytokines on neonatal naïve CD8<sup>+</sup> T cell phenotype and function.

### **Fetal Extrathymic T Cell Differentiation**

The human fetal liver contains rearranged VDJ transcripts of the TCR  $\beta$  chain as early as 7.5 weeks of gestation, and pre-T $\alpha$  transcripts can be found as early as 6 weeks of gestation.<sup>312,313</sup> This raises the possibility that extrathymic differentiation of  $\alpha\beta$ -TCR-bearing T cells could occur in the fetal liver before such differentiation in the thymus. In the adult liver, CD4<sup>hi</sup>CD8<sup>-</sup> and CD4<sup>-</sup>CD8<sup>-</sup> T cells with characteristics distinct from those of NK T cells (which also may have, in part, an extrathymic origin) have been described in conjunction with detection of transcripts for pre-T $\alpha$  and the RAG genes. Thus, it is possible that some liver T cells may be generated *in situ* even in adults.

Extrathymic differentiation of  $\alpha\beta$  T cells may occur in the fetal intestine, because the lamina propria of the fetal intestine contains CD3<sup>+</sup>CD7<sup>+</sup> lymphocytes expressing pre-T $\alpha$  transcripts as early as 12 to 14 weeks of gestation, and these cells have the capacity to differentiate into  $\alpha\beta$  T cells.<sup>314</sup> Although it is unclear if these CD3<sup>+</sup>CD7<sup>+</sup> precursor cells have a thymic or other origin, the V $\beta$  repertoire of  $\alpha\beta$  T-lineage cells in the fetal intestine differs substantially from that of contemporaneous fetal  $\alpha\beta$  T-lineage cells found in the circulation, suggesting their independent origin.<sup>314</sup> Extrathymic intestinal T cell development has been clearly shown to occur in mice in specialized structures of the small intestine (cryptopatches), but no analogous structures containing immature lymphocytes have been observed in humans.<sup>315</sup> In humans, the lamina propria and epithelium of the jejunum are potential sites of extrathymic T cell development in adults, in that immature lymphocytes with markers indicative of T-lineage commitment (CD2<sup>+</sup>CD7<sup>+</sup>CD3<sup>-</sup>) are found at these sites. These cells co-localize with transcripts for pre-T $\alpha$  and the RAG-1 gene,<sup>316</sup> consistent with this tissue being a site of T cell differentiation.

### **Fetal and Neonatal T Cell Function**

**In Vitro Assays of T Cell Activation.** Before presenting results of studies in which fetal and neonatal versus adult T cell activation and function have been compared, we shall consider some limitations of prior *in vitro* studies of human T cells. As discussed in detail earlier, naïve T cell activation follows engagement of the  $\alpha\beta$ -TCR-CD3 complex by cognate peptide antigen presented on MHC molecules on the APC, most typically a DC. Full activation usually requires additional co-stimulatory interactions, such as engagement of CD28 on the T cell by CD80 or by CD86 on the APC (see Figs. 4-1 and 4-5), although many others may also play a role, depending on the *in vivo* context. In many earlier studies of human T cells, the cells were polyclonally activated with mitogenic

lectins, such as phytohemagglutinin (PHA), concanavalin A (Con A), or pokeweed mitogen (PWM). These mitogens appear to cross-link surface molecules involved in T cell activation, such as CD3 or CD28, and probably many others, as well as surface molecules on APCs. Their precise mode of molecular action is not known, however. In the last 2 decades, monoclonal antibodies (mAbs) with defined specificity for surface proteins also have been used as polyclonal T cell activators. mAbs reactive with the CD3- $\epsilon$  protein are used, alone or in conjunction with anti-CD28 mAb. Anti-CD28 mAb is used to mimic the co-stimulatory effect of engagement of CD28 by CD80 or CD86. Neither mitogenic lectins nor mAbs, however, fully mimic the intracellular signal transduction events that occur after physiologic activation of T cells by APCs presenting antigen peptides. For example, the effects on T cell intracellular signaling following engagement of CD28 by mAb differs substantially from that observed following engagement by CD80 and CD86, the physiologic ligands.<sup>317</sup> Depending on the experimental conditions, the epitope recognized, and the form of the mAb (e.g., bivalent versus monovalent, with or without Fc domains), mAbs to a surface molecule may act as either agonists or antagonists of that molecule's function.

Furthermore, most studies comparing neonatal versus adult T cell activation have used unfractionated T cells or unpurified circulating mononuclear cells. Memory T cells, however, generally have more robust signaling and activation-induced gene expression than are seen in naïve T cells, including responses induced by anti-CD3 mAb or by antigenic peptide-MHC complexes.<sup>318-322</sup> Naïve T cells also seem to be particularly dependent on co-stimulation through engagement of CD28, whereas memory T cells are less so and may use a variety of other co-stimulatory pathways.<sup>323</sup> Therefore, studies in which neonatal T cells were compared with naïve T cells from adults are more likely to indicate bona fide ontogenetically related differences in activation or effector function than are studies with unpurified cells.

**Fetal T Cell Function.** A minority but substantial proportion of T cells in the second trimester fetal spleen are CD45RA<sup>lo</sup>-CD45RO<sup>hi</sup>, a T cell population that is absent from the spleen of young infants.<sup>292</sup> These fetal CD45RO<sup>hi</sup> T cells express high levels of CD25 (IL-2 receptor  $\alpha$  chain) and proliferate with IL-2, suggesting that they have recently been activated and undergone expansion.<sup>292</sup> In contrast with adult CD45RO<sup>hi</sup> T cells, however, these fetal spleen CD45RO<sup>hi</sup> T cells express low surface levels of CD2 and LFA-1 and proliferate poorly after activation with either anti-CD2 or anti-CD3 mAb, suggesting that they are not fully functional.<sup>292</sup> Their  $\alpha\beta$ -TCR repertoire is diverse, suggesting that these T cells are expanding in a non-antigen-specific manner. Such antigen-independent expansion can occur in cases where the number of niches for T cells in the peripheral lymphoid tissue is large relative to the number of T cells (e.g., following adoptive transfer of T cells into lymphopenic recipients).<sup>146</sup> It also is plausible that this may be the case in the rapidly growing fetus, particularly early in gestation. Whether these fetal spleen CD45RO<sup>hi</sup> T cells contribute to the postnatal T cell compartment, however, is unknown.

Mucosal T cells are present in the fetal intestine by 15 to 16 weeks of gestation, and these cells have the capacity to secrete substantial amounts of IFN- $\gamma$  after treatment with

anti-CD3 mAb in combination with exogenous IFN- $\alpha$ .<sup>324</sup> IFN- $\alpha$  directs differentiation of naïve CD4<sup>+</sup> T cells, including those of the neonate, toward a T<sub>H</sub>1 effector cytokine profile dominated by production of IFN- $\gamma$  and not IL-4, IL-5, or IL-13.<sup>56</sup> A similar mechanism may occur in these fetal explant cultures. Although it is not clear what T cell type is the major source of IFN- $\gamma$  in this tissue, these observations suggest the possibility that a similar T<sub>H</sub>1 skewing of T cell responses might occur in cases of fetal viral infection involving the intestine in which type I IFN (IFN- $\alpha/\beta$ ) is induced.

**Neonatal T Cell Proliferation and IL-2 Production and Responsiveness after Activation in Vitro.** Most studies have found that in response to stimulation in vitro with mitogenic lectins, bacterial superantigens, or allogeneic cells proliferation, as assessed by incorporation of <sup>3</sup>H-thymidine, and IL-2 production by circulating neonatal T cells and by adult T cells is similar.<sup>265,325-331</sup> This argues that the limitations in proximal signal transduction for neonatal T cells may not be of functional consequence, at least for cytokine production and initial DNA synthesis in response to strong stimuli.

In general, neonatal T cells, nearly all of which are naïve, and antigenically naïve (CD45RA<sup>hi</sup>) adult T cells do not proliferate as well or produce as much IL-2 as unfractionated adult T cells after activation by anti-CD2 or anti-CD3 mAb.<sup>221,332-335</sup> These differences might be attributable, at least in part, to the presence of large numbers of memory T cells in the adult but not the neonatal T cell populations, which, as discussed earlier, are more responsive to anti-CD2 or anti-CD3 mAb stimulation.

Studies in which antigenically naïve CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells from neonates and adults were directly compared also have found decreased responses by neonatal cells, however. For example, compared with adult naïve CD4<sup>+</sup> T cells, neonatal naïve CD4<sup>+</sup> T cells produced less IL-2 mRNA and expressed fewer high-affinity IL-2 receptors in response to stimulation with anti-CD2 mAb.<sup>336-338</sup> These differences were abrogated when phorbol ester, which bypasses proximal signaling pathways, was included,<sup>336</sup> suggesting that the capacity to express IL-2 and high-affinity receptors is not absolutely limited for neonatal cells, but signals leading to their induction may not be transmitted efficiently. Similarly, the production of IL-2 by neonatal naïve CD4<sup>+</sup> T cells is reduced compared with that by adult CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells after allogeneic stimulation with adult monocyte-derived DCs (D. Lewis, unpublished data, 2004), again arguing that neonatal cells may be intrinsically limited in their ability to be physiologically activated for IL-2 production.

The ability of activated T cells to efficiently divide in response to IL-2 depends on the expression of high-affinity IL-2 receptors, which consists of CD25 (IL-2 receptor  $\alpha$  chain),  $\beta$  chain (shared with the IL-15 receptor), and the  $\gamma$ c cytokine receptor (shared with multiple other cytokine receptors). In contrast with IL-2 production, neonatal T cells appear to express similar or higher amounts of CD25 after stimulation with anti-CD3 mAb.<sup>326</sup> This finding is consistent with the signal transduction pathways leading to the induction of CD25 being distinct from those involved in IL-2 production, and with neonatal T cells have a relatively selective limitation in signals required for cytokine production, rather than a generalized limitation acting at an early step of the

activation cascade. Basal expression of the  $\gamma$ c cytokine receptor by neonatal T cells is lower than that by either adult CD45RA<sup>hi</sup> or CD45RO<sup>hi</sup> T cells.<sup>339</sup> The importance of this finding is unclear, because activated neonatal T cells proliferate in response to exogenous IL-2 as well as or better than adult T cells, as indicated by <sup>3</sup>H-thymidine incorporation.<sup>326</sup> Radioactive thymidine incorporation assays, however, do not provide mitotic information at the single cell level and examine only DNA synthesis and not actual cell proliferation. The application of recently developed techniques, such as cell membrane staining with CFSE,<sup>340</sup> which allows an assessment of the mitotic history of individual cells, should be helpful in better defining the replicative potential of neonatal T cells.

Two in vitro studies suggest that neonatal T cells may be less able to differentiate into effector cells in response to neoantigen (see section on neonatal T cell co-stimulation and anergy). One study, using limiting dilution techniques and circulating mononuclear cells from CMV-nonimmune donors, found that the frequency of neonatal T cells proliferating in response to whole inactivated CMV antigen was significantly less than that of adult T cells.<sup>97</sup> A pitfall of this study is that it used a complex antigen preparation, and one to which the T cells of adults might have previously been primed by infections other than CMV. Another study<sup>341</sup> found that neonatal mononuclear cells had decreased antigen-specific T cell proliferation and IL-2 production in response to a protein neoantigen, keyhole limpet hemocyanin, compared with those in adult cells. Although these results require confirmation, they are consistent with the more limited ability of neonatal naïve CD4<sup>+</sup> T cells to produce IL-2 in response to allogeneic DCs than that of adult naïve cells (D. Lewis, unpublished data, 2004).

**Neonatal T Cell Cytokine and Chemokine Production.** In contrast with IL-2, the production of most other cytokines or their cognate mRNAs by unfractionated neonatal T cells or the CD4<sup>+</sup> T cell subset appears to be reduced in response to multiple stimuli, including anti-CD3 mAb mitogen, or pharmacologic agents (e.g., the combination of calcium ionophore and phorbol ester) compared with that in adult T cells. For most cytokines (IL-3, IL-4, IL-5, IL-6, IL-10, IL-13, IFN- $\gamma$ , and GM-CSF), this is a marked reduction<sup>326,342-347</sup>; for a few, such as TNF- $\alpha$ ,<sup>348</sup> the reduction is modest. As with neonatal T cells, naïve T cells from adults have a reduced capacity to produce most of these cytokines compared with that of adult memory/effector T cells,<sup>347,349,350</sup> although adult naïve T cells may produce substantial amounts of IL-13.<sup>351</sup> The low capacity of neonatal T cells to produce IFN- $\gamma$  and IL-4 is due to an almost complete absence of IFN- $\gamma$  and IL-4 mRNA-expressing cells,<sup>343</sup> which is paralleled by a lack of cells expressing detectable levels of these cytokines following polyclonal activation and analysis by flow cytometry after intracellular staining.<sup>352-355</sup>

These results suggest that part of the deficiency in cytokine production by neonatal T cells is due to the fact that almost all neonatal T cells are naïve. But are naïve neonatal T cells equivalent to adult naïve T cells in cytokine production? We have found that highly purified naïve CD4<sup>+</sup> T cells from neonates have a reduced capacity to produce IFN- $\gamma$  in vitro compared with that of adult naïve CD4<sup>+</sup> T cells following stimulation with the same pool of monocyte-

derived DCs from multiple unrelated blood donors.<sup>356</sup> This finding strongly suggests that the capacity of neonatal naïve CD4<sup>+</sup> T cells to produce IFN- $\gamma$  is intrinsically more limited, even when a potent, physiologic APC population is used for antigen presentation.

Cytokine production by neonatal CD8<sup>+</sup> T cells has not been as well characterized as for the CD4<sup>+</sup> T cell subset. The lack of a memory (CD45RO<sup>hi</sup>) CD8<sup>+</sup> T cell subset in the neonate appears to account for reduced production of the chemokine RANTES (CCL5) by neonatal T cells compared with that by adult cells.<sup>357</sup> A striking result, which needs to be confirmed, is that neonatal naïve CD8<sup>+</sup> T cells produce substantially more IL-13, which is characteristic of T<sub>H</sub>2 immune responses, than that produced by analogous adult cells after stimulation with anti-CD3 and anti-CD28 mAbs and exogenous IL-2.<sup>358</sup> It will be of interest to determine if this unusual cytokine profile also applies to antigen-specific immune responses mediated by neonatal CD8<sup>+</sup> T cells, such as to viral pathogens.

Neonatal T cells have been intensively studied for their cytokine secretion phenotype, but relatively little is known regarding the postnatal ontogeny of T cell cytokine production during the first year of life. A study using PHA as a stimulus found that the capacity of peripheral blood lymphocytes obtained from newborns was similar to umbilical vein cord blood in having a low capacity to produce IFN- $\gamma$ , IL-4, and IL-10.<sup>359</sup> The capacity of peripheral blood lymphocytes to produce all three of these cytokines gradually increased during the first year of life,<sup>359</sup> consistent with the acquisition of increased cytokine production as a result of the progressive acquisition of memory T cells resulting from exposure to foreign antigens.

**Mechanisms for Decreased Cytokine Production in Neonatal T Cell.** Secretion of most cytokines by T cells requires de novo transcription and translation of the cytokine gene. Cytokine induction by T cells is a complex process involving multiple signal transduction pathways that become active following engagement of the  $\alpha\beta$ -TCR-CD3 complex and co-stimulatory molecules,<sup>204,360</sup> which culminates in the intranuclear accumulation of transcription factors required for cytokine gene expression, including members of the NFAT, nuclear factor- $\kappa$ B (NF- $\kappa$ B)/Rel, and AP-1 (fos/jun) families.<sup>361</sup> For many cytokine genes, a key event leading to de novo gene transcription is an activation-induced increase in the concentration of free intracellular calcium ( $[Ca^{2+}]_i$ ), which is required for NFAT nuclear location and transcriptional activity.<sup>361</sup>

Certain studies comparing adult and neonatal T cells or CD4<sup>+</sup> T cells have suggested that neonatal T cells have substantial limitations in proximal signal transduction events that are required for the expression of cytokine genes and other activation-dependent molecules, such as CD40 ligand and Fas ligand. These limitations include a generalized decrease in the overall level of activation-induced tyrosine phosphorylation of intracellular proteins compared with that in unfractionated adult T cells,<sup>335</sup> decreased activation-induced phosphorylation of CD3- $\epsilon$ , decreased phosphorylation and enzyme activity of the Lck and ZAP-70 tyrosine kinases and the ERK2, JNK, and p38 kinases,<sup>362</sup> and reduced basal and activation-induced levels of phospholipase C isozymes.<sup>363</sup> It remains unclear if these reported deficiencies

in proximal signal transduction events apply specifically to neonatal naïve T cells but not to adult naïve T cells, because these studies did not fractionate adult T cells into naïve and memory subsets. One study has found that highly purified neonatal naïve CD4<sup>+</sup> T cells have a substantially reduced increase in  $[Ca^{2+}]_i$  following anti-CD3 mAb cross-linkage, compared with that observed in identically treated adult naïve cells.<sup>364</sup> Although the mechanism for this reduced calcium response remains to be defined, it is plausible that this reduction may account, in part, for reduced neonatal T cell expression of genes positively regulated by NFAT, such as secreted cytokines and, as discussed later on, CD40 ligand.

Reduced IL-4 and IFN- $\gamma$  mRNA expression by polyclonally activated neonatal CD4<sup>+</sup> and CD8<sup>+</sup> T cells compared with that observed in adult T cells is due primarily to reduced transcription of these cytokine genes. These differences in cytokine mRNA expression do not appear to solely reflect differences in proximal signal transduction, because they have been observed not only following activation through the  $\alpha\beta$ -TCR-CD3 complex<sup>342</sup> but also after activation with ionomycin and phorbol myristate acetate (PMA),<sup>343</sup> which bypass proximal signal transduction events. IFN- $\gamma$  and IL-4 are expressed mainly by memory/effector T cell populations, rather than by the naïve T cell populations<sup>349</sup>; thus, the reduced expression of these cytokines by neonatal T cells can be accounted for by the lack of memory/effector cells in the circulating neonatal T cell population. For many genes, including the IFN- $\gamma$  gene, DNA methylation of the locus represses transcription by decreasing the ability of transcriptional activator proteins to bind to regulatory elements, such as promoters and enhancers.<sup>365,366</sup> Thus, reduced expression of IFN- $\gamma$  by neonatal T cells may also result in part from greater methylation of DNA in the IFN- $\gamma$  gene locus in neonatal and adult naïve T cells than in adult memory T cells.<sup>367,368</sup>

In addition to decreased cytokine gene transcription, decreased cytokine mRNA stability also may play a role for reduced cytokine production by neonatal T cells. For example, decreased IL-3 production by neonatal T cells appears to be due mainly to reduced IL-3 mRNA stability, rather than to decreased gene transcription.<sup>345</sup> The mechanism for this reduced mRNA stability remains unclear. Decreased mRNA stability also has been observed for other cytokines after stimulation of cord blood mononuclear cells,<sup>369</sup> but whether this also holds for purified neonatal T cells has not been addressed.

#### **Cytokine Production by Neonatal T Cells after Short-Term In Vitro Differentiation.**

The generation of effector T cells from naïve precursors in response to antigen in vivo can be mimicked by in vitro stimulation, such as by engagement of the  $\alpha\beta$ -TCR-CD3 complex in conjunction with accessory cells (non-T cells contained in PBMCs) and exogenous cytokines.<sup>370</sup> Neonatal T cells, if polyclonally activated under conditions that favor repeated cell division (strong activation stimuli in common with the provision of exogenous IL-2), resemble antigenically naïve adult T cells in efficiently acquiring the characteristics of effector cells. These characteristics include a CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> surface phenotype, an enhanced ability to be activated by anti-CD2 or anti-CD3 mAb, and an increased capacity to produce cytokines (e.g., IL-4, IFN- $\gamma$ ).<sup>221,329,342,371</sup>

The signals that are involved in determining whether T cells become producers of IFN- $\gamma$  or IL-4 is discussed later in more detail in the section on differentiation and homeostasis of activated T cells.

Although neonatal CD4<sup>+</sup> T cells can be effectively primed for expression of effector cytokines by strong mitogenic stimuli, their capacity to differentiate into T<sub>H</sub>1 effector cells under more physiologic conditions may be more limited: Neonatal naïve CD4<sup>+</sup> T cells stimulated with allogeneic DCs were found to have decreased frequency of IFN- $\gamma$ <sup>+</sup> cells, based on intracellular cytokine staining, compared with that observed in adult naïve CD4<sup>+</sup> T cells in response to short-term (i.e., 24 to 48 hours' duration) stimulation by allogeneic DCs.<sup>356</sup>

This decreased expression of IFN- $\gamma$  by neonatal CD4<sup>+</sup> T cells activated under these more physiologic conditions of DC-mediated allogeneic stimulation probably is due to several factors. First, neonatal CD4<sup>+</sup> T cells are less effective than adult naïve cells at inducing the co-cultured DCs to produce IL-12, a key cytokine for promoting IFN- $\gamma$  production.<sup>356</sup> Second, neonatal naïve CD4<sup>+</sup> T cells have decreased expression of CD40 ligand (discussed in more detail later on), which is important in the acquisition of antigen-specific CD4<sup>+</sup> T cells with T<sub>H</sub>1 immune function.<sup>216</sup> Third, neonatal CD4<sup>+</sup> T cells have decreased expression of certain transcription factors, such as the NFATc2 protein, that may play a role in the induction of IFN- $\gamma$  gene transcription as well as IL-2 and CD40 ligand expression.<sup>347,372,373</sup> Fourth, the greater methylation of DNA of the IFN- $\gamma$  genetic locus in neonatal T cells than in adult naïve T cells may also contribute to a reduced and delayed acquisition of IFN- $\gamma$  production following activation *in vitro*.<sup>368</sup> Together, these mechanisms intrinsic to the T cell, as well as immaturity of DC function (see section on antigen presentation in the fetus and neonate), may account for the delayed acquisition of IFN- $\gamma$  production by antigen-specific CD4<sup>+</sup> T cells after infection in the neonatal period (see section on antigen-specific T cell function in the fetus and neonate).

### **Fetal and Neonatal T Cell Expression of Tumor Necrosis Factor Ligand Family Members**

**CD40 Ligand.** CD40 ligand (CD154), a member of the TNF ligand family, is expressed at high levels on the cell surface by activated but not by resting CD4<sup>+</sup> T cells. CD40 ligand engages CD40, a molecule expressed by APCs—including DCs, mononuclear phagocytes, and B cells—and, perhaps, by CD8<sup>+</sup> T cells. The CD40 ligand–CD40 interaction is essential for many events in adaptive immunity, including the generation of memory CD4<sup>+</sup> T cells of the T<sub>H</sub>1 type (capable of producing IFN- $\gamma$  but not IL-4), memory B cells, and immunoglobulin isotype switching.<sup>374</sup>

Durandy and colleagues<sup>375</sup> reported that a substantial proportion of circulating fetal T cells between 19 and 31 weeks of gestation expressed CD40 ligand *in vitro* in response to polyclonal activation. Whether fetal T cells that can express CD40 ligand have a distinct surface phenotype, such as evidence of prior *in vivo* activation<sup>292</sup> or spontaneous cell proliferation<sup>123</sup> from those lacking this capacity is unclear. By contrast, T cells from later-gestational-age fetuses and from neonates have a much more limited capacity to produce CD40 ligand after activation with calcium ionophore and phorbol ester.<sup>375-378</sup>

Expression of CD40 ligand by activated neonatal CD4<sup>+</sup> T cells remains reduced for at least 10 days postnatally, but is almost equal to adult cells by 3 to 4 weeks after birth.<sup>375</sup> (D. Lewis, unpublished data, 2000). In most of these studies, activated neonatal CD4<sup>+</sup> T cells of cord blood expressed markedly lower amounts of CD40 ligand surface protein and mRNA than either adult CD45RA<sup>hi</sup> or CD45RO<sup>hi</sup> CD4<sup>+</sup> T cells.<sup>377-379</sup> Thus, decreased CD40 ligand expression may not be due to the lack of a memory/effector population in the neonatal T cell compartment, but may represent a true developmental limitation in cytokine production.

Decreased CD40 ligand production by neonatal T cells also has been documented in the mouse,<sup>380</sup> suggesting that it may be a feature of RTEs. Consistent with this idea, human CD4<sup>hi</sup>CD8<sup>-</sup> thymocytes, the immediate precursors of antigenically naïve CD4<sup>+</sup> T cells, also have a low capacity to express CD40 ligand.<sup>378,381</sup> As with most T cell–derived cytokines characteristic of effector cells, when neonatal T cells are strongly activated *in vitro* into an effector-like T cell population, they acquire a markedly increased capacity to produce CD40 ligand on restimulation, demonstrating that this reduction is not a fixed phenotypic feature.<sup>375,378</sup>

In view of the importance of CD40 ligand in multiple aspects of the immune response,<sup>374</sup> limitations in CD40 ligand production could contribute to decreased antigen-specific immunity mediated by T<sub>H</sub>1 effector cells and B cells in the neonate. A potential limitation of the initial studies showing a relative deficiency of CD40 ligand expression by neonatal T cells is that they used calcium ionophore and phorbol ester for stimulation, a combination that maximizes the production of CD40 ligand but may not accurately mimic physiologic T cell activation. Reduced CD40 ligand surface expression by purified neonatal naïve CD4<sup>+</sup> T cells compared with that observed in adult naïve CD4<sup>+</sup> T cells also has been observed after stimulation with a variety of stimuli that engage the  $\alpha\beta$ -TCR–CD3 complex, bacterial superantigen (which engages the V $\beta$  segment of the TCR  $\beta$  chain), anti-V $\beta$  mAbs, and anti-CD3 mAbs, either alone or in combination with anti-CD28 mAb,<sup>364</sup> suggesting that this reduction is likely to be applicable to physiologic T cell activation. Similar results have been independently obtained for anti-CD3 and anti-CD28 mAb stimulation using unfractionated neonatal and adult T cells.<sup>362</sup> Other studies, however, have found equivalent levels of CD40 ligand expression by neonatal and adult T cells using anti-CD3 mAb stimulation,<sup>382,383</sup> suggesting that the particular *in vitro* conditions used (e.g., the particular anti-CD3 mAb and cell culture conditions) may influence the outcome of the assay.

The ability of neonatal and adult T cells to produce CD40 ligand in response to allogeneic stimulation, a condition that should closely mimic T cell activation through the recognition of foreign peptide–MHC complexes, has also been studied. Neonatal CD4<sup>+</sup> T cells stimulated allogeneically can express some CD40 ligand and induce IL-12 production by DCs after 3 days of culture, but the ability of adult T cells to do so was not evaluated.<sup>384</sup> Another study found that CD40 ligand expression by neonatal T cells was similar to that by adult T cells after 5 days of allogeneic stimulation with irradiated adult monocyte-derived DCs.<sup>385</sup> By contrast, other studies<sup>356</sup> found that CD40 ligand expression by purified neonatal naïve CD4<sup>+</sup> T cells was substantially less than in adult naïve CD4<sup>+</sup> T cells after 24 to 48 hours of stimulation. This reduced

CD40 ligand production was accompanied by reduced IL-12 production (by monocyte-derived DCs) and IL-2 and IFN- $\gamma$  production (by naïve CD4<sup>+</sup> T cells). Together, these findings suggest that CD40 ligand surface expression initially may be more limited for neonatal naïve CD4<sup>+</sup> T cells, but that with continued priming, at least in vitro, this can be overcome.

Thus, the differentiation of neonatal naïve CD4<sup>+</sup> T cells into T<sub>H</sub>1 effector cells by CD40 ligand- and IL-12-dependent processes may be limited during the early stages of T cell differentiation.

**Other Tumor Necrosis Factor Family Ligands.** Fas ligand, another member of the TNF ligand family, plays a key role in inducing apoptotic cell death on target cells that express Fas on the surface. Fas ligand may trigger the apoptosis of any cell type that expresses Fas and in so doing eliminate intracellular pathogens, such as viruses. A more prominent role of the Fas ligand-Fas interaction, at least in humans, is to eliminate previously activated lymphocytes and prevent autoimmune disease.<sup>386</sup> Thus, human Fas deficiency is associated with antibody-mediated autoimmunity rather than defects in viral clearance.

Neonatal T cells have decreased Fas ligand expression after anti-CD3 and anti-CD28 mAb stimulation compared with that in adult cells.<sup>362</sup> Whether neonatal T cells have a decreased level of Fas expression as well remains to be determined. Iwama and colleagues<sup>387</sup> reported that circulating levels of Fas ligand are elevated in newborns, but the cellular source of this protein and its functional significance are unclear. The role of Fas-Fas ligand interactions in regulating apoptosis of neonatal T cells is discussed in the section on neonatal T cell apoptosis.

### Neonatal T Cell Co-stimulation and Anergy

Neonatal T cells produce IL-2 and proliferate as well as do adult T cells in response to the combination of anti-CD3 mAb and mouse APCs expressing human CD80 or CD86, indicating that CD28-mediated signaling is intact.<sup>281</sup> This finding also is supported by a study showing that anti-CD28 mAb treatment of neonatal T cells markedly augments their ability to produce IL-2 and proliferate in response to anti-CD2 mAb.<sup>337,338</sup>

Superantigens activate T cells by binding to a portion of the TCR  $\beta$  chain outside of the peptide antigen recognition site but otherwise mimic activation by peptide-MHC complexes in most respects. Neonatal T cells differ from adult CD45RA<sup>hi</sup> T cells in their tendency to become anergic rather than competent for increased cytokine secretion following priming with bacterial superantigen bound to MHC class II-transfected murine fibroblasts.<sup>330</sup> This anergic tendency is developmentally regulated, because CD4<sup>hi</sup>CD8<sup>-</sup> thymocytes, the immediate precursors of antigenically naïve CD4<sup>+</sup> T cells, also are prone to anergy when treated under these conditions.<sup>388</sup> Consistent with this anergic tendency, newborns with toxic shock syndrome-like exanthematous disease, in which the V $\beta$ 2-bearing T cell population is markedly expanded in vivo by the superantigen TSST-1, have a greater fraction of anergic V $\beta$ 2-bearing T cells than is found in adults with TSST-1-mediated toxic shock syndrome.<sup>389</sup>

Some studies also have found that neonatal but not adult CD4<sup>+</sup> T cells primed by alloantigen, in the form of Epstein-

Barr virus (EBV)-transformed human B cells, become non-responsive to restimulation by alloantigen or by a combination of anti-CD3 and anti-CD28 mAbs.<sup>390,391</sup> Preliminary studies implicate a lack of Ras signaling as the basis for this reduced responsiveness.<sup>391</sup> Together, these results, taken with those using bacterial superantigen, suggest that neonatal and, presumably, fetal T cells have a greater tendency to become anergic, particularly under conditions in which production of inflammatory mediators or co-stimulation (e.g., by CD40, CD80, or CD86 on the APC) may be limited.

ICOS is a CD28 homologue that interacts with B7RP-1, a B7 family molecule expressed on both APCs and non-hematopoietic cells.<sup>250</sup> ICOS is not expressed by naïve T cells but is detectable at the later stages of naïve T cell activation, and is constitutively expressed by established effector and memory T cells.<sup>250</sup> Although murine studies initially indicated that the ICOS-B7RP-1 interaction is important for the activation of T<sub>H</sub>2 rather than T<sub>H</sub>1 effector cells, more recent investigations also have implicated ICOS co-stimulation in T<sub>H</sub>1-predominant immunopathology.<sup>392,393</sup> The expression of ICOS and B7RP-1 by neonatal cells has not been reported.

### Fetal and Neonatal Effector CD4<sup>+</sup> T Cell Generation In Vitro

Activated neonatal CD4<sup>+</sup> T cells can be differentiated in vitro into either T<sub>H</sub>1- or T<sub>H</sub>2-like effector cells by incubation for several days to weeks with IL-12 and anti-IL-4 antibody or with IL-4 and anti-IL-12 antibody, respectively.<sup>56,284,394,395</sup> In most cases, IL-2 is added after the initial activation phase to promote survival and expansion of the effector cells. Treatment of neonatal T cells with IL-4 and anti-IL-12 upregulates GATA-3,<sup>396</sup> which acts as a master transcription factor promoting T<sub>H</sub>2 effector generation. Treatment of neonatal CD4<sup>+</sup> T cells with the combination of IL-12 and anti-IL-4 mAb probably also is effective at inducing T-bet, a master transcriptional regulator promoting T<sub>H</sub>1 effector generation. These studies also indicate that neonatal T cells express functional receptors for IL-4 and IL-12, including the activation-induced IL-12 receptor  $\beta_2$  subunit.<sup>56</sup> Mature single-positive (CD4<sup>hi</sup>CD8<sup>-</sup> or CD4<sup>hi</sup>CD8<sup>hi</sup>) fetal thymocytes obtained as early as 16 weeks of gestation can be also differentiated into either T<sub>H</sub>1 or T<sub>H</sub>2 effector cells by such cytokine treatment,<sup>397</sup> indicating that the capacity to acquire a polarized cytokine profile is established relatively early in fetal life.

Purified naïve (CD45RA<sup>hi</sup>) neonatal T cells proliferate substantially more in response to IL-4 than do analogous adult cells,<sup>398</sup> suggesting a way by which neonatal T cells might be more prone to become T<sub>H</sub>2 effectors. Studies by Delespesse and associates<sup>284</sup> also suggest that neonatal and adult CD45RA<sup>hi</sup> CD4<sup>+</sup> T cells may differ in their tendency to become T<sub>H</sub>2-like effector cells under certain conditions in vitro; when these cells were primed using a combination of anti-CD3 mAb, a fibroblast cell line expressing low amounts of the CD80 co-stimulatory molecule, and exogenous IL-12, production of IL-4 by neonatal CD4<sup>+</sup> T cells was enhanced compared with that by adult cells. Moreover, these investigators found that the neonatal effector T cells generated had a substantially lower capacity to produce IFN- $\gamma$  than adult cells, and these differences persisted even when endogenous IL-4 was blocked with an anti-IL-4 receptor antibody.<sup>399</sup> This tendency of neonatal CD4<sup>+</sup> T cells to develop a T<sub>H</sub>2- or T<sub>H</sub>0-like cytokine profile may not necessarily apply to more

physiologic conditions of stimuli, however, because no IL-4 production by neonatal naïve CD4<sup>+</sup> T cells was detected in response to allogeneic DC stimulation (D. Lewis, unpublished data, 2004).

### **Fetal and Neonatal T Cell Chemokine Receptor Expression**

The differential expression of chemokine receptors by T cells is important in their selective trafficking either to sites where naïve T cells may potentially encounter antigen for the first time, such as the spleen and lymph nodes, or to inflamed tissues for effector functions.<sup>400</sup> CCR7 expression by naïve T cells allows these cells to recirculate between the blood and uninflamed lymphoid organs, which constitutively express the two major ligands for CCR7: CCL19 and CCL21. Naïve T cells in the adult express CCR1, CCR7, and CXCR4 on their surface and have low to undetectable levels of CCR5. The role served by CCR1 and CXCR4 expression on naïve T cells is unclear, and CCR1 may be nonfunctional in this cell type.<sup>401</sup> Neonatal naïve T cells have a phenotype similar to those of adult naïve cells, except that they lack CCR1 surface expression, and unlike adult naïve T cells, they do not increase CXCR3 expression, nor do they decrease CCR7 expression, after activation by means of anti-CD3 and anti-CD28 mAbs.<sup>282,402</sup> The CCR7 expressed on neonatal T cells is functional and mediates chemotaxis of these cells in response to CCL19 and CCL21.<sup>403</sup> These results suggest that activated neonatal T cells may be limited in their capacity to traffic to nonlymphoid tissue sites of inflammation and, instead, may continue to recirculate between the blood and peripheral lymphoid organs.

CCR5 recognizes a number of chemokines that are produced at high levels by leukocytes at sites of inflammation, including CCL2 (MIP-1 $\alpha$ ), CCL4 (MIP-1 $\beta$ ), and CCL5 (RANTES), and is an important chemokine receptor for the entry of T cells into inflamed or infected tissues. Neonatal T cells can increase their surface expression of CCR5 by treatment with either mitogen or IL-2.<sup>404</sup> The observation that CCR5 is expressed by fetal mesenteric lymph node T cells during the second trimester of pregnancy<sup>246</sup> suggests that this CCR5 can be upregulated *in vivo* by a mechanism that does not involve antigenic stimulation. CCR5 expression on CD4<sup>+</sup> T cells gradually increases after birth, in parallel with the appearance of memory cells, suggesting that this process occurs *in vivo* as part of memory cell generation.<sup>405</sup>

As discussed earlier, neonatal naïve CD4<sup>+</sup> T cells also have the capacity to acquire expression of chemokines characteristic of T<sub>H</sub>1 or T<sub>H</sub>2 effectors following their differentiation in a polarized cytokine milieu (IL-12 and anti-IL-4 for T<sub>H</sub>1 and IL-4 and anti-IL-12 for T<sub>H</sub>2). The T<sub>H</sub>1 effectors generated *in vitro* tend to express CXCR3, CCR5, and CX3CR1, whereas T<sub>H</sub>2 effectors tend to express CCR4 and, to a lesser extent, CCR3.<sup>400,406,407</sup> Studies of freshly isolated memory CD4<sup>+</sup> T cells suggest that expression of CXCR3 and CCR4 may be more accurate predictors of cells with T<sub>H</sub>1 and T<sub>H</sub>2 cytokine profiles, respectively.<sup>408,409</sup> In many cases, a combination of chemokine receptors—for example, CXCR3 and CCR5 for the T<sub>H</sub>1 cytokine producers—may be the most predictive of highly polarized patterns of cytokine production by memory T cells.<sup>409</sup>

### **Early Postnatal Ontogeny of Memory T Cell Subsets *In Vivo***

Memory T cells are heterogeneous in their expression of CCR7. CCR7<sup>hi</sup> T cells (central memory cells) appear to preferentially recirculate between the secondary lymph nodes and blood, have limited effector function, and may serve as a reservoir for the generation of additional memory cells. The CCR7<sup>lo</sup> cell population (effector memory cells) is enriched in memory cells that can rapidly induce effector functions, such as IFN- $\gamma$  or IL-4 production or cytotoxin expression. The CCR7<sup>lo</sup> cell subset also is enriched in the expression of other chemokine receptors, which facilitates these cells preferential entry into inflamed or infected tissues.<sup>400</sup> It has been proposed that central memory cells are intermediates between naïve T cells and effector memory T cells,<sup>410</sup> but this concept remains highly controversial. A study of the TCR repertoire of human CD8<sup>+</sup> T cells suggests that most effector memory cells are not derived from central memory precursor,<sup>411</sup> but it is unclear if this also applies to the peripheral CD4<sup>+</sup> T cells.

The memory CD4<sup>+</sup> T cell subset in infants and young children has a significantly higher ratio of central memory to effector memory CD4<sup>+</sup> T cells than that observed in adults.<sup>226</sup> The frequency of effector memory CD4<sup>+</sup> T cells that can produce IFN- $\gamma$  and the amount of IFN- $\gamma$  produced per cell in response to bacterial superantigen, however, are similar in the blood of infants and young children and in that of adults.<sup>226</sup> This finding indicates that effector memory cells generated during infancy are functionally similar to those of adults. It is likely that the greater proportion of central memory cells also applies to memory CD4<sup>+</sup> T cell responses that occur in the first few months of life, but this remains to be shown. The mechanism responsible for the greater fraction of central memory cells in infants and children is unclear. One possibility is that the decreased proportion of effector memory CD4<sup>+</sup> T cells may reflect reduced activity of IL-12/IL-23–dependent T<sub>H</sub>1 pathway, because effector memory CD4<sup>+</sup> T cells are markedly reduced in IL-12R $\beta$ 1 deficiency, which ablates IL-12 and IL-23 signaling.<sup>225</sup>

### **Fetal and Neonatal T Cell–Mediated Cytotoxicity**

T cell–mediated cytotoxicity involves two major pathways of killing of cellular targets either through the secretion of the perforin and granzyme cytotoxins or through the engagement of Fas by Fas ligand (Fig. 4-7). The recent and growing use of cord blood for hematopoietic cell transplantation, and the finding that its use is associated with reduced graft-versus-host disease compared with that seen with adult bone marrow, have led to great interest in the capacity of neonatal T cells to mediate cytotoxicity and to potentiate graft rejection.

Early studies mostly used unfractionated mononuclear cells as a source of killer cells in a variety of non–antigen-specific assays, such as lectin-mediated cytotoxicity or redirected cytotoxicity using anti-CD3 mAb. Reduced cytotoxicity was observed with lectin-activated cord blood lymphocytes, particularly if purified T cells were used.<sup>412-414</sup> T cells also can be sensitized *in vitro* for cytotoxicity using allogeneic stimulator cells followed by testing for cytotoxic activity against allogeneic target cells. Using this approach, most studies have found that neonatal T cells are moderately less effective than adult T cells as cytotoxic effector cells.<sup>415-418,419</sup> As with the acquisition of T<sub>H</sub>1 effector function by neonatal

**Figure 4-7** Two major mechanisms of antigen-specific major histocompatibility complex (MHC) class I-restricted T cell-mediated cytotoxicity. Engagement of  $\alpha\beta$  T cell receptor ( $\alpha\beta$ -TCR) of CD8<sup>+</sup> T cells by antigenic peptides bound to major histocompatibility complex (MHC) class I molecules on the target cell leads to T cell activation and target cell death. **A**, Cytotoxicity may occur by the extracellular release of the contents of cytotoxic granules from the T cell, including perforins, granzymes, and other cytotoxins, such as granulysin. Perforins introduce pores by which granzymes can enter into the target cell, leading to the triggering of apoptosis and cell death. **B**, Activation of T cells results in their surface expression of Fas ligand, which engages Fas on the target cell, resulting in the delivery of death signal culminating in apoptosis. Other related molecules, such as TRAIL (TNF-related apoptosis-inducing ligand), may play a role in cytotoxicity.

CD4<sup>+</sup> T cells, more substantial defects in T cell-mediated cytotoxicity by neonatal T cells after allogeneic priming is observed when no exogenous cytokines, such as IL-2,<sup>420,421</sup> are added, suggesting that this decreased cytolytic activity might be physiologically significant *in vivo*. The mechanism for reduced neonatal T cell-mediated cytotoxicity remains poorly understood. Two studies have found that only a low percentage of neonatal CD8<sup>+</sup> T cells constitutively express perforin, whereas approximately 30% of adult CD8<sup>+</sup> T cells contain this protein.<sup>422,423</sup> By contrast, another study found that approximately 30% of neonatal T cells expressed perforin, a frequency that was similar to that for adult T cells.<sup>424</sup>

Effector and memory CD8<sup>+</sup> T cells kill more efficiently than antigenically naïve T cells after stimulation with lectin or anti-CD3 mAb<sup>425</sup> or after allogeneic sensitization.<sup>218,426,427</sup> Thus, the apparent deficiency of neonatal cytotoxic T lymphocyte (CTL) activity after *in vitro* activation or priming may in some part reflect the absence among neonatal CD8<sup>+</sup> T cells of effector and memory cells, as identified by their expression of CD45RO or by their lack of CD27 and CD28, or by both.<sup>428</sup>

The capacity of fetal T cells to mediate cytotoxicity has until recently not received as much scrutiny, despite its relevance to the development of fetal therapy using HSCs. CD8<sup>+</sup> T cells bearing  $\alpha\beta$ -TCRs can be cloned as polyclonal

lines from human fetal liver by 16 weeks of gestation.<sup>312,313</sup> These CD8<sup>+</sup> T cell lines have proliferative activity in response to allogeneic stimulation,<sup>312,313</sup> but their reactivity toward HLA antigens and their cytolytic activity are not known. More compelling is a study documenting robust fetal effector CD8<sup>+</sup> T cell responses, including clonal expansion, IFN- $\gamma$  production, and perforin expression, in response to congenital CMV infection<sup>429</sup> (see section on T cell response to congenital infection). This finding demonstrates that the capacity to generate a functional CD8<sup>+</sup> T cell effector population *in vivo* is established *in utero*, at least under conditions of chronic stimulation.

### Neonatal T Cell Apoptosis

The elimination of effector T cells by apoptosis is important for lymphocyte homeostasis, with a failure of this process resulting in autoimmunity and severe immunopathology, such as hemophagocytosis. This process can be studied using effector T cells that are generated *in vitro* from naïve precursors either by acutely withdrawing exogenous cytokines, such as IL-2, used in effector generation, or by reactivating the effector cells (e.g., using anti-CD3 mAb). IL-2, in particular, not only promotes the clonal expansion of T cells but also makes effector T cells vulnerable to apoptosis following its withdrawal. This susceptibility of effector T cells to apoptosis compared with naïve T cells is due to decreased expression of Bcl-2 and upregulation of Fas and the p55 (type I) and p75 (type II) TNF- $\alpha$  receptors (TNFRs).<sup>430</sup> Engagement of Fas or TNFRs by their cognate ligands results in the rapid induction of effector cell apoptosis. Effector B cells are similarly prone to the induction of apoptotic cell death by these pathways. Together, these observations may account for the tendency of mice with genetic disruptions of either IL-2 or its specific receptor components (CD25 [IL-2 receptor  $\alpha$  chain], IL-2 receptor  $\beta$  chain, and the  $\gamma$ c cytokine receptor) to develop abnormal expansions of T lymphocyte populations. In mice with compromised IL-2 production or IL-2 receptor signaling, reduced regulatory T cell function also may contribute to such T cell expansion (see section on regulatory T cells of the neonate).

Circulating mononuclear cells from cord blood, including naïve CD4<sup>+</sup> T cells, are more prone than those from the adult circulation to undergo spontaneous apoptosis *in vitro*.<sup>290,306,309,431,432</sup> The mechanism does not involve Fas engagement, because Fas levels are low to undetectable on freshly isolated neonatal lymphocytes, including CD4<sup>+</sup> and CD8<sup>+</sup> T cells.<sup>432-436</sup> This finding is consistent with limitation of expression mainly to memory/effector cells, which are largely absent in the neonatal circulation.<sup>435</sup> The Bcl-2 family of intracellular proteins includes members that either prevent or promote apoptosis by their effects on mitochondrial integrity. The increased tendency of neonatal naïve CD4 and unfractionated T cells to undergo apoptosis may be related to their expression of a lower ratio of Bcl-2 (anti-apoptotic) to Bax (pro-apoptotic) protein compared with that in adult T cells.<sup>306,437</sup> Neonatal naïve T cells have a more marked decrease than adult T cells in expression of Bcl-2 and Bcl-XL (also antiapoptotic) following 7 days in culture without exogenous cytokines.<sup>309</sup> Treatment of neonatal naïve CD4<sup>+</sup> T cells with IL-7 can block spontaneous apoptosis,<sup>290,309,310</sup> and this effect is accompanied by increased expression of Bcl-2 and Bcl-XL.<sup>290,309</sup> The tendency for neonatal T cells to

spontaneously undergo apoptosis can also be blocked by incubation with insulin-like growth factor-1 (IGF-1), although the mechanism is unclear.<sup>432</sup> The circulating levels of soluble Fas, soluble TNF, and soluble p55 TNFR increase in the first several days after birth,<sup>438</sup> and it has been proposed that the apoptotic tendency of neonatal lymphocytes may be downregulated in the immediate postnatal period by these factors.

Although neonatal T cells have an increased tendency to undergo spontaneous apoptosis, their activation *in vitro* (priming) may render them less prone than adult cells to undergo apoptosis by Fas ligand or TNF- $\alpha$  engagement, probably because they express less Fas, p55 TNFR, TNFR-associated death domain (TRADD), and caspase-3 molecules that are involved in this process.<sup>437,439</sup> By contrast, restimulation of primed neonatal T cells using anti-CD3 mAb induces greater apoptosis than occurs with use of similarly treated adult T cells; this anti-CD3 mAb-induced pathway in neonatal cells appears to be Fas independent.<sup>437</sup> These results suggest a mechanism by which the clonal expansion of neonatal T cells might be limited following activation through the  $\alpha\beta$ -TCR-CD3 complex, and the means to counteract this apoptotic tendency, such as administration of IL-2, other exogenous  $\gamma\epsilon$  cytokine receptor-utilizing cytokines, or IGF-1.<sup>432</sup> It remains unclear, however, whether adult naïve T cells primed under the same conditions as for neonatal T cells retain the tendency of unfractionated adult T cells for greater Fas- and p55 TNFR-mediated apoptosis and reduced anti-CD3 mAb-mediated apoptosis.

Neonatal circulating mononuclear cells, probably including T cells, also are more prone than adult mononuclear cells to undergo apoptosis after engagement of MHC class I achieved by mAb treatment,<sup>431</sup> apparently by a mechanism independent of Fas-Fas ligand interactions. The physiologic importance of the spontaneous and MHC class I-induced apoptotic pathways for fetal lymphocytes is unclear. It is plausible that an increased tendency of fetal T lymphocytes to undergo apoptosis after engagement of MHC class I might be a mechanism to maintain tolerance against noninherited maternal alloantigens.

### Regulatory T Cells of the Neonate

CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells appear to play an important role in peripheral tolerance to autoantigens,<sup>440</sup> transplantation antigens,<sup>441</sup> and antigens derived from normal endogenous bacterial flora of the gut.<sup>442</sup> The importance of this regulatory T cell population in humans in preventing autoimmune enteritis and endocrine disease is clearly illustrated by the immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance (IPEX) syndrome. This disorder is the first recognized example in humans of a single-gene deficiency that appears to result in a selective defect of regulatory T cells, rather than those that are involved with effector function. The syndrome is due to defects in the gene encoding FoxP3, a member of the forkhead protein family of transcription factors. FoxP3 is expressed by CD4<sup>+</sup> T cells, with particularly high levels contained in the CD4<sup>+</sup>CD25<sup>+</sup> subset of T cells, which include cells with regulatory (immunosuppressive) function. FoxP3-deficient mice also lack regulatory T cells, whereas enforced expression of FoxP3 in naïve murine CD4<sup>+</sup> T cells confers a regulatory phenotype,<sup>443</sup> suggesting that this transcription factor may act as

the key factor for the induction and possibly function of regulatory CD4<sup>+</sup> T cells.

Murine studies indicate that the accumulation of peripheral CD4<sup>+</sup>CD25<sup>+</sup> T cells requires IL-2 and the components of the high-affinity IL-2 receptor.<sup>444</sup> The high-affinity IL-2 receptor consists of CD25 (IL-2R  $\alpha$  chain), the IL-2R  $\beta$  chain (CD122), which also is used by the IL-15 receptor, and the  $\gamma\epsilon$  cytokine receptor that also is used by receptors for IL-4, IL-7, IL-9, IL-15, and IL-21.<sup>445,446</sup> How CD4<sup>+</sup>CD25<sup>+</sup> T cells regulate autoreactive or alloreactive T cells remains poorly understood. *In vitro* studies suggest that cell-cell contact is required. Studies have implicated TGF- $\beta$  (either secreted or regulatory T cell-associated), IL-10, and CTLA-4 as mediating the inhibitory effects of regulatory cells, but the relative importance of these mechanisms is controversial.<sup>444</sup> It also is unclear if these inhibitory effects *in vivo* are mainly indirect (e.g., through regulatory T cell-APC interactions) or occur through regulatory T cell-nonregulatory T cell interactions after the regulatory T cell has first interacted with an APC<sup>444</sup> (see also previous section on regulatory T cells).

About 5% of circulating CD4<sup>+</sup> T cells in neonates, infants, and young children express high levels of CD45RA and CD25 and contain CD45RO transcripts.<sup>447</sup> This T cell subset may be a transitional population between antigenically naïve and memory/effector T cells, although its antigen specificity has not been reported. These cells have some surface phenotypic similarities to a population of CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells described in the circulation of adult humans and in mice. Both murine and human studies have shown that CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells can inhibit the activation of non-CD25<sup>+</sup> T cells *in vitro*.<sup>442,448-450</sup> In a recent study, however, only adult but not neonatal CD4<sup>+</sup>CD25<sup>+</sup> T cells were capable of suppressing T cell responses to self-antigen.<sup>451</sup> Additional characterization of the function of neonatal CD4<sup>+</sup>CD25<sup>+</sup> T cells and their expression of markers characteristic of regulatory cells, such as FoxP3, will be of interest.

### Natural Killer T Cells of the Neonate

As discussed earlier (see section on NK T cells), NK T cells are distinct from most  $\alpha\beta$  T cells in their restricted  $\alpha\beta$ -TCR repertoire and their recognition of antigens presented by the nonclassic MHC molecules, CD1d. Murine studies suggest that NK T cells may contribute to host defense in certain infections, promote airway hyperreactivity in allergen-induced asthma,<sup>452</sup> and regulate immunopathology (as in autoimmunity and graft-versus-host disease),<sup>453</sup> but the immunologic role of human NK T cells remains poorly defined, as do the ligands recognized by their TCRs. Only small numbers of NK T cells (less than 1.0% of circulating T cells) are present in the neonatal circulation, but these subsequently increase with aging.<sup>454</sup> This finding suggests that NK T cells may undergo postnatal expansion, for example, in relation to exposure to a ubiquitous antigen presented by CD1d molecules, or that their production by the thymus or at extrathymic sites occurs mainly postnatally. Neonatal NK T cells are similar to adult NK T cells in having a memory/effector-like cell surface phenotype, including expression of CD25, the CD45RO isoform, and a low level of expression of L-selectin.<sup>455,456</sup> In the case of murine NK T cells, many of these activation phenotypic features are found on NK T cells during intrathymic development, indicating that these are a

result of differentiation rather than prior antigenic stimulation in the periphery before birth.

The neonatal NK T cell population can be expanded *in vitro* using a combination of anti-CD3 and anti-CD28 mAbs, PHA, IL-2, and IL-7.<sup>457</sup> Although neonatal NK T cells have a surface phenotype similar to that of adult NK T cells, they produce only limited amounts of IL-4 or IFN- $\gamma$  on primary stimulation, indicating functional immaturity.<sup>455</sup> This decreased capacity may be due to mechanisms similar to those for the reduced IFN- $\gamma$  production by neonatal CD4<sup>+</sup> T cells, such as decreased levels of the NFATc2 transcription factor or increased methylation of the IFN- $\gamma$  genetic locus.

Following *in vitro* expansion, neonatal NK T cells produce higher levels of IL-4 and lower amounts of IFN- $\gamma$  than those produced by similarly treated adult NK T cells.<sup>457</sup> The cytokine profile of neonatal NK T cells demonstrates greater plasticity than that of adult NK T cells: Expansion of the neonatal NK T cell population and priming using either DC1 or DC2 cells in conjunction with PHA, IL-2, and IL-7 result in an IL-4-predominant or an IFN- $\gamma$ -predominant cytokine expression profile, respectively. By contrast, similarly treated adult NK T cells retain their ability to produce both cytokines,<sup>457</sup> suggesting a loss of plasticity of NK T cells toward T<sub>H</sub>1 versus T<sub>H</sub>2 polarization after birth. Polarization of neonatal NK T cells toward IL-4 but not IFN- $\gamma$  secretion might be potentially useful in the treatment of graft-versus-host disease and autoimmune diseases by adoptive transfer.<sup>240,241</sup>

The capacity of cytokine-derived neonatal NK T cells and those directly isolated from the infant to mediate cytotoxicity has not been reported. Neonatal CD56<sup>+</sup> T cells constitutively express less perforin than do adult cells.<sup>423</sup> Because the CD56<sup>+</sup> T cell population is highly enriched in CD1d-restricted NK T cells, NK T cell cytotoxicity probably is limited at birth and gradually increases with age. Culturing of neonatal NK T cells *in vitro* for several weeks results in acquisition of potent cytotoxic activity against a variety of tumor cell targets,<sup>458</sup> indicating that developmental limitations can be overcome following expansion and differentiation.

## Gamma-Delta T Cells

### Phenotype and Function

Gamma-delta T cells, which express a TCR heterodimer consisting of a gamma ( $\gamma$ ) and a delta ( $\delta$ ) chain in association with the CD3 complex proteins, are rarer than  $\alpha\beta$  T cells in most tissues. A major exception is the intestinal epithelium, where they predominate.<sup>459</sup> Although some  $\gamma\delta$ -TCRs can recognize conventional peptide antigens presented by MHC, most directly recognize three-dimensional nonprotein or protein structures. The antigen-combining site of the  $\gamma\delta$ -TCR shares some structural features with that of immunoglobulin molecules,<sup>460</sup> which is consistent with preferential recognition of three-dimensional structures by both of these receptors.

Human  $\gamma\delta$  T cells expressing the V $\gamma$ 2V $\delta$ 2 receptors can proliferate and secrete cytokines after recognition of isopentenyl and prenyl phosphates derived from mycobacteria<sup>461,462</sup> or of alkylamines derived from many species of bacteria, including important neonatal pathogens such as *Listeria* and *Escherichia coli*.<sup>459,463-465</sup> Human  $\gamma\delta$  T cells express NKG2D, which recognizes the MHC class I-like molecule MICA.<sup>466,467</sup> This NKG2D-MICA interaction enhances the

antigen-dependent effector function of V $\gamma$ 2V $\delta$ 2  $\gamma\delta$  T cells.<sup>468</sup> Such enhancement *in vivo* may be a consequence of the induction of MICA on APCs by mycobacteria and other pathogens.<sup>468</sup>

This *in vitro* activation of  $\gamma\delta$  T cells probably is relevant *in vivo*, because increased numbers are found in the skin lesions of patients with leprosy and in the blood of patients with malaria<sup>459,463</sup> and acute herpesvirus infections.<sup>469,470</sup> Resident  $\gamma\delta$  T cells of the murine skin can produce epithelium-specific growth factors that may help maintain epithelial integrity during stress.<sup>471</sup> The observation that MICA is expressed on heat shock-stressed epithelial cells, and, presumably, in stressed or infected epithelium *in vivo*, is consistent with a similar role for human  $\gamma\delta$  T cells.

Gamma-delta T cells also may have important immunosurveillance function for malignancy, because murine cutaneous  $\gamma\delta$  T cells can kill skin carcinoma cells by a mechanism that involves engagement of NKG2D by Rae-1 and H60, which have homology with human MICA.<sup>472</sup> Murine studies also suggest that  $\gamma\delta$  T cells may help decrease inflammatory responses to pathogens, such as *Listeria*, by killing activated macrophages by cell-mediated cytotoxicity.<sup>473</sup>

Most activated  $\gamma\delta$  T cells express high levels of perforin, serine esterases, and granulysin and are capable of cytotoxicity against tumor cells and other cell targets, such as infected cells.<sup>474</sup> Gamma-delta T cells also can secrete a variety of cytokines *in vitro*, including TNF- $\alpha$ , IFN- $\gamma$ , and IL-4,<sup>459,463</sup> as well as chemokines that may help recruit inflammatory cells to the tissues. Cytokine production can be potently activated by products from live bacteria, such as isobutylamine<sup>475</sup> and by type I IFN or by agents that potently induce it, such as oligonucleotides containing unmethylated CpG motifs.<sup>476</sup>

Murine studies suggest that these cells are critical for mucosal immunity. Mice lacking  $\gamma\delta$  T cells have markedly decreased numbers of intestinal IgA plasma cells and demonstrate decreased IgA production after oral immunization with foreign protein and adjuvant.<sup>477</sup> Murine  $\gamma\delta$  T cells also may contribute to defense of the host against intracellular pathogens, including HSV, *Listeria*, and *Mycobacterium tuberculosis*, particularly if  $\alpha\beta$  T cell function is compromised.<sup>478-480</sup> Human V $\gamma$ 2V $\delta$ 2  $\gamma\delta$  T cells following adoptive transfer into SCID mice can mediate rapid and potent antibacterial activity against both gram-positive and gram-negative bacteria, with protection associated with the production of IFN- $\gamma$ .<sup>481</sup>

Only about 2% to 5% of T-lineage cells of the thymus and peripheral blood express  $\gamma\delta$ -TCR in most persons.<sup>482</sup> Unlike in most  $\alpha\beta$  T cells, whose development requires an intact thymus, a significant proportion of  $\gamma\delta$  T cells can develop by a thymic-independent pathway, and normal numbers of  $\gamma\delta$  T cells are found in cases of complete thymic aplasia.<sup>482</sup> This may be explained, at least in part, by the differentiation of  $\gamma\delta$  T cells directly from primitive lymphohematopoietic precursor cells found in the small intestine, as has been demonstrated in the mouse.<sup>483</sup>

### Ontogeny of Gamma-Delta T Cell Receptor Gene Rearrangement

The human TCR  $\gamma$  and  $\delta$  chain genes undergo a programmed rearrangement of dispersed segments analogous to that of

the TCR  $\alpha$  and TCR  $\beta$  chain genes. The TCR  $\gamma$ , TCR  $\delta$ , and TCR  $\beta$  gene loci of immature double-negative cells appear to undergo rearrangement in the thymus at the same time.<sup>484</sup> If the TCR  $\gamma$  and TCR  $\delta$  gene rearrangements are productive, this may somehow suppress TCR  $\beta$  chain rearrangement. Alternatively, if the TCR  $\beta$  chain gene is productively rearranged, this may suppress TCR  $\gamma$  and TCR  $\delta$  rearrangement. Signals through the pre-TCR complex that includes the TCR  $\beta$  chain may be involved in this suppression, although this suggestion is controversial.<sup>484</sup> Unlike with  $\alpha\beta$  T cells, the development of  $\gamma\delta$  T cells occurs normally in the absence of a pre-TCR complex.<sup>485</sup> Most  $\gamma\delta$  T cells lack surface expression of either CD4 or the CD8  $\beta$  chain, suggesting that they may not undergo the process of positive selection that is obligatory for  $\alpha\beta$  T cells.<sup>486</sup> Whether  $\gamma\delta$  cells undergo negative selection is unclear.<sup>487</sup>

Rearranged TCR  $\delta$  genes are first expressed extrathymically in the liver and primitive gut between 6 and 9 weeks of gestation.<sup>488,489</sup> Rearrangement of the human TCR  $\gamma$  and TCR  $\delta$  genes in the fetal thymus begins shortly after its colonization with lymphoid cells, with TCR  $\delta$  protein detectable by 9.5 weeks of gestation.<sup>243</sup> Gamma-delta T cells comprise about 10% of the circulating T cell compartment at 16 weeks, a percentage that gradually declines to less than 3% by term.<sup>291,490</sup>

Although there is potential for the formation of a highly diverse  $\gamma\delta$ -TCR repertoire, peripheral  $\gamma\delta$  T cells use only a small number of V segments, which vary with age and with tissue location. These can be divided into two major groups, V $\gamma$ 2V $\delta$ 2 cells and V $\delta$ 1 cells, in which a V $\delta$ 1-bearing TCR  $\delta$  chain predominantly pairs with a TCR  $\gamma$  chain using a V $\gamma$  segment other than V $\gamma$ 1. Most  $\gamma\delta$ -TCR<sup>+</sup> thymocytes in the first trimester of fetal life express V $\delta$ 2 segments. This is followed by  $\gamma\delta$ -TCR<sup>+</sup> thymocytes that express V $\delta$ 1, which predominate at least through infancy in the thymus. Most circulating fetal and neonatal  $\gamma\delta$  T cells also are V $\delta$ 1 bearing, with only about 10% bearing V $\delta$ 2,<sup>454</sup> and these V $\delta$ 1 cells constitute the predominant  $\gamma\delta$  T cell population of the small intestinal epithelium after birth. In contrast with the early-gestation fetal thymus and the fetal and neonatal circulation, V $\delta$ 2 T cells predominate in the fetal liver and spleen early during the second trimester<sup>491,492</sup> and appear before  $\gamma\delta$  TCR<sup>+</sup> thymocytes,<sup>243,493</sup> suggesting that they are produced extrathymically by the fetal liver.

As indicated by TCR spectratyping, the TCR  $\delta$  chains utilizing either V $\delta$ 1 or V $\delta$ 2 segments usually are oligoclonal at birth.<sup>494,495</sup> Because this oligoclonality also is characteristic of the adult  $\gamma\delta$  T cell repertoire, this is not due to postnatal clonal expansion but reflects an intrinsic feature of this cell lineage. By age 6 months,  $\gamma\delta$  T cells bearing V $\gamma$ 2 V $\delta$ 2 segments become predominant and remain so during adulthood,<sup>496</sup> probably because of their preferential expansion in response to ubiquitous antigen(s), such as endogenous bacterial flora.<sup>464</sup>

### **Ontogeny of Gamma-Delta T Cell Function**

Although neonatal  $\gamma\delta$  T cells proliferate in vitro in response to mycobacterial lipid antigens,<sup>497</sup> they express lower levels of serine esterases than do adult  $\gamma\delta$  T cells, suggesting they are less effective cytotoxic cells.<sup>498</sup> Gamma-delta T cell clones derived from cord blood also have a markedly reduced capacity to mediate cytotoxicity against tumor cell extracts.<sup>490</sup>

Because these neonatal clones also have lower CD45RO surface expression than that observed in the adult clones, their reduced activity may reflect their antigenic naïveté. In contrast with freshly isolated neonatal  $\gamma\delta$  T cells, activation and propagation of these fetal and neonatal  $\gamma\delta$  T cells in culture (e.g., with exogenous IL-2) do not enhance their function. The function of fetal liver  $\gamma\delta$  T cells remains unclear, although one report suggests that they have cytotoxic reactivity against maternal MHC class I<sup>493</sup> and thereby may prevent engraftment of maternal T cells.

### **Antigen-Specific T Cell Function in the Fetus and Neonate**

#### ***Delayed Cutaneous Hypersensitivity, Graft Rejection, and Graft-versus-Host Disease***

Skin test reactivity to cell-free antigens assesses a form of DTH that requires the function of antigen-specific CD4<sup>+</sup> T cells. Skin test reactivity to common antigens such as *Candida*, streptokinase-streptodornase, and tetanus toxoid usually is not detectable in neonates.<sup>499-501</sup> Absence of such reactivity reflects a lack of antigen-specific sensitization, because in vitro T cell reactivity (e.g., cellular proliferation by peripheral blood mononuclear cells) to these antigens also is absent. When leukocytes, and presumably antigen-specific CD4<sup>+</sup> T cells, from sensitized adults are adoptively transferred to neonates, children, or adults, however, only neonates fail to respond to antigen-specific skin tests.<sup>502</sup> As discussed later on, this finding indicates that the neonate may be deficient in other components of the immune system required for DTH, such as APCs or producers of inflammatory chemokines or cytokines. Such deficiencies may account, at least in part, for diminished skin reactivity in the neonate after specific sensitization or after intradermal injection with T cell mitogens.<sup>503,504</sup> Diminished skin reactivity to intradermally administered antigens persists postnatally up to 1 year of age.<sup>505</sup>

Neonates, including those born prematurely, are capable of rejecting foreign tissues, such as skin grafts, although the this rejection may be delayed compared with adults.<sup>506</sup> Experiments using human-SCID mouse chimeras also suggest that second trimester human fetal T cells are capable of becoming cytotoxic effector T cells in response to foreign antigens, and in rejecting solid tissue allografts.<sup>507</sup> Clinical transplantation of fetal blood from one unaffected fraternal twin to another with  $\beta$ -thalassemia did not result in marrow engraftment, despite a sharing of similar MHC haplotypes; instead, there was a postnatal recipient cytotoxic T cell response against donor leukocytes.<sup>508</sup> A T cell response to alloantigens can also be detected in newborns following in utero irradiated red blood cell transfusions from unrelated donors; these neonates have a significantly greater percentage of CD45RO<sup>hi</sup> T cells than is seen in healthy controls.<sup>509,510</sup> Thus, fetal T cells appear similar to neonatal T cells in being able to mediate allogeneic responses in vivo, including graft rejection.

Another indication that neonatal T cells can mediate allogeneic responses is the fact that blood transfusions rarely induce graft-versus-host disease in the neonate. Rare cases of persistence of donor lymphocytes and of graft-versus-host disease have developed following intrauterine transfusion in the last trimester as well as in transfused premature neonates, however.<sup>511-514</sup> Because the infusion of fresh leukocytes

induces partial tolerance to skin grafts,<sup>506</sup> tolerance for transfused lymphocytes might occur by a similar mechanism, predisposing the fetus or neonate to graft-versus-host disease. Together, these observations suggest a partial immaturity in T cell and inflammatory mechanisms required for DTH and for graft rejection.

### **T Cell Reactivity to Environmental Antigens**

Specific antigen reactivity theoretically can develop in the fetus by exposure to antigens transferred from the mother, by transfer of specific cellular immunity from maternal lymphocytes, or by infection of the fetus itself.<sup>515</sup> Several studies suggest that fetal T cells have become primed to environmental or dietary protein allergens as a result of maternal exposure and transfer to the fetus.<sup>516-518</sup> A criticism of these studies is that the antigen-specific proliferation is low compared with the basal proliferation of cord blood mononuclear cells. In addition, many of these studies used antigen extracts rather than defined recombinant proteins or peptides, and these may have nonspecific stimulatory effects.

Prenatal sensitization has been assessed by incorporation of <sup>3</sup>H-thymidine by cord blood mononuclear cells, as well as antigen-induced cytokine production, as determined using either reverse transcriptase–polymerase chain reaction (PCR) assay for cytokine transcripts (IL-4, IL-5, IL-9, and IFN- $\gamma$ ), cell culture supernatant cytokine enzyme-linked immunosorbent assays (ELISAs) (for IL-5, IL-10, and IL-13),<sup>519-521</sup> and a cell-based cytokine ELISA for IL-4 and IFN- $\gamma$ .<sup>522</sup> In some studies, the production of IL-10 in these cultures is high relative to that of the classic T<sub>H</sub>2 cytokines (IL-4, IL-5, IL-9, and IL-13). IFN- $\gamma$  production was 100-fold higher than IL-4 production, a ratio that is still reduced compared with that in adult cells. This cytokine profile has been interpreted as a T<sub>H</sub>2-biased response or a regulatory T cell (IL-10–dominant) response. Whether T<sub>H</sub>2 priming of fetal T cells to environmental antigens is a risk factor for the postnatal development of atopic disease remains controversial. Its frequent occurrence suggests that priming per se may be a normal outcome of fetal exposure to such antigens.<sup>519,520</sup>

Prenatal priming of T cells by environmental allergens can be demonstrated as early as 20 weeks of gestation, based on their proliferative responses to seasonal allergens.<sup>523</sup> These responses are weak, however, and the cytokine profile was not reported. In one study, protein allergen–specific T cell proliferation detected at birth was more common when allergen exposure occurred in the first or second trimester rather than in the third trimester.<sup>518</sup> This finding could reflect decreased maternal-fetal transport of antigen during late pregnancy or an intrinsic capacity of early- and late-gestation fetal T cells to be primed.

### **Fetal T Cell Sensitization to Maternally Administered Vaccines and Maternally Derived Antigens**

In contrast with protein allergens, antigen-specific fetal T cell priming to vaccines has not been documented, such as following maternal vaccination during the last trimester of pregnancy with tetanus toxoid or inactivated influenza virus

A or B.<sup>524</sup> Absence of such priming suggests that fetal sensitization to foreign proteins may be relatively inefficient, particularly when exposure is temporally limited. Whether this reflects relatively inefficient maternal-fetal transfer of protein antigens or intrinsic limitations of the fetus for antigen presentation and T cell priming, or both, is unclear. Even if it is assumed that the capacity for fetal T cells to be primed by foreign antigens is similar to that of antigenically naïve adult T cells, the immune response to maternally derived foreign vaccine proteins by fetal T cells would be expected to be poor compared with the maternal response, because the antigen probably would enter into the fetal circulation with little if any accompanying activation of the innate response required for efficient T cell activation.

Growing evidence, however, suggests that fetal T cell sensitization can occur in cases of antigen exposure due to chronic infection of the mother with parasites or viruses: Parasite (schistosomal, filarial, and plasmodial) antigen-specific cytokine production by peripheral blood lymphocytes, probably of T cell origin, was detectable at birth in infants without congenital infection who were born to infected mothers.<sup>525,526</sup> Of interest, this apparent T cell immunity persisted for at least 1 year after birth in the absence of postnatal infection with parasites and was associated with downregulation of *Mycobacterium bovis* Calmette-Guérin (bacille Calmette-Guérin [BCG])–specific IFN- $\gamma$  production following neonatal administration of BCG vaccine.<sup>525</sup> These results suggest that fetal exposure to parasitic antigens without infection can downregulate subsequent postnatal T<sub>H</sub>1 responses to unrelated antigens. HIV peptide–specific IL-2 production by cord blood CD4<sup>+</sup> T cells also has been reported in uninfected infants born to HIV-infected mothers, suggesting that fetal T cell sensitization can occur in cases of chronic viral infection of the mother without congenital infection.<sup>527</sup>

### **Maternal Transfer of T Cell Immunity to the Fetus**

The literature contains many reports of cord blood lymphocyte proliferation or cytokine production in response to antigens that the fetus is presumed not to have encountered. These antigen responses have been attributed to passive transfer of T cell immunity from the mother. For example, in studies in which in vitro reactivity of lymphocytes was studied between birth and the first week of life, specific reactivity to tuberculin purified protein derivative (PPD),<sup>528,529</sup> *Mycobacterium leprae*,<sup>530</sup> measles,<sup>531</sup> and rubella<sup>532</sup> was observed. Infants with pathogen or vaccine reactive lymphocytes usually constituted a minority (less than 20%) of those born to mothers without evidence of active infection, however, and the data were interpreted as evidence for the transfer of maternal cellular immunity.<sup>532,533</sup> Responses usually are weak and may represent laboratory artifacts rather than true sensitization. It also is important to consider that mycobacterial products, such as PPD or *M. leprae* extracts, can activate  $\gamma\delta$  T cells in the absence of specific prior sensitization. Lipoglycan antigens bound to CD1 may mediate these responses. In vitro reactivity of neonatal T cells to extracts of gram-negative bacteria or *S. aureus* also has been reported.<sup>534-536</sup> Some of these stimuli may act as mitogens or superantigens, however, rather than as MHC-restricted peptide antigens. T cells, including those from the neonate, are effectively activated by superantigens of *S. aureus* and other bacteria.<sup>265,329</sup>

Although maternal-to-fetal transfer of leukocytes occurs, their number in the fetus is very low (usually <0.1%)<sup>537</sup>; accordingly, detectable antigen-specific cellular immunity by conventional assays is unlikely. Thus, reports of neonatal T cell responses as a result of transfer of maternal immunity should remain suspect unless the T cell population is identified and its antigen specificity and MHC restriction are demonstrated.

### T Cell Response to Congenital Infection

**CD4<sup>+</sup> T Cells.** Pathogen-specific T cell proliferative responses and cytokine responses (IL-2 and IFN- $\gamma$ ) in infants and children with congenital infection (e.g., with *Treponema pallidum*, CMV, varicella-zoster virus [VZV], or *Toxoplasma*) are markedly decreased compared with such responses in infants and children with postnatal infection, or are absent entirely.<sup>538-543</sup> These assays mainly detected CD4<sup>+</sup> T cell responses, because antigen preparations (e.g., whole cell lysates of virally infected cells) and APC populations (e.g., peripheral blood monocytes and B cells as the predominant APCs with few DCs) were used that favor activation of MHC class II-restricted rather than class I-restricted responses. These reduced CD4<sup>+</sup> T cell responses are particularly true with first- or second-trimester infections. With severe infections in the first trimester, a direct deleterious effect on T cell development is possible. T cells from infants and children with congenital toxoplasmosis, however, retain the ability to respond to alloantigen, mitogen, and, in one case, tetanus toxoid.<sup>543</sup> A more recent study by King and colleagues<sup>526</sup> has examined adaptive immune responses to *Plasmodium falciparum* antigens using cord blood from neonates in an area of Kenya with a high rate of maternal-to-fetal malarial transmission. These investigators found that malaria antigen-induced CD4<sup>+</sup> T cell cytokine production (IFN- $\gamma$ , IL-4, and IL-13) was detectable in these neonates, but not in samples from North American neonates.<sup>526</sup> Thus, the limited ability of the fetus to mount CD4<sup>+</sup> T cell responses to pathogen-derived antigens is not absolute, and dual T<sub>H</sub>1- and T<sub>H</sub>2-type immune responses can develop after some congenital infections or fetal exposure to pathogenic antigens from the mother.

The reduced CD4<sup>+</sup> T cell responses seen in many types of congenital infection may be the result of antigen-specific unresponsiveness (e.g., anergy, deletion, or ignorance—the failure of the CD4<sup>+</sup> T cell to be initially activated by antigen). As discussed earlier, it is unlikely that a decreased TCR repertoire limits these immune responses, particularly after the second trimester onward. Decreased responses do not occur to all pathogens: In one study, 10-year-old children congenitally infected with mumps had DTHs to mumps antigen, indicating persistence of mumps-specific memory/effector T cells.<sup>544</sup>

**CD8<sup>+</sup> T Cells.** CD8<sup>+</sup> T cell responses to congenital infections appear to be relatively robust, which is in marked contrast with those of CD4<sup>+</sup> T cells. In congenital CMV infection, high frequencies of CMV-specific CD8<sup>+</sup> T cells were detectable by staining with CMV peptide-MHC class I tetramers, and these cells demonstrated perforin expression, cytolytic activity, and the capacity to produce cytokines, such as IFN- $\gamma$ , similar to those of chronically infected adults.<sup>429</sup> Similarly, in HIV-1 infection, an expansion of HIV-specific cytotoxic T cells was detected at birth, indicating that fetal T cells were activated

by viral antigens.<sup>545</sup> In another case of in utero HIV infection, HIV-specific T cell-mediated cytotoxicity was detected at age 4 months and persisted for several years despite a high HIV viral load.<sup>546</sup> Congenital infection with *Trypanosoma cruzi* also results in a marked expansion of CD8<sup>+</sup> T cells over CD4<sup>+</sup> T cells, with evidence of oligoclonality of the TCR repertoire, indicating that this is antigen driven.<sup>547</sup> These CD8<sup>+</sup> T cells are enriched in markers for activation (HLA-DR<sup>hi</sup>), memory (CD45RO<sup>hi</sup>), and end-stage effector cells (CD28<sup>-</sup>), and for cytotoxicity (perforin<sup>+</sup>), and have markedly greater capacity to produce IFN- $\gamma$  and TNF- $\alpha$  than is seen in CD8<sup>+</sup> T cells from uninfected newborns; in comparison with CD8<sup>+</sup> T cells, CD4<sup>+</sup> T cells in these congenitally infected newborns appear to have undergone much less clonal expansion and acquisition of effector function.<sup>547</sup> Congenital infection with viruses or *Toxoplasma* during the second and third trimesters may result in the appearance of CD45RO<sup>hi</sup> memory T cells and an inverse ratio of CD4<sup>+</sup> to CD8<sup>+</sup> T cells,<sup>548-550</sup> findings that also suggest that fetal CD8<sup>+</sup> T cells are activated and expanded in response to serious infection. These alterations in CD45RO expression by T cells in congenital infection may persist at least through early infancy.<sup>551,552</sup>

### T Cell Response to Postnatal Infections and Vaccination

**CD4<sup>+</sup> T Cells.** Postnatal infection with HSV results in antigen-specific proliferation and cytokine (IL-2 and IFN- $\gamma$ ) production by CD4<sup>+</sup> T cells. These responses are substantially delayed, however, compared with those in adults with primary HSV infection.<sup>553,554</sup> It is unclear at what postnatal age the kinetics of this response becomes similar to that in adults. Recent studies of CMV-specific CD4<sup>+</sup> T cell immunity (expression of IL-2, IFN- $\gamma$ , and CD40 ligand) in older infants and young children with primary infection found substantially reduced responses compared with those in adults with infection of similar duration.<sup>226</sup> This reduced CD4<sup>+</sup> T cell response was associated with persistent shedding of the virus into secretions.<sup>226</sup> It is likely that reduced CMV-specific CD4<sup>+</sup> T cell responses also apply to the neonate and young infant with perinatal or postnatally acquired infection, who also persistently shed the virus for several years following acquisition. Of interest, as in congenital CMV infection,<sup>429</sup> older infants and young children with primary CMV infection had robust CMV-specific CD8<sup>+</sup> T cell responses similar to those in adults.<sup>226,555</sup>

Infants between 6 and 12 months of age also demonstrate lower IL-2 production in response to tetanus toxoid than that observed in older children and adults.<sup>327</sup> This finding suggests that either antigen-specific memory CD4<sup>+</sup> T cell generation or function is decreased during early infancy. Whether this reflects limitations in antigen processing, T cell activation and co-stimulation, or proliferation and differentiation remains unclear.

In contrast with postnatally acquired herpesvirus infections or inactivated vaccine antigens, BCG vaccination at birth versus 2 months or 4 months of age was equally effective in inducing CD4<sup>+</sup> T cell proliferative and IFN- $\gamma$  responses to PPD, extracellular *M. tuberculosis* antigens, and an *M. tuberculosis* intracellular extract.<sup>93,556</sup> The responses were robust not only at 2 months following immunization but also at 1 year of age, and no skewing toward T<sub>H</sub>2 cytokine

production was noted,<sup>556</sup> even by PPD-specific CD4<sup>+</sup> T cell clones.<sup>93</sup> Thus, early postnatal administration of BCG vaccine does not result in decreased vaccine-specific T<sub>H1</sub> responses, tolerance, or T<sub>H2</sub> skewing. How these responses compare with those in older children and adult vaccinees is not known. Early BCG vaccination also may influence antigen-specific responses to unrelated vaccine antigens. BCG given at birth increased T<sub>H1</sub>- and T<sub>H2</sub>-specific responses and antibody titers to hepatitis B surface antigen (HBsAg) given simultaneously.<sup>557</sup> BCG given at birth did not enhance the T<sub>H1</sub> response to tetanus toxoid given at 2 months of age but did increase the T<sub>H2</sub> response (IL-13 production). It is likely that BCG vaccination may accelerate DC maturation, so that these cells can augment either T<sub>H1</sub> or T<sub>H2</sub> responses.

The T cell-specific response to oral poliovirus vaccine (OPV), another live vaccine, suggests a decreased T<sub>H1</sub> response. Neonates given OPV at birth and at 1, 2, and 3 months of age demonstrate lower OPV-specific CD4<sup>+</sup> T cell proliferation and IFN- $\gamma$  production and have fewer IFN- $\gamma$ -positive cells compared with adults who were immunized as children but not recently reimmunized.<sup>558</sup> By contrast, their antibody titers were higher than those in adults, suggesting that CD4<sup>+</sup> T cell help for B cells is not impaired. It is plausible that OPV may be less effective at inducing a T<sub>H1</sub> response than BCG in neonates and young infants because of its limited replication, site of inoculation, or ability to stimulate APCs in a manner conducive to T<sub>H1</sub> immunity, relative to BCG, which induces persistent infection in the recipient.

Although neonates and young infants have been suggested to have skewing of CD4<sup>+</sup> T cell responses toward a T<sub>H2</sub> cytokine profile, this may be an oversimplification. For example, the tetanus toxoid-specific response following vaccination indicates that both T<sub>H1</sub> (IFN- $\gamma$ ) and T<sub>H2</sub> (IL-5 and IL-13) memory responses occur, particularly following the third vaccine dose at 6 months of age.<sup>182</sup> The tetanus toxoid-specific T<sub>H1</sub> response may transiently decrease by 12 months of age, whereas T<sub>H2</sub> responses are not affected.<sup>182</sup>

**CD8<sup>+</sup> T Cells.** As discussed, CD8<sup>+</sup> T cell responses to CMV infection acquired in utero<sup>429</sup> or during infancy and early childhood<sup>555</sup> are robust, and it is likely that this also applies for infection acquired perinatally or during the early infancy. Cytotoxic responses to HIV in perinatally infected infants suggest that CD8<sup>+</sup> T cells capable of mediating cytotoxicity have undergone clonal expansion in vivo as early as 4 months of age.<sup>559</sup> Their cytotoxicity may be reduced and delayed in appearance compared with that in adults, however.<sup>560</sup> There is also decreased HIV-specific CD8<sup>+</sup> T cell production of IFN- $\gamma$  by young infants after perinatal HIV infection,<sup>561</sup> and an inability to generate HIV-specific cytotoxic T cells following highly active antiretroviral therapy (HAART).<sup>562</sup> When evaluated beyond infancy, cytolytic activity directed to HIV envelope proteins was commonly detected, but cytolytic activity directed against gag or pol proteins was rarely detected,<sup>545</sup> suggesting that the antigenic repertoire of cytotoxic CD8<sup>+</sup> T cells was less diverse than in adults.

HIV-1 infection may inhibit antigen-specific immunity by depleting circulating DCs,<sup>563</sup> impairing antigen presentation,<sup>564</sup> decreasing thymic T cell output,<sup>565</sup> and promoting T cell apoptosis.<sup>566</sup> In addition, maintenance of HIV-specific CD8<sup>+</sup> T cells with effector function depends on HIV-specific CD4<sup>+</sup> T cells and may be selectively and severely impaired by

the virus. Regardless of the precise mechanism, the suppressive effects of HIV-1 on cytotoxic responses may be relatively specific for HIV-1, because HIV-infected infants who lack HIV-specific cytotoxic T cells may maintain cytolytic T cells against EBV and CMV.<sup>561,562</sup> Surprisingly, some of the inhibitory effects of HIV-1 infection also may occur in HIV-exposed but uninfected infants born to HIV-infected mothers.<sup>565,567</sup>

In one older study, RSV-specific cytotoxicity was more pronounced and frequent in infants 6 to 24 months of age than in younger infants.<sup>568</sup> These results, which need to be repeated using more current assays, suggest that the CD8<sup>+</sup> T cell response to RSV gradually increases with postnatal age. Murine studies indicate that RSV infection suppresses CD8<sup>+</sup> T cell-mediated effector activity (IFN- $\gamma$  production and cytolytic activity) and that only transient memory CD8<sup>+</sup> T cell responses occur following infection.<sup>569</sup> Longitudinal studies of CD8<sup>+</sup> T cell immunity to RSV in children and adults following primary and secondary infection will be of interest to determine if this immunoevasive mechanism applies to humans.

## Summary

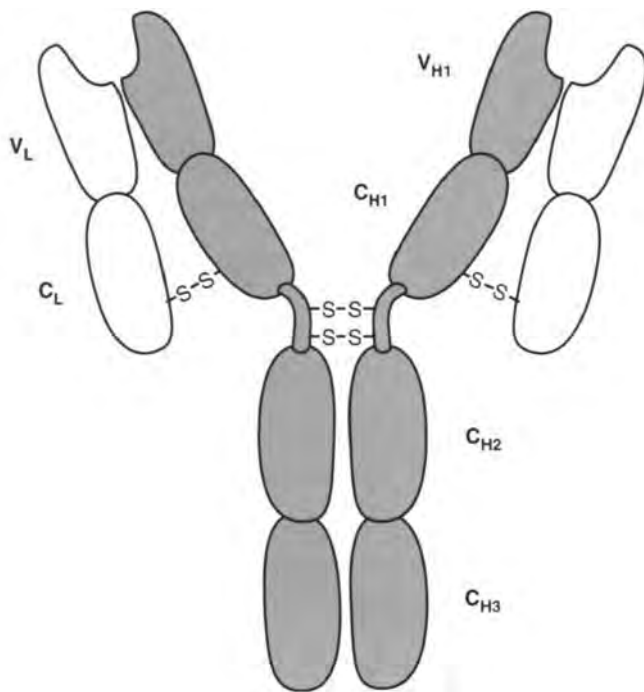

T cell function in the fetus and neonate is impaired compared with that in adults. Diminished functions include T cell participation in cutaneous DTH and, as also discussed in the next section, T cell help for B cell differentiation. Selectively decreased cytokine production by fetal and neonatal T cells, such as decreased IFN- $\gamma$  secretion and expression of CD40 ligand, may contribute to these deficits. The repertoire of  $\alpha\beta$ -TCR probably is adequate, except in early gestation. Following fetal or neonatal infection, the acquisition of CD4<sup>+</sup> T cell antigen-specific responses typically is delayed. In vitro studies suggest that deficiencies of DC function and activation and differentiation of antigenically naive CD4<sup>+</sup> T cells into memory/effector T cells may be contributory. In contrast with diminished CD4<sup>+</sup> T cell function, CD8<sup>+</sup> T cell-mediated cytotoxicity and cytokine production in response to strong chronic stimuli, such as congenital CMV infection or allogeneic cells, appear to be intact in the fetus and neonate. The mother does not transfer T cell-specific immunity to the fetus. T cell sensitization may occur during fetal life to environmental allergens, but such sensitization must be confirmed.

## B CELLS AND IMMUNOGLOBULIN

### Basic Aspects of B Cells and Immunoglobulin Production

#### Overview

Mature B cells are lymphocytes that are identifiable by their surface expression of immunoglobulin. Immunoglobulin, which is synonymous with antibody, is a heterotetrameric protein consisting of two identical heavy chains and two identical light chains linked by disulfide bonds (Fig. 4-8).<sup>570</sup> As with the TCR, the amino-terminal portion of the antibody chains is highly variable as a consequence of the assembly of V, D, and J gene segments (heavy chain) or V and J segments (light chain) to a monomorphic constant (C) region. Antibody molecules are distinct from the  $\alpha\beta$ -TCR, however, in

**Figure 4-8** Structure of an immunoglobulin molecule. The immunoglobulin molecule consists of two heavy chains (dark shading) and two light chains (unshaded) linked together by disulfide bonds. The antigen-combining site is formed by amino-terminal region of the heavy and light chains contained in the V<sub>H</sub> and V<sub>L</sub> domains of the heavy and light chains, respectively. For IgG, IgD, and IgA, the constant region C<sub>H3</sub> domain of the heavy chain encodes isotype or subclass specificity, which determines the ability of the immunoglobulin to fix complement, bind to Fc receptors, and be actively transported from the mother to the fetus during gestation. IgM and IgE (not shown) are structurally similar except that they contain an additional C<sub>H4</sub> domain conferring these properties, and they lack a hinge region.

that they typically recognize antigens found on intact proteins or other molecules, such as complex carbohydrates. Thus, the B cell recognition of antigen is typically highly sensitive to its three-dimensional structure.

B cells are activated to proliferate and differentiate into antibody-secreting cells after surface immunoglobulin (sIg) binds antigen. The sIg molecule is invariably associated with the nonpolymorphic membrane proteins, Ig- $\alpha$  (CD79a) and Ig- $\beta$  (CD79b), which, in conjunction with sIg, constitute the B cell receptor (BCR). Ig- $\alpha$  and Ig- $\beta$ , which are structural and functional homologues of the CD3 complex proteins, are expressed as disulfide-linked heterodimers and contain ITAM motifs in their cytoplasmic tails. As in T cells, these ITAMs act as docking sites for signaling molecules, such as the Lyn and Syk tyrosine kinases.

For B cells to be activated effectively and to produce antibody against protein antigens requires help from T cells in most cases. This help is in the form of soluble cytokines, such as IL-4 and IL-21,<sup>571</sup> and of cell surface-associated signals, such as CD40 ligand, which is transiently expressed on the surface of activated CD4<sup>+</sup> T cells. The engagement of CD40, which is constitutively expressed by the B cell, also is instrumental in inducing B cells to undergo immunoglobulin isotype switching, for example, from IgM to IgE (see Fig. 4-4). In isotype switching, the C region at the carboxy terminus of

the immunoglobulin heavy chain gene is replaced with another isotype-specific segment, but the antigen-combining site at the amino terminus is preserved. In cases in which the antigen has multiple and identical surface determinants (e.g., complex polysaccharides, certain viral proteins with repetitive motifs) and multiple sIgs are cross-linked, antigen binding alone may be sufficient to induce B cell activation without cognate (direct cell-cell interaction) help from T cells. In this case, other signals derived from non-T cells, such as cytokines, or from microorganisms, such as bacterial lipoproteins or bacteria-derived DNA containing unmethylated CpG motifs, may enhance antibody responses.<sup>572</sup>

As with T cells, B cells receive additional regulatory signals from the engagement of surface molecules other than the BCR that act as either co-stimulatory or inhibitory molecules. Of the co-stimulatory molecules, a complex consisting of CD19, CD21, and CD81 is best defined.<sup>573</sup> CD21, also known as complement receptor 2, binds the CD3d fragment of the C3 complement component. CD19 and CD81 transmit intracellular activation signals after complement binding to CD21. Gene disruption experiments indicate that expression of both CD19 and CD21 by B cells is essential for production of antibody to protein antigens.<sup>574</sup> Mice lacking complement receptor 2 (of which CD21 is one component) also have a reduced ability to respond to low doses of polysaccharide antigens, which may account for the increased susceptibility to infection with *Streptococcus pneumoniae* in these animals.<sup>575</sup>

The activation of B cells by BCR engagement and co-stimulation is counterbalanced by a number of surface molecules on the B cell that transmit inhibitory intracellular signals. For example, B cell activation is suppressed when a surface receptor for the Fc (fragment crystallizable) portion of IgG, Fc $\gamma$ RIIB, is engaged concurrently with the BCR by antigen-IgG complexes.<sup>576</sup> This serves as a negative feedback mechanism mediated by immunoreceptor tyrosine-based inhibitory motif (ITIM) motifs to limit antibody production; for example, gene knockout mice lacking Fc $\gamma$ RIIB have substantially increased levels of circulating antibody after immunization.<sup>577</sup>

In addition to their secretion of antibodies, mature B cells express MHC class II and also may participate in antigen processing and presentation to CD4<sup>+</sup> T cells. Memory B cells are probably more effective than antigenically naïve B cells, because they constitutively express higher surface levels of CD80 or CD86 molecules that provide co-stimulatory signals to T cells. Interactions between ICOS on the T cell and B7RP-1 (B7h or ICOS ligand) on the B cells may also be essential.<sup>197</sup> The preferential source of protein for antigenic peptides presented to T cells by B cells probably is sIg-protein complexes internalized from the cell surface. The internalized proteins are degraded to peptides that can then be presented back on the B cell surface bound to MHC class II molecules. Because the sIg-antigen interaction is of high affinity, B cell antigen presentation theoretically permits CD4<sup>+</sup> T cells to be activated at relatively low concentrations of antigen. Depending on the particular antigen, however, experimental conditions and nature of the responding T cell (naïve or memory), the presentation of protein antigen by resting (antigenically naïve) B cells can result in either CD4<sup>+</sup> T cell activation, apoptosis, or antigen-specific tolerance. The observation that CD4<sup>+</sup> T cell T<sub>H</sub>1 immunity is intact in patient with X-linked agammaglobulinemia suggests that B cells do not play a

central role in MHC class II antigen presentation.<sup>578</sup> DCs are likely to be more important than B cells for presenting protein antigens to CD4<sup>+</sup> T cells in vivo, particularly in an infectious or inflammatory context.

### **Immunoglobulin Structure and the Genetic Basis for Immunoglobulin Diversity**

The amino-terminal region of each pair of heavy and light chains is variable; together these form the antigen-binding fragment (Fab) portion of immunoglobulin, which contains the antigen-binding site (see Fig. 4-8). As with the TCR, the variable region of each chain can be subdivided into three hypervariable CDR1, CDR2, and CDR3 regions, and four intervening, less variable framework regions. The three-dimensional folding of the antibody molecules results in the approximation of the three CDR regions into a contiguous antigen recognition site, with CDR3 located at the center and the CDR1 and CDR2 regions forming the outer border of the site.<sup>579</sup> The carboxy-terminal portion of the heavy and light chain genes is monomorphic or constant (i.e., is a C region) and consists of three constant heavy (CH) domains and one constant light (CL) domain, respectively (see Fig. 4-8). The heavy chains also have a hinge region at which the two halves are joined by disulfide bonds. The heavy chain C region is the Fc portion of immunoglobulin and contains sites that determine complement fixation, placental transport, and binding to leukocyte Fc receptors. The portion of the heavy chain C region encoded by the last exon of heavy chain gene defines antibody isotype or isotype subclass, of which there are nine in humans: IgM, IgD, IgG<sub>1</sub>, IgG<sub>2</sub>, IgG<sub>3</sub>, IgG<sub>4</sub>, IgA<sub>1</sub>, IgA<sub>2</sub>, and IgE. Light chains comprise two types, kappa and lambda, each containing a distinct type of C region.

The heavy chain and kappa and lambda light chains are synthesized independently from genes located on human chromosomes 14, 2, and 22, respectively. Analogous to the  $\beta$  chain of the TCR, the heavy immunoglobulin chain is encoded by V, D, J, and C regions. Approximately 38 to 46 functional V segments and 23 different D segments are dispersed over 1100 kilobases (kb) of DNA upstream of the JC region.<sup>112</sup> There are six different J segments located near the C region. Antibody gene rearrangement is required to bring the V, D, and J regions together to form a single exon that is juxtaposed to the C region so that the gene can be expressed (see Fig. 4-4). The same recombinase enzyme complex required for TCR gene rearrangement, including the RAG-1 and RAG-2 proteins, mediates this process. The assembly of the light chain genes from multiple potential segments is similar, except that D segments are not used. The human kappa light chain gene locus consists of 30 to 35 functional V segments, 5 J segments, and a single C segment, and the human lambda light chain gene locus encodes 29 to 33 functional V segments and 4 to 5 functional J segments, with each J associated with its own C segment.<sup>112</sup> As in the TCR chains, the CDR1 and CDR2 regions of the antigen-combining site are encoded entirely by the V segments, and the CDR3 is encoded at the junction of the V, D, and J segments.

As with the TCR genes, antibody diversity is generated by the juxtaposition of various combinations of V, D, and J segments and the imprecision in the joining process itself. Nucleotides at junctions may be removed by exonucleolytic activity or, alternatively, added by the TdT enzyme or as

P nucleotides. Finally, in the case of the heavy chain gene, D-to-D joining can occur, and D segments also can rearrange by inversion or deletion.<sup>580</sup> Together, these mechanisms permit a theoretical immunoglobulin repertoire of more than 10<sup>12</sup> specificities to be generated from fewer than 10<sup>3</sup> somatic gene segments. For reasons that are not clear, however, immunoglobulin heavy chain V segment usage by immature pre-B cells and antigenically naïve B cells appears to be dominated by relatively few segments.<sup>581,582</sup> Thus, actual immunoglobulin diversity is less than would be predicted if segment usage were completely random. As in the case of the TCR genes, the CDR3 region appears to be the most important source of diversity.

The rearrangement process maximizes the generation of diversity at the expense of precision. Consequently, a majority of pre-B cells fail to produce a functional immunoglobulin molecule, do not mature, and subsequently die. The inefficiency of generating productive rearrangements for both heavy and light chains is offset by the high rate of proliferation of immature pro- and pre-B cells. Still further diversification is possible later in B cell differentiation by processes known as somatic mutation and receptor editing, which are described later on.

### **B Cell Maturation and Pre-immune Selection**

**Pro-B Cell and Pre-B Cell Maturation.** The pro-B cell is the most immature cell type that is known to be committed to differentiate along the B lineage. It is thought to be derived from a less mature lymphocyte progenitor that retains the capacity for differentiation into the major lymphocyte lineages. B cell differentiation may be a default pathway that occurs in the absence of Notch 1 signaling,<sup>583</sup> which promotes T-lineage cell development. Human pro-B cells have a CD10<sup>hi</sup>CD19<sup>hi</sup>CD34<sup>hi</sup> surface phenotype. They also express the RAG and TdT proteins and undergo D-to-J and then V-to-DJ immunoglobulin heavy chain gene rearrangements. D-to-J heavy chain gene rearrangements also may occur in immature lymphocytes that are not committed to the B lineage, but V-to-DJ rearrangement may be a characteristic feature of committed B-lineage cells. In cases in which the immunoglobulin heavy chain is productively rearranged, it is expressed cytoplasmically and on the B-lineage cell surface as part of the pre-BCR complex, which consists of a surrogate light chain (a VpreB and a  $\lambda 5/14.I$  segment<sup>584,585</sup>) in association with Ig- $\alpha$ -Ig- $\beta$  heterodimers. Expression of the pre-BCR complex defines the pre-B cell stage, and pre-B cells have a CD10<sup>hi</sup>CD19<sup>hi</sup>CD34<sup>-</sup> surface phenotype. Pro-B cells and pre-B cells of the adult are found only in the bone marrow. In the fetus, these cells are found in the liver and omentum and in smaller numbers in the lung and kidney.<sup>586</sup>

The heavy chain gene usually rearranges first, initially with a joining of a D segment to a J segment.<sup>587</sup> Rearrangement results in the excision of intervening DNA as signal joint circles (analogous to the TRECs generated during TCR gene rearrangement) so that the heavy chain gene segments can be transcribed as a single unit. If the D-to-J segment is productively rearranged, its transcripts are translated into DJC heavy chain protein. If a nonproductive D-to-J rearrangement occurs, a second attempt at productive D-to-J rearrangement usually is made by the heavy chain gene on the other chromosome 14. D-to-J heavy chain gene rearrangement and protein expression are followed by the joining of a V segment

to the D-to-J segment. Productive V(D)J rearrangement results in the expression of full-length heavy chain protein in the cytoplasm. In humans, the first easily recognized pre-B cells are those that contain cytoplasmic IgM heavy chains but no light chains or sIg.

The expression of the pre-BCR by the pre-B cell blocks rearrangement of the other heavy chain gene allele (allelic exclusion) and results in proliferation of the pre-B cell for four to five divisions,<sup>588</sup> with concurrent downregulation of RAG and TdT activity. The human pro-B cell to pre-B cell transition is dependent on the ability to form a functional pre-BCR complex and is blocked by mutations in the C $\mu$  segment of the heavy chain gene, Ig- $\alpha$ , the cytoplasmic Btk tyrosine kinase, and the B cell linker (BLNK) cytoplasmic adapter protein.<sup>589</sup> The requirement for Ig- $\alpha$ -Ig- $\beta$ , Btk, and BLNK probably is attributable to their role in pre-BCR signal transduction.<sup>589,590</sup> No known ligand for pre-BCR has been defined, and much of its extracellular domain of heavy chain is dispensable for its function,<sup>591</sup> suggesting that it may have ligand-independent basal signaling function. After cell proliferation, the pre-B cell exits from cycling, upregulates RAG and TdT activity, and promotes immunoglobulin light chain rearrangement.<sup>592</sup> In some pre-B cells, productive light chain rearrangements can occur in the absence of productive heavy chain rearrangements, at least in the fetal bone marrow, suggesting that heavy chain gene rearrangement is not obligatory for light chain rearrangement.<sup>587</sup>

After the expression of the pre-BCR, a similar process of gene rearrangement subsequently occurs to assemble light chain genes from V and J segments. Allelic exclusion also usually acts at the light chain level, so that only a single type of light chain is produced. Kappa light chain gene rearrangement usually occurs first, and if neither kappa chain gene rearrangement is productive, this apparently permits lambda chain gene rearrangement to proceed.<sup>593</sup> Approximately 60% of human immunoglobulin molecules utilize kappa light chains, and the remainder use lambda light chains.<sup>594</sup> If rearrangement and expression of a complete kappa or lambda light chain subsequently occur, a functional immunoglobulin molecule is assembled and expressed as sIg. The end result of allelic exclusion is that a B cell usually synthesizes only a single immunoglobulin protein, although each cell has the genetic information to produce two heavy chains and four light chains. Compared with that of the heavy chain, allelic exclusion of immunoglobulin light chains is relatively "leaky" such that 0.2% to 0.5% of circulating B cells express both a kappa and a lambda light chain in their surface IgM.<sup>595</sup>

#### **Transitional B Cells and Surface Ig-Mediated Selection.**

The initial expression of sIg by B-lineage cells is in the form of both the IgM and IgD isotypes. This is the result of alternative mRNA splicing of the exons of the heavy chain gene that encode isotype specificity. In human adults, these IgM<sup>hi</sup>IgD<sup>hi</sup> transitional B cells are distinct from pre-B cells in their lack of CD10 expression<sup>596</sup> and are the immediate precursors of B cell emigrants from the bone marrow. Murine studies indicate that after these transitional B cells emigrate from the bone marrow, they undergo further maturation in peripheral lymphoid organs, such as the spleen, to become fully mature naïve B cells.

Transitional B cells are similar to thymocytes in that they undergo negative and positive selection processes based on

sIg complex signaling before becoming mature naïve cells that are activated in the periphery by foreign antigens. Evidence for positive and negative selection of B cells in human adults comes from comparisons of the immunoglobulin repertoire of pre-B and transitional B cells versus that of mature naïve B cells.<sup>597</sup>

Positive selection of immature transitional B cells likely occurs in the bone marrow as well as in the periphery (see later) and requires an intact BCR complex and presumably involves either some interaction of the antigen-combining site of the BCR with self-molecules<sup>598</sup> or basal signaling by the BCR complex, or both.<sup>599</sup> In contrast with positive selection of thymocytes, which involves mainly cortical epithelial cells that present self-peptides, B cell positive selection is a poorly understood process.

Murine experiments, such as utilizing B cells expressing self-reactive transgenic sIg, have shown that negative selection can either eliminate (clonal deletion) or inactivate (clonal anergy) or change the Ig specificity (receptor editing) of potentially autoreactive antigenically naïve B cells in the bone marrow.<sup>600,601</sup> Clonal deletion may be favored when developing B cells encounter self-antigen displayed on cell membranes, and clonal anergy may be favored when these B cells encounter soluble self-antigen.<sup>600</sup> Receptor editing of the rearranged immunoglobulin chain genes occurs through secondary V-to-J light chain gene rearrangements. This involves V segments located 5' and J segments that are located 3' to the current VJ rearrangement. Replacement of V heavy chain gene segments with previously unrearranged upstream V segments in mature B cells also is possible, but this is a rare form of editing. As suggested by mouse studies, only 10% of naïve B cells produced in the bone marrow may leave the periphery to colonize peripheral lymphoid organs as a result of these negative selection processes. Receptor editing may be the predominant mechanism for B cell tolerance in the bone marrow.<sup>602</sup>

#### **Maturation of Transitional B Cells into Naïve B Cells.**

Transitional B cells of the murine spleen initially localize to the outer periarteriolar sheaths. The maturation of transitional B cells also requires engagement of the B-cell activating factor (BAFF) receptor with BAFF, a TNF ligand family member.<sup>603,604</sup> BCR-derived and other signal transduction events involved in positive selection also may determine whether these cells will become antigenically naïve follicular B cells, marginal zone B cells, or B-1 B cells, each of which has a distinct phenotype, location, and function in immunity. A critical parameter in determining the fate of transitional B cells is apparently BCR signal strength.<sup>605,606</sup> Similar fate decisions may occur among human transitional B cells, but information on the cellular and molecular events involved is limited. Follicular B cells include most of those that are those involved in adaptive immune responses to T-dependent antigens, such as proteins, and are the predominant naïve B cell subset of cells in the circulation or secondary lymphoid tissue. The following discussion of B cell activation and differentiation by foreign antigen applies to follicular B cells, unless noted otherwise. Marginal zone and B-1 B cells, which have distinct roles from follicular B cells in immunity, are discussed in separate sections later on.

The commitment to a follicular B cell fate results in upregulation of CXCR5. This chemokine receptor recognizes

CXCL13, a chemokine produced within the follicles that promotes the entry of the B cell into the follicle.<sup>607</sup> In some cases, negative selection of transitional B cells may occur by a process of follicular exclusion, in which they fail to upregulate CXCR5.<sup>600</sup> CXCR5 upregulation and follicular entry coincide with the acquisition of mature B cell functions, including a decreased tendency to undergo apoptosis after BCR engagement, an increased responsiveness to T cell help (e.g., CD40 ligand and soluble cytokines), increased expression of CD86, and maturation of intracellular signaling in response to BCR engagement.

### **Naïve B Cell Activation, Clonal Expansion, Immune Selection, and T Cell Help**

Mature antigenically naïve B cells of the follicular subset that survive positive and negative selection are IgM<sup>hi</sup>IgD<sup>hi</sup>CD27<sup>lo/-</sup>.<sup>608</sup> They also express CXCR4 and CXCR5, which promotes their recirculation between the follicles of the peripheral lymphoid organs, including the spleen, lymph nodes, and Peyer's patches, which express the chemokine ligands for these receptors, and the blood and lymph.<sup>609</sup> The encounter of naïve B cells of the follicle with antigen recognized by the sIg triggers their activation and proliferation under appropriate conditions. This may initially involve the formation of immune synapse with an APC, such as a DC, analogous to that formed as part of initial naïve T cell activation.<sup>610</sup> As with naïve T cells, activation of naïve B cells by BCR engagement has a relatively high signal threshold compared with that of memory cells,<sup>611</sup> a feature that may prevent inappropriate activation by low-affinity self-antigens. In the case of protein antigens, this is followed by antigen internalization and entry into the MHC class II antigen presentation pathway.<sup>612</sup> Activation also increases B cell expression of CCR7, which promotes B cell movement toward the outer border of the T cell zone,<sup>613</sup> and of OX40 ligand,<sup>614</sup> which can provide T cell co-stimulation.

In T cell-dependent activation, antigenically naïve CD4<sup>+</sup> T cells probably are first activated by DCs independently of B cells in the periarteriolar lymphoid sheath region of the spleen and the paracortical region of the lymph nodes. CD4<sup>+</sup> T cells that are activated by DCs bearing antigenic peptide-MHC class II complexes and CD80-CD86 co-stimulatory molecules express CD40 ligand, OX40, ICOS, and CXCR5.<sup>615,616</sup> These activated CD4<sup>+</sup> T cells may either leave the lymphoid organ to become effector or memory T cells or become CD4<sup>+</sup> T cells specialized to provide help to B cells.<sup>617</sup> CD4<sup>+</sup> T cells destined to leave the lymphoid organ and to enter sites of tissue inflammation and participate in inflammatory responses (e.g., T<sub>H</sub>1 cytokine secretion) are P-selectin<sup>hi</sup>, CXCR3<sup>+</sup>, and CXCR5<sup>+</sup>.

By contrast, CD4<sup>+</sup> T cells that are retained in the lymph node and that eventually enter the follicle as T follicular helper cells are P-selectin<sup>-</sup> and CXCR3<sup>-</sup> but express CXCR5. This CXCR5 expression promotes movement of these CD4<sup>+</sup> T cells to the outer border of the T cell zone, to contact antigen-activated B cells at the edge of the follicular zone (also known as the mantle region).<sup>618</sup> Here, CD4<sup>+</sup> T cell activation is reinforced by recognition of antigenic peptides displayed on MHC class II molecules of the B cell, and the interaction of CD40 ligand and OX40 on the T cell with CD40 and OX40 ligand on the B cell enhances B cell activation. OX40 engagement of the CD4<sup>+</sup> T cell also promotes its

differentiation into an effector cell producing T<sub>H</sub>2 rather than T<sub>H</sub>1 cytokines and promotes upregulation or retention of expression of CXCR5. These CXCR5<sup>hi</sup> CD4<sup>+</sup> T cells then enter into the follicle, where they provide help to B cells as T follicular helper cells.<sup>193,194</sup> T follicular helper cells are CD57<sup>hi</sup><sup>619</sup> and provide B cell help by expressing CD40 ligand, secreting cytokines such as IL-4<sup>620</sup> and, probably, IL-21,<sup>571</sup> and providing ICOS-dependent B cell co-stimulation.<sup>621</sup>

During the initial immune response, most antigenically naïve follicular B cells are derived from clones expressing antibody variable regions with relatively low affinity for antigen. As in the case of the TCR, activation through the BCR is also not necessarily an all-or-none phenomenon. For example, high-affinity binding to IgM of the BCR may allow B cell proliferation to occur in the absence of any T cell help, whereas lower-affinity binding may result in proliferation only in the presence of additional T cell-derived signals.<sup>622</sup>

Antigen-specific B cells proliferate strongly within the B cell follicle, leading to the formation of germinal centers. The more avidly the B cell binds antigen, the stronger is the stimulus to proliferate. The major source of antigen for triggering the extensive B cell proliferation of the germinal center may be provided by antigen complexed with antibody bound to Fc receptors on follicular DCs, although this point is controversial.<sup>623</sup> The follicular DC is a nonhematopoietic cell type that appears to have the unusual capacity to bind antigen-antibody complexes for long periods on their cell surface.

Immunoglobulin variants are generated among germinal center B cells by the process of somatic hypermutation, in which immunoglobulin genes accumulate apparently random point mutations within productively rearranged V, D, and J segments. These variants undergo a selection process favoring B cells that bear sIg with high affinity for antigen. Such high-affinity immunoglobulin provides high levels of BCR signaling, favoring germinal center B cell survival rather than a default pathway of apoptosis. Somatic hypermutation requires an activation-induced cytidine deaminase (AID), which is expressed only by germinal center B cells.<sup>624</sup> It remains unclear how the effects of the mutator are focused on the variable region of immunoglobulin and its immediate flanking sequences. The peak of somatic mutation is approximately 10 to 12 days after immunization with a protein antigen.<sup>625</sup> Although some light chain receptor editing may occur in human germinal centers, it does not appear to be an important influence on shaping the final immunoglobulin repertoire after somatic hypermutation takes place.<sup>626</sup>

Germinal center B cells that receive appropriate survival signals leave the germinal center to persist as memory B cells, which are CD27<sup>hi</sup>.<sup>608</sup> The engagement of CD40 on germinal center B cells by CD40 ligand on T cells is absolutely required for memory B cell generation but may not be involved in initial germinal center B cell proliferation.<sup>627</sup> Efficient memory B cell generation requires the binding by CD21 on B cells of C3 complement components, such as C3d, apparently derived from the classic complement pathway.<sup>628</sup> Once a memory B cell is generated, further somatic mutation of its immunoglobulin genes apparently does not occur.<sup>629</sup> Memory B cells enter the recirculating lymphocyte pool, where they preferentially colonize the skin and mucosa, sites that are likely to have direct contact with antigen, as well as the marginal zone of the spleen, where they are poised to respond to

blood-borne antigens. Once memory B cells are generated, they appear to persist indefinitely even in the absence of any subsequent exposure to the inciting antigen.<sup>630-632</sup>

### **Generation of Plasma Cells and the Molecular Basis for Immunoglobulin Secretion**

Some activated B cells become plasmablasts and migrate to extrafollicular regions of the lymph node or spleen, where they become short-lived plasma cells that mainly produce IgM. Differentiation of these plasma cells does not require and may be inhibited by the CD40 ligand–CD40 interaction.<sup>633</sup> This accounts for relatively normal or increased IgM responses in patients with genetic deficiency of CD40 ligand. In the absence of CD40 engagement, germinal center B cells that have survived the selection process probably differentiate by a default pathway to become long-lived plasma cells, which can persist in the spleen and bone marrow for at least a year.<sup>634</sup> In mice, long-lived plasma cells are distinguishable from short-lived plasma cells by their lack of MHC class II expression.<sup>634</sup> Plasma cells are concentrated in peripheral lymphoid tissue, liver, and bone marrow, as well as in lymphoid tissue of the gastrointestinal and respiratory tracts.

The membrane-bound form of immunoglobulin is slightly longer than the secreted form and contains a carboxy-terminal region that anchors the molecule in the cell membrane. The secretory form of immunoglobulin lacks this membrane-anchoring segment as a result of a change in splicing of the heavy chain mRNA. Maturation of B cells into plasma cells is associated with a marked increase in their capacity to secrete immunoglobulin and with loss of sIg expression. Plasma cells rather than mature B cells account for most of the secreted antibody during both primary and secondary immune responses. Human memory B cells can differentiate into plasma cells in response to antigen-independent mechanisms, such as exposure to oligonucleotides containing unmethylated CpG DNA (a ligand for TLR-9) or activated T cells.<sup>632</sup> Such polyclonal activation of memory B cells has been proposed to maintain levels of specific antibody for a lifetime once a memory B cell response has been generated.

### **Switching of Immunoglobulin Isotype and Class**

Human B cells produce five isotypes of antibody: IgM, IgD, IgG, IgA, and IgE. The IgG and IgA isotypes can be, respectively, divided into the IgA<sub>1</sub> and IgA<sub>2</sub> and the IgG<sub>1</sub>, IgG<sub>2</sub>, IgG<sub>3</sub>, and IgG<sub>4</sub> subclasses. During their process of differentiation into plasma cells, B cells are able to change from IgM to other antibody isotypes without changing antigen specificity (see Fig. 4-4). With the exception of IgD expression, this switching usually involves isotype recombination, the genetic replacement of the IgM-specific portion of the constant region (C<sub>H</sub>) of the heavy chain with a new isotype-specific gene segment. As in V(D)J recombination, the intervening DNA is excised as a large circle. Isotype recombination is mediated by switch regions that are positioned immediately upstream of each of the isotype-specific C regions, with the exception of IgD. Successive multiple isotype switching by a single B cell also can occur, for example, IgM to IgA to IgG to IgE.<sup>635</sup>

Genetic studies of the hyper-IgM syndrome, in which there is a generalized block in isotype switching from IgM to

other isotypes, have revealed that the process requires interactions between CD40 ligand on the T cell and CD40 on the B cell, the AID gene product (which also is required for somatic hypermutation), and the uracil *N*-glycolyase (UNG) enzyme.<sup>624</sup> Mutations in all of these genes have been identified in persons with the hyper-IgM syndrome, but the precise function of AID and UNG in this process remains unclear. Secreted cytokines derived from T cells or other cell types play an important role in promoting or inhibiting switching to a specific isotype. For example, IL-4 or IL-13 is absolutely required for isotype switching to IgE, a process that can be inhibited by the presence of IFN- $\gamma$ .<sup>636</sup> Cytokine-induced switching to a particular isotype segment strongly correlates with the cytokine-inducing transcription that is initiated immediately upstream of this region. In some instances, hormones also may play a role in isotype switching. For example, vasoactive intestinal peptide in conjunction with CD40 engagement can induce human B cells to produce high levels of IgA<sub>1</sub> and IgA<sub>2</sub>.<sup>637</sup>

During a primary immune response, isotype switching by B cells appears to occur shortly after these cells enter into the follicle.<sup>638</sup> These B cells may have received the requisite T cell–derived signals (i.e., cytokines and CD40 ligand) during their interaction with T cells at the border between the follicle and T cell zones. Switch recombination after primary immunization is evident in peripheral lymphoid tissue 4 days after immunization with protein antigen and peaks between 10 and 18 days.<sup>639</sup> Switch recombination also is triggered during memory B cell responses, is detectable within 24 hours of secondary immunization, and peaks between 3 and 4 days.<sup>639</sup> Most memory B cells or plasma cells switch to another isotype by gene rearrangement, and somatic mutations are most common in antibodies other than IgM. Some adult B cells express surface IgM but not IgD or other isotypes, however; these cells appear to consist of memory B cells that have not undergone isotype switching but are somatically mutated.<sup>640</sup> Somatic hypermutation also occurs in IgM<sup>+</sup> B cells from patients with CD40 ligand deficiency.<sup>641</sup> Finally, isotype switching and memory B cell generation without somatic hypermutation occur in mice lacking Bcl-6, a mutation that results in the absence of germinal centers.<sup>642</sup> Thus, isotype switching and somatic hypermutation can occur independently in at least some contexts.

### **Regulation of B Cell Proliferation and Differentiation**

B cell activation and differentiation are subject to regulation at multiple steps by cell-cell contact and soluble factors, as well as by intracellular signaling molecules and transcription factors. Such regulation may be specific for particular stages of B cell development. For example, Btk, a tyrosine kinase expressed by B-lineage cells, plays a role in cell activation after engagement of the pre-BCR or BCR complexes. Functional mutations in Btk result in the syndrome of X-linked agammaglobulinemia, in which B cell development is arrested at a pre-B cell stage.<sup>643</sup> BAFF, a TNF ligand family member, which is produced by mononuclear phagocytes and DCs, is important for B-lineage cell survival and proliferation at later stages, such as the transitional and mature B cells.<sup>644</sup> By contrast, the engagement of CD40 by CD40 ligand is not required for B cell development but is essential for the

generation of memory B cells from mature antigenically naïve B cells.<sup>195</sup> Cytokines, such as TNF- $\alpha$ , and chemokines, such as CXCL12 (SDF-1), that are expressed in the bone marrow microenvironment appear to be important for long-term plasma cell survival.<sup>645</sup> As previously discussed, most cytokines secreted by T cells, such as IL-2, IL-4, and IFN- $\gamma$ , are not essential for B cell development but are important regulators of B cell isotype.<sup>636</sup>

Finally, particular transcription factors or combination of these play key roles in regulating virtually all of the steps of B-lineage cell differentiation. For example, the Pax-5 transcription factor acts as both a transcriptional activator of many genes involved in B cell development and as a transcriptional repressor of inappropriate non-B cell lineage genes.<sup>646</sup> In the case of plasma cell differentiation, the B lymphocyte-induced maturation protein-1 (BLIMP-1) transcription factor inhibits the activity of Pax5 and promotes a gene expression program that favors plasmablast differentiation and antibody secretion.<sup>647</sup>

### Marginal Zone B Cells of the Spleen

Spleen marginal zone memory B cells can be distinguished from antigenically naïve B cells by their high levels of surface expression of CD148, a protein tyrosine phosphatase, and CD27.<sup>648</sup> The human spleen has distinct anatomic sites that may play specialized roles in the production of antibody against blood-derived particulate antigens and purified repetitive carbohydrate antigens. Important examples of such carbohydrate antigens are the capsular polysaccharides of pathogenic bacteria, such as *S. pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Antigens and leukocytes enter the spleen through vascular sinusoids located in the red pulp that are in proximity to the marginal zone area. The white pulp area contains periarteriolar sheaths of lymphocytes, mainly T cells, as well as periarteriolar follicles, which are mainly B cells. These, in turn, are surrounded by a microanatomic site known as the marginal zone that contains loose clusters of B cells, DCs, macrophages, and some CD4<sup>+</sup> T cells.<sup>649</sup>

Marginal zone B cells have unique phenotypic and functional properties that may be important in their response to blood-borne particulate antigens and to polysaccharide antigens. Murine and human marginal zone B cells of the spleen have similar IgM<sup>hi</sup>IgD<sup>lo</sup>CD21<sup>hi</sup> surface phenotypes<sup>650</sup> and include naïve and memory B cell subsets.<sup>651-653</sup> Compared with naïve follicular B cells, marginal zone B cells express lower levels of IgD and CD23 and higher levels of CD21. Marginal zone B cells, along with B-1 B cells, which are discussed later on, are important sources of early IgM response to blood-borne antigens, such as those associated with the surface of circulating bacteria.<sup>654</sup> The high levels of CD21 expression by marginal zone B cells may facilitate their binding of C3d-coated blood-borne antigens, such as encapsulated bacteria.<sup>575</sup> In addition, marginal zone B cells are more readily activated by non-BCR signals, such as LPS, and more rapidly become effector cells than naïve follicular B cells after activation.<sup>655</sup> This enhanced reactivity may be important in their being able to respond to purified polysaccharide antigens in the absence of T cell signals. Marginal zone B cells also appear “poised” to differentiate into plasmablasts because of their constitutive expression of the BLIMP-1 transcription

factor, which acts as a master transcriptional regulator promoting plasma cell differentiation.<sup>647</sup>

Splenic B cells of the marginal zone have been implicated as the key population in mediating responses to blood-borne particulate antigens. These particulate antigens may be taken up immature DCs in the blood and transported to the spleen, where they interact with marginal zone B cells to rapidly induce IgM-secreting plasmablasts.<sup>654,656</sup> Splenic marginal zone B cells also may be required for the generation of antibody responses to purified polysaccharide antigens. As discussed later on, this immune response does not require T cell help (see section on development of B cell capacity to respond to T cell-dependent [TD] and T cell-independent [TI] antigens). Immunization with TI antigens before human splenectomy maintains the capacity of the immune system to respond to these antigens subsequently.<sup>657</sup> This finding suggests that the activation of splenic B cells recognizing polysaccharide antigens may result in their migration and persistence in other lymphoid organs. The pathways by which capsular polysaccharide antigens reach the marginal zone are unknown, and the role that marginal zone DCs or macrophages play in activating marginal zone B cells to produce antibody to purified polysaccharides remains poorly understood.

How human marginal zone B cells differentiate from naïve precursors also remains poorly understood. In mice, transitional B cells of the spleen appear to give rise to naïve marginal zone cells in cases in which BCR signaling is relatively weak. Transitional B cells that express low levels of CD1d have been proposed as the immediate precursors of murine marginal zone B cells, which are CD1<sup>hi</sup>,<sup>606</sup> but whether human marginal zone B cells are CD1<sup>hi</sup> remains unclear. Murine marginal zone B cells express relatively high levels of the LFA-1 and VLA-4 integrins. These integrins are involved in retaining these B cells in the marginal zone compartment by binding to their respective ligands—ICAM-1 and VCAM-1.<sup>658</sup>

The origin of marginal zone B cells that participate in the response to polysaccharide antigens also remains controversial. Naïve marginal zone B cells are relatively sessile, which had suggested that this population would be the major contributor to polysaccharide antigen responses in vivo. A recent study, however, suggests that naïve follicular B cells in the circulation can enter the marginal zone and acquire a marginal zone phenotype and respond to purified polysaccharide immunization in the absence of T cell help.<sup>659</sup> These findings, which require confirmation, raise the possibility that the splenic microenvironment may induce B cells with a follicular phenotype to acquire the characteristics and immunologic function of marginal zone B cells.

### B-1 and B-2 Cells

B cells that express CD5 and that have low levels of surface expression of CD45RA appear to represent a distinct B cell subset that has been termed B-1. The B-1 subset can be further divided into B-1a cells, in which CD5 is expressed on the cell surface, and B-1b cells, in which CD5 expression is limited to the RNA level.<sup>660</sup> B cells that lack CD5 mRNA or protein expression and that are CD45RA<sup>hi</sup> compose the B-2 lineage; they include most of the peripheral B cells in the adult, as well as most marginal zone B cells of the spleen. In mice, B-1 cells are restricted largely to the peritoneal and

pleural cavities; this compartmentalization suggests a specialized function.<sup>654</sup> By contrast, human B-1a cells are more widely distributed in the circulation and in the follicular mantle regions of the tonsil, spleen, and other lymphoid tissue.<sup>650</sup>

In mice, naïve B-1 cells and marginal zone B cells both are important contributors to the early production of IgM in response to blood-borne particulate antigens and to other T-independent antigens. Murine B-1 cells and marginal zone B cells also share other features that are distinct from follicular B cells, such as expression of CD9, a high level of effectiveness as APCs for T cells in vitro, an enhanced capacity to be activated by LPS or CD40 engagement, and an ability to rapidly enter the cell cycle after activation.<sup>654</sup> It is possible that these common features are involved in the rapid onset of immune responses mediated by B-1 and marginal zone B cells. In contrast with mice, however, most human B-1 cells have an IgM<sup>hi</sup>IgD<sup>hi</sup>CD21<sup>lo</sup>CD23<sup>hi</sup> surface phenotype that is distinct from that of human splenic marginal zone B cells, which are predominantly IgM<sup>hi</sup>IgD<sup>lo/-</sup>CD21<sup>hi</sup>CD23<sup>-</sup>.<sup>650</sup> These phenotypic differences, along with those in cell distribution, raise the possibility that the B-1 cells in humans may have immunologic roles distinct from those of murine B-1 cells and marginal zone B cells.

B-1 and B-2 cells appear to be subject to different positive and negative influences of the preimmune (i.e., before exposure to foreign antigen) immunoglobulin repertoire.<sup>661,662</sup> B-1 cells have a tendency to produce antibodies that are mainly of the IgM isotype and that are polyreactive; that is, individual antibodies typically are of low affinity but are able to react with multiple unrelated antigens. In contrast with B-1 cells, B-2 cells typically produce high-affinity antibodies that usually are monoreactive, bind only a single antigen or highly related antigens,<sup>663</sup> and often are of isotypes other than IgM.<sup>664,665</sup> B-1 cells are commonly reactive with both self-antigens, such as DNA, and foreign antigens, such as viral proteins or bacteria-derived products, such as phosphorylcholine. In mice, strong BCR signals during transitional B cell maturation favor differentiation into B-1 cells over other cell fates, and this may account for the tendency of these cells to be polyreactive. The expression on B-1a cells of CD5, which probably serves as a negative regulator of BCR signaling, may help protect autoreactive B-1a cells from negative selection and apoptosis.<sup>654</sup> Murine B-1 cells also may be relatively resistant, compared with B-2 cells, to the induction of Fas expression after CD40 engagement, and to Fas-mediated apoptosis.<sup>654</sup>

In the adult human, somatic hypermutation of immunoglobulin molecules is common for both B-1 and B-2 cells. This finding suggests that both cell types in humans are subject to an antigen-driven selection process after activation<sup>662,666</sup> and that activated B-1 cells tend to become memory cells that have not undergone isotype switching.<sup>667</sup> Whether B-1 cells are derived from a separate lineage or are induced to differentiate from a common precursor that is shared with B-2 cells<sup>668</sup> remains controversial.

As discussed later, B-1 cells predominate during early fetal development. These cells have been proposed to play a role in regulation and development of the immune system in early ontogeny, perhaps in the induction of tolerance to self-antigens, or in host defense, by provision of polyreactive IgM antibodies that are pathogen reactive.

## Ontogeny of B Cells and Immunoglobulins

### B Cell Development and Immunoglobulin Isotype Expression

**Conventional B Cells.** Pre-B cells are first detected in the human fetal liver and omentum by 8 weeks of gestation and in the fetal bone marrow by 13 weeks of gestation.<sup>669,670</sup> Between 18 and 22 weeks of gestation, pro- or pre-B cells also can be detected in the liver, lung, and kidney.<sup>586</sup> These fetal organs also express the CXCL12 (SDF-1) chemokine, which serves as a critical chemoattractant for B cell precursors expressing the CXCR4 chemokine receptor.<sup>671</sup> These findings raise the possibility that B cell lymphopoiesis may occur in these organs in situ at this stage of fetal development.

By mid-gestation, the bone marrow is the predominant site of pre-B cell development.<sup>672</sup> B cell lymphopoiesis occurs solely in the bone marrow after 30 weeks of gestation and for the remainder of life.<sup>586</sup> The neonatal circulation contains higher levels of CD34<sup>+</sup>CD38<sup>-</sup> progenitor cells that are capable of differentiating into B cells than are found in the bone marrow compartment of children or adults.<sup>673</sup> The concentration of B cells in the circulation is higher during the second and third trimesters than at birth and further declines by adulthood.<sup>287,674</sup> B cells expressing surface IgM are present by 10 weeks of gestation.<sup>669</sup> Unlike IgM<sup>+</sup> adult B cells in the peripheral lymphoid organs, most of which also express surface IgD, fetal B cells at this stage express IgM without IgD.<sup>669,675</sup> Such IgM<sup>+</sup>IgD<sup>-</sup> B cells constitute a transitory stage between pre-B cells and mature IgM<sup>+</sup>IgD<sup>+</sup> B cells, and it is at this stage that the CD21 surface molecule is expressed.

Murine studies have shown that exposure of transitional IgM<sup>+</sup>IgD<sup>-</sup> B cells to antigens, including those found in the adult bone marrow, results in clonal anergy rather than activation.<sup>676</sup> The susceptibility of transitional IgM<sup>+</sup>IgD<sup>-</sup> cells to clonal anergy maintains B cell tolerance to soluble self-antigens present at high concentrations. Thus, antigen exposure in utero may induce B cell tolerance rather than an antibody response and may account for the observation that early congenital infection sometimes results in pathogen-specific defects in immunoglobulin production. In some cases, such as congenital mumps, these defects may occur despite normal T cell responses, such as DTH,<sup>544</sup> suggesting a direct inhibitory effect on antigen-specific B cell function.

Between 8 and 11 weeks of gestation, transcripts for IgA and IgG can be detected in the liver,<sup>677</sup> followed shortly by the appearance of B cells bearing sIg of the IgA, IgG, and IgD isotypes. By 16 weeks of gestation, fetal bone marrow B cells expressing sIg of all heavy chain isotypes are detectable.<sup>678</sup> The stimulus for isotype switching during fetal development remains unclear, because in the adult, isotype switching typically occurs in response to B cell activation by foreign protein antigens. The frequency of B cells in tissues rapidly increases, so that by 22 weeks of gestation, the proportion of B cells in the spleen, blood, and bone marrow is similar to that in the adult.<sup>675,669</sup>

Neonatal B cells have increased surface levels of IgM compared with those for adult B cells; these differences persist for several years.<sup>679,680</sup> In a flow cytometric study in which nonspecific binding was carefully excluded, neonatal B cells expressing surface IgG or IgA were below the limit of detectability (i.e., less than 1% of circulating B cells).<sup>681</sup> True

germinal centers in the spleen and lymph nodes are absent during fetal life but appear during the first months after postnatal antigenic stimulation.<sup>682</sup>

**B-1 Cells.** Another distinct feature of fetal and neonatal B cells is the high frequency of CD5 expression, indicating that they belong to the B-1a subset.<sup>683</sup> More than 40% of B cells in the fetal spleen, omentum, and circulation at mid-gestation are CD5<sup>+</sup>,<sup>664,665,684</sup> but lesser numbers are found in the fetal liver and bone marrow.<sup>684</sup> CD5<sup>+</sup> B cells also are present in the neonatal circulation<sup>280</sup> and gradually decline with postnatal age.<sup>664,685,686</sup> Like adult B-1a cells, the fetal and newborn B-1a cells express IgM antibodies that are polyreactive, including reactivity with self-antigens, such as DNA.<sup>663-665,687</sup>

Although CD5<sup>+</sup> B cells may help to regulate the immune system in early ontogeny, including the induction of tolerance to self-antigens, they lack most surface markers characteristic of previously activated B cells.<sup>664</sup> The extent to which human CD5<sup>+</sup> and CD5<sup>-</sup> B cells represent distinct lineages remains contentious. For example, activation using a combination of antibody to IgM, engagement of CD40, and exogenous IL-4 results in the loss of CD5 expression by both neonatal and adult CD5<sup>+</sup> cells,<sup>680</sup> raising the possibility of a precursor-product relationship between CD5<sup>+</sup> and CD5<sup>-</sup> B cells.

B-1 cells constitute the major source of the low amounts of circulating “natural” IgM present at birth produced in the absence of antigenic stimulation. Murine studies have defined a role for natural IgM: Mice in which secretory but not surface IgM was eliminated by gene targeting had decreased primary responses to T cell-dependent antigens<sup>688</sup> and an increased susceptibility to acute peritonitis from endogenous bacteria due to a lack of natural IgM antibodies.<sup>689</sup> Although natural IgM antibodies are of low affinity, they can activate complement, which may allow antigenically naïve B cells to become activated as a result of receiving of co-stimulation via CD21 (complement receptor 2). Natural IgM does not appear to play a role in enhancing the response to polysaccharide antigens, at least in mice.<sup>688-690</sup>

### Development of the Immunoglobulin Repertoire

**V(D)J Segment Usage.** The primary or preimmune immunoglobulin repertoire, which consists of all antibodies that can be expressed before encounter with antigen, is determined by the number of different B cell clones with distinct antigen specificity. This preimmune immunoglobulin repertoire is limited during the initial stages of B cell development in the fetus in comparison with that in the adult. In the early to mid-gestation human fetus, the set of V segments used to generate the heavy chain gene is smaller than in the adult.<sup>691,692</sup> The V segments are scattered throughout the heavy chain gene locus.<sup>693</sup> Differences in the usage of particular heavy chain D and J segments between the first and second trimesters and term also have been identified.<sup>580</sup> These developmental differences are intrinsic rather than the result of environmental influences, because they occur in immature B cell precursors lacking a pre-BCR complex.

By the third trimester, the V and D segment heavy chain gene repertoire of peripheral B cells appears to be similar to that of the adult, although there may be overrepresentation of certain segments, such as DH7-27.<sup>694</sup> Certain heavy chain

V segments expressed in adult B cells are not found in neonatal B cells,<sup>695,696</sup> but it is unlikely that this limits the neonatal humoral immune response. Other V segments, such as V<sub>H3</sub>, are present at a greater frequency in the preimmune Ig repertoire.<sup>696,697</sup> This increased representation may confer on antibody molecules the ability to bind protein A of *S. aureus*, thus providing some intrinsic protection during the perinatal period.

**Role of CDR3 Length and Terminal Deoxytransferase.** The length of the CDR3 region of the immunoglobulin heavy chain, which is formed at the junction of the V segment with the D and J segments, is shorter in the mid-gestation fetus than at birth<sup>698</sup> or in adulthood, including in pre-B cells.<sup>699</sup> This is due, in part, to decreased TdT, which is responsible for N-nucleotide additions. This decreased TdT expression is an intrinsic property of neonatal CD34<sup>+</sup> precursor cells not yet committed to the B lineage, because in vitro differentiation of B-lineage cells from neonatal CD34<sup>+</sup> cells results in lower amounts of TdT than are present in similar cells generated from adult CD34<sup>+</sup> cells.<sup>700</sup>

Up to 25% of heavy chain CDR3 regions in fetal B cells lack N additions, and in the remaining, the size of the N-nucleotide additions is smaller than for neonatal or adult CDR3 regions. The CDR3 region is the most hypervariable portion of immunoglobulins, and a short CDR3 region significantly reduces the diversity of the fetal immunoglobulin repertoire.<sup>695</sup> The CDR3 region of the heavy chain gene remains relatively short at the beginning of the third trimester and gradually increases in length until birth.<sup>137,694,701,702</sup>

Because the CDR3 region is at the center of the antigen-binding pocket of the antibody,<sup>579</sup> reduced CDR3 diversity could limit the efficiency of the antibody response. A complete lack of amino-terminal additions would be predicted to result in antibodies with combining sites that are relatively flat and potentially inefficient at combining with antigen.<sup>580</sup> The importance of shortened CDR3 regions by themselves in limiting antibody responses is doubtful, however, because gene knockout mice lacking TdT produce normal antibody responses following immunization or infection.<sup>268</sup> Although a combination of lack of TdT and limitations in V and D usage could limit the ability of the fetal B cells to recognize a full spectrum of foreign antigens, particularly before mid-gestation, such a “hole in the repertoire” has not been documented.

In mice, premature expression of TdT during fetal development achieved by transgenesis appears to be detrimental in adulthood by preventing the appearance of certain antibody specificities, such as with antibodies that are reactive with phosphorylcholine.<sup>703</sup> This perturbation results in the increased susceptibility of mice to *S. pneumoniae*, which contains phosphorylcholine as a cell wall component, and suggests that a lack of TdT expression during early ontogeny may be important for normal repertoire formation.

An analysis of productive and nonproductive lambda light chain gene repertoire of the human fetal spleen at 18 weeks of gestation found evidence indicating positive selection, receptor editing (an indication that developing B cells are encountering self-antigens that mediate negative selection), and expansion of B cells expressing specific light chains.<sup>704</sup> Similar findings apply to the kappa light chain repertoire of cord blood B cells.<sup>705</sup> Together, these findings suggest that the

preimmune fetal immunoglobulin repertoire is significantly shaped by self-antigens.

**Somatic Hypermutation.** Although most neonatal and fetal immunoglobulin heavy chain gene variable regions appear not to have undergone somatic mutation,<sup>696,698</sup> the relevant studies examined heavy chain transcripts for IgM, an isotype in which somatic mutation is uncommon in the adult, except in IgM<sup>+</sup>IgD<sup>-</sup> memory B cells.<sup>706,707</sup> By contrast, somatic mutations are detectable in some neonatal B cells expressing IgG or IgA transcripts.<sup>702</sup> Among neonatal B cells that bear somatic mutations, the mutational frequency per length of DNA is similar to that of adult B cells. Together, these observations indicate that somatic hypermutation occurs normally by birth in the B cell compartment.

### Neonatal B Cell Surface Phenotype

In adults, CD10 expression ceases at the antigenically naïve B cell stage. By contrast, most fetal bone marrow and spleen B cells express CD10.<sup>683,708</sup> CD10<sup>+</sup> B cells may constitute an immature transitional population but are functionally mature as indicated by their ability to undergo isotype switching. Small numbers of CD10<sup>+</sup> B cells are found at birth and these gradually decline during infancy.<sup>709</sup>

Increased expression of CD38 on neonatal B cells also has been observed.<sup>679,680</sup> Unfractionated neonatal B cells, a majority of which are CD5<sup>+</sup>, and adult naïve B cells have similar levels of surface IgD, CD19, CD21, CD22, CD23, CD40, CD44, CD80, CD81, and CD86.<sup>679,680,710-713</sup> Expression of the CCR6 and CXCR5 chemokine receptors is similar by both cell types,<sup>714,715</sup> but neonatal B cells may have modestly lower levels of CCR7 than those observed in adult cells.<sup>715</sup> Rijkers and colleagues<sup>716</sup> reported that neonatal B cells also have reduced CD21 expression, possibly accounted for by an increased percentage of CD21<sup>-</sup> cells in the neonatal CD5<sup>-</sup> B cell subset.<sup>711</sup> Surface expression of the FcγRII receptor (CD32) is reduced on neonatal B cells,<sup>679,717</sup> possibly rendering them less subject to the inhibitory effect of antigen-antibody complexes.

Neonatal CD5<sup>-</sup> B cells have reduced expression of several adhesion molecules, including CD11a, CD44, CD54 (ICAM-1), and L-selectin.<sup>715,718</sup> A similar reduction is found in the CD5<sup>-</sup> B cells of adult patients during the first 3 months after either autologous or heterologous bone marrow transplantation but resolves by 14 months after transplantation.<sup>718</sup>

Circulating neonatal B cells have lower levels of MHC class II than those observed for adult splenic B cells and, unlike adult cells, an inability to increase intracellular calcium after engagement of MHC class II by mAb.<sup>719</sup> Moreover, because neonatal B cells proliferate as well as or better than adult splenic B cells after MHC class II engagement,<sup>719</sup> these alterations in signaling appear unlikely to compromise neonatal B cell function. A more recent finding<sup>720</sup> is absence of significant differences in MHC class II expression by circulating fetal B cells of the third trimester of pregnancy and in that by adult cells.

Cerutti and colleagues<sup>721</sup> reported that circulating neonatal B cells, of which approximately 90% were of the B-1a subset, expressed CD28, which typically is found on T cells and not on B cells. Neonatal B cells also expressed substantially more CD27 and CD80 than do adult spleen B cells, in which greater than 95% of the cells are of the B-2

subset. Whether this unusual neonatal surface phenotype also applies to the adult B-1a subset was not determined. What role CD28 on B cells plays in the immune response in vivo also is unclear. Nonetheless, the presence of CD80 and CD27, markers for adult memory B cells, suggest that some circulating neonatal B-1a cells have undergone activation in vivo.

### Fetal and Neonatal T Cell-Dependent Immunoglobulin Production and Isotype Switching

Early in vitro studies of neonatal immunoglobulin production utilized PWM, a polyclonal activator of both T and B cells. In this system, immunoglobulin production was low compared with that in adults, and mixing experiments suggested that neonatal T cells acted as suppressors of immunoglobulin production by either adult or neonatal B cells. Further fractionation of the T cell populations in this assay suggested that in the absence of memory/effector T cells, antigenically naïve (CD45RA<sup>hi</sup>CD45RO<sup>lo</sup>) CD4<sup>+</sup> T cells of either the neonate or the adult acted as suppressors of antibody production.<sup>221</sup> The relevance of the suppression to neonatal B cell responses in vivo remains unclear, however. In any case, priming of neonatal or adult antigenically naïve CD4<sup>+</sup> T cells in vitro resulted in their acquisition of a CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> phenotype and, concurrently, an ability to enhance rather than suppress PWM-induced immunoglobulin production.<sup>221</sup> This increased capacity for B cell help probably reflects the fact that priming of naïve T cells induces enhanced expression of CD40 ligand and cytokines needed for T cell-dependent help for B cell responses.

When B cells are activated by exogenous cytokines (e.g., IL-4, IL-10, or cytokine-containing supernatants from activated T cells) and a cellular source of CD40 ligand (e.g., CD40 ligand expressing fibroblasts) or EBV infection, neonatal B cell production of IgM, IgG<sub>1</sub>, IgG<sub>2</sub>, IgG<sub>3</sub>, IgG<sub>4</sub>, and IgE is similar to that in adult antigenically naïve B cells.<sup>378,722-724</sup> Isotype switching is associated with cell division, and neonatal and adult B cells demonstrate a similar acquisition of switching starting after the third cell division.<sup>725</sup> Pre-B cells have the capacity for isotype switching even during fetal ontogeny: For example, isotype switching and IgE and IgG<sub>4</sub> production by fetal B and pre-B cells at 12 weeks of gestation can be induced in vitro.<sup>683,726-728</sup> IgA<sub>1</sub> and IgA<sub>2</sub> are produced in similar amounts by antigenically naïve fetal and adult B cells on stimulation with anti-CD40 antibody and vasoactive intestinal peptide hormone. Fetal pre-B cells also can synthesize IgA under these conditions.<sup>637</sup> When human fetal or neonatal B cells develop in, or are adoptively transferred into, SCID mice, they are capable of isotype switching and immunoglobulin production if appropriate T cell-derived signals are present.<sup>507,729,730</sup>

Other studies, however, suggest that isotype switching and antibody production by fetal and neonatal B cells is limited compared with these processes in antigenically naïve (IgM<sup>+</sup>IgD<sup>+</sup>) adult B cells. Durandy and colleagues<sup>379</sup> found that IgM, IgG, and IgE production by fetal B cells at mid-gestation was substantially lower than that of neonatal or adult B cells, suggesting an intrinsic hyporesponsiveness to CD40 or cytokine receptor engagement, or both. Neonatal B cells produce substantially less IgA than do adult naïve B cells in the presence of adult T cells stimulated by anti-CD3 mAb (as a source of CD40 ligand) and exogenous

cytokines, such as IL-10.<sup>731</sup> These limitations of fetal and neonatal isotype switching and antibody production probably reflect intrinsic limitations of B cell function, particularly when T cell help may be limited. Such limited production is not due to decreased activation or proliferation, because neonatal B cells proliferate normally in response to engagement of CD40 or surface IgM, or both.<sup>680</sup>

Neonatal T cells activated for a few hours and histologically fixed provide less help for neonatal B cell immunoglobulin production and isotype switching than do similarly treated adult T cells.<sup>378</sup> Because the help provided by these fixed T cells probably is through CD40 ligand, reduced expression of CD40 ligand (or similar activation-induced molecules) by naïve neonatal T cells in the first few hours after activation may limit fetal and neonatal B cell immune responses. Whether decreased neonatal DC function also contributes to diminished B cell responses has not been determined.

IgM and IgG synthesis are detected as early as 12 weeks of gestation in fetal organ cultures.<sup>732</sup> Immunoglobulin-secreting plasma cells are detectable by week 15 of gestation, and those secreting IgG and IgA by 20 and 30 weeks of gestation, respectively.<sup>733</sup> In general, neonatal B cells can differentiate into IgM-secreting plasma cells as efficiently as adult cells. Splawski and Lipsky<sup>734</sup> found that T cell-dependent immunoglobulin production by neonatal CD5<sup>+</sup> and CD5<sup>-</sup> B cells is more readily inhibited by agents that raise intracellular cyclic adenosine monophosphate (cAMP), such as prostaglandin E<sub>2</sub> (PGE<sub>2</sub>).

#### **Development of B Cell Capacity to Respond to T Cell-Dependent and T Cell-Independent Antigens**

##### **Definition of T-Dependent and T-Independent Antigens.**

The chronology of the response to different antigens differs, depending on the need for cognate T cell help (Table 4-6). Largely on the basis of findings on murine studies, antigens can be divided into those dependent on a functional thymus and cognate help (direct cell-cell interactions) provided by mature  $\alpha\beta$  T cells (T-dependent antigens) and those partially or completely independent of T cell help (T-independent antigens). The T-independent (TI) antigens can be further divided into TI type I and TI type II, in accordance with their dependence on cytokines produced by T cells (or other cells).

Most proteins are T-dependent antigens requiring cognate T cell-B cell interaction for production of antibodies (other

than small amounts of IgM). The antibody response to T-dependent antigens is characterized by the generation of memory B cells with somatically mutated, high-affinity immunoglobulin and the potential for isotype switching.

TI type I antigens are those that bind to B cells and directly activate them in vitro to produce antibody without T cells or exogenous cytokines. In the human, one such TI type I antigen is fixed *Brucella abortus*. TI type II antigens are mostly polysaccharides with multiple identical subunits, and certain proteins that contain multiple determinants of identical or similar antigenic specificity. Responses to these antigens are enhanced in vitro and in vivo by a variety of cytokines, including IL-6, IL-12, IFN- $\gamma$ , and GM-CSF.<sup>735-738</sup> NK cells, T cells, or macrophages may provide these cytokines. TI type II responses also are enhanced by bacterially derived LPS, lipoproteins, porin proteins, or unmethylated CpG DNA.<sup>737,739,740</sup> This enhancement probably occurs primarily by engagement of TLR on B cells.<sup>572</sup> The response to TI type II antigens is characterized by the lack of B cell memory or somatic hypermutation and is restricted largely to the IgM and IgG<sub>2</sub> isotypes.<sup>716</sup>

**Response to T-Dependent Antigens.** The capacity of the neonate to respond to T-dependent antigens is well established at birth (see Table 4-6) and is only modestly reduced in comparison with the response in the adult. Any of several mechanisms, alone or in combination, may be responsible for this modest reduction: decreased DC interactions or function with CD4<sup>+</sup> T cells or B cells; limitations in CD4<sup>+</sup> T cell activation and expansion into a T helper/effector cell population; impaired cognate interactions between CD4<sup>+</sup> T cells and B cells; or an intrinsic B cell defect. Another possibility is that T-dependent antigens preferentially upregulate CD22, which raises the threshold for B cell activation, on neonatal compared with adult B cells.<sup>711</sup>

Most studies of the neonatal immune response to T-dependent antigens have not evaluated antibody affinity, a reflection of somatic mutation, or isotype expression. Such responses might be limited early in the immune response because of decreased CD40 ligand expression by CD4<sup>+</sup> T cells.<sup>364,376-379</sup> Studies are needed to determine if reductions in CD40 ligand expression by antigen-specific T cells also occurs in response to neonatal vaccination, and, if so, whether such reduced expression correlates with reduced memory B cell development, decreased isotype switching, and somatic hypermutation.

**Table 4-6 Hierarchy of Antibody Responsiveness to Different Antigens**

Species	Type of Antigen	Examples of Antigen	Age at Onset of Antibody Response
Mouse	T cell-dependent	TNP-KLH	Birth
	T cell-independent type I	TNP- <i>Brucella abortus</i>	Birth
	T cell-independent type II	TNP-Ficoll	Delayed (2-3 wk of age)
Human	T cell-dependent	Tetanus toxoid, HbsAg, <i>Haemophilus influenzae</i> conjugate vaccine, bacteriophage $\phi$ X174	Birth
	T cell-independent type I	TNP- <i>B. abortus</i>	Birth
	T cell-independent type II	Bacterial capsular polysaccharides ( <i>H. influenzae</i> type b, <i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i> , GBS)	Delayed (6-24 mo of age)

GBS, group B streptococci, HbsAgs, hepatitis B surface antigen; KLH, keyhole limpet hemocyanin; TNP, trinitrophenol.

**Response to T-Independent Antigens.** Antibody production by human neonatal B cells to a TI type I antigen in vitro (*B. abortus*) is only modestly reduced<sup>741</sup> (see Table 4-6). This reduction may reflect a decreased ability of antigen-activated B cells to proliferate rather than a decreased precursor frequency of antigen-specific clones.<sup>741</sup>

In humans and mice, the response to TI type II antigens is the last to appear chronologically (see Table 4-6). This helps to account for the neonate's susceptibility to infection with encapsulated bacteria, such as group B streptococci,<sup>742,743</sup> and the poor response to polysaccharide antigens, such as the unconjugated capsular polysaccharides of *H. influenzae* type b, meningococci, and pneumococci, until approximately 2 to 3 years of age. The poor response in children younger than 2 years of age is associated with their lack of circulating memory (CD27<sup>hi</sup>) B cells that express IgM and have not undergone isotype switching.<sup>744</sup> The reduction or absence of these IgM memory B cells in adult patients after splenectomy suggests that they may depend on the spleen micro-environment for their generation or long-term survival. Whether the decreased responses to TI type II antigens during early childhood reflects an intrinsic B cell immaturity or decreased function of other cells such as APCs of the spleen, or both, remains unclear.

Decreased expression of CD21 on neonatal B cells has been proposed as a possible mechanism for limitations in TI type II response in the neonate. CD19 is expressed in association with CD21, the type 2 complement receptor, and serves to transduce B cell-activating signals when CD21 is engaged by C3 complement components, thereby inducing polysaccharide-reactive B cells to proliferate in vivo. Genetic disruption experiments in mice support the idea that the type 2 complement receptor, which includes CD21 and CD35 in mice, is important for TI type II antibody responses to pathogens, such as *S. pneumoniae*.<sup>575</sup> In vitro studies of human splenic tissue suggest that TI type II antigens activate complement and bind C3, and then localize to the marginal zone splenic B cells expressing type 2 complement receptors.<sup>716</sup> Incubation of human splenic tissue with pneumococcal polysaccharides and complement results in preferential binding of the polysaccharide and C3, presumably as a complex, to CD21<sup>+</sup> B cells of this area of the spleen.<sup>745</sup> Rijkers and colleagues<sup>716</sup> and Griffioen and associates<sup>746</sup> found lower CD21 expression on neonatal B cells than on adult B cells.<sup>746</sup> This group of investigators<sup>747</sup> also found that the response to bacterial polysaccharides (at approximately 2 to 3 years of age) correlates with the appearance of B cells expressing CD21 in the marginal zone region of the spleen.

These observations argue for an intrinsic immaturity in B cell responsiveness to TI type II antigens. Decreased expression of CD21 by neonatal B cells has not been confirmed by others, however.<sup>679,713</sup> Alternative mechanisms, such as limitations in APC populations of the splenic marginal zone, also have not been excluded.

Human neonatal B cells demonstrate a marked decrease in CD22 expression following engagement of IgM, a stimulus used to mimic a TI type II antigen.<sup>711</sup> Because CD22 is a negative regulator of B cell activation, however, this finding does not readily explain the diminished response, unless it results in hyperresponsive neonatal B cells prone to apoptosis.

Dextran-conjugated anti-immunoglobulin mAbs have been used to mimic the events in TI type II antibody

responses in vitro.<sup>737</sup> Human neonatal B cells respond to this stimulus as well as adult B cells, suggesting that the lack of the neonatal TI type II response is not due to an intrinsic limitation of B cell function.<sup>748</sup> B cells that respond to dextran-conjugated anti-immunoglobulin mAbs, however, may be functionally distinct from B cells that respond to polysaccharides or other TI type II antigens.

Murine neonatal B cells are able to proliferate in response to the TI type II antigen trinitrophenol (TNP)-Ficoll, or to the polyclonal stimulus goat-anti-murine IgM, if CpG-containing oligonucleotides with unmethylated cytosine residues are present<sup>740</sup>; such unmethylated CpG DNA is known to activate these cells through TLR-9.<sup>749</sup> CpG oligonucleotides also induce human cord blood and adult peripheral blood B cells to respond similarly in terms of cell proliferation, the production of chemokines (CCL3 [MIP-1 $\alpha$ ] and CCL4 [MIP-1 $\beta$ ]), and upregulation of CD86 and MHC class II expression.<sup>715</sup> Thus, neonatal B cells appear to have an intact TLR-9-mediated B cell activation pathway.

### **Specific Antibody Response by the Fetus to Maternal Immunization and Congenital Infection**

**Response to Fetal Immunization in Animal Models.** Early studies by Silverstein and colleagues of the antibody response of fetal sheep and rhesus monkeys to immunization with foreign proteins were conceptually important in establishing two major features of the ontogeny of B cell immune competence for T cell-dependent antigens in larger mammals. First, immune competence for T cell-dependent antigens is established early during fetal ontogeny: Primary immunization of fetal rhesus monkeys between 103 and 127 days of gestation (out of a total of 160 days) with sheep red blood cells (SRBCs), a T cell-dependent antigen, results in the formation of SRBC-reactive B cells in the spleen; reimmunization 3 weeks later results in a rapid antibody response utilizing IgG.<sup>750</sup> In fetal sheep, the antibody response to bacteriophage  $\phi$ X174 occurs as early as 40 days after conception,<sup>751</sup> and again, isotype switching is evident during the fetal response. Together, these findings suggest that B cell response to protein antigens, including isotype switching and probably memory cell generation, are functional during fetal life. Second, these responses occur in a predictable, stepwise fashion for particular antigens. For example, in fetal sheep, the antibody response to keyhole limpet hemocyanin and lymphocytic choriomeningitis virus are first detectable at about 80 and 120 days, respectively, after conception.<sup>751</sup> These differences in the responsiveness to particular antigens are not explained by limitations in the repertoires of surface Ig or  $\alpha\beta$ -TCRs, because it is known that a diverse repertoire is established early in ontogeny.

No correlation exists between the physical or chemical characteristics of particular antigens and their immunogenicity during ontogeny. For example, bacteriophage  $\phi$ X174 and bacteriophage T4 both are particulate antigens that should interact in a similar manner. In fetal sheep, however, bacteriophage T4 becomes immunogenic 60 days after  $\phi$ X174 does so. Baboon fetuses immunized with HBsAg vaccine have a robust IgG antibody response, and this response is boosted by postnatal immunization.<sup>752</sup>

**Response to Maternal Immunization.** In studies by one group of investigators, antibody responses by the human

fetus may occur following maternal immunization with tetanus toxoid during the third trimester but not earlier, as shown by the presence of IgM tetanus antibodies at birth.<sup>753,754</sup> Whether tetanus-specific IgG responses at birth were reduced, as suggested by reports of reduced CD4<sup>+</sup> T cell responses to tetanus vaccine in young infants,<sup>327</sup> remains unclear. Infants with tetanus-specific antibodies at birth had enhanced secondary antibody responses following tetanus immunization, indicating that fetal antigen exposure was a priming event rather than a tolerizing one.<sup>753</sup> By contrast, Englund and associates<sup>524</sup> were unable to demonstrate neonatal tetanus toxoid-specific IgM antibody or T cell proliferation following maternal tetanus toxoid vaccination in the third trimester. Similarly, no fetal response to maternal immunization with inactivated trivalent influenza vaccine was noted.<sup>524</sup> If a fetal antibody response to maternal vaccination with polysaccharide-protein conjugate vaccines occurred, such vaccines could be used during pregnancy to ensure that protective antibody levels were present at birth.

**Response to Intrauterine Infection.** Specific antibody may be present at birth to agents of intrauterine infection, including rubella virus, CMV, HSV, VZV, and *Toxoplasma gondii* and often can be used to diagnose congenital infection. Not all fetuses have an antibody response to intrauterine infection, however; specific IgM antibody was undetectable in 34% of infants with congenital rubella,<sup>755</sup> 19% to 33% of infants with congenital *Toxoplasma* infection,<sup>756,757</sup> and 11% of infants with congenital CMV infection.<sup>758</sup> When congenital infection is severe during the first or second trimester, antibody production may be delayed until late childhood.<sup>542</sup> This delay may reflect a lack of T cell help, because antigen-specific T cell responses often are reduced in parallel with B cell responses.

Congenital *Toxoplasma* infection may lead to detectable IgE and IgA anti-*Toxoplasma* antibodies at birth or during early infancy.<sup>759</sup> Similarly, filaria- or schistosome-specific IgE is present in the sera of most newborns following maternal filariasis or schistosomiasis.<sup>760</sup> Thus, T cell-dependent isotype switching and immunoglobulin production occurs during fetal life, at least for certain pathogens. In fact, with some infectious agents, such as *Toxoplasma*, IgA or IgE antibodies may be more sensitive than IgM antibodies for diagnosis of congenital infection. The titers of IgA and IgE anti-*Toxoplasma* antibodies may be lower at 20 to 30 weeks of gestation than after birth,<sup>761-763</sup> however, indicating that their production is delayed in the context of congenital infection.

### **Specific Antibody Responses by the Neonate and Young Infant to Protein Antigens**

Immunization of neonates usually elicits a protective response to protein antigens, including tetanus and diphtheria toxoids,<sup>764</sup> OPV,<sup>765</sup> *Salmonella* flagellar antigen,<sup>742,743</sup> bacteriophage  $\phi$ X174,<sup>766</sup> and HBsAg (with hepatitis B vaccine).<sup>767</sup> The response to some vaccines, however, may be less vigorous in the neonate than in older children or adults. A diminished primary response to recombinant hepatitis B vaccine has been noted in term neonates lacking maternally derived HBsAg antibody, compared with that in unimmunized children and adults.<sup>767,768</sup> The ultimate anti-HBsAg titers achieved in neonates after secondary and tertiary immunizations are similar to those in older children, indicating that neonatal immuni-

zation does not result in tolerance.<sup>767</sup> If initial immunization is delayed until 1 month of age, the antibody response to primary hepatitis B vaccination is increased and nearly equivalent to that in older children, suggesting that the developmental limitations responsible for reduced antibody responses are transient.<sup>767,769</sup> Similarly, 2-week-old infants immunized with a single dose of diphtheria or tetanus toxoid demonstrated delayed production of specific antibody compared with that in older infants; by 2 months of age, their response was similar to that of 6-month-old infants,<sup>770</sup> suggesting rapid maturation of T-dependent responses. The switch from IgM to IgG also may be delayed following neonatal vaccination for some (e.g., *Salmonella* H vaccine<sup>743</sup>) but not all (e.g., bacteriophage  $\phi$ X174<sup>766</sup>) antigens. Immunization of infants born to HIV-infected mothers with recombinant HIV-1 gp120 vaccine in MF59 adjuvant, beginning at birth, also resulted in high antibody titers, indicating that early postnatal vaccination is not tolerigenic.<sup>771</sup>

Unlike with other vaccines, in newborns given whole-cell pertussis vaccination, not only may they demonstrate a poor initial antibody response, but their subsequent antibody response to certain antigenic components, such as pertussis toxin, may be less than in infants initially immunized at 1 month of age or older,<sup>772-774</sup> suggesting low-level tolerance. Whole-cell pertussis vaccine immunization of premature infants (born at 28 to 36 weeks of gestation) at 2 months of age elicited responses similar to those in 2-month-old term infants,<sup>765</sup> indicating that this putative tolerigenic period wanes rapidly and is relatively independent of gestational age. This low-level tolerance appears to be restricted to whole-cell pertussis vaccine, because an inhibitory effect has not been observed following administration of diphtheria or tetanus toxoid<sup>764</sup> or hepatitis B vaccine given within 48 hours of birth.<sup>767</sup> Administration of OPV at birth enhanced rather than inhibited the response to subsequent immunization, also indicating that immunization through the mucosal route does not produce tolerance.<sup>775</sup>

The antibody response to measles vaccine given at 6 months of age is significantly less than when the vaccine is given at 9 or at 12 months of age, even when the inhibitory effect of maternal antibody is controlled for.<sup>776</sup> This decreased response is not due to a lack of measles-specific T cells, because measles antigen-specific T cell proliferation and IL-12 and IFN- $\gamma$  proliferation were similar in the three age groups.<sup>776-778</sup> The basis for this reduced response is not known.

### **Specific Antibody Responses by the Term Neonate to Polysaccharide and Polysaccharide-Protein Conjugates**

In contrast with the response to protein antigens, the newborn's response to polysaccharide antigens is absent or severely blunted, as demonstrated by an inability to mount an antibody response to unconjugated *H. influenzae* type b polysaccharide vaccine or to group B streptococcal capsular antigens after infection. The response to some polysaccharide antigens can be demonstrated by 6 months of age, but the response to vaccination with *H. influenzae* or *N. meningitidis* type C, or to most pneumococcal polysaccharides, is poor until approximately 18 to 24 months.<sup>779</sup> This inability to respond to polysaccharides and other TI type II antigens is not clearly understood but evidently is not due to a lack of

the appropriate antibody repertoire, at least for *H. influenzae*.<sup>780</sup> The delayed postnatal appearance of marginal zone B cells in the spleen has been proposed to account for this delayed response (see section on development of B cell capacity to respond to T cell-dependent and T cell-independent antigens), although this suggestion remains controversial.

Covalent conjugation of *H. influenzae* capsular polysaccharide to a protein carrier renders it immunogenic in infants as young as 2 months of age and primes for an enhanced antibody response to unconjugated vaccine given at 12 months of age. Because the response to the unconjugated vaccine usually is poor at this age, the conjugate vaccine is thought to have induced polysaccharide-specific B cell memory.<sup>781</sup> Similarly, the administration of a single dose of *H. influenzae* type b polysaccharide-tetanus toxoid conjugate to term neonates as early as a few days of age may enhance the antibody response to unconjugated *H. influenzae* type b polysaccharide vaccine at 4 months of age.<sup>782</sup> This enhanced response is weak, however, and does not occur when the neonate is primed with tetanus toxoid followed by immunization with conjugate vaccine at 2 months of age.<sup>783</sup>

Coupling of the *H. influenzae* type b polysaccharide to a protein carrier converts a TI type II antigen to a T-dependent antigen.<sup>784</sup> This is accompanied by an enhanced magnitude and higher-avidity antibody response on subsequent boosting, presumably resulting from T-dependent memory B cell generation and somatic hypermutation. The early interactions between T cells and B cells in response to such carbohydrate-protein conjugate vaccines are summarized in Figure 4-9. Conjugation of *H. influenzae* type b polysaccharide to tetanus or diphtheria toxoid does not change the repertoire of the antibodies produced from that of the free polysaccharide.<sup>780,781</sup> The neonatal response to conjugate vaccines now mimics the response to other T-dependent antigens. Vaccination with protein-capsular polysaccharide conjugate vaccines containing polysaccharides of *S. pneumoniae* (types 4, 6B, 9V, 14, 18C, 19F, and 23F)<sup>785-787</sup> and *N. meningitidis* (types A and C)<sup>788</sup> is immunogenic in infants as young as 2 months of age and primes them for subsequent memory responses.

### Antibody Responses by the Premature Infant to Immunization

Preterm neonates of 24 weeks of gestation or greater produce antibody to protein antigens such as diphtheria toxoid, diphtheria-pertussis-tetanus vaccine, and oral and inactivated poliovirus vaccines as well as do term neonates, when the vaccines are administered at 2, 4, and 6 months of age.<sup>765,789-791</sup> The antibody response in premature infants to multiple doses of hepatitis B vaccine, initially administered at birth, are clearly reduced compared with that in term infants.<sup>792</sup> These titers are substantially increased if immunization of the premature is delayed until 5 weeks of age, indicating the importance of postnatal age rather than of a particular body weight.<sup>793</sup>

The antibody levels after three doses of *H. influenzae*-type capsular polysaccharide-tetanus conjugate vaccine are significantly less in premature infants than in term infants, however, when vaccination is begun at 2 months of age.<sup>794</sup> This reduced antibody response is particularly true in premature infants with chronic lung disease,<sup>795</sup> in whom it may result in part from glucocorticoid treatment. As in term infants, the

**Figure 4-9** Interactions between B cells and T cell in the response to vaccines consisting of purified carbohydrate (e.g., bacterial capsular polysaccharide) covalently linked to protein carrier. The carbohydrate moiety of the conjugate is bound by surface immunoglobulin (Ig) on B cells, resulting in the internalization of the conjugate. Peptides derived from the protein moiety of the conjugate are presented by major histocompatibility complex (MHC) class II on the B cell, resulting in the activation of the T cell and expression of CD40 ligand. Engagement of CD40 on the B cell by CD40 ligand, in conjunction with cytokines secreted by the T cell, results in carbohydrate-specific B cell proliferation, immunoglobulin isotype switching, secretion of antibody, and memory B cell generation.

response of premature infants to polysaccharide antigens remains diminished during the first 2 years of life.

### Maternally Derived Immunoglobulin G Antibody

The mechanism by which IgG is transferred to the fetus is only incompletely understood but depends on the recognition of maternal IgG through its Fc domain. IgG is internalized by the trophoblast, possibly by pinocytosis.<sup>796</sup> The next step in transport involves the FcRn, an intracellular IgG receptor that is a unique  $\beta_2$ -microglobulin-associated nonpolymorphic member of the MHC class I family.<sup>797</sup> FcRn lacks a functional peptide-binding groove and, instead, uses a different region of the molecule for binding IgG through its Fc domain. IgG bound to FcRn receptor undergoes transcytosis across the syncytiotrophoblast, followed by its release into the interstitium in the vicinity of endothelial cells surrounding fetal villous vessels.<sup>798</sup> How IgG is internalized and transported across the endothelium of fetal villous vessels is unclear, because these cells express only low or undetectable amounts of FcRn.<sup>796</sup> In addition to the syncytiotrophoblast, FcRn is widely expressed by nonplacental tissues, where it binds to pinocytosed IgG and recycles it to the circulation. This recycling system accounts for the very long half-life of IgG.

Maternal IgG and FcRn expression can be detected in placental syncytiotrophoblasts during the first trimester,<sup>797</sup> but transport does not occur, because circulating fetal concentrations of IgG remain below 100 mg/dL until about 17 weeks. The maternally derived placental cytotrophoblast, which is found between the syncytiotrophoblast and the fetal endothelium during the first trimester, may act as a barrier to IgG transport. This cytotrophoblast layer becomes

**Figure 4-10** Immunoglobulin (IgG, IgM, and IgA) levels in the fetus and in the infant the first year of life. The IgG of the fetus and newborn infant is solely of maternal origin. The maternal IgG disappears by age 9 months, by which time endogenous synthesis of IgG by the infant is well established. The IgM and IgA of the neonate are entirely endogenously synthesized because maternal IgM and IgA do not cross the placenta. (Data from Saxon A, Stiehm ER. The B-lymphocyte system. In Stiehm ER [ed]. Immunologic Disorders in Infants and Children, 3rd ed. Philadelphia, WB Saunders, 1989, pp 40-67.)

discontinuous as the villous surface area expands during the second trimester.<sup>797</sup>

IgG is detectable in the fetus by 17 weeks of gestation, after which circulating concentrations of IgG in the fetus rise steadily, reaching half of the term serum concentration by about 30 weeks, and equaling that of the mother by about 38 weeks.<sup>799,800</sup> In some instances, fetal IgG concentrations may exceed those of the mother,<sup>801</sup> which is associated with the IgG concentration within the syncytiotrophoblast prior to its release into the fetal interstitial space.<sup>802</sup>

The fetus synthesizes little IgG, so that the concentration in utero reflects almost solely maternally derived antibody (Fig. 4-10).<sup>803</sup> Accordingly, the degree of prematurity is reflected in proportionately lower neonatal IgG concentrations. The IgG<sub>2</sub> concentration in cord blood relative to that in maternal blood is low at birth, particularly in preterm infants, whereas the overall fetal-to-maternal ratio is usually near 1.0 for the other IgG subclasses.<sup>804-806</sup> The low IgG<sub>2</sub> concentration appears to reflect a relatively low affinity of the receptor involved in the IgG trophoblastic uptake for IgG<sub>2</sub>. IgM, IgA, IgD, and IgE do not cross the placenta. Evidence for transamniotic transfer of IgG to the fetus also is lacking.<sup>802</sup>

#### Placental Transfer of Specific Antibodies

The fetus receives IgG antibodies against antigens to which the mother has been exposed by infection or vaccination

(see Table 4-5). For example, in mothers immunized with *H. influenzae* type b capsular polysaccharide antigen at 34 to 36 weeks of gestation, concentrations of anticapsular antibody are high and result in protective antibody levels in her infant for approximately the first 4 months of life. In the absence of recent immunization or natural exposure, the maternal antibody IgG antibody titer may be too low to be protective to the neonate. Protection of the infant may be absent even if the mother is protected, because she has memory B cells and can mount a rapid recall antibody response on infectious challenge. In addition, if maternal antibodies are primarily IgM antibodies directed against gram-negative pathogens, such as *E. coli* and *Salmonella*,<sup>742,743</sup> the fetus will not be protected because IgM does not traverse the placenta. Finally, premature infants may not receive sufficient amounts of IgG for protection, because the bulk of maternal IgG is transferred to the fetus after 34 weeks of gestation,<sup>807</sup> thereby accounting for the greater susceptibility of premature compared with term neonates to certain infections, such as with VZV.<sup>808</sup>

**Inhibition of Neonatal Antibody Responses by Maternal Antibodies.** Maternal antibody also may inhibit the production by the fetus or newborn of antibodies of the same specificity. This inhibition varies with the maternal antibody titer and with the type and amount of antigen. Maternal anti-

Table 4-7 Levels of Immunoglobulins in Sera of Normal Subjects, by Age<sup>a</sup>

Age	IgG		IgM		IgA		Total Immunoglobulins

body markedly inhibits the response to measles and rubella vaccine, but not mumps vaccine<sup>809</sup>; this is the reason for delaying measles-mumps-rubella (MMR) vaccine until at least 12 months of age. Inhibition of the response to these live-attenuated viral vaccines may result in part from reduced replication of vaccine virus in the recipient.

Maternal antibodies also may inhibit the neonatal response to nonreplicating vaccines such as whole-cell pertussis vaccine,<sup>774</sup> diphtheria toxoid,<sup>810</sup> *Salmonella* flagellar antigen,<sup>743</sup> and inactivated poliovirus vaccine.<sup>811</sup> Maternal antibody may bind to and mask the immunogenic epitope, preventing it from binding to surface Ig and activating antigen-specific B cells. In addition, the formation of antigen-maternal IgG antibody complexes can inhibit activation of B cells via surface Ig by simultaneous engagement of the inhibitory FcγRII receptor by the IgG component of the complex. Alternatively, maternal antibody may lead to the rapid clearance of vaccine antigen and decreased immunogenicity. Finally, for certain antibodies, such as anti-HbsAg, neither maternal antibodies nor hepatitis B immune globulin administration has a substantial inhibitory effect on the newborns immune response to hepatitis B vaccination.

## Immunoglobulin Synthesis by the Fetus and Neonate

### Immunoglobulin G

IgG is the predominant immunoglobulin isotype at all ages (Table 4-7).<sup>812</sup> In adults, IgG<sub>1</sub> is the predominant subclass, accounting for approximately 70% of total IgG; IgG<sub>2</sub>, IgG<sub>3</sub>, and IgG<sub>4</sub> account for approximately 20%, 7%, and 3% of the total, respectively.<sup>813</sup> Passively derived maternal IgG is the source of virtually all of the IgG subclasses detected in the normal fetus and neonate. Because the IgG plasma half-life is about 21 days, these maternally derived levels fall rapidly after birth. IgG synthesized by the neonate and that derived from the mother are approximately equal when the neonate reaches 2 months of age; by 10 to 12 months of age, the IgG

is nearly all derived from synthesis by the infant. As a consequence of the fall in passively derived IgG and increased synthesis of IgG, values reach a nadir of approximately 400 mg/dL in term infants at 3 to 4 months of age and rise thereafter (see Table 4-7 and Fig. 4-10). The premature infant has lower IgG concentrations at birth, which reach a nadir at 3 months of age; mean IgG values of 82 and 104 mg/dL are observed in infants born at 25 to 28 and 29 to 32 weeks of gestation, respectively.

By 1 year, the total IgG concentration is approximately 60% of that in adults. IgG<sub>3</sub> and IgG<sub>1</sub> subclasses reach adult concentrations by 8 years, whereas IgG<sub>2</sub> and IgG<sub>4</sub> do so by 10 and 12 years of age, respectively.<sup>814</sup> As discussed earlier, maternal IgG may inhibit certain postnatal antibody responses by binding to FcγRII receptors and by rapidly clearing or masking potential antigens. The slow onset of IgG synthesis in the neonate, however, is predominantly an intrinsic limitation of the neonate, rather than of maternal antibody; indeed, a similar pattern of IgG development was observed in a neonate born to a mother with untreated agammaglobulinemia.<sup>815</sup>

The slow rise in IgG<sub>2</sub> concentrations parallels the poor antibody response to bacterial polysaccharide antigens (e.g., *H. influenzae* polyribosyl ribitol phosphate [PRP]), antibodies, which are predominantly IgG<sub>2</sub>.<sup>816</sup> Of interest, the postpartum order in which adult levels of isotype expression are achieved closely parallels the order of the *heavy chain gene* segments that encode these isotypes. Thus, postnatal regulation of isotype switching is mediated in part at the heavy chain gene locus (e.g., its chromatin configuration may be developmentally regulated).

Although passive maternal antibody plays an important role in protection, it limits the value of immunoglobulin and antibody levels in the diagnosis of immunodeficiency or infection in the young infant.

### Immunoglobulin M

IgM is the only isotype besides IgG that binds and activates complement, requiring only a single IgM molecule for acti-

vation. IgM increases from a mean of 6 mg/dL in premature infants born at less than 28 weeks of gestation to 11 mg/dL at term,<sup>817,818</sup> which is approximately 8% of the maternal IgM level. This IgM, which is likely to be preimmune (i.e., not the result of a B cell response to foreign antigens), is enriched for polyreactive antibodies produced by B-1 cells. Murine studies suggest that such natural IgM plays an important role in innate defense against infection, allowing time for the initiation of antigen-specific B cell response; it also enhances antigen-specific B cell responses through its ability to fix complement and thereby co-stimulate B cell activation through complement receptor 2 (CD21).<sup>688-690</sup> Some of the human neonatal IgM is monomeric and therefore nonfunctional, however, as opposed to its usual pentameric functional form.<sup>819,820</sup>

Postnatal IgM concentrations rise rapidly for the first month and then more gradually thereafter, presumably in response to antigenic stimulation (see Fig. 4-10 and Table 4-7). By 1 year of age, values are approximately 60% of those in adults. The postnatal rise is similar in premature and in term infants.<sup>819</sup> Elevated (greater than 20 mg/dL) IgM concentrations in cord blood suggest possible intrauterine infections,<sup>821</sup> but many infants with congenital infections have normal cord blood IgM levels.<sup>758</sup>

### **Immunoglobulin A**

IgA does not cross the placenta, and its concentration in cord blood usually is 0.1 to 5.0 mg/dL, approximately 0.5% of the levels in maternal sera.<sup>818</sup> Concentrations are similar in term and in premature neonates,<sup>817</sup> and both IgA<sub>1</sub> and IgA<sub>2</sub> are present.

At birth, the frequency of IgA<sub>1</sub>- and IgA<sub>2</sub>-bearing B cells is equivalent. Subsequently, a preferential expansion of the IgA<sub>1</sub>-bearing cell population occurs, presumably as a result of postnatal exposure to environmental antigens.<sup>822</sup> Concentrations in serum increase to 20% of those in adults by 1 year of age and rise progressively through adolescence (see Table 4-7). Increased cord blood IgA concentrations are observed in some infants with congenital infection.<sup>821</sup> Elevated IgA is common in young infants infected by vertical transmission with HIV. IgA has a relatively short half-life in plasma of approximately 5 days. Secretory IgA is present in substantial amounts in the saliva by 10 days after birth.<sup>823</sup>

### **Immunoglobulin D**

IgD is detectable by sensitive techniques in serum from cord blood in term and premature infants.<sup>817,824</sup> Mean serum levels at birth are approximately 0.05 mg/dL<sup>818</sup> and increase during the first year of life. Circulating IgD has no clear functional role. The immune response of mice in which IgD expression has been eliminated by gene targeting appears to be normal. On the other hand, surface IgD can replace surface IgM in B cell function in the mouse. Together, these results suggest that the functions of IgM and IgD are largely redundant.

### **Immunoglobulin E**

Although IgE synthesis by the fetus is detectable as early as 11 weeks, concentrations of IgE in cord blood are typically low, with a mean of approximately 0.5% of that of maternal levels.<sup>818</sup> This IgE is of fetal origin, and concentrations are higher in infants born at 40 to 42 weeks of gestation than in

those born at 37 to 39 weeks.<sup>818</sup> The rate of postnatal increase varies and is greater in infants predisposed to allergic disease or greater environmental exposure to allergens.<sup>825,826</sup> The concentration of IgE at birth appears to have limited predictive value for later development of atopic disease.<sup>827</sup>

## **Summary**

The neonate is partially protected from infection by passive maternal IgG antibody, predominantly transferred during the latter third of pregnancy. Fetal IgG concentrations are equal to or higher than maternal concentrations after 34 weeks of gestation. The inability of the neonate to produce antibodies in response to polysaccharides, particularly bacterial capsular polysaccharides, limits resistance to bacterial pathogens to which the mother has little or no IgG antibody. The basis for this defect remains unclear, but it may reflect an intrinsic limitation of B function or a deficiency in the anatomic microenvironment required for B cells to become activated and differentiate into plasma cells. By contrast, the neonatal IgM response to most protein antigens is intact and only slightly limited for IgG responses to certain vaccines. Nevertheless, a clear difference between neonates and older infants has been observed in the magnitude of the antibody response to most protein neoantigens, but this difference rapidly resolves following birth. A limited antibody response of premature infants to immunization with protein antigens occurs during the first month of life but not subsequently. Thus, chronologic (i.e., postnatal) age is more of a determinant of antibody responses to T-dependent antigens than is gestational age. Isotype expression by B cells after immunization with T-dependent antigens is limited by altered T cell function, such as reduced CD40 ligand production, and intrinsic limitations of B cell maturation and function. These limitations are exaggerated in the fetus.

## **NATURAL KILLER CELLS**

### **Basic Aspects of Natural Killer Cells and Their Function**

#### **Overview**

NK cells are large granular lymphocytes with cytotoxic function that do not rearrange either the TCR or immunoglobulin genes and therefore lack surface expression of TCR-CD3 and sIg. Virtually all circulating human NK cells in the adult express the NKp30 and NKp46 natural cytotoxicity receptors that appear to be NK cell specific.<sup>828,829</sup> Most adult NK cells also express proteins that are not unique to the NK cell lineage and are found on T cells or other cell types. These proteins include killer inhibitory receptors (KIRs), CD94-NKG2 family members, NKG2D, and 2B4, which are involved in either negative (KIR and CD94-NKG2A) or positive (NKG2D and 2B4) regulation of natural cytotoxicity. Most adult NK cells also express CD2, CD16, CD56, and CD161 (NKR-P1A) molecules,<sup>829-831</sup> and approximately 50% express CD57.<sup>830</sup> CD16 is a component of the FcγRIIIB receptor, which is activated by binding IgG coated on target cells. CD2 and CD57 may be involved in NK cell adhesion to either target cells or endothelium. Although the function of CD56 in NK cells is unclear, it has been used as

a marker to differentiate subpopulations of NK cells (see later).<sup>832</sup> The function of CD161 is unclear. Finally, most or all NK cells express proteins involved in the intracellular propagation of activation signals, including CD3- $\xi$ , Fc $\epsilon$ R1 $\gamma$ , and DNAX-activation protein (DAP) 10 and DAP-12.<sup>833</sup> NK cells are produced mainly in the bone marrow and appear to be derived from a common T cell and NK cell precursor cell (see later).

NK cells are functionally defined by their ability to lyse virally infected or tumor target cells in a non-MHC-restricted manner that does not require prior sensitization.<sup>834</sup> NK cells preferentially recognize and kill cells with reduced or absent expression of MHC self-class I expression (natural cytotoxicity). This is in contrast with cytotoxic T cells, which are triggered to lyse targets following the recognition of foreign antigenic peptides bound to self-MHC (MHC-restricted cytotoxicity) or self-peptides bound to foreign MHC (allogeneic cytotoxicity). This property also endows NK cells with the capacity to reject bone marrow grafts from persons lacking recipient MHC alleles even if they do not express foreign MHC alleles. This phenomenon is known as hybrid resistance and may be important in the immunology of the rejection of nonautologous hematopoietic cell grafts. Donor NK cells may also facilitate donor cell engraftment and a graft-versus-leukemia effect when mismatched hematopoietic cell transplants are given to leukemia patients.<sup>835</sup> NK cells also have the ability to kill target cells that are coated with IgG antibodies, a process known as antibody-dependent cellular cytotoxicity (ADCC). ADCC requires the recognition of IgG bound to the target cell by the NK cell Fc $\gamma$ RIIIB receptor (CD16).<sup>836</sup>

NK cells are particularly important in the early containment of viral infections, especially with pathogens that may initially avoid control by adaptive immune mechanisms. Viral infection of host cells by those of the herpesvirus group, including HSV, CMV, and VZV, and some adenoviruses leads to decreased surface expression of MHC class I molecules, which is discussed in more detail under "Viruses" in the section on host defense against specific classes of neonatal pathogens. Viral protein-mediated decreases in expression of MHC class I may limit the ability of CD8<sup>+</sup> T cells to lyse virally infected cells, and to clonally expand from naïve precursors. These virus-mediated effects may be particularly important during early infection, when CD8<sup>+</sup> T cells with appropriate antigen specificity are present at a low frequency. By contrast, decreased MHC class I expression facilitates recognition and lysis by NK cells. The importance of NK cells in the initial control of human herpesvirus infections is suggested by the observation that persons with selective deficiency of NK cells or of their function are prone to severe infection with HSV, CMV, and VZV (D. Lewis and C. Wilson, unpublished observations, 1992).<sup>837,838</sup>

### Natural Killer Cell Development

The bone marrow is assumed to be the major site for post-natal NK cell production. CD34<sup>+</sup> cells lacking markers for mature cell lineages (Lin<sup>-</sup>) and expressing CD7 or CD38 are found in the adult bone marrow and the neonatal or adult circulation and appear to be enriched for NK cell progenitors.<sup>839,840</sup> Committed NK cell precursors in mice are identified by their expression of the IL-2R $\beta$  chain, an obligatory component of functional receptors for both IL-2 and

IL-15. Murine NK cell precursors appear to require Flt3 ligand or c-kit ligand, or both, for their differentiation from HSCs, but not cytokines that utilize the  $\gamma$ c cytokine receptor.<sup>840</sup> In humans, culture of CD34<sup>+</sup> HSCs with Flt3 ligand or c-Kit ligand results in the induction of IL-2R $\beta$  chain expression and increased levels of CD34 on the cell surface. These CD34<sup>hi</sup>IL-2R $\beta$ <sup>hi</sup> cells, which lack CD7 and CD56 and other NK cell markers, appear to be committed NK cell precursors, because their subsequent culture with IL-15 results in acquisition of most features of mature NK cells, including expression of CD56, KIR, and NKG2A, as well as natural cytotoxicity and the capacity for cytokine and chemokine production.<sup>841</sup>

Various immature precursor populations in the bone marrow and circulation, such as CD34<sup>+</sup>CD7<sup>+</sup>Lin<sup>-</sup> cells can differentiate into NK cells, thymocytes or lymphoid DCs, depending on the culture conditions employed, suggesting the existence of a common T/NK/lymphoid DC progenitor.<sup>842,843</sup> A close relationship of NK cells to T lymphocytes is also suggested by the transient cytoplasmic expression of the CD3- $\epsilon$  and CD3- $\delta$  components by unactivated human fetal liver NK cells.<sup>830,844</sup> The precise point at which there is an irreversible commitment to NK cell lineage development in vivo remains unclear.

In vitro studies suggest a NK lineage cell developmental sequence in which NKR-P1A expression is acquired early. A small population of CD3<sup>-</sup>CD7<sup>+</sup>CD16<sup>-</sup>CD56<sup>-</sup>NKR-P1A<sup>+</sup> lymphocytes in the neonatal and adult circulation suggests that this cell type constitutes a normal intermediate stage in NK cell development.<sup>845</sup> This cell surface phenotype may be followed by acquisition of NKp30, NKp46, 2B4, and NKG2D expression, based on the phenotype of reconstituting NK cells that appear in bone marrow transplant recipients<sup>846</sup> and in vitro differentiation studies.<sup>847</sup> At the later stages, NK cells acquire surface expression of KIR, CD94-NKG2A, CD2, CD16, and CD56 and the capacity for natural cytotoxicity and cytokine production.<sup>839,843,845,847</sup>

IL-15 is particularly important for directing uncommitted lymphocyte precursors to differentiate into the NK cell lineage<sup>848</sup> and for promoting the survival of mature NK cells.<sup>849</sup> NK cells are absent from mice that are genetically deficient in IL-15, components of the IL-15 receptor, or IRF-1 transcription factor, which is required for IL-15 production.<sup>850</sup> The major source of IL-15 for NK cell development probably is stromal fibroblasts of the bone marrow. IL-15 signaling can occur by its binding to a trimeric complex consisting of the IL-15 receptor  $\alpha$  chain, the IL-2 receptor  $\beta$  chain and the  $\gamma$ c chain. In addition, IL-15 bound to IL-15 receptor  $\alpha$  chains on one cell can activate another cell that expresses only IL-2 receptor  $\beta$  and  $\gamma$ c chains but not IL-15 receptor  $\alpha$  chain. This dependence on IL-15 signaling probably accounts for the absence of NK cells as well as T cells in X-linked SCID, which is due to a genetic deficiency of  $\gamma$ c cytokine receptor chain.<sup>117</sup> IL-7, which also uses the  $\gamma$ c chain for its signaling, is not required for human NK cell development, because patients with IL-7 receptor  $\alpha$  chain deficiency lack T cells but have normal numbers of NK cells.<sup>117</sup> IL-21, a recently identified cytokine produced by activated CD4<sup>+</sup> T cells that also uses a  $\gamma$ c-containing receptor,<sup>446</sup> can promote human NK cell development in vitro.<sup>851</sup> It is unclear, however, if IL-21 is produced within the human bone marrow microenvironment in vivo, where it could influence NK cell development.

**Figure 4-11** Positive and negative regulation of natural killer (NK) cell cytotoxicity by receptor-ligand interactions. NK cell cytotoxicity is inhibited by engagement of killer inhibitory receptors (KIRs) by major histocompatibility complex (MHC) class I molecules, such as human leukocyte antigens HLA-B and HLA-C. In addition, NK cells are inhibited when the CD94-NKG2 complex, a member of the C-type lectin family, on the NK cell is engaged by HLA-E. HLA-E binds hydrophobic leader peptides derived from HLA-A, -B, and -C molecules and requires these for its surface expression. Thus, HLA-E surface expression on a potential target cell indicates the overall production of conventional MHC class I molecules. These inhibitory influences on NK cell cytotoxicity are overcome if viral infection of the target cell results in decreased MHC class I and HLA-E levels. NK cell cytotoxicity is positively regulated by the engagement of NKG2D, which interacts with MICA, MICB, and ULBPs; 2B4, which interacts with CD48; and natural cytotoxicity receptors, such as NKp30 and NKp46, for which the ligands on the target cell are unknown. CD16 is an Fc receptor for immunoglobulin G (IgG) and mediates antibody-dependent cellular cytotoxicity against cells coated with antibody (e.g., against viral proteins found on the cell surface). Positive receptors mediate their intracellular signals through associated CD3- $\zeta$ , Fc $\epsilon$ R1, DAP10, or DAP12 proteins. MICA and MICB, MHC class I-related chains A and B; ULBPs, UL16 (a cytomegalovirus protein)-binding proteins.

### Natural Killer Cell Inhibitory Receptors

NK cell cytotoxicity is regulated by a complex array of inhibitory and activating receptor-ligand interactions with target cells (Fig. 4-11). NK cells are inhibited overall by recognition of MHC class I, or segments derived from them, that are expressed on nontransformed, uninfected cells. Binding of the NK cell to MHC class I is presumed to provide a net inhibitory signal that predominates over activating signals. Infection of the host target cell can downregulate inhibitory ligands, such as MHC class I, and upregulate other molecules promoting NK cell-mediated cytotoxicity, such as LFA-3 and MICA and MICB. How these multiple signals are appropriately integrated to regulate cytotoxicity remains unclear. Two major families of MHC class I receptors exist in humans: KIRs and the CD94-containing C-type lectins.<sup>852,853</sup> The major inhibitory receptor of the CD94 family consists of a heterodimer of CD94 and NKG2 A, each of which is encoded by a single nonpolymorphic gene. CD85j (ILT 2), a member of the immunoglobulin-like transcript family, also is expressed on NK cells and can bind to both MHC class I and nonclassical MHC, such as HLA-G.<sup>854</sup> Because its role in regulating NK cell cytotoxicity is not well defined, however, it is not discussed further.

KIRs vary in size depending on whether they contain two (KIR2D) or three (KIR3D) extracellular immunoglobulin-like domains, and whether they have long or short cyto-

plasmic domains. The long cytoplasmic domain contains an ITIM, which is tyrosine phosphorylated following KIR engagement; this recruits protein tyrosine phosphatases that inhibit NK cell activation and cytotoxicity.<sup>855</sup> KIR with short cytoplasmic motifs also are known as killer-activated receptors (KARs) and provide activating rather than inhibitory signals. KIRs and KARs are encoded in a tight gene cluster, forming haplotypes that are inherited in codominant fashion. Persons may inherit haplotypes that contain up to 11 KIR genes, whereas others may have a haplotype lacking any functional inhibitory KIRs (i.e., those KIRs with cytoplasmic ITIM).<sup>856</sup> Further complexity is due to the possibility of multiple alleles at KIR loci.<sup>852</sup> Most human KIRs recognize either HLA-B or HLA-C alleles, although one has been identified that recognizes certain alleles of HLA-A.<sup>852</sup> Particular KIRs often recognize closely related MHC class I alleles. Although KIR binding may be influenced by particular peptides that are bound to the MHC class I groove, this typically has a relatively subtle impact.

These potential limitations in KIR recognition of self-MHC class I alleles, which could theoretically lead to NK cell autoreactivity, may be overcome by CD94-NKG2 A. Consistent with this idea, an analysis of multiple NK cell clones from normal human donors found that the minority of NK cells that lacked all KIR with ITIM motifs invariably expressed CD94-NKG2 A.<sup>857</sup> Like KIRs with long cytoplasmic tails, the NKG2 A protein also has a cytoplasmic ITIM that mediates

NK cell inhibition. The external domains of CD94 and NKG2 A are both C-type lectins that are structurally distinct from KIR, however, and the CD94–NKG2 A complex recognizes HLA-E rather than classic HLA molecules. HLA-E preferentially binds nine–amino acid hydrophobic peptides derived from the leader sequences of HLA-A, -B, and -C molecules.<sup>24</sup> Because HLA-E requires these leader sequences for its intracellular assembly, stability, and transport, the amount of HLA-E on the cell surface is an indication of the overall levels of conventional MHC class I molecules that are expressed by the potential target cell.<sup>858</sup>

### **Natural Killer Cell Adhesion**

Most resting NK cells are found in the circulation and spleen. The small population of circulating NK cells that are CD16<sup>low</sup>– and CD56<sup>+</sup> may be specialized in the surveillance of solid organs, including the maternal decidua.<sup>859</sup> As for cytotoxic T cells, target cell recognition can be divided into a binding phase and an effector phase of either NK cell triggering or inactivation. A number of NK cell–target cell interactions may be utilized for binding (e.g., CD2–CD58, CD27–CD70,  $\beta_2$  integrin–ICAM, CD44–MAdCAM-1<sup>860</sup>), and some of these interactions may also play a role in triggering NK cell activation.

### **Natural Killer Cell–Activating Receptors and Cytotoxicity**

NKp30, NKp44, and NKp46 are natural cytotoxicity receptors that are members of the immunoglobulin superfamily. NKp30 and NKp46 are expressed on resting NK cells, but NKp44 is expressed only after treatment of NK cells with cytokines, such as IL-2. NKp30 and NKp46 use homo- or heterotrimers of CD3- $\zeta$  or the Fc $\epsilon$ R1 $\gamma$  chains, or both, which contain ITAMs, to transmit their intracellular signals (see Fig. 4-11). NKp46 uses DAP-12, another ITAM-containing protein, for this purpose. All of these receptors appear to activate intracellular tyrosine kinases, such as Zap-70 and Syk.<sup>833</sup> The ligands that are used by these receptors for killing tumor cells or cells infected with herpesviruses remain unclear. NKp44 and NKp46 have been reported to be able to trigger NK cell cytotoxicity through their recognition of influenza virus hemagglutinin and Sendai (parainfluenza family) virus hemagglutinin-neuraminidase.<sup>861</sup> The importance of such NK cell recognition in influenza infection *in vivo* is unknown, however, and may be limited by the ability of NK cells to reach the respiratory epithelial cell, the major cell type that is productively infected.

NKG2 D is an activating receptor on NK cells as well as on certain T cell populations. Engagement of NKG2 D triggers activation of the phosphatidylinositol (PI) 3-kinase pathway by the NKG2 D–associated DAP 10 adapter protein (see Fig. 4-11).<sup>833</sup> NKG2 D recognizes MICA and MICB, which are nonclassic MHC molecules that are expressed on stressed or infected cells,<sup>862</sup> as well as UL16-binding proteins (ULBPs). ULBPs are a group of GPI-linked MHC class I–like molecules expressed on many cell types that were first identified and named based on their ability to bind to the human CMV UL16 viral protein. In CMV infection, the secretion of UL16 probably limits NK cell– and T cell–mediated activation by binding to ULBPs on the potential activating target cell surface. Little is known of how ULBP expression is regulated during infection *in vivo*.

The proteins 2B4 (CD244) and NTBA are members of the SLAM protein family and are expressed on most NK cells.<sup>863</sup> The first, 2B4, binds to CD48, a protein that is expressed by B cells and T cells; the ligand for NTBA remains unclear. Both 2B4 and NTBA engagement triggers NK cell activation through SLAM-associated protein (SAP), an intracellular adapter protein. The X-linked lymphoproliferative syndrome is due to genetic deficiency of SAP and results in severe, often life-threatening infection from primary EBV infection, with a high associated risk for the development of lymphoma or chronic hypogammaglobulinemia.<sup>863</sup> SAP deficiency allows alternative molecules, the SH2-domain–containing phosphatases (SHPs), to bind the cytoplasmic tails of 2B4 and NTBA. This results in inhibition of NK cell function rather than merely the loss of activating function, a mechanism that may contribute to the severity and sequelae of EBV infection in these patients. In human NK cells, the activating signals involve DAP-10.<sup>864</sup>

Certain members of the MHC class I KIR and CD94 receptor families also are candidates to contribute to NK cell activation. These activating KIRs, such as KIR2DS, also are referred to as KARs. KARs retain the characteristic extracellular immunoglobulin-like domains of KIRs but have short cytoplasmic tails that lack ITIMs and, instead, associate with DAP 12.<sup>833</sup> Similarly, the NKG2 C component of the CD94–NKG2 C heterodimeric receptor lacks an ITIM and activates NK cells by its association with DAP 12.<sup>865</sup> The KARs and the CD94-containing C-type lectin receptors have identical or very similar ligand specificity as their respective inhibitory forms. How NK cells integrate the effects on natural cytotoxicity of activating forms of the KIR family or C-type lectin receptors that recognize the same or similar ligands as their inhibitory counterparts remains unclear.

As with T cells, NK cell–mediated cytotoxicity involves the release of perforin and granzymes from pre-formed cytotoxic granules. NK cell–mediated cytotoxicity also may be mediated by Fas ligand<sup>866</sup> or TRAIL<sup>867</sup> expressed on the activated NK cell surface. Fas ligand–mediated cytotoxicity appears to occur mainly following treatment of NK cells with stimulatory cytokines, such as IL-2, or during ADCC, rather than during natural cytotoxicity (see section on ADCC). Most mouse studies suggest that Fas ligand–mediated cytotoxicity in NK cells is of minor or no importance compared with perforin/granzyme-dependent cytotoxicity in the control of viral infections.<sup>868</sup> Fas–Fas ligand interactions also may not be essential for human NK cell control of viral infections: Persons with the autoimmune lymphoproliferative syndrome (ALPS), in which there is dominant-negative inhibition of Fas, do not experience an increased severity of herpesvirus infections, such as with CMV.<sup>869</sup>

### **Antibody-Dependent Cellular Cytotoxicity**

In addition to natural cytotoxicity, NK cell–mediated ADCC is triggered when IgG bound to target cells engages the Fc $\gamma$ RIIIA receptor on the NK cell.<sup>836</sup> The Fc $\gamma$ RIIIA receptor, which is also found on macrophages and a small subset of T cells, consists of the CD16 molecule, which binds IgG via its Fc domain, and its associated homo- or heterotrimers of CD3- $\zeta$  or the Fc $\epsilon$ R1 $\gamma$  chain, or both.<sup>833</sup> Because of the relative ease with which ADCC can be triggered experimentally, substantially more is known of the events in activation and effector function than for natural cytotoxicity. As in the

case of T cell activation, FcγRIIIA engagement appears to sequentially activate tyrosine kinases of the Src and Syk families, followed by downstream signals, that include increased  $[Ca^{2+}]_i$  and activation of Rho, Ras, p38 mitogen-activated protein kinase, and extracellular signal-regulated kinases.<sup>833</sup> In contrast with natural cytotoxicity, in which perforin/granzyme-dependent mechanisms appear to be predominant, ADCC appears to utilize both perforin/granzyme- and Fas ligand-dependent cytotoxic mechanisms.<sup>870</sup>

### Natural Killer Cell Cytokine Responsiveness and Dependence

NK cell proliferation and cytotoxicity are enhanced *in vitro* by cytokines produced by T cells (IL-2, IFN-γ), APCs (IL-1, IL-10, IL-12, IL-18, and IFN-α), and nonhematopoietic cells such as bone marrow mesenchymal cells (IL-15, stem cell factor, and Flt3 ligand) and fibroblasts (IFN-β). Certain CC chemokines, such as monocyte chemoattractant protein-1 CCL2 (monocyte chemoattractant protein [MCP]-1), CCL3 (MIP-1α), and CCL4 (MIP-1β), also may enhance NK cell function. IL-15, which appears critical for the development of NK cells in the bone marrow, also promotes the survival of mature NK cells<sup>849</sup> and, like IL-12, increases the expression of perforin and granzymes.<sup>871</sup> NK cell cytotoxicity *in vivo* is modestly decreased in mice genetically deficient in IFN-γ,<sup>872</sup> IL-12,<sup>873</sup> or IL-18,<sup>874</sup> and markedly depressed in combined IL-12 and IL-18 deficiency. These findings suggest that IL-12 and IL-18 largely act in a nonredundant fashion to help maintain NK cell cytotoxicity *in vivo*, and this maintenance is mediated, at least in part, by the induction of IFN-γ by these cytokines. The role of the recently identified members of the IL-12 family—that is, IL-23 and IL-27<sup>875</sup>—in regulating NK cell function *in vivo* remains unclear.

When NK cells are primed by cytokine exposure or are triggered *in vitro* for ADCC, they also become prone to apoptosis in the absence of exogenous cytokine exposure. Apoptosis of primed NK cells can occur *in vitro* after engagement of their surface CD2, CD16, or CD94 molecules.<sup>876</sup> Analogous to effector T cell populations, this tendency for NK effector cells to undergo apoptosis may help limit total NK cell numbers and avoid abnormal lymphoproliferation. The extent to which NK cell apoptosis occurs *in vivo*, particularly following natural cytotoxicity, is unknown.

### Natural Killer Cell Cytokine and Chemokine Production

NK cells are also important producers of IFN-γ and TNF-α in the early phase of the immune response to viruses, and IFN-γ may promote the development of CD4 T cells into T<sub>H</sub>1 effector cells. NK cell-mediated IFN-γ production may be induced by the ligation of surface β<sub>1</sub> integrins on the NK cell surface,<sup>877</sup> as well as by the cytokines IL-1, IL-12, and IL-18,<sup>878</sup> which are produced by DCs and mononuclear phagocytes. The combination of IL-12 and IL-15 also potently induces NK cells to produce the CC chemokine MIP-1α (CCL-3),<sup>879</sup> which may help chemoattract other types of mononuclear cells to sites of infection, where NK cell-mediated lysis takes place. NK cells from HIV-infected persons also are able to produce a variety of CC chemokines, including MIP-1α, MIP-1β, and RANTES in response to treatment with IL-2 alone; these chemokines may help prevent HIV infection of T cells and mononuclear phagocytes by

acting as antagonists of the HIV co-receptor. NK cells also can be triggered to produce a similar array of cytokines during ADCC *in vitro*, but the role of such ADCC-derived cytokines in regulating immune responses *in vivo* remains poorly defined.

Some of the cytokine-dependent mechanisms by which NK cells, T cells, and APCs may influence each other's function, such as in response to infection with viruses and other intracellular pathogens, are summarized in Figure 4-12. In addition, studies in mice indicate that cytokines produced by NK cells, such as IFN-γ, also may allow the B cells to respond to TI-type antigens, such as purified polysaccharides and certain protein antigens with repetitive B cell epitopes.<sup>880</sup> Human NK cells also have been shown to produce T<sub>H</sub>2 cytokines such as IL-5 and IL-13, but the importance of these in regulating immune function *in vivo* remains unclear.

### Peripheral Natural Killer Cell Subsets

Mature NK cells found outside of the bone marrow can be further subdivided into CD56<sup>hi</sup> and CD56<sup>lo</sup> populations that demonstrate low and high levels, respectively, of CD16 surface expression.<sup>881</sup> CD56<sup>hi</sup> cells usually are only a minority of mature NK cells in the circulation but express CCR7 and L-selectin and predominate in lymph node tissue. Compared with CD56<sup>lo</sup> cells, CD56<sup>hi</sup> cells have a limited capacity to carry out either natural cytotoxicity or ADCC. By contrast, CD56<sup>lo</sup> NK cells have a much more limited capacity to produce cytokines and chemokines than that observed for the CD56<sup>hi</sup>

**Figure 4-12** Cytokines link innate and antigen-specific immune mechanisms against intracellular pathogens. Activation of T cells by antigen-presenting cells, such as dendritic cells and mononuclear phagocytes, results in the expression of CD40 ligand and the secretion of cytokines, such as interleukin (IL)-2 and interferon (IFN)-γ. Mononuclear phagocytes are activated by IFN-γ and the engagement of CD40 with increased microbicidal activity. Mononuclear phagocytes produce tumor necrosis factor (TNF)-α, which enhances their microbicidal activity in a paracrine or autocrine manner. Mononuclear phagocytes also secrete the cytokines IFN-α/β, IL-12, IL-15, IL-18, IL-23, and IL-27. These cytokines promote T<sub>H</sub>1 effector cell differentiation and most also promote natural killer (NK) cell activation. IL-15 (*not shown*) also is particularly important for the generation of effector and memory CD8<sup>+</sup> T cells. NK cell activation is further augmented by IL-2 and possibly by IL-21, which are produced by CD4<sup>+</sup> T cells. Activated NK cells in turn secrete IFN-γ, which further enhances mononuclear phagocyte activation and T<sub>H</sub>1 effector cell differentiation.

subset.<sup>882</sup> These features suggest that the CD56<sup>hi</sup> subset could regulate lymph node T cells and DCs through cytokine secretion. The precursor-product relationship between CD56<sup>lo</sup> and CD56<sup>hi</sup> NK cells and the mechanisms by which they are generated in vivo (e.g., CD56<sup>hi</sup> cells have been proposed as terminal effector cells)<sup>883</sup> remain controversial.

### **Natural Killer Cells of the Maternal Decidua and Their Regulation by Human Leukocyte Antigen G**

The maternal decidua contains a prominent population of NK cells, and these cells may help contribute to the maintenance of pregnancy. NK cells belonging to the CD56<sup>hi</sup> subset (high capacity for cytokine production and low capacity for cytotoxicity) predominate. Murine studies suggest that NK cell-derived cytokines, such as IFN- $\gamma$ , may play a role in helping remodel the spiral arteries of the placenta. Although the NK cell populations of the decidua have a low capacity for cytotoxicity, their presence in a tissue lacking expression of conventional MHC class I molecules could potentially contribute to placental damage and fetal rejection. The expression by trophoblast of HLA-G (see section on nonclassic antigen presentation molecules), which is at particularly high levels during the first trimester of pregnancy, has been hypothesized to engage inhibitory receptors on maternal NK cells of the decidual or circulation in order to limit such damage. HLA-G-mediated inhibition of NK cell cytotoxicity may involve engagement of CD94–NKG2 A, certain KIRs, CD85j (ILT2), or as-yet uncharacterized receptors.<sup>884</sup>

### **Natural Killer Cell Development and Function in the Fetus and Neonate**

#### **Fetal and Neonatal Natural Killer Cell Development and Surface Phenotype**

The development of human NK cells precedes that of  $\alpha\beta$  T cells during ontogeny, demonstrating their thymic independence. The fetal liver produces NK cells as early as 6 weeks of gestation, which become increasingly abundant during the second trimester.<sup>830</sup> CD34<sup>+</sup>CD38<sup>+</sup>Lin<sup>-</sup> cells of the second trimester fetal liver give rise to NK-like cells rather than T-lineage cells after culture in vitro with the cytokines IL-7, IL-15, and Flt-3 ligand,<sup>885</sup> suggesting that the fetal liver is the main site of development of NK cells rather than extrathymic T cells. In the murine fetal thymus, NK cells appear prior to  $\alpha\beta$ -TCR<sup>+</sup> thymocytes.<sup>886</sup> A similar sequence of events applies in humans, but the immunologic importance of thymus-derived NK cells remains unclear. The bone marrow is the major site for NK cell production from late gestation onward.

The precise developmental sequence of NK cell maturation in the bone marrow remains poorly understood. CD34<sup>+</sup>Lin<sup>-</sup> cells expressing CD7 or CD38 are found in the adult bone marrow and the neonatal or adult circulation and appear to be enriched for NK cell progenitors.<sup>104,839</sup> In vitro treatment of these progenitor cells with cytokines or stromal cells, or both, results in the appearance of CD56<sup>+</sup> cells with NK cell features, including natural cytotoxicity and CD94 surface expression.<sup>887,888</sup>

Studies using in vitro cultures of single neonatal CD34<sup>+</sup>Lin<sup>-</sup> blood cells suggest that during differentiation

the commitment to NK lineage is made first, followed by the acquisition of inhibitory receptors.<sup>889</sup> CD34<sup>+</sup> cells with these or similar characteristics in the thymus also can differentiate into thymocytes or lymphoid DCs, depending on the culture conditions, suggesting the existence of a common T/NK/lymphoid DC.<sup>842</sup>

IL-15 appears to be critical for directing less committed lymphocyte precursors into the NK lineage,<sup>848,890</sup> and for promoting the survival of mature NK cells.<sup>849</sup> Neonatal mononuclear cells produce less IL-15 than do adult cells after LPS stimulation.<sup>891</sup> It is unlikely, however, that this applies to IL-15-producing cells at major sites of NK cell development, such as the fetal bone marrow and fetal liver, because NK cells are present in greatest numbers in the circulation during the second trimester of fetal development,<sup>892</sup> and their number in the neonatal circulation (approximately 15% of total lymphocytes) is typically the same as or greater than in adults.<sup>830</sup> These observations suggest that developing NK lineage cells in fetus and neonate have normal IL-15 responsiveness.

In contrast with adult NK cells, most fetal liver NK cells express the CD3- $\epsilon$  and CD3- $\delta$  components associated with the TCR and lack CD16 surface expression<sup>830</sup>. Virtually all fetal and neonatal NK cells lack expression of CD57.<sup>893,894</sup> The surface expression of CD7, CD16, CD18, CD44, and the KIR (p70 or NKB1) by circulating neonatal and adult NK cells is similar.<sup>893,894</sup> The fraction of fetal and neonatal NK cells that express CD2 or CD56, however, is reduced by about 30% to 50%, compared with that in the adult.<sup>830,831,893,895</sup> Fetal NK cells, unlike adult NK cells, also may frequently express CD28, but it is unclear if they respond to engagement by CD80 or CD86, the ligands of CD28.

#### **Fetal and Neonatal Natural Killer Cell-Mediated Cytotoxicity**

The cytolytic function of NK cells increases progressively during fetal life to reach values approximately 50% (a range of 15% to 60% in various studies) of those in adult cells at term, as determined in assays using tumor cell targets, such as the K562 erythroleukemia cell line, and either unpurified<sup>1414,896-901</sup> or NK cell-enriched preparations.<sup>830,893,897,899,902-904</sup> Reduced cytotoxic activity by neonatal NK cells has been observed in studies using cord blood from vaginal or cesarean section deliveries or peripheral blood obtained 2 to 4 days after birth.<sup>905</sup> Full function is not achieved until the age of at least 9 to 12 months. Cytolytic function is also markedly reduced by bacterial sepsis in neonates.<sup>905</sup> NK cells from the premature infant also have reduced cytotoxic function compared with those of the term neonate.<sup>830,906</sup> The reduced cytolytic activity appears to reflect primarily diminished postbinding cytotoxic activity and diminished recycling to kill multiple targets. This reduction of cytolytic activity parallels the reduced number of CD56<sup>+</sup> NK cells—when only CD56<sup>+</sup> neonatal NK cells are studied, their cytolytic activity is usually similar to that in adult NK cells.<sup>830,903</sup> This finding might not seem consistent with the notion that in adults, the CD56<sup>lo</sup> NK cells are more cytolytic than the CD56<sup>hi</sup> subset.<sup>882</sup> Many neonatal NK cells, however, have much lower or undetectable levels of CD56 compared with those in the adult CD56<sup>lo</sup> NK cell subset, suggesting that they are less mature than this adult cell population.

Whether neonatal NK cells have decreased cytolytic activity compared with that of adult cells depends in part on the target cell used. For example, NK cells from term neonates were found to have similar cytotoxic activity as adult cells against non-K562 tumors. Decreased cytotoxic activity by neonatal NK cells compared with adult cells also is consistently observed with HSV-infected<sup>830,907,908</sup> and CMV-infected target cells.<sup>909</sup> By contrast, both neonatal and adult NK cells have equivalent cytotoxic activity against HIV-1-infected cells.<sup>906,910</sup> These results suggest that ligands on the target cell or its intrinsic sensitivity to induction of apoptosis may influence fetal and neonatal NK cell function. The mechanisms of these pathogen-related differences remain unclear, but may contribute to the severity of neonatal HSV infection.

Paralleling the reduction in natural cytotoxic activity of neonatal cells, ADCC of neonatal mononuclear cells is approximately 50% of that of adult mononuclear cells, including against HSV-infected targets.<sup>906</sup> In contrast with natural cytotoxicity, decreased ADCC mediated by purified neonatal NK cells appears to be caused in part by an adhesion defect in the presence of antibody.<sup>894</sup>

As they do for adult NK cells, cytokines such as IL-2, IL-12, IL-15, IFN- $\alpha$ , IFN- $\beta$ , and IFN- $\gamma$  can augment the cytolytic activity of neonatal NK cells within a few hours.<sup>893,894,911,912</sup> Consistent with the ability of IL-2 and IFN- $\gamma$  to augment their cytolytic activity, neonatal NK cells express on their surface receptors for IL-2 and IFN- $\gamma$  in numbers that are equal to or greater than those of adult NK cells.<sup>913</sup> Neonatal NK cells are less responsive to activation by the combination of IL-12 and IL-15 than are adult NK cells, however, as indicated by the induction of CD69 surface expression.<sup>914,915</sup>

Circulating neonatal NK cells have increased natural cytotoxic activity and ADCC activity on incubation from 18 hours to 3 weeks with IL-2, IL-12, IL-15, or IL-18 or combinations, which leads to their differentiation into lymphokine-activated killer (LAK) cells.<sup>66,419,441,895,906,908,912,914-920</sup> Neonatal LAK cells often have cytotoxic activity equivalent to that of adult LAK cells, suggesting that neonatal NK cells have a normal capacity to be primed by exogenous cytokines.

The generation of neonatal LAK cells from NK cells also increases their surface expression of CD56 as a result of differentiation of CD56<sup>-</sup> NK cells into CD56<sup>+</sup> LAK cells, rather than expansion from the preexisting neonatal CD56<sup>+</sup> NK population.<sup>917,921</sup> This finding suggests that the neonatal CD56<sup>-</sup> NK cell population is a phenotypically and functionally immature NK cell subset that gives rise to a mature CD56<sup>+</sup> population.

The mechanisms responsible for decreased NK cell-mediated cytotoxicity in the neonate are undefined. Soluble MHC class I is present at a 10-fold greater concentration in cord serum than that in adult serum; the greater concentration could contribute to decreased neonatal NK cytotoxicity, perhaps by engaging KIRs.<sup>908</sup> Exposure to levels of soluble MHC class I present in cord blood has only a modest inhibitory effect on NK cytotoxicity in vitro,<sup>908</sup> however, so this is unlikely to be a major factor. Cell-mediated suppression also has been proposed, although this effect has not been shown in mixing experiments.<sup>922</sup> Nor is decreased neonatal NK cell-mediated cytotoxicity due to decreased binding to target cells,<sup>908</sup> or to decreased levels of intracellular perforin or granzyme B.<sup>917</sup>

Treatment of neonatal NK cells, including the CD56<sup>-</sup> subset, with ionomycin and PMA enhances natural cytotoxicity to levels present in adult NK cells.<sup>917</sup> This increase is blocked by inhibitors of granule exocytosis, indicating that decreased release of granules containing perforin and granzyme may contribute to reduced neonatal NK cytotoxicity. Finally, decreased neonatal NK cytotoxicity is not determined at the level of the HSC or later precursor cells of the NK cell lineage: Donor-derived NK cells appear early following cord blood transplantation, with good cytotoxicity effected through the perforin/granzyme and Fas-Fas ligand cytotoxic pathways.<sup>923</sup>

### **Cytokine Production by Neonatal Natural Killer Cells**

Neonatal NK cells produce IFN- $\gamma$  as effectively as adult NK cells in response to exogenous IL-2 and HSV<sup>924</sup> or to polyclonal stimulation with ionomycin and PMA.<sup>354</sup> IL-12-induced production of IFN- $\gamma$  by neonatal mononuclear cells (most likely NK cells) may be reduced compared with that in adult cells.<sup>85,911</sup> Purified neonatal NK cells, however, produce substantially more IFN- $\gamma$  than adult NK cells after stimulation with the combination of IL-12 and IL-18.<sup>924a</sup> Fewer neonatal NK cells express TNF- $\alpha$  than do adult NK cells following ionomycin and PMA stimulation.<sup>354</sup> The production of other cytokines by neonatal NK cells, particularly with physiologic stimuli, is not known.

### **Natural Killer Cells in Congenital Infection**

Congenital viral or *Toxoplasma* infection during the second trimester may increase the number of circulating NK cells.<sup>892</sup> Elevation of number of NK cells can persist until birth, accompanied by decreased NK cell expression of the CD45RA isoform and increased expression of the CD45RO isoform of the CD45 tyrosine phosphatase.<sup>551</sup> This CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> phenotype suggests in vivo activation, similar to that in NK cells incubated in vitro with IL-2 or tumor cell targets.<sup>925</sup>

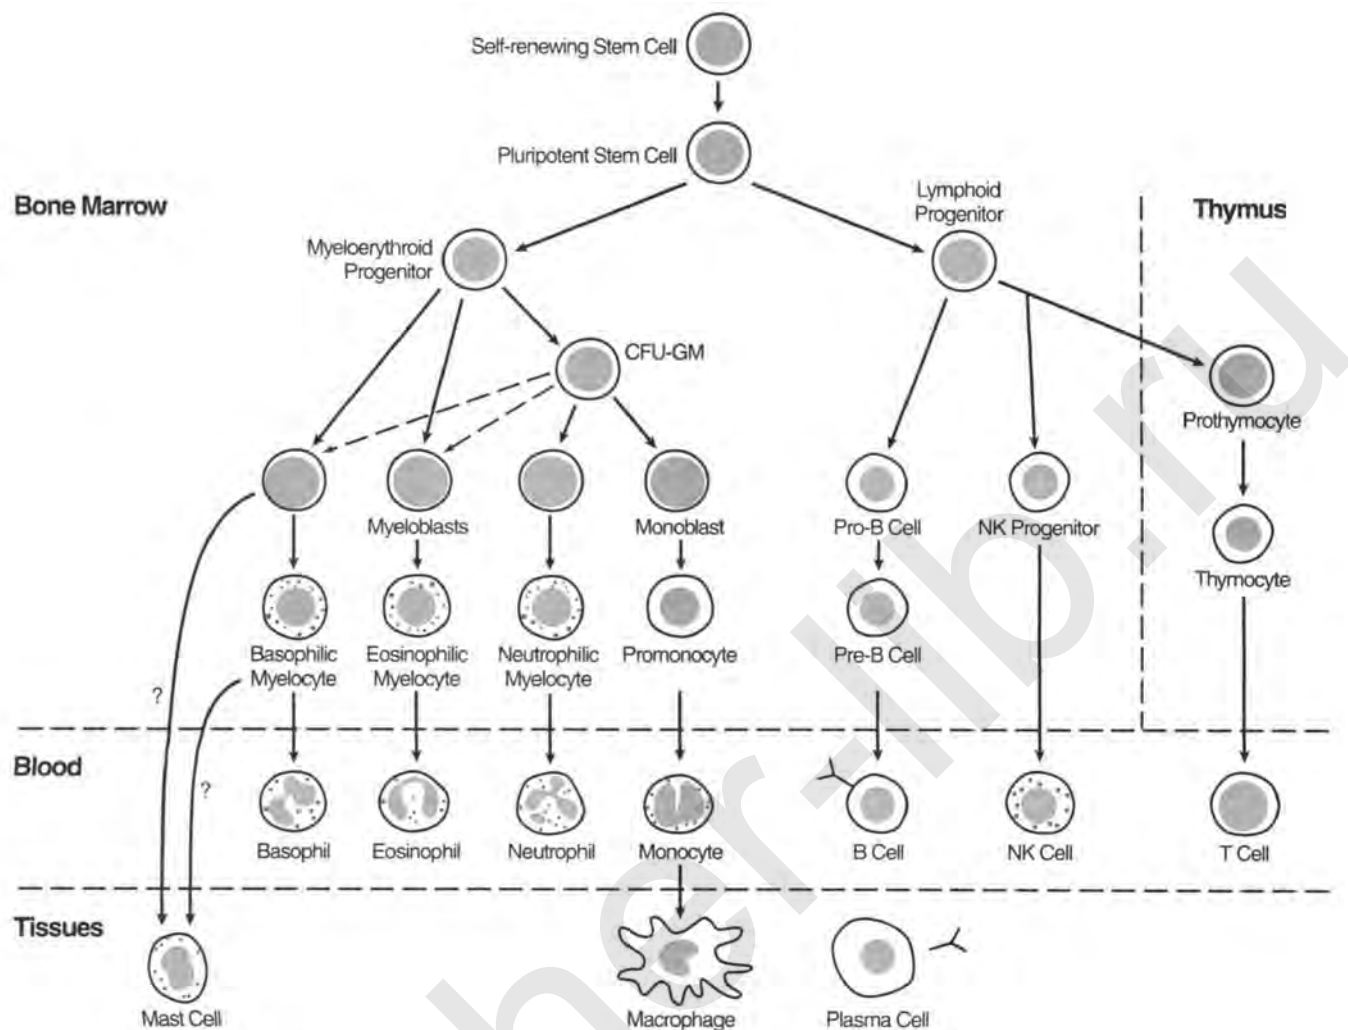

### **Summary**

Although NK cells appear early during gestation and are present in normal numbers by mid- to late gestation, approximately 50% of these cells at birth are CD56<sup>-</sup>. This surface phenotype is a marker for NK cell immaturity, but the relationship between CD56<sup>-</sup> and CD56<sup>+</sup> cells is unclear. Neonatal NK cells have decreased cytotoxicity to several target cells, including virus-infected target cells, compared with adult NK cells, most of which are CD56<sup>+</sup>. Neonatal NK cell cytotoxicity can be augmented by incubation with cytokines in vitro, suggesting a potential immunotherapeutic strategy.

## **PHAGOCYTES**

### **Origin and Differentiation of Phagocytes**

Phagocytes are derived from a common precursor myeloid stem cell, which often is referred to as the colony-forming unit-granulocyte-monocyte (CFU-GM) (Fig. 4-13). The formation of myeloid stem cells from pluripotent HSCs and further differentiation of the myeloid precursor into mature granulocytes and monocytes are governed by (1) stromal

**Figure 4-13** Myeloid and lymphoid differentiation and tissue compartments in which they occur. CFU-GM, colony-forming unit–granulocyte-macrophage.

cells present in the bone marrow environment and the cell-cell contacts between these cells and hematopoietic progenitors and (2) soluble colony-stimulating factors (CSFs) and other cytokines produced by these and other cells (see Table 4-2).<sup>926,927</sup> Factors that act primarily on early HSCs include stem cell factor (also known as steel factor or c-Kit ligand) and Flt-3 ligand. The response to these factors is enhanced by granulocyte colony-stimulating factor (G-CSF) and thrombopoietin, hematopoietic growth factors originally identified by their ability to enhance the production of neutrophils and platelets, respectively, and by IL-1, IL-3, and IL-6. Other factors act later and are more specific for given myeloid lineages: GM-CSF acts to increase the production of neutrophils, eosinophils, and monocytes; G-CSF acts to increase neutrophil production; macrophage colony-stimulating factor (M-CSF) acts to increase monocyte production; and IL-5 enhances eosinophil production.

The precise role of these mediators in normal steady-state hematopoiesis is becoming clearer, primarily as a result of studies in mice with targeted disruptions of the relevant genes. Genetic defects in the production of biologically active stem cell factor or its receptor c-Kit lead to mast cell

deficiency and severe anemia, with less severe defects in granulocytopoiesis and in formation of megakaryocytes,<sup>928</sup> whereas deficiency of Flt-3 ligand has no overt effect except on B cell progenitors. Deficiency for both Flt-3 ligand and c-Kit has a more severe phenotype than for either alone, indicating partial redundancy in their function. Deficient production of M-CSF is associated with some diminution in macrophage numbers and a marked deficiency in maturation of osteoclasts (presumably from monocyte precursors), which results in a form of osteopetrosis.<sup>929</sup> Mice with a targeted disruption of G-CSF or its receptor and humans with mutations in the G-CSF receptor are neutropenic (although they do not completely lack neutrophils) and have fewer multilineage hematopoietic progenitor cells.<sup>927</sup> By contrast, in mice, GM-CSF deficiency causes pulmonary alveolar proteinosis but does not affect the numbers of neutrophils, monocytes, or eosinophils, whereas IL-5 deficiency results in an inability to increase the numbers of eosinophils in response to parasites or allergens. Thus, hematopoietic growth factors appear to play complex and, in some cases, partially overlapping roles in normal steady-state production of myeloid cells.

In response to an infectious or inflammatory stimulus, CSF production is increased. Under these conditions, concentrations sufficient to enhance growth and differentiation of myeloid cells are produced and are believed to play an important role in the enhanced marrow production and release of granulocytes and monocytes that are observed. Similarly, when given exogenously, these factors enhance production of the indicated cell lineages.<sup>930</sup>

## Neutrophilic Polymorphonuclear Leukocytes

### *Origin and Derivation of Neutrophils in the Mature Host*

Polymorphonuclear leukocytes or granulocytes are derived from CFU-GM. Neutrophilic granulocytes are the principal cells of interest in relation to defense against pyogenic pathogens. This section specifically addresses these cells. The first identifiable committed granulocyte precursor is the myeloblast, which sequentially matures into myelocytes, metamyelocytes, bands, and mature neutrophilic granulocytes or polymorphonuclear leukocytes. Myelocytes and more mature neutrophilic granulocytes cannot replicate and constitute the postmitotic neutrophilic storage pool.<sup>931</sup> Mature neutrophils enter the circulation, where they remain for 8 to 10 hours and are distributed equally and dynamically between circulating cells and those adherent to the vascular endothelium.<sup>931</sup> After leaving the circulation, neutrophils normally do not recirculate, and after about 24 hours in tissues, they die.

The postmitotic neutrophil storage pool is an important reserve, because these cells can be rapidly released into the circulation in response to inflammation. Furthermore, increased production of stem cells in response to inflammation requires approximately 5 to 7 days before it can contribute to increased neutrophil output. Accelerated maturation or replication from nonstem cells in the mitotic compartment may enhance this neutrophil output somewhat. Nevertheless, the storage pool size is a critical determinant of the host's capacity to increase neutrophil output in response to infection.

As indicated, the control of granulocyte production and release is regulated by CSFs or hematopoietic growth factors. Neutrophil production is specifically favored by G-CSF but also is facilitated by the more broadly acting IL-3 and GM-CSF. These factors enhance the proliferation of neutrophil precursors by driving progenitor cells to enter the cell cycle and, in the case of G-CSF, biasing progenitors capable of differentiating into granulocytes or monocytes into the neutrophil differentiation pathway. Granulocyte production also appears to be under potential negative regulation by prostaglandins and iron-containing proteins such as lactoferrin.<sup>927,931</sup> These negative regulators are produced by granulocytes and monocytes, suggesting that mature cells may self-regulate production. Release of neutrophils from the marrow may be enhanced in part by cytokines, including IL-1 and TNF- $\alpha$ , in response to infection or inflammation.<sup>926</sup>

### *Migration to Sites of Infection*

After release from the bone marrow into the blood, neutrophils circulate until they are called on to enter the tissues at sites of infection or injury. Neutrophils adhere selectively to endothelium in inflamed tissues but not in

normal tissues. The adhesion and subsequent migration of neutrophils through blood vessels and into the tissues are governed by cell adhesins expressed on the neutrophil and on the vascular endothelium and by specific chemotactic factors.

### **Adhesion**

The adhesion molecules that are known to play a central role in neutrophil adherence are derived from one of three families of cell surface glycoproteins: the selectins, the integrins, and certain members of the immunoglobulin gene superfamily.<sup>932,933</sup>

The selectins are named by the cell types in which they are primarily expressed: L-selectin by leukocytes, E-selectin by endothelial cells, and P-selectin by platelets and endothelial cells. Selectins are named for their ability to bind to specific types of carbohydrates that are selectively expressed on different tissues; binding is mediated through a lectin-like domain found in all family members. L-selectin is constitutively expressed on leukocytes and appears to bind to tissue- or inflammation-specific carbohydrate-containing ligands on endothelial cells. E-selectin and P-selectin are expressed only on activated, not resting, endothelial cells or platelets. E- and P-selectin bind to sialylated glycoproteins on the surface of leukocytes, including P-selectin glycoprotein ligand-1 (PSGL-1). L-selectin binds to glycoproteins (including CD34 and MAdCAM-1) and to glycolipids that are expressed on vascular endothelial cells in specific tissues.

The integrins are a large family of heterodimeric proteins composed of an  $\alpha$  and a  $\beta$  chain. Integrins expressing a  $\beta_2$  (CD18) chain, which associates on the plasma membrane with one of four  $\alpha$  (CD11) chains, are found only on leukocytes. The  $\beta_2$  integrins play a critical role in neutrophil function, because unlike other types of leukocytes, neutrophils do not express other integrins in substantial amounts. The  $\beta_2$  integrins (also known as leukocyte integrins) are constitutively expressed on neutrophils, but both their abundance and their avidity for their endothelial ligands are increased after activation of neutrophils—for example, in response to chemotactic factors. LFA-1 (CD11a-CD18) and Mac-1 (CD11b-CD18) appear to play the predominant role in leukocyte-endothelial cell interactions, whereas CD11c-CD18 plays a lesser role and CD11d-CD18 participates in leukocyte-leukocyte interactions. The endothelial ligands for LFA-1 are members of the immunoglobulin-like family and include ICAM-1 and ICAM-2. Both are constitutively expressed on endothelium, but ICAM-1 expression is increased markedly by exposure to inflammatory mediators, including IL-1, TNF- $\alpha$ , and LPS.

These adhesion molecules and chemotactic factors act in a coordinated fashion to allow neutrophil recruitment into tissues in response to infection or injury. In response to injury or inflammatory cytokines, P-selectin is transferred from endothelial or platelet stores to the surface of the endothelium of capillaries or postcapillary venules within minutes. This mechanism allows neutrophils in the blood to adhere in a low-avidity fashion, which results in rolling of these cells along the vessel walls. This step is transient and reversible unless a second, high-avidity interaction is triggered. If, at the time of the low-avidity binding, neutrophils also encounter chemotactic factors (discussed later) released from the tissues or from the endothelium itself, they rapidly

upregulate the avidity of the LFA-1 and Mac-1 integrins and translocate additional LFA-1 and Mac-1 from specific granules to the neutrophil cell surface. This process enhances binding to ICAM-1 and ICAM-2 on endothelial cells. The high-avidity interaction of these integrins with ICAMs, in the presence of a gradient of chemotactic factors from the tissue to the blood vessel, appears to trigger the migration of neutrophils across the endothelium and into the tissues. Over a matter of several hours, the intensity of this response can be further upregulated by the *de novo* expression of E-selectin and increased expression of ICAM-1 on endothelium in response to mediators (e.g., platelet-activating factor [PAF], TNF- $\alpha$ ) produced at the site of infection or injury.

The profound importance of integrin- and selectin-mediated leukocyte adhesion processes in the normal inflammatory response is illustrated by the genetic leukocyte adhesion deficiency syndromes.<sup>934</sup> Deficiency of the common  $\beta_2$  integrin chain results in the absence on the plasma membrane of all  $\beta_2$  integrins. This results in inability of leukocytes to exit the bloodstream and reach sites of infection and injury in the tissues. Affected patients are profoundly susceptible to infections with pathogenic and nonpathogenic bacteria, have poor tissue healing, and commonly die in the first years of life. Such patients not uncommonly present in early infancy with delayed separation of the umbilical cord, omphalitis, and severe bacterial infection without pus formation. A related syndrome—leukocyte adhesion deficiency syndrome type II—is due to a defect in synthesis of the carbohydrate selectin ligands. This disorder results in a similar defect in neutrophil function and predisposition to infection but also is associated with more general problems related to defects in proper glycosylation of proteins. Studies of mice deficient in specific selectins indicate that P-selectin and E-selectin play partially redundant roles, and that L-selectin acts in concert with either of these two selectins and their ligands to facilitate neutrophil recruitment to sites of inflammation.

### Chemotaxis

Chemotaxis is important for focusing the delivery of leukocytes to the site of infection or injury. Random movement of leukocytes, even if accelerated by stimuli, would be inefficient. Sensing of chemotactic gradients is achieved through cell surface receptors for specific chemotactic factors. A number of receptors for specific chemotactic factors have been molecularly cloned and are related by their common structure. This is consistent with their interaction with heterotrimeric G proteins, which serve to transduce the signal from these receptors. Chemotactic agents may be derived directly from bacterial components or surrogates, such as *N*-formylated Met-Leu-Phe (fMLP) peptide; from activated complement, such as C5a; and from host cell lipids, such as leukotriene B<sub>4</sub> (LTB<sub>4</sub>) and PAF. These chemotactic agents are produced within minutes, because they are derived from preexisting microbial or host components.<sup>935</sup> In addition, a large family of chemotactic cytokines (chemokines) are synthesized by macrophages and other cells within hours (see Tables 4-1 and 4-2).<sup>43,936,937</sup> Chemokines may be displayed on the luminal side of the vascular endothelium through binding to proteoglycans and appear to play an important role in the maintenance and evolution of the inflammatory response.

The receptors for chemotactic agents are located on the cell surface, and additional stores are present in cytoplasmic granules. On exposure to low concentrations of chemotactic agents, the cells express additional receptors on the plasma membrane; some of these are of higher affinity and increase the ability of the cell to sense the chemotactic agent.<sup>938</sup> The cells also sense the spatial gradient of chemotactic agents; a difference of as little as 0.1% can be detected. The cells then orient so that they are flattened at the end toward the highest concentration (the lamellipodium) and have a thin tail (the uropod) at the opposite end. This polarization of the cell requires an intact cytoskeleton network and a fluid cell membrane. The polarized cell contains increased numbers of receptors for chemotactic agents and for IgG at the flattened lamellipodium. Chemotactic agents engaged to receptors on the neutrophil lamellipodium trigger a local and selective release of granules, which contain a pool of the  $\beta_2$  integrins, including Mac-1. Adhesion to the endothelium is thereby augmented at this point of contact, and translocation between endothelial cells is facilitated. Neutrophils may then attach to and ultimately pass through the basement membrane to reach the tissues. PECAM-1 (CD31), which is expressed on both neutrophils and endothelial cells, and components of the extracellular matrix (e.g., fibronectin and laminin) contribute at this stage.<sup>939</sup> Release of digestive enzymes from lysosomes also may facilitate movement of neutrophils through the endothelium and tissues. Neutrophils must undergo considerable deformation to allow diapedesis through the endothelium. Migration through the tissues also is likely to be facilitated by the reversible adhesion and de-adhesion between ligands on the neutrophil surface, including the integrins, with components of the extracellular matrix, such as fibronectin and collagen.

### Phagocytosis and Killing

Phagocytosis by neutrophils occurs in two phases: recognition and ingestion.<sup>940</sup> The recognition phase usually involves binding of opsonized bacteria to specific receptors on the cell surface. Opsonin-independent surface phagocytosis also may occur but is less efficient, particularly for encapsulated organisms. Opsonization, a process whereby immunoglobulin, complement, or certain other host-derived proteins, or all three, are bound to the surface of the organism, is discussed later in this chapter. Neutrophils contain specific receptors for the Fc portion of the IgG molecule (Fc $\gamma$  receptors) and receptors for two different forms of the activated third component of complement.<sup>576</sup> C3b is bound by CR1, and C3bi by CR3 and CR4; CR3 and CR4, respectively, are the CD11b-CD18 and CD11c-CD18 integrins described previously.<sup>941</sup> Opsonized bacteria bind and cross-link Fc $\gamma$  and C3b-C3bi receptors, and this cross-linkage transmits a signal for ingestion and, in the case of Fc $\gamma$  receptors, for the activation of the cell's microbicidal mechanisms. Signal transduction from these receptors is not fully elucidated but appears to involve a series of intracellular events, including increases in [Ca<sup>2+</sup>]; and activation of tyrosine kinases, serine/threonine protein kinases (including protein kinase C), phospholipase A<sub>2</sub>, and small guanosine triphosphate (GTP)-binding proteins.

Once ingested, microbes are exposed to a variety of potent microbicidal products. Oxygen-dependent microbicidal

mechanisms are of central importance, as illustrated by the severe compromise in defenses against a wide range of pyogenic pathogens (with the exception of catalase-negative bacteria) observed in children with a genetic defect in this system.<sup>942</sup> This disorder—chronic granulomatous disease—results from a defect in one of four intracellular proteins that together form the phagocyte oxidase. This oxidase consists of two plasma membrane-associated and two cytosolic components. In response to activation of the cell—for example, during receptor-mediated phagocytosis—these four components are assembled in the plasma membrane into an enzymatic complex that transfers an electron to the oxygen molecule. This forms superoxide anion, which has weak microbicidal activity and is a precursor for more toxic compounds, including hydrogen peroxide and hydroxyl radicals. The assembly of the oxidase in the plasma membrane allows these products to be secreted into the nascent or fully formed phagocytic vacuole, where their activity can be focused on the microbe. The activity of hydrogen peroxide also can be augmented by myeloperoxidase, a protein stored in neutrophil granules, which are discharged into the phagocytic vacuole.

In addition to myeloperoxidase, the neutrophil contains other granule proteins with potent microbicidal activity. These mediate oxygen-independent killing. Many of these are relatively small, cationic proteins with direct microbicidal activity, including the defensins, elastase, cathepsin G, and a protein that binds selectively to gram-negative lipopolysaccharide, bactericidal permeability-increasing (BPI) protein.<sup>658,943,944</sup>

### Production of Inflammatory Mediators by Neutrophils

Neutrophils produce leukotrienes, primarily LTB<sub>4</sub>, PAF, and certain cytokines that facilitate the inflammatory response. These include IL-1,<sup>945</sup> TNF- $\alpha$ ,<sup>946</sup> and members of the CXC chemokine family, such as IL-8 (CXCL8).<sup>43,936</sup> Thus, in addition to playing a direct role in microbicidal killing, neutrophils may modulate the inflammatory response.

## Neutrophils in the Fetus and Neonate

### Neutrophil Production and Release

Neutrophil precursors are detected first in the yolk sac and then in the liver, spleen, and bone marrow, appearing somewhat later than macrophage precursors.<sup>947,948</sup> Mature neutrophils are first detected by 14 to 16 weeks of gestation. The numbers of circulating neutrophil precursors (CFU-GMs) are 10- to 20-fold higher in the fetus and neonate than in the adult, and neonatal bone marrow also contains an abundance of neutrophil precursors.<sup>947,949</sup> The rate of proliferation of circulating neutrophil precursors in the human neonate appears to be near maximal,<sup>947,950</sup> however, suggesting that the capacity to increase the numbers of CFU-GMs in response to infection may be limited. In contrast with the numbers of CFU-GMs, in the mid-gestation human fetus, the numbers of postmitotic neutrophils in the fetal liver and bone marrow are markedly lower than in term newborns and adults.<sup>951</sup> Furthermore, at this stage of gestation, neutrophils constitute less than 10% of circulating leukocytes, rising to values of 50% to 60% at term.

Within hours of birth, the numbers of circulating neutrophils increase sharply in term and preterm neonates.<sup>952,953</sup> One study of healthy term neonates reported absolute neutrophil counts at 4 hours of  $9.5 \times 10^3$  to  $21.5 \times 10^3/\text{mm}^3$  (10th to 90th percentile) and an immature-to-mature neutrophil ratio of 0.05 to 0.27.<sup>954</sup> The number of neutrophils normally peaks shortly thereafter, whereas the fraction of neutrophils that are immature (bands and less mature forms) remains constant at about 15% (Fig. 4-14). Values may be influenced by a number of factors. Most important is the response to sepsis. Septic infants may have normal or increased neutrophil counts. Sepsis and other perinatal complications, including maternal hypertension, periventricular hemorrhage, and severe asphyxia, can cause neutropenia, however, and severe or fatal sepsis often is associated with persistent neutropenia, particularly in preterm neonates.<sup>947,955,956</sup> Neutropenia may be associated with increased margination of circulating neutrophils, which occurs early in response to infection.<sup>931</sup> Neutropenia that is sustained, however, often reflects depletion of the neonate's, particularly the premature

**Figure 4-14** Change in total number of neutrophils (*left*) and in ratio of immature to total neutrophils (I:T, *right*) in the neonate. (Data from Manroe BL, Weinberg AG, Rosenfeld CR, et al. The neonatal blood count in health and disease. I. Reference values for neutrophilic cells. *J Pediatr* 95:89-98, 1979.)

neonate's, limited postmitotic neutrophil storage pool. Accordingly, septic neutropenic neonates in whom the neutrophil storage pool is depleted are more likely to die than are those with normal neutrophil storage pools.<sup>956</sup> Leukemoid reactions also are observed at a frequency of approximately 1% in term neonates in the absence of infection or other definable cause. Such reactions appear to reflect increased marrow production of neutrophils and are not consistently associated with increased G-CSF concentrations.<sup>957</sup>

As discussed earlier, CSFs, particularly G-CSF, are important for neutrophil production, survival, and optimal function. Mononuclear cells and monocytes from mid-gestation fetuses and premature neonates generally produce less G-CSF and GM-CSF after stimulation *in vitro* than do similar cell populations from adults, whereas cells from term neonates produce amounts that are similar to or modestly less than those of adults (see Table 4-4). In contrast with these findings, circulating G-CSF levels in healthy infants are highest in the first hours after birth, and levels in premature neonates are generally higher than in term neonates.<sup>958-960</sup> Levels decline rapidly in the neonatal period and subsequently decline more slowly with aging. One study reported a direct correlation between circulating levels of G-CSF and the blood absolute neutrophil count, although this finding has not been confirmed in other studies.<sup>958,959</sup> Plasma G-CSF levels tend to be elevated in infected mature and premature neonates,<sup>960</sup> although some studies have found considerable overlap with the levels of those who are uninfected.<sup>961</sup> In one report, G-CSF levels in neutropenic neonates without sepsis were not elevated above normal, whereas levels in neutropenic adults undergoing chemotherapy were markedly increased.<sup>962</sup> Although the cause of neutropenia in these neonates was not described, these observations raise the possibility that deficient G-CSF production might be a contributory factor to neutropenia in some neonates.

Overall, the available data suggest that the most critical deficiency in phagocyte defenses in the fetus and neonate, particularly the premature neonate, is their limited ability to accelerate neutrophil production in response to infection. This age-specific limitation appears to result in large part from a limited neutrophil storage pool, and perhaps a more limited ability to increase neutrophil production in response to infection. This limitation in neutrophil production is not clearly due to a deficiency in the production of G-CSF *in vivo*, although such deficiency may be a factor in some cases. As discussed under "Colony-Stimulating Factors" in the section on adjunctive therapy of pyogenic infections, trials of G-CSF or GM-CSF have been undertaken to determine whether this form of intervention can ameliorate these deficits in neutrophil production.

### **Migration to Sites of Infection**

In addition to defects in neutrophil production in response to infection, a substantial body of evidence suggests that the ability of neonatal neutrophils to migrate from the blood into sites of infection and inflammation may be reduced or delayed.<sup>963</sup> In human neonates, the early inflammatory response in the skin often contains a larger number of eosinophils than in adults, and the transition from a neutrophilic to a mononuclear cell-dominated response is delayed. Similarly, the influx of neutrophils into the peritoneal cavity in response to fMLP, group B streptococci, or *E. coli* was

markedly reduced in neonatal rats compared with that in adult rats<sup>964</sup>; this occurred in spite of greater release of marrow neutrophil stores in neonates than in adults. This diminished delivery of neutrophils may result in part from defects in adhesion and chemotaxis.

Adhesion of neonatal neutrophils under resting conditions is normal or at most modestly impaired, whereas adhesion of activated cells is deficient.<sup>965,966</sup> Adhesion of neonatal neutrophils to activated endothelium under conditions of flow similar to those found in capillaries or postcapillary venules is variable but on average only 40% to 45% of that observed with adult neutrophils.<sup>967,968</sup> This decreased adhesion appears to reflect, at least in part, a deficiency in the abundance of L-selectin and ability to shed this protein from the surface of neonatal neutrophils and decreased binding of these cells to P-selectin.<sup>967-969</sup> Many studies<sup>967,968,970</sup> find that resting neonatal and adult neutrophils have similar amounts of the  $\beta_2$  integrins Mac-1 (CD11b-CD18) and LFA-1 (CD11a-CD18) on their plasma membrane. Neutrophils from term and, in particular, preterm neonates, however, have a reduced ability to upregulate expression of these integrins after exposure to chemotactic agents, which is due in part to reduced intracellular stores of these molecules in their granules. This reduced capacity for integrin upregulation is associated with a parallel decrease in adhesion to activated endothelium or purified ICAM-1.<sup>971</sup> Two studies, however, have concluded that expression of Mac-1 and LFA-1 is not reduced on resting or stimulated neonatal neutrophils, and that diminished expression observed in other studies may be an artifact of the methods used to purify neutrophils.<sup>969,972</sup> Nonetheless, the preponderance of data suggests that a deficit in adhesion underlies in part the diminished ability of neonatal neutrophils to migrate through endothelium into tissues.<sup>967,971</sup>

In nearly all studies in which neutrophil migration has been examined *in vitro*, chemotaxis of neonatal neutrophils was less than that of adult neutrophils (Table 4-8). When compared directly, chemotaxis of neonatal peripheral blood neutrophils seems to be more impaired than that of cord blood neutrophils.<sup>973</sup> Some studies have found that chemotaxis remains less than that of adult cells until the infant reaches at least 1 to 2 years of age, whereas others have suggested more rapid maturation.<sup>973,974</sup> The response of neonatal neutrophils to a variety of chemotactic factors, including fMLP, LTB<sub>4</sub>, PAF, and IL-8, is reduced.<sup>975-977</sup> Neutrophil chemotaxis in premature infants is at least as impaired as that of term neonates. Most<sup>963</sup> but not all<sup>978</sup> studies have found that the number and affinity of receptors for fMLP are similar in adult and in neonatal neutrophils, whereas receptors for C5a may be reduced.<sup>979</sup> Thus, decreased chemotaxis probably is due in large part to an event downstream of binding of the chemotaxin to its specific receptor, such as the increases in [Ca<sup>2+</sup>]<sub>i</sub> and inositol phospholipid generation and the change in cell membrane potential within the neutrophil.<sup>980,981</sup> An additional factor may be the reduced deformability of neonatal neutrophils, particularly immature granulocytes, which may limit their ability to enter the tissues after binding to the vascular endothelium.<sup>966</sup> This defect appears to reflect a diminished capacity of neonatal neutrophils to reorganize their cytoskeleton in response to stimulation, rather than altered amounts of tubulin or actin.<sup>963</sup>

Table 4-8 Chemotaxis of Neonatal Granulocytes

Cell Source	Assay	Stimulus	Percentage of Adult Response	Comment	Reference
Cord blood	3- $\mu$ m Nucleopore filter	EAS	79	Normal random motility	973
Peripheral blood	Agarose	ZAS	27	Low until 2 yr of age	974
Cord blood, peripheral blood	3- $\mu$ m Nucleopore filter	EAS	125	Still low at 6 mo of age; normal chemokinesis	1051
Cord blood	Agarose	ZAS	$\leq$ 30	More severe with lower concentration of ZAS	982
Peripheral blood	5- $\mu$ m cellulose filter, whole blood	ZAS	79	Ill neonates = 62%	1423
Cord blood	Cellulose filter, 3, 5, or 8 $\mu$ m	Casein	37-60	Normal random motility, normal chemokinesis	1424
Cord blood	Agarose	EAS	60-80	Normal random motility	1425
Peripheral blood	3- $\mu$ m cellulose		<15		
Peripheral blood	5- $\mu$ m cellulose filter	ZAS	88		1426
Peripheral blood	Cellulose filter	ZAS	-50	Equal to adult by 2 wk response	1427
Cord blood	Agarose	fMLP	70	Low until 1 yr of age	976

EAS, endotoxin-activated serum; fMLP = *N*-formylated Met-Leu-Phe peptide (bacterial surrogate); ZAS, zymosan-activated serum.

Because chemotaxis by neonatal neutrophils is relatively more impaired at low than at high concentrations of chemotactic factors,<sup>982</sup> decreased generation of chemotactic factors in neonatal serum<sup>973,982</sup> may compound the intrinsic chemotactic deficits of neonatal neutrophils. The generation of other chemotactic agents, such as LTB<sub>4</sub>, by neonatal neutrophils appears to be normal, however.<sup>983</sup> Finally, not all changes in response to chemotactic factors are abnormal in neonatal neutrophils: Upregulation of the type 1 complement receptor (CR1) is normal or at most slightly impaired.<sup>972,984</sup>

#### Phagocytosis and Killing of Bacteria by Neonatal Neutrophils

Under optimal in vitro conditions, neutrophils from healthy human term and preterm neonates bind and ingest gram-positive and gram-negative bacteria as well as or only slightly less efficiently than do cells from adults.<sup>963,985,986</sup> Levels of opsonins, including IgG, and of complement are reduced in serum from neonates, in particular preterm neonates. Consistent with this finding, phagocytosis of bacteria by neutrophils from preterm but not term neonates is reduced compared with that observed for cells from adults when assayed in whole blood.<sup>987-989</sup> This deficiency appears to be due primarily to differences in plasma components rather than to differences between neutrophils.<sup>987</sup> Neutrophils from preterm neonates, however, also have reduced numbers of receptors for IgG—Fc $\gamma$ RIII (CD16)—and for complement—C3bi (CD11b-CD18, also known as Mac-1), compared with neutrophils from term neonates and adults.<sup>972,989,990</sup> Neutrophils from preterm neonates also express less of the LPS co-receptor CD14 and are less able to upregulate CD11b and to secrete elastase in response to LPS.<sup>991</sup>

When concentrations of opsonins are limited,<sup>992</sup> neutrophils from term neonates ingest bacteria less efficiently than those from adults. The basis for this decreased efficiency is unknown, because Fc $\gamma$ RII, Fc $\gamma$ RIII, CR1, and CR3 expression is similar.<sup>989</sup> Decreased upregulation of the C3bi receptor, which is the  $\beta_2$  integrin Mac-1, by neonatal neutrophils in response to chemotactic factor or LPS priming may play a role.<sup>993,994</sup>

Killing of ingested gram-positive and gram-negative bacteria and *Candida* organisms by neutrophils from healthy neonates has been normal in most studies.<sup>963,986</sup> Variable and usually mildly decreased bactericidal activity has been noted against *Pseudomonas aeruginosa*,<sup>995</sup> *S. aureus*,<sup>996</sup> and certain strains of group B streptococci, however.<sup>997-999</sup> Deficits in killing by neonatal neutrophils were found to be more apparent at high ratios of bacteria to neutrophils.<sup>1000</sup> Microbicidal activity of neutrophils from sick or stressed neonates (most of whom were born prematurely and had sepsis, respiratory impairment, hyperbilirubinemia, premature rupture of membranes, or hypoglycemia) is more clearly reduced<sup>1001,1002</sup> despite normal<sup>1002</sup> or only variably decreased<sup>1001</sup> phagocytosis. It should be noted, however, that neutrophils from adults with similar illnesses also may have diminished microbicidal activity.<sup>1001</sup> Whether neonatal neutrophils are more severely compromised by illness than those of comparable adults remains to be determined.

Studies to elucidate the mechanisms for differences in microbicidal activity of human neonatal neutrophils have focused on the generation of microbicidal toxic oxygen metabolites.<sup>963,986</sup> In most studies, generation of superoxide anion by human neonatal and fetal neutrophils has been similar to that observed in adult cells. Similarly, neutrophils from term and preterm neonates generate hydrogen peroxide at least as efficiently as cells from adults. By contrast, production of the toxic hydroxyl radical and chemiluminescence (an index of oxygen radical production) may be decreased.<sup>1003</sup> Group B streptococci are highly susceptible to killing by hydroxyl radical but relatively resistant to the action of superoxide anion and hydrogen peroxide.<sup>1004</sup> Thus, if generation of hydroxyl radical by neutrophils from some neonates is deficient, this may contribute to a defect in microbicidal activity for a clinically important pathogen.

Oxygen-independent microbicidal mechanisms of neonatal neutrophils remain poorly characterized. Their ability to release the lysosomal enzymes lysozyme and  $\beta$ -glucuronidase appears to be intact.<sup>963,986</sup> Their content of specific granules and the release of specific granule contents (e.g., lactoferrin) on activation appear to be reduced, how-

ever. Compared with adult neutrophils, neonatal neutrophils are deficient in BPI, a cationic antimicrobial protein with activity against gram-negative bacteria that is present in primary granules, despite comparable amounts of myeloperoxidase and defensins.<sup>1005</sup>

### **Effects of Immunomodulators**

After systemic treatment with G-CSF and GM-CSF, expression of CR3 (CD11b-CD18) on neonatal neutrophil increases.<sup>950</sup> Studies performed *in vitro* indicate that IFN- $\gamma$  and GM-CSF enhance the chemotactic response of neonatal neutrophils.<sup>950,1006</sup> At higher concentrations, however, GM-CSF inhibits chemotaxis; such concentrations are associated with enhancement of oxygen radical production.<sup>1007</sup> The methylxanthine pentoxifylline exhibits a biphasic enhancement of chemotaxis by neonatal neutrophils.<sup>963</sup> None of these agents causes full normalization of chemotaxis compared with that in adult cells. Of potential concern, indomethacin, which is used clinically to facilitate ductal closure in premature neonates, impairs chemotaxis of cells from term and preterm neonates.<sup>1008</sup> Clinical trials of immunomodulators are discussed in the section on adjunctive therapy of pyogenic infections.

### **Eosinophilic Granulocytes**

In adults and older children, eosinophils represent a small percentage of the circulating granulocytes. Their numbers are increased in allergic states, parasitic (particularly metazoal) infections, and in certain autoimmune or malignant disease states. In the fetus and neonate, eosinophils commonly represent a sizable fraction of the total number of circulating granulocytes. At 18 to 30 weeks of gestation, total granulocytes represent only about 10% of total circulating leukocytes, whereas eosinophils constitute 10% to 20% of total granulocytes.<sup>1009</sup> Similarly, in premature neonates, the numbers of eosinophils are increased relative to those in term neonates, often reaching values of 1500 to 3000 cells per mm<sup>3</sup> and representing up to one third of total granulocytes in the first month of life.<sup>1010,1011</sup> The postnatal increase of eosinophils lags behind that of neutrophils, peaking at the third to fourth week of postnatal life. A relative increase in the abundance of eosinophils in inflammatory exudates is seen in neonates, paralleling their greater numbers in the circulation.<sup>968</sup> In addition to prematurity, certain conditions have been associated with a relatively greater degree of eosinophilia; these include Rh disease, total parenteral nutrition, and transfusions.<sup>1010</sup> In contrast with conditions such as allergic and parasitic diseases, neonatal eosinophilia is not associated with increased amounts of circulating IgE.<sup>1011</sup> The basis or the significance of the eosinophilic tendency of the neonate is not known. Certain of the functional deficits observed in neonatal neutrophils, such as the diminished expression of adhesion molecules important in leukocyte migration into tissues, have been observed in neonatal eosinophils.<sup>968</sup>

### **Mononuclear Phagocytes**

#### **Origin and Differentiation in the Adult**

Blood monocytes are derived from bone marrow precursors (monoblasts and promonocytes), which in turn are the precursors of tissue macrophages. Together, monocytes and

tissue macrophages are referred to as mononuclear phagocytes. These cells have multiple functions, including the clearance of dead host cells, phagocytosis of microbes, presentation of antigen to T cells, secretion of inflammatory mediators, and cell-mediated cytotoxicity.

Under steady-state conditions, monocytes are released from the bone marrow within 24 hours and circulate in the blood for 1 to 3 days before moving to the tissues.<sup>1012</sup> Once they have left the blood, monocytes do not recirculate but differentiate into macrophages, which are present in all tissues. Monocytes lose granule myeloperoxidase as they differentiate into tissue macrophages. Other changes depend on the local tissue conditions. For example, monocytes and peritoneal macrophages rely primarily on anaerobic glycolysis, whereas alveolar (lung) macrophages utilize aerobic cytochrome oxidation as well.<sup>1013,1014</sup> The functions of macrophages are readily modulated by cytokines, and macrophages can fuse to form multinucleated giant cells. The estimated life span of macrophages in the tissues is 4 to 12 weeks, and they are capable of limited replication *in situ*.<sup>1013,1014</sup>

#### **Migration to Sites of Infection: Adherence, Chemotaxis, and Delayed Hypersensitivity Reactions**

Like neutrophils, mononuclear phagocytes express the adhesion molecules L-selectin and  $\beta_2$  integrins. These cells, unlike neutrophils, also express substantial amounts of the  $\alpha_4\beta_1$  integrin (VLA-4).<sup>1015,1016</sup> Expression of VLA-4 allows monocytes, unlike neutrophils, to adhere efficiently to endothelium expressing VCAM-1, the ligand for VLA-4. VCAM-1 is a member of the immunoglobulin gene superfamily, which is expressed only on endothelial cells that have been activated by exposure to cytokines or bacterial products such as LPS. The avidity of VLA-4 for VCAM-1 is low in the absence of activation, but activation of monocytes by chemotactic factors enhances avidity, allowing firm adhesion and presumably transendothelial migration.<sup>1016</sup> VLA-4 allows monocytes to enter tissues in states in which there is little or no neutrophilic inflammation, such as DTHs. The expression of VLA-4 also may account for the capacity of monocytes but not neutrophils to enter tissues in patients with the type I leukocyte adhesion deficiency syndrome, who lack  $\beta_2$  integrin expression due to a genetic deficiency of CD18 (discussed previously).

Like that in neutrophils, monocyte chemotaxis is induced by bacterial products, such as fMLP, and by activated complement components, PAF, and LT $B_4$ . Chemokines (see Tables 4-1 and 4-2) that are chemotactic for neutrophils, however, are not generally chemotactic for monocytes, and vice versa—neutrophils are most responsive to certain CXC chemokines, such as CXCL8 (IL-8), while monocytes respond to CC chemokines, such as CCL2 (MCP-1).<sup>43,937</sup>

The acute inflammatory response induced by a transient irritant (e.g., dermal abrasion) is characterized by an initial infiltration of neutrophils that is followed within 6 to 12 hours by the influx of mononuclear phagocytes.<sup>1012</sup> The orchestration of this sequential influx of leukocytes appears to be governed by the temporal order in which specific chemokines and endothelial adhesins are expressed and by the slower migration rate of monocytes versus neutrophils. Cutaneous DTH responses are characterized by an influx of mononuclear phagocytes and lymphocytes. This response reaches maximum at 24 to 72 hours after antigen infiltration.

Experimental evidence in mice and humans undergoing DTHs suggests that this process is governed, at least in part, by cytokines. These include IL-1, TNF- $\alpha$ , and chemokines, which are produced by DCs, epithelial cells, and mast cells, and IL-2 and IFN- $\gamma$ , which are produced by effector T cells infiltrating the subcutaneous tissues.<sup>937,1017</sup> The expression of these cytokines and the induction by IFN- $\gamma$  of MHC class II antigen reach their maximum before the peak influx of cells and induration, consistent with a role in causation.

### **Antimicrobial Properties of Monocytes and Macrophages**

Although neutrophils ingest and kill pyogenic bacteria more efficiently, resident macrophages are the initial line of phagocyte defense against microbial invasion in the tissues. When the microbial insult is modest, these cells may be sufficient to clear the microbes. If they are not, mononuclear phagocytes then direct the recruitment of circulating neutrophils and monocytes through the production of inflammatory mediators and cytokines. Monocytes and macrophages express each of the three Fc $\gamma$  receptors for IgG<sup>576</sup>; Fc $\alpha$  receptors for IgA<sup>1018</sup>; CR1 and CR3 receptors for C3b and C3bi, respectively<sup>1019</sup>; and CD14, multiple TLRs, and receptors that allow them to phagocytose unopsonized unencapsulated bacteria, yeasts, certain viruses, and effete cells, such as mannose-fucose,  $\beta$ -glucan, and scavenger receptors.<sup>47,940,1020</sup> Phagocytosis is greatly facilitated when the microbe or particle is coated with immunoglobulin, complement, or both (i.e., opsonization, discussed later).

Phagocytosis of particles and subsequent microbicidal mechanisms of mononuclear phagocytes parallel those of neutrophils in most respects. Mononuclear phagocytes generate reactive oxygen metabolites, but in lesser amounts than are produced by neutrophils. Circulating monocytes but not tissue macrophages contain myeloperoxidase, which facilitates the microbicidal activity of hydrogen peroxide. The expression of microbicidal granule proteins differs somewhat in mononuclear phagocytes versus neutrophils; for example, human mononuclear phagocytes express  $\beta$ -defensins but not the  $\alpha$ -defensins, which are expressed at high levels by neutrophils.<sup>1021</sup> Several unique mechanisms of antimicrobial activity are mediated primarily by activated macrophages, as discussed later on.

The microbicidal activity of resident tissue macrophages is relatively modest. This limited activity may be important in allowing macrophages to remove dead or damaged host cells and small numbers of microbes without excessively damaging tissues through release of microbicidal materials, which also are toxic to host cells. Macrophage microbicidal and proinflammatory functions are enhanced in a process commonly referred to as macrophage activation, discussed next.<sup>986,1022</sup>

### **Mononuclear Phagocyte Activation**

Macrophage activation results from the integration of signals emanating from TLRs following their engagement by microbial structures or molecules released by necrotic host cells (see section on DCs), cytokines derived from other cells, including IFN- $\gamma$  and, to a more limited extent, TNF- $\alpha$  or GM-CSF, activated complement components, and immune complexes, and by the engagement of CD40 on macrophages by CD40 ligand on activated CD4<sup>+</sup> T cells.<sup>1022,1023</sup> Cytokines

produced by activated macrophages, including TNF- $\alpha$ , GM-CSF, IL-12 family of cytokines, IL-15, and IL-18, can further amplify macrophage activation through autocrine or paracrine mechanisms, as described in more detail later.

The increased antimicrobial activity of activated macrophages results in part from increased expression of Fc $\gamma$ RI, enhanced phagocytic activity, and increased production of reactive oxygen metabolites in response to phagocytic or other stimuli. Other antimicrobial mechanisms induced by activation of these cells include the catabolism of tryptophan by indoleamine 2,3-dioxygenase, scavenging of iron, and production of nitric oxide and its metabolites by the inducible nitric oxide synthase (iNOS). The last is a major mechanism by which activated murine macrophages inhibit or kill a variety of intracellular pathogens. Expression of iNOS by human macrophages is less consistently observed and less robust than that noted for murine macrophages, and the role of nitric oxide in the antimicrobial activity of human macrophages is uncertain.<sup>1024</sup>

Activation of macrophages plays a critical role in defense against infection with intracellular bacterial and protozoal pathogens that replicate within phagocytic vacuoles of resting macrophages. Support for this notion comes from studies in humans and mice with genetic deficiencies in proteins that participate in macrophage activation. Humans with genetic deficiencies involving the IFN- $\gamma$  receptor, IL-12, the IL-12 receptor, or STAT-1 (a signaling molecule downstream of the IFN- $\gamma$  receptor) suffer unduly from infections with *Mycobacteria* spp. and *Salmonella* spp.<sup>1025</sup> Similarly, mice deficient in these cytokines or their receptors are much more susceptible to these infections and to infections with other intracellular pathogens, including *T. gondii*. Deficiency of TNF- $\alpha$  or its receptors also impairs defenses to certain of these pathogens, including *L. monocytogenes* and mycobacteria.<sup>1026</sup> Patients with the X-linked hyper-IgM syndrome, which is due to a defect in CD40 ligand, have defects in antibody production that result from the importance of CD40 ligand in T cell-mediated help for B cell responses (see section on T cell help for antibody production).<sup>195</sup> In addition, these patients are predisposed to disease due to *Pneumocystis jiroveci* and *Cryptosporidium parvum*. Mice with CD40 ligand deficiency also are at greater risk for infection with *P. jiroveci* but, unlike those with IFN- $\gamma$ , IL-12, or TNF- $\alpha$  deficiency, are not more susceptible to infection with *L. monocytogenes*.<sup>161</sup> These findings suggest that secreted cytokine- and CD40 ligand-mediated macrophage activation may play, at least in part, distinct roles in host defense.

### **Regulation of the Immune and Inflammatory Responses by Cytokines Produced by Mononuclear Phagocytes**

In addition to the induction of increased antimicrobial activity, mononuclear phagocytes produce a number of cytokines when activated by ligand binding to TLRs and by engagement of CD40, cytokines, activated complement components, immune complexes, or other mediators.<sup>1022,1023</sup> These mononuclear phagocyte-derived cytokines contribute to the systemic response to infection, including the induction of fever and the acute-phase response, and play important local roles in the regulation of inflammation (see Table 4-2).<sup>1027,1028</sup> IL-1, TNF- $\alpha$ , IL-6, and IFN- $\alpha/\beta$  (also known as type I IFN) induce fever by stimulating vascular endothelial cells in the

hypothalamic area to produce PGE<sub>2</sub>. PGE<sub>2</sub> acts in turn on cells within the anterior hypothalamus to cause fever, which accounts for the antipyretic effect of drugs that inhibit prostaglandin synthesis. Fever may have a beneficial role in host resistance to infection by inhibiting the growth of certain microorganisms and by enhancing host immune responses.<sup>1029</sup> TNF- $\alpha$ , IL-1, and IL-6 act on the liver to induce the acute-phase response, which is associated with decreased albumin synthesis and increased synthesis of complement components C3 and factor B, haptoglobin, fibrinogen, C-reactive protein, and other proteins. G-, GM-, and M-CSF enhance the production of their respective target cell populations, increasing the numbers of phagocytes available. At the sites of infection or injury, TNF- $\alpha$  and IL-1 increase endothelial cell expression of adhesion molecules, including E- and P-selectin, ICAM-1, and VCAM-1; increase endothelial cell procoagulant activity; and enhance neutrophil adhesiveness by upregulating  $\beta_2$  integrin expression.<sup>932,939</sup> CXC chemokines enhance the avidity of neutrophil  $\beta_2$  integrins for ICAM-1 and attract neutrophils into the inflammatory-infectious focus; CC chemokines play a similar role in attracting mononuclear phagocytes and lymphocytes.<sup>43,936</sup> These and additional factors contribute to edema, redness, and leukocyte infiltration, which characterize inflammation.

Mononuclear phagocytes (and DCs) are important sources of IFN- $\alpha/\beta$ , IL-12, IL-15, and IL-18.<sup>42,53,1022,1030,1031</sup> These cytokines enhance NK cell lytic function and production of IFN- $\gamma$  and facilitate the development of effector T<sub>H1</sub> and CD8<sup>+</sup> T cells, which play a critical role in control of infection with intracellular bacterial, protozoal, and viral pathogens and inhibit the development of T<sub>H2</sub> T cells.<sup>89,179</sup> IFN- $\alpha/\beta$  also directly inhibits viral replication in host cells,<sup>1032,1033</sup> as do IFN- $\gamma$  and TNF- $\alpha$ .<sup>1034</sup> IFN- $\gamma$  enhances the capacity of macrophages to produce IL-12 and TNF- $\alpha$  and inhibits IL-10 production, thereby amplifying its own production and T<sub>H1</sub> T cell responses.<sup>89,1035</sup>

The production of cytokines by mononuclear phagocytes normally is restricted temporally and anatomically to cells in contact with microbial products, antigen-stimulated T cells, or other agonists (discussed previously) found at sites of infection or secondary lymphoid organs draining these sites. When produced in excess, however, these cytokines are injurious.<sup>1036,1037</sup> When excess production of proinflammatory cytokines occurs systemically, septic shock and disseminated intravascular coagulation may ensue, underscoring the importance of closely regulated and anatomically restricted production of proinflammatory mediators.

Tight control of inflammation normally is achieved by a combination of positive and negative feedback regulation. For example, TNF- $\alpha$ , IL-1, and microbial products that induce their production also cause macrophages to produce cytokines that attenuate inflammation, including IL-10,<sup>1038</sup> TGF- $\beta$ ,<sup>1039</sup> and the IL-1 receptor antagonist.<sup>945</sup> The production of these anti-inflammatory cytokines also is enhanced by exposure of macrophages to cytokines produced by T<sub>H2</sub> T cells, including IL-4, IL-10, IL-13, and TGF- $\beta$ . By contrast, cytokines produced by T<sub>H1</sub> T cells, particularly IFN- $\gamma$ , attenuate the production of IL-10.

Activated mononuclear phagocytes also secrete a number of noncytokine products that are potentially important in host defense mechanisms. These include complement components, fibronectin, and lysozyme.<sup>1040</sup>

## Mononuclear Phagocytes in the Fetus and Neonate

Macrophages are detectable as early as 4 weeks of fetal life in the yolk sac and are found shortly thereafter in the liver and then in the bone marrow.<sup>1041</sup> The capacity of the fetus and the neonate to produce monocytes, as indicated by development of macrophage colonies when fetal liver or neonatal bone marrow or blood is grown in culture, is at least as great as that of adults.<sup>1042</sup> The numbers of monocytes per volume of blood in neonates are equal to or greater than those in adults.<sup>1043</sup>

The numbers of tissue macrophages in human neonates are less well characterized. Limited data in humans, which are consistent with data in various animal species, suggest that the lung contains few macrophages until shortly before term.<sup>1044</sup> Postnatally, the numbers of lung macrophages increase to adult levels by 24 to 48 hours in healthy monkeys.<sup>1045</sup> The blood of premature neonates contains increased numbers of pitted erythrocytes or erythrocytes containing Howell-Jolly bodies.<sup>1046</sup> Because these abnormal erythrocytes normally are removed by splenic and perhaps liver macrophages, the numbers or function, or both, of these macrophages may be reduced in the fetus and premature infant.

### Migration to Sites of Infection and Delayed Hypersensitivity

The influx of monocytes into sites of inflammation is delayed and attenuated in neonates compared with that observed in adults.<sup>1047,1048</sup> Similarly, cutaneous DTH, which depends on an influx of monocytes and lymphocytes into the site, is diminished in neonates.<sup>502,506,1049</sup> This is true even when antigen-specific T cell responses are evident in vitro, suggesting that decreased migration of monocytes and lymphocytes into the tissues is responsible for the poor response in neonates. These differences may result from decreased generation of chemotactic factors, such as CC chemokines, or decreased chemotaxis of neonatal monocytes, or both.

Whether neonatal monocyte chemotaxis is impaired is unclear. In all but one of the studies<sup>1050</sup> in which cord blood chemotaxis and adult monocyte chemotaxis were compared, no difference was found. In the two studies in which peripheral blood rather than cord blood was used,<sup>973,1051</sup> however, chemotaxis of neonatal cells was less than that of adult cells and remained less until the child reached 6 to 10 years of age.<sup>974</sup> The basis for reduced chemotaxis is unknown.

Data regarding adhesion molecules on monocytes from neonates are limited to two conflicting reports. One study reported increased amounts of the  $\beta_2$  integrin Mac-1 (CD11b-CD18) on resting and activated neonatal monocytes,<sup>972</sup> whereas the other found expression to be modestly lower.<sup>1052</sup>

The capacity of fetal and neonatal macrophages to process and present antigen to T cells was discussed previously in the section on antigen presentation by neonatal monocytes and B cells.

### Activity of Monocytes and Macrophages against Pyogenic Pathogens

Monocytes from human neonates ingest and kill *S. aureus*, *E. coli*, and group B streptococci as well as do monocytes

from adults.<sup>997,1050,1053-1055</sup> The ability of neonatal monocyte-derived macrophages (monocytes cultured in vitro) to phagocytose bacteria or other particles through receptors for mannose-fucose, IgG, complement, and opsonin-independent pathways appears not to differ from that of similarly prepared cells from adults. The production of microbicidal oxygen metabolites by neonatal and adult monocytes also is similar.<sup>1054,1056-1059</sup>

Neonatal and adult monocyte-derived macrophages phagocytose but do not efficiently kill *Candida* and group B streptococci. Incubation with IFN- $\gamma$  or GM-CSF activates adult macrophages, allowing them to kill these organisms.<sup>1060-1062</sup> By contrast, GM-CSF but not IFN- $\gamma$  activates neonatal macrophages to produce superoxide anion and to kill these organisms. The lack of response to IFN- $\gamma$  by neonatal macrophages was associated with normal binding to but decreased signaling downstream of IFN- $\gamma$  receptors. The poor response of neonatal macrophages to IFN- $\gamma$  may be compounded by the diminished production of this cytokine by neonatal NK and T cells, as described in previous sections.

Neonatal tissue macrophages are difficult to obtain, and few studies of their microbicidal activity have been performed. Macrophages obtained from aspirated bronchial fluid of neonates were less effective at killing the yeast form of *Candida* than were bronchoalveolar macrophages from adults.<sup>1063</sup> To our knowledge, this result has not been reproduced, and the decreased effectiveness could reflect differences in the source of cells, rather than representing a true difference between neonates and adults. Nonetheless, similar studies with alveolar macrophages from newborn and particularly premature newborn monkeys, rabbits, and rats also showed reduced phagocytic or microbicidal activity, or both.<sup>1064-1069</sup>

### Activity of Monocytes and Macrophages against Intracellular Pathogens

Control of infection with obligatory or facultative (i.e., capable of) intracellular pathogens is mediated by factors that limit entry into cells, inhibit intracellular replication, induce microbial killing or dormancy within cells, or lyse infected cells prior to microbial replication. Neonatal monocytes ingest and kill *T. gondii*<sup>1070,1071</sup> and *L. monocytogenes* (C. Wilson, unpublished data, 1980). In contrast with the results with *Candida* and group B streptococci noted earlier, both monocyte-derived and placental macrophages from human neonates are activated by IFN- $\gamma$  to kill or restrict the growth of *Toxoplasma* as effectively as cells from adults.<sup>1062</sup>

Neonatal monocytes, monocyte-derived macrophages, and fetal macrophages are not more permissive than adult cells for replication of HSV.<sup>1072,1073</sup> Monocytes and macrophages also can inhibit viral replication by lysing virus-infected cells in either the absence or the presence of antibody.<sup>1074</sup> Monocytes from neonates may be slightly less cytotoxic than those from adults in the absence of antibody, but they are equivalent in the presence of antibody.<sup>1074,1075</sup>

Exogenous IFN- $\gamma$  induces resistance to *L. monocytogenes* infection in neonatal rats and to HSV infection in neonatal mice.<sup>1076,1077</sup> This finding suggests that in these species, the antimicrobial activity of host macrophages (and other host cells mediating resistance to these microbes) can be enhanced sufficiently to be protective, given the provision of this cytokine. This also implies that the deficit in production

of IFN- $\gamma$  and certain other cytokines (e.g., TNF- $\alpha$ ) that facilitate resistance to these microbes may be an important factor in the neonate's increased susceptibility, which is discussed later.

### Cytokine and Inflammatory Mediator Production by Mononuclear Phagocytes from the Fetus and Neonate

Monocytes and macrophages are stimulated to produce G-, GM-, and M-CSF and the proinflammatory cytokines IL-1, TNF- $\alpha$ , IL-6, and IL-8 by a number of mediators. These mediators include LPS, which activates cells through the TLR-4-MD2 receptor complex<sup>47,1020</sup>; group B streptococci, which activate cells through TLR-2 plus TLR-6 and through an as-yet undefined TLR or TLR-related receptor<sup>1078</sup>; and IL-1,<sup>1079</sup> which activates cells through the type I IL-1 receptor. In response to these stimuli, neonatal monocytes and blood mononuclear cells produce these cytokines in variable amounts, ranging from approximately 25% to 75% of the amounts produced by adult cells (summarized in Table 4-2). TNF- $\alpha$  production by monocyte-derived and tissue (placental) macrophages from term neonates is reduced to a greater extent than occurs with blood monocytes and appears to be upregulated less by IFN- $\gamma$  than in cells from adults.<sup>1080</sup> In some studies, however, production of G-CSF, IL-1 $\beta$ , and IL-6 by neonatal monocytes was similar to that in adult cells,<sup>88,344,962,1080-1084</sup> and in other studies, production of IL-1 $\alpha$ , IL-6, and IL-8 by whole blood, which probably reflected production predominantly by monocytes, was greater than in adult cells.<sup>354,1085</sup> Monocytes from preterm neonates produce less TNF- $\alpha$ , G-CSF, and IL-8 in response to LPS than those from term neonates and adults. Collectively, these findings suggest that neonatal monocytes and macrophages have a variable and relatively subtle deficiency in the production of proinflammatory cytokines compared with that in adult cells.

Reduced production of proinflammatory mediators by neonatal monocytes and blood mononuclear cells appears to be balanced in most contexts by a comparable reduction in the generation of the anti-inflammatory cytokines, IL-10 and TGF- $\beta$ .<sup>1083,1086-1088</sup> This may not be the case in certain pathologic contexts, however. Alveolar macrophages from preterm neonates with hyaline membrane disease produce less IL-10 in vivo relative to TNF- $\alpha$  than alveolar macrophages from term neonates.<sup>1089,1090</sup> This imbalance may be a factor in the development of inflammatory lung disease.

The production by neonatal monocytes of IFN- $\alpha/\beta$ , IL-12, IL-15, and IL-18 also appears to be modestly reduced. These cytokines inhibit viral replication and enhance NK, T<sub>H</sub>1, and CD8<sup>+</sup> T cell differentiation and function, so these deficiencies collectively could impede defenses against viral and nonviral intracellular pathogens. In earlier studies, production of IFN- $\alpha/\beta$  by neonatal mononuclear cells and monocytes was normal in response to a variety of inducers including HSV and other viruses.<sup>82,1091</sup> As noted earlier in the section on circulating neonatal DCs, however, more recent studies using whole blood or blood mononuclear cells have found that HSV-induced IFN- $\alpha/\beta$  production and the fraction of cells that produced IFN- $\alpha/\beta$  in response to HSV were diminished compared with those in adults, particularly for prematurely born infants.<sup>83</sup> Neonatal blood cells also

produced less IFN- $\alpha/\beta$  when stimulated with parainfluenza viruses.<sup>69,72,84</sup> Overall, these more recent studies suggest that neonatal cells produce approximately 10% to 30% as much IFN- $\alpha/\beta$  as produced by adult cells. It is likely that the decreased production of IFN- $\alpha/\beta$  by neonatal blood cells in response to viruses or unmethylated CpG DNA reflects predominantly decreased production by DC2 cells rather than monocytes, but this association has been shown directly only for the response to unmethylated DNA.<sup>72</sup> One group of investigators reported that the production of IL-12 and IL-15 by blood mononuclear cells (which probably reflected production by monocytes) from term neonates after stimulation with LPS was approximately 25% of that by cells from adults.<sup>369,891</sup> Joyner and colleagues and La Pine and associates also reported that neonatal blood mononuclear cells produced less IL-12 and IL-18, although the reduction in IL-18 was modest (approximately 65% of the amounts produced by cells from adults).<sup>1092,1093</sup> Other investigators, however, have reported that neonatal and adult blood mononuclear cells stimulated with *S. aureus*, other gram-positive and gram-negative bacterial cells, produce equivalent amounts of IL-12.<sup>86,88</sup> Nonetheless, the results of studies with blood mononuclear cells and DCs from neonates suggest that in response to most stimuli, cells from neonates produce less IL-12 and IFN- $\alpha/\beta$  than those from adults.

When bioassays are used collectively to measure chemokines that are chemotactic for monocytes, no differences in production by neonatal and adult cell preparations are observed.<sup>1053,1054</sup> This does not exclude deficits in production of individual chemokines, however. Indeed, cord blood mononuclear cells produced only approximately 25% as much of the CC chemokine CCL3 (MIP-1 $\alpha$ ) as that from adult cells.<sup>1083</sup> The extent to which these assays reflect chemokine production by monocytes is not known.

The basis for lower production of cytokines by neonatal monocytes and macrophages in response to microbial products that signal through TLRs is incompletely understood. Yan and colleagues reported that neonatal monocytes have reduced amounts of MyD88, an intracellular adapter protein that is essential for proinflammatory cytokine production downstream of TLR.<sup>1094</sup> Because MyD88 also is an adapter downstream of the IL-1 and IL-18 receptors,<sup>1079</sup> reduced expression of MyD88 by neonatal monocytes also could explain reduced responses to IL-1. These investigators also reported that the expression of TLR-4 and CD14 was similar on neonatal and on adult monocytes, and neonatal monocytes failed to upregulate the expression of these molecules in response to LPS, which may reflect impaired LPS signaling due to reduced expression of MyD88. To our knowledge, the expression of other TLR has not been directly assessed in neonatal monocytes. Others report that unstimulated neonatal monocytes express similar or slightly reduced amounts of CD14, a co-receptor for LPS and certain other microbial structures that trigger monocyte cytokine production through TLR-4 and some other TLRs.<sup>92,1081,1095</sup> Compared with blood from healthy adults, neonatal blood contains lower amounts of soluble CD14, but similar amounts of soluble LPS-binding protein (LBP), and the concentrations of both rise in response to infection, as they do in adults.<sup>1096</sup> Like CD14, LBP is important in the activation of TLR-4 by LPS. The reduced amounts of soluble CD14 may account for the earlier observation that neonatal cord

blood contains lower amounts of a soluble protein(s) that facilitates the response of monocytes to LPS.<sup>1081</sup>

Overall, the foregoing results indicate neonatal monocytes, macrophages, and mixed blood mononuclear cells commonly produce lesser amounts of many cytokines, chemokines, and IFN- $\alpha/\beta$  in response to activation by microbial ligands or other proinflammatory cytokines. The molecular basis for these differences is incompletely understood; such differences may reflect a general reduction in signaling in response to these mediators and more selective deficits in the induction of specific cytokines, such as the p35 subunit of IL-12.<sup>93</sup>

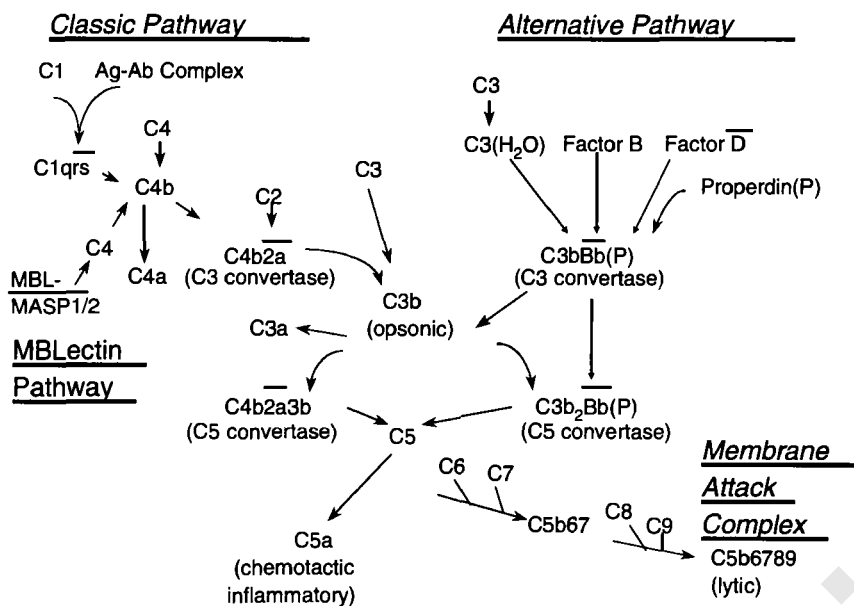

Engagement of CD40 on mononuclear phagocytes by CD40 on activated T cells also is an important pathway for the induction of macrophage activation and cytokine production. Because the expression of CD40 ligand on activated neonatal T cells may be diminished (see earlier), macrophage activation through this pathway may be compromised in neonates. This pathway would be further compromised if CD40 expression on neonatal monocytes or macrophages was reduced. Data on this point are conflicting, however, with one group reporting comparable expression<sup>1097</sup> and another group reporting reduced expression.<sup>1098</sup>

## Summary

The most clearly defined, clinically important deficits in neonatal phagocytic defenses are the diminished neutrophil storage pool and the reduced ability of neonatal neutrophils to migrate from the blood to sites of infection. Phagocytosis and killing by neonatal neutrophils are largely intact but are compromised when opsonins are limiting or the bacterial density is high. These deficits are greater in preterm neonates. Blood monocytes from neonates are normal in number and similar to adult monocytes in phagocytic and microbicidal activity. By contrast, migration of neonatal monocytes into sites of inflammation or DTH is reduced. Tissue macrophages from neonatal animals have reduced phagocytic and microbicidal activity, and this also may be the case in humans. The capacity of mononuclear phagocytes to produce both pro- and anti-inflammatory cytokines may be modestly reduced in term neonates and further reduced in premature neonates. These modest deficiencies may be compounded by a concomitant deficiency in production of IFN- $\gamma$  by neonatal T cells and NK cells and by impaired responsiveness of neonatal mononuclear phagocytes to IFN- $\gamma$ .

## HUMORAL MEDIATORS OF INFLAMMATION AND OPSONIZATION

A wide range of humoral factors participate in the response to infection and inflammation.<sup>839-841</sup> Some of these factors normally are present in plasma, including complement components, mannan-binding lectin (MBL), fibronectin, coagulation factors, and components of the kinin system. Others, such as products of arachidonic acid metabolism (the prostaglandins, PAF, and leukotrienes), endorphins, amines (including histamine, catecholamines, and serotonin), and lysosomal enzymes, are produced and released from leukocytes, endothelial cells, and other cells. Studies in animal models have implicated some of these mediators in the unfavorable response of neonatal animals to infection<sup>1099,1100</sup>

**Figure 4-15** Complement activation. The classic and mannan-binding lectin (MBL) pathways of activation intersect with the alternative pathway at C3. The MBL pathway of activation (not shown) is identical to the classic pathway starting with the cleavage of C4. Once C3 is activated, this is followed by activation of the terminal components, which generate the membrane attack complex (C5b6789). Enzymatically active proteases, which serve to cleave and activate subsequent components, are shown with an overbar.

and suggest the possibility that therapy directed toward modulating production of the mediators may be beneficial. A better understanding of the relative role of these mediators in particular clinical situations, such as septic shock, will be required, however, to develop rational approaches to modulate their production or actions.

## Complement

The complement system is composed of serum proteins that can be activated sequentially in an orderly cascade. The complement cascade can be activated through one of three pathways—the classic, MBL, and alternative pathways, each of which leads to the generation of activated C3, C3 and C5 convertases, and the membrane attack complex. Reviews of the complement system are available.<sup>1101</sup>

### Classic and Mannan-Binding Lectin Pathways

Activation of the classic pathway is initiated when antibodies capable of engaging C1q to their Fc portion (IgM, IgG<sub>1</sub>, IgG<sub>2</sub>, and IgG<sub>3</sub> in humans) complex with microbial (or other) antigens. The formation of complexes alters the conformation of IgM and juxtaposes two IgG molecules, which creates an appropriate binding site for C1q. This is followed by the sequential binding of C1r and C1s to C1q. C1s can then cleave C4 followed by C2, and the larger fragments of these bind covalently to the surface of the microbe or particle, forming the classic pathway C3 convertase (C2aC4b). C3 convertase cleaves C3, thereby liberating C3b, which binds to the microbe or particle, and C3a, which is released into the fluid phase.

MBL activates the complement cascade in a similar manner. When MBL engages the surface of a microbe, its conformation is altered, creating a binding site for MASP1 and MASP2, which are the functional equivalents of C1r and C1s. These in turn cleave C4 and C2, and their larger fragments bind to the surface of the microbe or particle, forming the classic pathway C3 convertase. C-reactive protein, a host-derived acute-phase protein that binds to structures on the surface of certain bacteria, particularly *S. pneumoniae*,

also may substitute for antibody in the activation of the classic pathway.<sup>1028,1102</sup>

### Alternative Pathway

The alternative pathway is phylogenetically older and constitutively active. Although it is facilitated by the F(ab')<sub>2</sub> portion of antibody, antibody is not required for its activation. The continuous but inefficient hydrolysis of C3 in solution creates a binding site for factor B. This complex is in turn cleaved by factor D, generating C3b and Bb. If C3b and Bb bind to a microorganism, they form a more efficient system, which binds and activates additional C3 molecules, depositing C3b on the microbe and liberating C3a into the fluid phase. This interaction is facilitated by factor P (properdin) and inhibited by alternative pathway factors H and I. The classic pathway, by creating particle-bound C3b, also can activate the alternative pathway, thereby amplifying complement activation (Fig. 4-15). This amplification step may be particularly important in the presence of small amounts of antibody.

Bacteria vary in their capacity to activate the alternative pathway, which is determined by their ability to bind C3b and to protect the complex of C3b and Bb from the inhibitory effects of factors H and I. Sialic acid, a component of many bacterial polysaccharide capsules, including those of group B streptococci and *E. coli* K1, favors factor H binding. Thus, many virulent pathogens are protected from the alternative pathway by their capsules, although this protection may vary from strain to strain. Antibody is needed for efficient opsonization of such organisms.

### Terminal Components and Membrane Attack Complex

Bound C3b, C4b, and C2a together form the C5 convertase, which cleaves C5. The smaller fragment, C5a, is released into solution. The larger fragment, C5b, binds to the surface of the microbe and triggers the recruitment of the terminal components, C6 to C9, which together form the membrane attack complex.

### Biologic Consequences of Complement Activation

Binding of C3b on the microbial surface facilitates microbial killing or removal, through the interaction of C3b with CR1 receptors on phagocytes. C3b also is cleaved to C3bi, which binds to the CR3 receptor (Mac-1, Cd11b-CD18) and CR4 receptor (CD11c-CD18). C3bi receptors are  $\beta_2$  integrins, which are present on neutrophils, macrophages, and certain other cell types and also play a role in cell adhesion, as noted in previous sections of this chapter. Along with IgG antibody, which binds to Fc $\gamma$  receptors on phagocytes, C3b and C3bi promote phagocytosis and killing of bacteria and fungi.

C3b also is a key component of the C5a convertase, which leads to the cleavage of C5, release of C5a into the fluid phase, binding of C5b on the microbial surface, and formation of the membrane attack complex. This complex can be assembled only in lipid-containing cell membranes, which include the outer membrane of gram-negative bacteria and the plasma membrane of infected host cells. Once assembled in the membrane, this complex may lyse the cell. Such lysis appears to be a central defense mechanism against meningococci and systemic gonococcal infection. Certain gram-negative organisms have mechanisms to impede complement-mediated lysis, and gram-positive bacteria are intrinsically resistant to complement-mediated lysis because they do not have an outer membrane. As a result, in contrast with the important role of complement-mediated opsonization, complement-mediated lysis may play a limited role in defense against common neonatal bacterial pathogens.

The soluble fragment of C5, C5a, and, to a more limited degree, C3a and C4a cause vasodilatation and increase vascular permeability. C5a also is a potent chemotactic factor for neutrophils, monocytes, and eosinophils. It stimulates these cells to degranulate, adhere to endothelium, and release leukotrienes, which themselves are potent mediators of inflammation.

In addition to these roles for complement in innate immunity, complement facilitates B cell responses to T cell-dependent antigens. As discussed in the section on B cells and immunoglobulin, C3d bound to antigen complexed with antibody (produced as part of the initial B cell response) amplifies the antibody response by simultaneous engagement of the C3d receptor (CD21) along with the B cell antigen receptor.<sup>574</sup> C3d also may facilitate B cell responses by enhancing the retention of antigen-antibody complexes on follicular DCs. Mice that are genetically deficient in C3, C4, or the complement receptors for C3b and C3d have diminished antibody responses to immunization with protein antigens.<sup>574</sup>

### Complement Biosynthesis

The hepatocyte appears to be the principal cell type that synthesizes complement components.<sup>732,1101</sup> Macrophages synthesize complement proteins, except those complement components that form the terminal membrane attack complex. Other cell types, including fibroblasts, may produce certain complement proteins.

### Complement in the Fetus and Neonate

Little, if any, maternal complement is transferred to the fetus. Fetal synthesis of complement components can be detected in tissues as early as 6 to 14 weeks of gestation,

Table 4-9 Summary of Published Complement Levels in Neonates<sup>a</sup>

Complement Component	Mean % of Adult Levels	
	Term Neonate	Preterm Neonate
CH <sub>50</sub>	56-90 (5) <sup>b</sup>	45-71 (4)
AP <sub>50</sub>	49-65 (4)	40-55 (3)
Clq	61-90 (4)	27-58 (3)
C4	60-100 (5)	42-91 (4)
C2	76-100 (3)	67-96 (2)
C3	60-100 (5)	39-78 (4)

depending on the specific complement component and tissue examined.<sup>732,1103</sup>

Table 4-9 summarizes published reports on classic pathway complement activity (CH<sub>50</sub>) and alternative pathway complement activity (AP<sub>50</sub>) and individual complement components in neonates. Substantial interindividual variability is seen, and in many term neonates, values of individual complement components or of CH<sub>50</sub> or AP<sub>50</sub> are within the adult range. Alternative pathway activity (AP<sub>50</sub>) and alternative pathway components (B, P) are more consistently decreased than are classic pathway (CH<sub>50</sub>) activity and components.

A clear deficiency has been identified in the amount of the terminal complement component C9, which is important for lytic activity against serum-sensitive, gram-negative microbes, and this deficiency correlates with poor killing of gram-negative bacteria by serum from neonates. The C9 deficiency in neonatal serum appears to be a more important factor in the inefficient killing of *E. coli* K1 than the deficiency in antigen-specific IgG antibodies.<sup>1104</sup> A functional deficiency of C3, which is deposited on microbes but is not efficiently cross-linked, may contribute to decreased opsonic activity.<sup>1105</sup>

Preterm infants demonstrate a greater and more consistent decrease in both classic and alternative pathway complement activity and concentrations of individual complement components.<sup>1106</sup> Mature but small-for-gestational-age infants have CH<sub>50</sub> and AP<sub>50</sub> values similar to those for healthy term

infants.<sup>1107</sup> The concentration of most complement proteins increases postnatally and reach adult values by 6 to 18 months of age.<sup>1108</sup>

### C-Reactive Protein

C-reactive protein can activate the classic complement pathway when bound to certain gram-positive bacteria. It does not cross the placenta. Term and preterm neonates can produce C-reactive protein as well as adults.<sup>1109</sup> Serum concentrations may be higher in healthy neonates than in healthy adults.

### Mannan-Binding Lectin

With rare exception, glycoproteins containing terminal mannose sugars are not found on extracellular proteins in mammals, because they are modified in the endoplasmic reticulum before transport through the Golgi complex. By contrast, terminal mannose, fucose, glucose, and *N*-acetyl glucosamine are found on the surfaces of gram-positive and gram-negative bacteria, mycobacteria, yeasts, and certain viruses and parasites.<sup>1110,1111</sup>

Tissue macrophages contain mannose-fucose receptors, which bind to microbes with surface mannose-fucose-containing carbohydrate polymers and thereby are activated for phagocytosis and killing. By contrast, neutrophils and blood monocytes lack mannose-fucose receptors. The liver, however, produces a homologous secreted protein, MBL, which also is referred to as mannose-binding protein. MBL can bind to microbes with surface mannose or fucose and facilitate phagocytosis and killing by neutrophils and monocytes.<sup>1110,1111</sup>

MBL is a member of a family of structurally homologous proteins known as collectins.<sup>1111</sup> MBL is a calcium-dependent lectin that circulates as an 18-mer composed of 3 to 6 identical homotrimeric structural units. MBL is homologous to C1q and can bind to C1q receptors on mononuclear phagocytes. It also activates complement, thereby opsonizing the microbe for phagocytosis and killing by neutrophils and monocytes. It is an acute-phase protein, so the concentration of MBL increases in inflammation. Engagement of MBL is impeded by capsular polysaccharides of most virulent gram-negative pathogens.

Approximately 5% to 7% of the general population is deficient in MBL as a result of a polymorphism in codon 54.<sup>1110,1111</sup> Although some persons with this deficiency may experience increased numbers of infections, most do not, suggesting that MBL plays an auxiliary role in host defense. The concentration of MBL in the blood of term neonates is similar to that in adults. Values in preterm neonates are approximately 50% lower,<sup>1112</sup> but whether this reduction contributes to their increased risk for infection is not known. Infants with lower levels of MBL in cord blood were noted to have higher rates of admission, particularly for viral infections, in the first year of life in one study.<sup>1113</sup>

### Surfactant Apoproteins

Surfactant apoproteins A and D also are members of the collectin family. They are synthesized by the type 2 alveolar epithelial cells and Clara cells in the lung epithelium, and

by certain extrapulmonary cell types.<sup>1111,1114</sup> Like MBL, surfactant apoprotein A binds to mannose-glucose polymers found on the surface of gram-positive and gram-negative bacteria, mycobacteria, and yeasts. Mice deficient in surfactant apoprotein A are much more susceptible to pulmonary infection with group B streptococci, *H. influenzae*, RSV, and *P. aeruginosa*. By contrast, mice deficient in surfactant apoprotein D appear to clear microbes normally. Thus, surfactant deficiency may be one factor in the greater risk of the preterm neonate for pulmonary infections.

### Lipopolysaccharide-Binding Protein

LBP is produced by the liver, and production is increased as part of the acute-phase response. LBP facilitates binding of LPS to CD14 and presumably thereafter to TLR-4.<sup>47,1023</sup> LBP and CD14 together lower by several orders of magnitude the concentration of LPS needed to prime or activate macrophages through TLR-4 and promote binding of gram-negative bacteria by these cells. Neonatal blood and adult blood contain similar amounts of LBP, and the concentration rises further in response to infection.<sup>1096</sup>

### Fibronectin

Fibronectin is a ubiquitous glycoprotein, which exists in two forms—circulating and tissue. The liver synthesizes most of the fibronectin found in the plasma, whereas fibroblasts, endothelial cells and other cell types synthesize tissue fibronectin. Fibronectin enhances the initial adherence of neutrophils and monocytes to endothelium.<sup>1115</sup> Fibronectin also has opsonic properties,<sup>1116,1117</sup> although compared with antibody or complement, it plays a minor role. It also may have a direct phagocytosis-enhancing effect on monocytes and stimulated neutrophils.<sup>861</sup> Fragments of fibronectin also are chemotactic for monocytes. Fibronectin may also activate mononuclear phagocytes and DCs through TLR-4.<sup>1118</sup>

Plasma fibronectin concentrations are low in neonates, particularly in pretermes.<sup>1119,1120</sup> Concentrations may be further reduced in sepsis, birth asphyxia, or respiratory distress syndrome. Plasma fibronectin concentrations reach the lower limit of normal for adults by 1 year of age.<sup>1121</sup>

### Opsonic Activity

Measurement of opsonic activity tests the ability of serum to enhance the phagocytosis (or phagocytosis and killing) of a particular organism or particle. Some organisms are effective activators of the alternative pathway, whereas others require antibody to activate complement. Thus, depending on the organism or particle tested, opsonic activity reflects specific antibody, MBL, C-reactive protein, classic or alternative complement pathway activity, or combinations of these. Accordingly, it is not surprising that the efficiency with which neonatal sera opsonize organisms is quite variable. For example, although opsonization of *S. aureus* was normal in neonatal sera in all studies,<sup>992,1122,1123</sup> opsonization of group B streptococci,<sup>1122,1124</sup> *S. pneumoniae*,<sup>1123</sup> *E. coli*,<sup>1122,1125</sup> and other gram-negative rods<sup>1122,1125</sup> was decreased against some strains and in some studies but not in others.

Neonatal sera generally are less able to opsonize organisms in the absence of antibody. This difference is compatible

with deficits in the function of the alternative and MBL pathways,<sup>1126-1128</sup> and with the moderate reduction in alternative pathway components. This difference is not due to a reduced ability of neonatal sera to initiate complement activation through the alternative pathway.<sup>1129</sup> Neonatal sera also are less able to opsonize some strains of group B streptococci in a classic pathway–dependent but antibody-independent manner, which may reflect deficits in classic pathway activation through C-reactive protein or activation of the MBL pathway.<sup>1124,1130</sup> The deficit in antibody-independent opsonization is accentuated in sera from premature neonates and may be further impaired by the depletion of complement components in septic neonates.

### Chemotactic Factor Generation

Complement activation also generates fluid-phase components with chemotactic activity for neutrophils and monocytes, most of which is due to C5a.<sup>1131</sup> Sera from term neonates generate less chemotactic activity than adult sera, and this diminished activity reflects a defect in complement activation rather than antibody.<sup>973,1051,1131</sup> It is likely that the differences found in these studies using sera from term neonates would be greater if sera from preterm neonates were tested, but this remains to be determined. These *in vitro* observations notwithstanding, preterm and term neonates do generate substantial amounts of activated complement products in response to infection *in vivo*.<sup>1132</sup>

### Summary

Compared with adults, neonates have moderately diminished alternative complement pathway activity, slightly diminished classic complement pathway activity, and decreased abundance of some terminal complement components. Fibronectin and MBL concentrations are also slightly lower. Consistent with these findings, neonatal sera are less effective than adult sera in antibody-independent opsonization and in opsonization when concentrations of antibody are limiting. Generation of complement-derived chemotactic activity also is moderately diminished. These differences are greater in preterm than in term neonates. Preterm neonates also may have compromised lung defenses as a result of reduced abundance of surfactant apoprotein A. These deficiencies, in concert with phagocyte deficits described earlier, may contribute to delayed inflammatory responses and impaired bacterial clearance in neonates.

## HOST DEFENSE AGAINST SPECIFIC CLASSES OF NEONATAL PATHOGENS

For the purposes of understanding host defenses required for protection, microbes can be broadly classified as extracellular pathogens, which include pyogenic bacteria, such as group B streptococci, and fungi, such as *Candida albicans* and intracellular pathogens. Intracellular pathogens can be further divided into those that replicate in the cytosol of host cells, which include viruses and *L. monocytogenes*, and those that replicate within phagocytic vacuoles, such as *T. gondii*. This section discusses host defenses to each type of pathogen, using group B streptococci, HSV, and *T. gondii* as

examples. Differences in immune function that predispose the neonate to infection are discussed, as are potential avenues for immunologic intervention. Additional details regarding the virulence determinants of specific microbes and relevant aspects of host defense are provided in the chapters on the specific organisms.

## Pyogenic Bacteria: Group B Streptococci

### Overview of Host Defense Mechanisms

Infection of the neonate with group B streptococci (i.e., “GBS”) in most cases results from aspiration of infected amniotic or vaginal fluid, followed by adherence to and subsequent invasion through the respiratory mucosa. Initial colonization is influenced by the organism’s ability to adhere to mucosal epithelial cells. Physical disruption of the mucosal epithelium may not be required for tissue invasion, because group B streptococci can enter into the cytoplasm of cultured respiratory epithelial cells by an actin microfilament–dependent process.<sup>1133</sup> Specific secretory IgA antibody and fibronectin may decrease bacterial adherence to the mucosa. Epithelial cells in the skin, tongue, and airways express  $\beta$ -defensins, which are potent antimicrobial peptides.<sup>1134</sup>  $\beta$ -Defensins are active against group B streptococci, as they are against group A streptococci in the skin,<sup>1135</sup> and constitute an important local defense mechanism.<sup>1136,1137</sup>

Once group B streptococci cross the mucosal epithelium and enters the tissues, phagocytes and opsonins become the critical elements of defense. Antibody and complement opsonize the bacteria for phagocytosis and killing by neutrophils and macrophages, but like all gram-positive bacteria, these organisms are resistant to lysis by complement. Strains of *E. coli* and other gram-negative bacteria that are lysed by antibody and complement are nonpathogenic in more mature hosts but may cause invasive infections in neonates.<sup>1104</sup> Group B streptococci and strains of *E. coli* that cause serious neonatal infections possess type-specific polysaccharide capsules, which impede or block antibody-independent activation of the alternative and MBL complement pathways.<sup>1124,1130,1138</sup> Consistent with this notion, there is an inverse correlation between the degree of encapsulation and the deposition of C3b on type III group B streptococci through the alternative pathway,<sup>1139</sup> although some studies have not found an effect of capsule on complement deposition.<sup>1140</sup>

Efficient complement activation leading to deposition of C3b and C3bi on the bacterial surface is dependent on type-specific anticapsular IgM or IgG antibody.<sup>1141</sup> Consistent with these findings, susceptibility to infection with type III group B streptococci is essentially limited to infants lacking type-specific antibody (see Chapter 13). Complement also plays an important role. In animal models, complement components C3 and C4 are required for protection before the development of type-specific antibodies, suggesting that antibody-independent activation of the C4 complement component by the MBL pathway is involved, whereas C3 but not C4 is required once type-specific antibodies are produced.<sup>1142</sup> C3 also is needed for optimal synthesis of group B streptococcal type-specific antibodies in animal models.<sup>1143</sup> IgG-coated and, in the lung, surfactant apoprotein A–coated bacteria are ingested by phagocytes, and ingestion is augmented by C3b and C3bi. Neutrophils and activated macro-

phages phagocytose IgM- and C3b-coated bacteria through the C3b and C3bi receptors, although this is less efficient than phagocytosis of IgG- and C3b-coated bacteria.<sup>1101</sup> In the presence of antibody and complement, fibronectin facilitates binding and phagocytosis of group B streptococci and facilitates protection in neonatal rats.<sup>1144,1145</sup>

Small numbers of group B streptococci may be cleared by resident lung macrophages.<sup>1065</sup> If the bacteria are not cleared, neutrophils and monocytes are recruited to the site of infection by chemotactic factors, including fMLP, C5a, LTB<sub>4</sub>, PAF, and chemokines (e.g., CXCL8).<sup>1146</sup> Many strains of group B streptococci contain an enzyme, C5a-ase, which degrades C5a. This enzyme appears to degrade human but not murine C5 and, consistent with this notion, impedes bacterial clearance in C5-deficient mice reconstituted with human C5 protein.<sup>1147</sup> In addition to recruitment of neutrophils from the circulation, release of the mature neutrophil storage pool and upregulation of neutrophil production by the bone marrow may be required to provide sufficient numbers of neutrophils to contain the infection.

Entry of neutrophils and monocytes into tissues is dependent on the upregulation of adhesion molecules on the lung vascular endothelium by inflammatory mediators and cytokines. Entry also is dependent on chemotactic factor-induced increases in the abundance and avidity of integrins on neutrophils and monocytes. Collectively, these events allow these cells to bind firmly to and migrate between vascular endothelial cells.<sup>932</sup> After entering the tissues, these phagocytes are drawn to the sites of infection because they contain the highest concentrations of chemotactic factors. Chemotactic factors also prime neutrophils and macrophages to more efficiently ingest and kill group B streptococci in situ.<sup>963,986</sup>

Ingested bacteria are exposed to a variety of potentially microbicidal products (discussed earlier). Although streptococci generate hydrogen peroxide, it appears that phagocytes must generate reactive oxygen metabolites to kill group B streptococci efficiently. Non-oxygen-dependent microbicidal factors, including acid, elastase, cathepsin G, and cationic proteins, also contribute to killing of bacteria by neutrophils.<sup>658</sup> IL-12 facilitates IFN- $\gamma$  production, and both cytokines enhance the resistance of neonatal rats to group B streptococcal infection.<sup>1148,1149</sup> The mechanism by which IFN- $\gamma$  enhances resistance is not known but may involve enhanced phagocyte microbicidal activity. Whether IFN- $\gamma$  contributes to protection in humans is not known.

In cases in which group B streptococci overwhelms neonatal defenses, septic shock may result and is the most frequent cause of death resulting from systemic infection due to group B streptococci in neonates. Septic shock results from systemic overproduction of inflammatory mediators, including TNF- $\alpha$ , IL-1, and IL-6, by phagocytes and other host cells.<sup>1027,1037</sup> Both encapsulated and unencapsulated type III group B streptococci induce production of these cytokines by human monocytes in vitro,<sup>1150</sup> and exogenous fibronectin synergizes with these organisms in this induction.<sup>1151</sup> A soluble factor from group B streptococci induces inflammatory mediator production by signaling through TLR-2 plus TLR-6; other components of group B streptococci induce these mediators through an as-yet undefined TLR or TLR-related receptor.<sup>1078</sup> Neutralization of TNF- $\alpha$  enhances survival in animal models,<sup>1152</sup> even when begun 12 hours

after inoculation with these organisms.<sup>1153</sup> Similarly, administration of IL-10, which inhibits production of TNF- $\alpha$  and other proinflammatory cytokines, enhances survival in animals.<sup>1154</sup> These findings have not been reproduced in humans, however. In fact, treatment of sepsis with a soluble TNF- $\alpha$  antagonist led to increased mortality in adults,<sup>1155</sup> and similar studies have not been undertaken in neonates.

### Neonatal Defenses

With rare exceptions,<sup>1156</sup> neonatal group B streptococcal infection occurs only in infants who do not receive protective amounts of group B streptococcal type-specific antibodies from their mothers.<sup>1141,1157</sup> Although the concentrations of group B streptococcal type-specific IgG antibodies in cord sera are usually slightly less than in maternal sera at term, term neonates born to mothers with protective concentrations of IgG antibodies generally are protected. In infants born before 34 weeks of gestation, the amounts of group B streptococcal type-specific antibodies often are markedly less than in the mother<sup>1158</sup>; accordingly, preterm neonates may not be protected even though their mothers' serum contains protective amounts of IgG antibodies.

Production of type-specific antibodies by infected neonates is unlikely to contribute to protection. Infected neonates commonly do not make detectable type-specific antibodies during the first month after infection, although a few transiently synthesize IgM but not IgG antibodies.<sup>1159</sup> By 3 months of postnatal age, sera from uninfected neonates and from those who had previous type III group B streptococcal infection usually contain type III group B streptococcus-specific IgM antibodies.<sup>1160,1161</sup> It is not clear, however, that these antibodies require the exposure of normal infants to type III group B streptococci; they could develop naturally or result from a cross-reactive immune response to another source of antigens to which the infant is exposed postnatally.

In the absence of type-specific antibodies, subtle but cumulative deficits in a number of other host defense mechanisms probably contribute to the neonate's susceptibility to group B streptococci. Type III group B streptococci efficiently adhere to mucosal epithelial cells of neonates, particularly ill neonates.<sup>1162,1163</sup> Neonates also lack secretory IgA and, compared with older children, have reduced amounts of fibronectin in their secretions. Reduced amounts of surfactant apoprotein A in the lungs of preterm neonates, a paucity of alveolar macrophages in the lungs of term and particularly preterm neonates before birth, and diminished phagocytosis and killing of bacteria by these cells may facilitate invasion through the respiratory tract. Limitations in the generation of chemotactic factors or deficits in the chemotactic responses of neonatal neutrophils, or both, may result in delayed recruitment of neutrophils to sites of infection. Once they reach sites of infection, neonatal neutrophils may kill bacteria less efficiently because of limited amounts of opsonins, because the local bacterial density has reached high levels, or because the microbicidal activity of neutrophils is decreased in certain neonates. Rapidly progressive infection can deplete the limited marrow neutrophil reserve to compound the problem.

Although the lack of type-specific antibodies and a multitude of subtle deficits in neonatal defenses together predispose to the development of invasive group B streptococcal disease, why does disease develop in less than 10% of

infants who both lack type-specific antibodies and are born to colonized mothers?<sup>1164</sup> At present, the answer to this question is incomplete. Among neonates who lack type-specific antibodies, the risk for development of group B streptococcal disease appears to be greater in those born to mothers with high-density genital tract colonization or group B streptococcal amnionitis and also may vary with the virulence of the strain. It also is likely that the variations in host defense between different persons contribute, such as differences in antibody-independent complement activation, and that these deficits are greater in more premature neonates.<sup>1165</sup>

### **Overview of Immunologic Interventions for Neonatal Group B Streptococcal Sepsis**

As summarized in the preceding section, the principal host defense deficits that predispose the neonate to infections with group B streptococci and other pyogenic pathogens appear to be a deficiency of opsonins, particularly protective antibodies, and a limited capacity to increase neutrophil production and mobilize neutrophils to sites of infection. Attempts have been made to address both of these deficits through immunologic interventions. Evidence is currently insufficient, however, to support the routine use of any form of immunologic intervention for prevention or adjunctive therapy of bacterial or fungal infections in the neonate.

### **Prevention**

Selective intrapartum chemoprophylaxis with penicillin or ampicillin clearly has reduced the rate of early-onset disease due to group B streptococci. The efficacy of this form of intervention is likely to be increased by the exclusive use of the risk factor–based approach (see Chapter 13). Even so, chemoprophylaxis cannot prevent all neonatal disease. A more appealing strategy would be to ensure that mothers have adequate amounts of IgG anti–group B streptococcal antibodies to protect their infants passively. Initial results of immunization of pregnant women with purified group B streptococcal polysaccharide were limited by a relatively low response rate of 60%. These limitations may be circumvented, however, by the development of group B streptococcal capsular polysaccharide–protein conjugate vaccines. Studies show that 80% to 93% of adults immunized with type Ia, Ib, II, III, and V capsular polysaccharide–protein conjugate vaccines respond with approximately fourfold titer rises, with geometric mean titers ranging from 2.7 µg/mL for type III to 18.3 µg/mL for type Ia.<sup>1141</sup> If these results can be reproduced, an equally immunogenic multivalent vaccine can be compounded, and issues related to maternal immunization can be addressed, this would provide an attractive approach to the prevention of group B streptococcal disease in neonates.

Before 1993, five major randomized, controlled trials evaluated the efficacy of intravenous immunoglobulin (IVIG) for the prevention of nosocomial or late-onset pyogenic infections in premature neonates, a group at increased risk of infection.<sup>1166</sup> Of these five studies, only one showed a statistically significant reduction in the frequency of infections,<sup>1167</sup> and none showed a reduction in mortality rate or length of hospital stay. A 1997 meta-analysis of 12 randomized controlled trials, which included 4933 infants, showed a slight but statistically significant reduction in the

incidence of sepsis ( $P < .02$ ).<sup>1168</sup> The most recent meta-analysis by the Cochrane collaboration in 2001, which included 19 randomized controlled trials with a total of 4986 infants, found a 3% reduction in sepsis ( $P = .02$ ).<sup>1169</sup> It should be noted that the stringency with which sepsis was defined in these studies varied. Perhaps more important, IVIG prophylaxis had no effect on mortality rates. Similarly, a recent multicenter randomized, controlled trial in premature neonates at increased risk due to total IgG concentrations less than 400 mg/dL found no significant reduction in sepsis or other tangible benefit of IVIG prophylaxis. Thus, the authors of the two meta-analyses and other reviews<sup>1168-1170</sup> concluded that IVIG is not indicated for routine prophylaxis in preterm and low-birth-weight neonates, because there is no effect on long-term outcome and the small apparent decrease in the rate of sepsis is not sufficient to justify the cost and potential risks associated with its use.

Recombinant G-CSF and GM-CSF augment granulocyte production and function in neonatal animals and provide some protection against challenge with pyogenic bacteria, including group B streptococci, in these neonatal animal models.<sup>950,1170,1171</sup> These findings prompted clinical trials to determine if administration of recombinant G-CSF or GM-CSF to human neonates would result in increased levels of circulating neutrophils and protect at-risk neonates from sepsis. Three randomized trials of prophylaxis with recombinant GM-CSF and one comparative observational study of prophylaxis with recombinant G-CSF have been conducted.<sup>950,1170,1172</sup> These studies have shown that both G-CSF and GM-CSF increase circulating neutrophil counts and appear to be well tolerated. A meta-analysis of the studies with GM-CSF showed no reduction in mortality rates, however.<sup>1172</sup> The small, nonrandomized observational study found that prophylactic administration of recombinant G-CSF to neutropenic low-birth-weight infants born to mothers with preeclampsia led to a reduction in proven bacterial infections in these patients.<sup>1173</sup> No randomized, controlled trials with G-CSF have been conducted, however, so its utility as a prophylactic agent is essentially untested. Thus, the available evidence does not support the prophylactic use of G-CSF or GM-CSF in neonates.

### **Adjunctive Therapy of Pyogenic Infections**

#### **PASSIVE ANTIBODY**

In three early studies, each of which evaluated a different population of patients, and two of which used a different preparation of IVIG, whereas the third study used a preparation of mixed immune globulins, concluded that the administration of IVIG as adjunctive therapy of neonatal sepsis reduced mortality.<sup>1166,1174</sup> Because of the small numbers of neonates studied, lack of concurrent controls, or absence of a prospective design, these studies did not provide sufficient information to form firm conclusions regarding efficacy; evidence of IVIG toxicity was not observed, however, in these and in two other prospective, controlled studies.<sup>1175-1177</sup> In the study by Weisman and co-workers,<sup>1175,1176</sup> all premature neonates were randomly assigned to receive IVIG selected for high titers of antibody to group B streptococci or albumin placebo within 12 hours of birth. Although no efficacy for prevention of late-onset infection was found, IVIG may have been beneficial among the 31 patients with

early-onset sepsis, which was most commonly due to group B streptococci. Among these 31, 5 of 16 placebo recipients but none of 14 IVIG-treated recipients died within the first 7 days of life. Two late deaths occurred in the IVIG group, however, so that survival at 8 weeks of age did not differ significantly from that in the control group, although the trend still favored the IVIG group. The treatment arm of the study was terminated early, because the monitoring group concluded that the prophylactic arm of the trial did not show efficacy of IVIG. Another study performed in Saudi Arabia suggested benefit from therapeutic administration of an IgM-containing immunoglobulin preparation not available in the United States, but this study did not include a randomized control group.<sup>1178</sup>

These studies have been followed by a number of relatively small but prospective clinical trials of adjunctive IVIG therapy for neonatal sepsis. These small studies were conducted in a variety of different countries with differing risks for infection, management approaches, and preparations of IVIG. The Cochrane collaboration performed a meta-analysis of 13 such randomized control trials from seven countries involving neonates with suspected or proved invasive bacterial or fungal infections.<sup>1169</sup> In the six trials (with 318 subjects) that included neonates with clinically suspected infection, IVIG had a marginal effect on mortality rate (relative risk 0.63; 95% confidence interval 0.41% to 1.00%,  $P = .05$ ). In the seven trials (with 262 subjects) that evaluated outcome only in neonates subsequently proved to have invasive infections, mortality also was marginally reduced by IVIG (relative risk 0.51; 95% confidence interval 0.31% to 0.98%,  $P = .04$ ). The authors concluded that the marginal statistical significance and the variability in study design and quality do not allow firm conclusions to be made at the present time.<sup>1169</sup> We agree with their conclusions. Although additional prospective, placebo-controlled studies of adjunct therapy with IVIG in septic neonates are indicated, the current evidence is insufficient to support routine use.

An alternative to the use of IVIG might be the use of hyperimmune immunoglobulin or mAb preparations. Hyperimmune group B streptococcal IVIG administered before infectious challenge significantly reduced the mortality rate among newborn rhesus monkeys infected with these organisms by the intragastric route; however, the control group in this experiment received neither conventional IVIG nor antibiotic therapy.<sup>1179</sup> Although preliminary studies with hyperimmune group B streptococcal IVIG suggested that it is well tolerated by neonates with suspected neonatal sepsis,<sup>1179</sup> no reports of its efficacy in a controlled trial have been published. Similarly, although a human mAb directed against the group B streptococcal-specific carbohydrate has been developed, provided protection in neonatal rats, and was shown to be safe in neonatal macaques,<sup>1180,1181</sup> it has not been tested in human clinical trials. Polyclonal human antibodies and humanized mAbs directed against components of staphylococci, including coagulase-negative staphylococci, have been developed but have not yet been evaluated clinically.

#### NEUTROPHIL TRANSFUSIONS

Neutrophil transfusions enhance survival rate in certain animal models of neonatal sepsis, but the clinical efficacy of neutrophil transfusion in septic human neonates is uncertain. Three of five controlled studies showed statistically

significant improvement in the survival rate for neonates receiving granulocyte transfusions compared with that for infants not receiving this therapy.<sup>1170</sup> Nonetheless, small sample sizes and differences in entry criteria for treatment and control groups, in methods of neutrophil preparation, in numbers of neutrophils per transfusion, in numbers of transfusions, and in bacterial pathogens causing disease preclude a meaningful meta-analysis of these studies. Although neutrophil storage pool depletion has been used as a selection criterion for neonates for whom transfusion may be beneficial, the difficulty in ascertainment of neutrophil storage pool size in clinical practice and the failure of this parameter to predict outcome in some studies make this measure an imperfect criterion in clinical practice. The utility of neutrophil transfusions is further compromised by the difficulty in obtaining these cells in a timely fashion and the potential complications of transfusions, including the risk of infection. For these reasons, neutrophil transfusions cannot be recommended as routine therapy for neonates with suspected or proven sepsis.

#### COLONY-STIMULATING FACTORS

Another approach to augmenting neutrophil numbers, function, or both is the administration of recombinant G-CSF or GM-CSF. Administration of both G-CSF and GM-CSF has shown benefit as adjunctive therapy for established pyogenic infections in experimental animals. In initial studies, administration of G-CSF to human neonates ranging in gestational age from 26 to 40 weeks with presumed early-onset sepsis significantly increased the numbers of circulating neutrophils, bone marrow neutrophil storage pool size, and neutrophil expression of CR3 receptors (CD11b-CD18) without short- or long-term adverse effects.<sup>1182-1184</sup> Subsequent studies have addressed therapeutic efficacy and safety, and two groups of investigators recently have published meta-analyses of these therapeutic trials in suspected or proven neonatal sepsis. The most comprehensive of these came from the Cochrane collaboration in 2003, which analyzed all causes of mortality in 257 infants with suspected sepsis from 7 randomized clinical trials.<sup>1172</sup> Survival was not improved by adjunctive treatment with G-CSF or GM-CSF; G-CSF was used in most of these studies. On the other hand, a subset analysis from three of these studies that included 97 infants with neutropenia (absolute neutrophil count less than  $1700/\text{mm}^3$ ) showed an apparent reduction in mortality (relative risk = 0.34; 95% confidence interval 0.12% to 0.92%). In an earlier meta-analysis of five studies involving 73 neonates who received G-CSF and 82 controls by Bernstein and colleagues, the mortality rate was significantly reduced ( $P < .05$ ), but if data from two nonrandomized trials were excluded, there was no significant difference (observed risk 0.43; 95% confidence interval 0.14% to 1.23%,  $P = .13$ ).<sup>1185</sup> No significant adverse effects of G-CSF adjunct therapy were noted in these studies, and one long-term follow-up study also found no adverse effects. Thus, as with the meta-analyses of adjunct therapy of neonatal sepsis with IVIG, data regarding the use of G-CSF for adjunctive therapy of neonatal sepsis indicate that it is safe and might be useful in some situations. Nonetheless, evidence is currently insufficient to support the routine use of G-CSF or GM-CSF as adjunctive therapy in septic neonates.

### Summary

Substantial advances have occurred in our understanding of factors that compromise the neonate's defenses against bacterial infections. As a result of this information, a number of clinical trials have evaluated the use of IVIG, G-CSF, or GM-CSF for the prophylaxis or adjunctive treatment of neonatal infections. The results from these studies have been disappointing or inconclusive. To date, there is no established role for these or any other form of immunologic therapies in the prevention or treatment of bacterial or fungal infections in human neonates. The existing data probably are sufficient to conclude that the prophylactic use of IVIG is not cost-effective and that such use of GM-CSF is not beneficial. Conversely, randomized clinical trials to test the potential benefit of IVIG in septic neonates or G-CSF in clinically septic neonates with neutropenia, or combinations of these agents, as adjunctive therapeutic agents for the treatment of neonatal sepsis may be indicated.

## Viruses

### Overview of Host Defense Mechanisms

Effective viral host defense mechanisms of vertebrates typically are dependent on a combination of innate and adaptive immune mechanisms that are highly interlinked. Because viruses replicate intracellularly, innate and adaptive mechanisms that control or block infection within cells, such as NK cells and CD8<sup>+</sup> T cells, respectively, and prevent spread of virus from cell to cell are the most critical for effective host defense. Antibody and complement also may modify viral expression, especially by preventing spread of virus into the central nervous system (CNS), but in most tissues the cellular immune response is critical for control of viral replication and the elimination of virally infected cells. This section focuses on host defenses operative against HSV-1 and HSV-2, both of which cause strikingly more severe primary disease in the neonate than in the immunocompetent adult.<sup>1186</sup> The immune responses to other viruses, such as CMV, HIV-1, and enteroviruses, are included where relevant. HSV-1 and HSV-2 mostly are collectively referred to here as HSV, because these two viruses are very closely related and, in most instances, have very similar pathogenic properties. The following discussion is based in large part on data from *in vivo* studies using HSV in mice and *in vitro* studies using human cells.

HSV is an enveloped virus with a large DNA genome that is contained within an inner core lined by capsid protein. The inner capsid is surrounded by a loose collection of proteins called the tegument. The production of HSV progeny results in the irreversible destruction of the host cell, resulting in viral release. Despite this lytic effect, a substantial proportion of both primary HSV-1 and HSV-2 infections are asymptomatic.<sup>1187</sup> Following recovery from acute infection, HSV persists for life in humans, owing to a latent state established in neurons, such as those of the trigeminal ganglion. In cells containing latent virus, the viral genome is in a circular configuration and associated with host-derived histone proteins.

### Innate Antiviral Immunity

The antiviral immune response generally can be divided into two phases. The first is an early, nonspecific phase (typically

the first 5 to 7 days in HSV infection) involving innate immune mechanisms. This is followed by a later, antigen-specific phase involving adaptive immunity mediated by T and B cells and their products.<sup>1188</sup> The early phase is critical, because infection either may be successfully contained or, alternatively, may disseminate throughout the host. An overview of the role that interferons, cytokines, and chemokines, and the innate immune cells that produce them, play in the control of HSV follows. Immunity by gamma-delta T cells, which appears to play an early and non-antigen-specific role in the response to HSV, is included here as an innate immune mechanism.

**Type I Interferons.** Type I IFN consists of IFN- $\alpha$  (encoded by multiple highly homologous and clustered genes) and IFN- $\beta$ , which utilize a common type I IFN receptor that is widely expressed. IFN- $\beta$  is made mainly by nonhematopoietic cell types, such as fibroblasts, in response to viral infection, whereas IFN- $\alpha$  is produced in particularly high levels by plasmacytoid DCs of the DC2 cell lineage.<sup>57,59</sup> HSV triggers high levels of type I IFN secretion by plasmacytoid DCs in a TLR-9-dependent fashion.<sup>51</sup> The HSV double-stranded DNA genome is unmethylated at CpG dinucleotide residues, and DNA containing these unmethylated residues is a TLR-9 ligand.<sup>749</sup> The secretion of high levels of IFN- $\alpha$  by DC2 cells results in a systemic antiviral state and enhances local adaptive immune responses, as result of the exposure of secondary lymphoid tissue to this cytokine.<sup>61</sup>

The type I IFN receptor mediates its effects by JAK tyrosine kinase-dependent phosphorylation of STAT-1 and STAT-2. STAT-1, STAT-2, and IRF-9 form a heterotrimeric complex that binds to IFN-stimulated response elements (ISREs) of genomic DNA and influences the gene transcription.<sup>1189</sup> STAT-1 also can homodimerize and bind to GASs ("gamma-interferon-activating sequences"), which induce a distinct set of genes from those utilizing ISREs.<sup>1032</sup> Because these STAT-1 homodimers (but not other STATs) and GAS-regulated genes are activated when IFN- $\gamma$  binds to its specific receptor,<sup>1032</sup> type I IFN may potentially induce genes that are characteristic of IFN- $\gamma$  responses, but not vice versa. However, for antiviral host defense in humans, including to HSV, only the ISRE genes appear to be critical.<sup>1190,1191</sup>

Substantial amounts of type I IFN are found in the tissues of HSV-infected animals and humans.<sup>1192,1193</sup> Although HSV efficiently induces type I IFN production, the virus is relatively resistant to its antiviral effects. This relative resistance may account for the limited effectiveness of type I IFN in treating recurrences of established HSV infections, such as of the eye. The resistance may be due in part to ability of the HSV ICP34.5 protein to prevent shutting off of host cell protein synthesis by type I IFN.<sup>1194</sup> HSV infection of certain cell types also may inhibit type I IFN-mediated activation of the JAK/STAT pathway.<sup>1195</sup> In contrast with the resistance to type I IFN alone, HSV may be controlled effectively in mice by a combination of type I IFN and IFN- $\gamma$ .<sup>1196</sup> Whether this synergy between type I IFN and IFN- $\gamma$  applies to human infection remains unclear.

**IFN- $\gamma$ .** IFN- $\gamma$  is produced by NK cells and  $\gamma\delta$  T cells, which are components of the early innate immune response to HSV, as well as by CD4<sup>+</sup> and CD8<sup>+</sup> T cells that appear later during the adaptive immune response. The effect on HSV infection of genetic disruption of IFN- $\gamma$  or the IFN- $\gamma$  receptor,

or of IFN- $\gamma$  neutralization in wild-type mice, has varied, depending on the model and dose of virus employed. In general, IFN- $\gamma$  is important in the initial containment of disease following primary infection at most sites, such as the vagina, footpad, skin, and cornea, rather than in maintaining latency.<sup>1197-1202</sup> In survivors of infection, the lack of IFN- $\gamma$  also was associated with increased viral load in the eye or trigeminal ganglion basally<sup>1197</sup> and after reactivation by ultraviolet (UV) irradiation<sup>1202</sup> or hyperthermia.<sup>1203</sup> Of interest, greater severity of HSV disease after corneal infection also was observed in mice lacking the IFN- $\gamma$  receptor than in those lacking the IFN- $\gamma$  ligand,<sup>1204,1205</sup> which raises the possibility of an as-yet unidentified additional ligand for the IFN- $\gamma$  receptor that contributes to host defense, although this finding also may reflect technical rather than meaningful biologic differences.

**IL-1 Family Cytokines.** IL-1 is induced at sites of HSV infection, such as the cornea, and may contribute to pathogenic inflammation.<sup>1206</sup> IL-1 $\alpha$  administered to neonatal mice can enhance survival,<sup>1207</sup> but the role of endogenously produced IL-1 in the control of HSV infections is unclear. In mice, the administration of IL-18, another IL-1 family member, provides substantial protection against systemic HSV infection by a mechanism dependent mainly on IFN- $\gamma$  but not on NK cells.<sup>1208</sup> Mice lacking IL-18 also are more vulnerable to intravaginal challenge with HSV.<sup>1209</sup>

**IL-12 Family.** The IL-12, IL-23, and IL-27 family of cytokines have multiple potentially important antiviral host effects, including promoting NK cell cytotoxicity, CD4<sup>+</sup> and CD8<sup>+</sup> T cell proliferation and differentiation (i.e., to T<sub>H</sub>1 cells and CTL, respectively), and IFN- $\gamma$  production by mature NK cells and T cells.<sup>1210</sup> These cytokines, in conjunction with type I IFN, also favor T<sub>H</sub>1 differentiation from naïve CD4<sup>+</sup> T cell precursors in humans.<sup>56</sup> This synergy may account for the predominance of IFN- $\gamma$ -producing virus-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells in most viral infections, such as with herpesviruses.<sup>1211</sup> IL-12 is produced by DCs, including those of the DC2 lineage, and mononuclear phagocytes infected with HSV infection in vitro,<sup>1212</sup> and IL-23 transcripts have been detected in the neuronal ganglia of HSV-infected mice.<sup>1213</sup> Although HSV infection of myeloid DCs also can downregulate IL-12 production in vitro,<sup>1214</sup> these infected cells may induce neighboring uninfected cells to produce IL-12. HSV-infected epithelial cells also appear to secrete factors that result in the induction of IL-12 by inflammatory leukocytes.<sup>1215</sup> Mice lacking both IL-12 and IL-23 are more susceptible to HSV infection,<sup>1209</sup> but it is unclear if these cytokines are important for control of HSV infection in humans. In fact, patients with a genetic deficiency that abrogates both IL-12 and IL-23 signaling do not seem prone to more severe infection with HSV or other viruses.<sup>225,1191</sup> In certain contexts, IL-12 and IL-23 may have a deleterious impact on the outcome of infection by contributing to inflammatory damage, such as in cases of established HSV keratitis.<sup>1216</sup>

**IL-15.** IL-15, which has a key role in NK cell development and CD8<sup>+</sup> T cell immunity, also is a potent activator of NK cells for enhanced cytotoxicity against most herpesviruses, including HSV.<sup>1217</sup> Exposure of human PBMCs to HSV also upregulates NK cell cytotoxicity by an IL-15-dependent

mechanism.<sup>1218</sup> In mice, serum levels of IL-15 can be detected, peaking at approximately 3 days after HSV inoculation,<sup>1219</sup> suggesting a role in innate immunity. Studies in mice given IL-15,<sup>1219</sup> or in which IL-15 or a component of its receptor has been genetically disrupted,<sup>1220</sup> support the importance of this cytokine in the control of systemic HSV infection.

**Chemokines.** HSV infection induces the secretion of a number of CXC and CC chemokines by leukocytes and epithelial cells that are important in leukocyte recruitment and maintenance of inflammation. These chemokines may have either beneficial or deleterious effects for a given site of infection. For example, in HSV keratitis, CCL3 (MIP-1 $\alpha$ ) contributes to inflammatory disease but does not influence viral replication,<sup>1221</sup> whereas CXCL8 (IL-8), a potent neutrophil chemoattractant, may be helpful in viral control.<sup>1222</sup> The CXC chemokine CXCL10 (MIG), when produced in the cornea, may be detrimental by causing an influx of mononuclear phagocytes that can spread HSV to the other parts of the eye.<sup>1272</sup> Chemokines also may skew the outcome of the adaptive immune response to viral infection. For example, CCL2 (MCP-1) in the cerebrospinal fluid of mice infected with HSV-2 may reduce survival by skewing CD4<sup>+</sup> T cell immunity toward a T<sub>H</sub>2 rather than a T<sub>H</sub>1 antiviral response.<sup>1223</sup> HSV-1 infection of mice induces high levels of intracerebral CCL2 in a TLR-2-dependent manner; TLR-2 deficiency is associated with improved survival,<sup>1224</sup> but it is unclear to what extent this improvement is due to reduced expression of CCL2 or other chemokines. Elevated cerebrospinal fluid levels of the CC chemokines CCL2, CCL3 $\alpha$ , and CCL5 (RANTES), and of CXCL8, also have been documented in cases of human HSV encephalitis,<sup>1225</sup> suggesting their role in CNS inflammation. CNS mononuclear phagocytes, such as macrophages or microglial cells, are likely sources of at least a portion of these chemokines, as supported by the capacity of these cell types to produce chemokines on infection with HSV in vitro.<sup>1226,1227</sup>

**Mononuclear Phagocytes.** Macrophages are likely to play an important role in the early and local containment of HSV infection by their secretion of cytokines and, at least in mice, by the expression of iNOS. In mice, early infection containment appears to involve mainly macrophages, which produce TNF- $\alpha$ , and  $\gamma\delta$  T cells, which produce IFN- $\gamma$ .<sup>1228</sup> Systemic depletion of mononuclear phagocytes or  $\gamma\delta$  T cells, or of the cytokines these cells produce, increases HSV-1 replication in the cornea<sup>1229</sup> and associated ganglia.<sup>480,1228</sup> HSV infection of mononuclear phagocytes also synergizes with IFN- $\gamma$  for promoting iNOS expression,<sup>1230</sup> which may be detrimental (keratitis)<sup>1231</sup> or beneficial (pneumonia<sup>1232</sup> and encephalitis<sup>1233</sup>), depending on the site of infection. HSV can directly infect mononuclear phagocytes in vitro, but the resultant infection usually is nonpermissive and does not result in viral replication. Such nonreplicative infection may result in apoptosis,<sup>1234</sup> which could limit antiviral immune mechanisms, such as cytokine production.

**Myeloid Dendritic Cells.** The in vivo role of DCs in the control of HSV is poorly understood. In the murine HSV-2 vaginal infection model, submucosal DCs but not other APC populations (e.g., B cells or macrophages) may be key for viral antigen presentation to T cells in the draining lymph nodes.<sup>1235</sup> As discussed previously (see section on neonatal

monocyte-derived DCs), culturing blood monocytes with IL-4 and GM-CSF result in their acquiring features of immature DCs, and these cells can be induced to acquire features of mature DCs using proinflammatory stimuli, such as TNF- $\alpha$ . HSV can efficiently infect both mature and immature monocyte-derived DCs<sup>1236,1237</sup> and is able to replicate in immature but not mature monocyte-derived DCs. HSV infection of monocyte-derived DCs also decreases expression of key co-stimulatory molecules and adhesion molecules,<sup>1238</sup> and of markers indicative of their maturity, such as CD83<sup>1239</sup>; this decrease is associated with a decreased capacity of these cells to activate T cells *in vitro*.<sup>1240</sup> Finally, HSV infection of purified DCs from adult humans stimulates them to secrete IFN- $\alpha$  and IL-1, but not to secrete IL-12 or to express increased amounts of CD80 or CD86.<sup>1241</sup> These findings suggest that DCs are not effectively activated by HSV infection and may be direct cellular targets of HSV-mediated immunosuppression. Mouse models have not demonstrated detectable *in vivo* infection of DCs after either infection of the footpad<sup>1242</sup> or vagina,<sup>1235</sup> however, raising the issue of how frequently these cells are infected *in vivo* in humans.

**Natural Killer Cells.** NK cells provide a particularly important restraint on viral replication and dissemination before the appearance of adaptive immunity, as shown by the severity of primary infections with herpesviruses, including HSV, CMV, and VZV in patients with a selective lack of NK cells.<sup>837</sup> Although the initial disease is severe, NK cell-deficient patients are able to eventually clear virus, presumably by T cell-mediated immunity<sup>837</sup> (D. Lewis and C. Wilson, unpublished data, 1990). Similarly, if NK cells in mice are eliminated using a specific antiserum given concurrently with HSV, the viral titers in internal organs and the mortality rate both are markedly increased; however, this treatment has no significant effect if started 5 days after viral challenge.<sup>1243</sup> NK cells accumulate at sites of viral inoculation, and depletion of these cells by specific antiserum results in local spread of the infection.<sup>1244</sup> Murine CMV studies suggest that NK cell-derived IFN- $\gamma$  may be more important than cytolytic activity for this early protection.<sup>1245</sup> IFN- $\gamma$  may act directly on some cell types, such as hepatocytes, to limit viral replication by a noncytolytic mechanism, as has been observed for other viruses, such as hepatitis B virus.<sup>1246-1248</sup> IFN- $\gamma$  also increases MHC expression (both class I and class II), which facilitates antigen presentation to CD4<sup>+</sup> and CD8<sup>+</sup> T cells. The presence of NK cell-derived IFN- $\gamma$  during the early phases of naive T cell activation also may increase expression of the T-bet transcription factor and may favor T cell differentiation into T<sub>H1</sub> cells.<sup>1249</sup>

**Gamma-Delta T Cells.** Gamma-delta T cells, particularly those bearing V $\gamma$ 2V $\delta$ 2 TCR (based on the current nomenclature), obtained from HSV-seropositive donors can lyse HSV-infected cells in a non-MHC-restricted manner.<sup>490</sup> They are discussed as part of the innate immune response because of evidence in mice that they appear early at sites of HSV infection *in conjunction* with mononuclear phagocytes. The ligands on the target cells that activates these T cells remain to be defined but probably are host-derived molecules, because such T cell activation also is observed with viruses that are not closely related to HSV, such as vaccinia virus.

## Adaptive Antiviral Immune Mechanisms

Adaptive immune responses mediated by HSV antigen-specific T cells and B cells are first detected 5 to 7 days after the onset of primary HSV infection in adult humans, with the peak response achieved at approximately 2 to 3 weeks after infection.<sup>554,1250,1251</sup> Antigen-specific immunity does not eradicate infection (i.e., achieve sterile immunity) but rather terminates active viral replication and the acute infection. T cells play the critical role in resolution of active HSV infection and the maintenance of viral latency.<sup>1252,1253</sup> The general importance of T cells in the control of human HSV and other herpesvirus infections is indicated by the increased susceptibility of persons with quantitative (e.g., purine nucleoside phosphorylase deficiency and late HIV infection) or qualitative (e.g., Wiskott-Aldrich syndrome) T cell and antigen presentation defects. Mouse studies suggest that both CD4<sup>+</sup> and CD8<sup>+</sup> T cells and IFN- $\gamma$  contribute to HSV clearance,<sup>1254</sup> and that CD4<sup>+</sup> T cells may be more important than CD8<sup>+</sup> T cells in the control of HSV infections of the skin and peripheral nervous system.<sup>1255</sup> The relative importance of CD4<sup>+</sup> and CD8<sup>+</sup> T cells in HSV infections in humans, including at particular sites, is uncertain, however. Of importance, B cells do appear to be able to provide protection in the absence of T cells.<sup>1200,1251,1255</sup>

**CD4<sup>+</sup> T Cells.** CD4<sup>+</sup> T cells may help control HSV infection by inhibiting viral replication through the production of IFN- $\gamma$ , TNF- $\alpha$ , and CD40 ligand.<sup>1199,1256</sup> The IFN- $\gamma$ -mediated increase in expression of the molecules involved in MHC class I antigen presentation also may help override the inhibition of MHC class I antigen presentation by HSV (see later). CD40 ligand expression by CD4<sup>+</sup> T cells also is essential for HSV-specific antibody production by B cells and antibody isotype switching, and for the ability of CD4<sup>+</sup> T cells to become long-term memory T cells, including those of the T<sub>H1</sub> subset.<sup>1257</sup> Genetic or antibody disruption of CD40 ligand-CD40 interactions in mice results in increased CNS infection and paralysis compared with that in wild-type mice after footpad inoculation with HSV, and in reductions in CD4<sup>+</sup> but not CD8<sup>+</sup> T cell responses.<sup>163</sup> In rare patients with CD40 deficiency, production of IFN- $\alpha$  by plasmacytoid DCs is decreased in response to HSV infection *in vitro*,<sup>1258</sup> which strongly supports the idea that CD40 engagement contributes to human antiviral immunity. CD4<sup>+</sup> T cells also promote the generation and survival of anti-HSV effector CD8<sup>+</sup> T cells in mice,<sup>1254,1259,1260</sup> but the precise mechanism remains unclear. Production of IL-2 by CD4<sup>+</sup> T cells also may contribute to the expansion and differentiation of effector CD8<sup>+</sup> T cells.

HSV-specific CD4<sup>+</sup> T cells in humans have been identified in the circulation<sup>1261</sup> and from sites of recurrent infection in the skin,<sup>1262,1263</sup> cervix,<sup>1264</sup> cornea,<sup>1265</sup> and retina.<sup>1265</sup> These CD4<sup>+</sup> T cells recognize peptide epitopes from a variety of HSV proteins, including those of the envelope, tegument, and capsid.<sup>1211,1264</sup> As suggested by murine studies,<sup>163,1266</sup> the development of HSV-specific CD4<sup>+</sup> T cell immunity critically depends on an intact CD28-CD80 or CD86 co-stimulatory pathway. The HSV-specific circulating CD4<sup>+</sup> T cell response of humans is characterized by a predominant T<sub>H1</sub> cytokine profile,<sup>1267</sup> consistent with the ability of the virus to induce type I IFN, IL-12, and IL-23 at sites of infection, as discussed earlier. HSV infection also may promote T<sub>H1</sub> immunity by

inducing T cells at early stages of activation to produce osteopontin, which helps maintain IL-12 production by APCs and inhibits IL-10 production, thereby favoring a  $T_H1$  adaptive immune response.<sup>1268</sup>

Finally, cytotoxic  $CD4^+$  T cells may directly lyse HSV-infected cells that express viral peptides on MHC class II molecules. Such cytotoxic  $CD4^+$  T cells frequently have been isolated from the circulation of HSV-infected persons after expansion *in vitro* and appear to compose about 30% of the cytotoxic T cells in HSV infection in mice.<sup>1262,1269</sup> The actual frequency of these HSV-specific cytotoxic  $CD4^+$  T cells in the human circulation is unknown. Human  $CD4^+$  cytotoxic cells can recognize peptides derived from viral glycoproteins found in the HSV lipid envelope,<sup>1252,1270,1271</sup> such as gB, gC, and gD,<sup>1272</sup> and it is likely that these viral glycoproteins enter into the MHC class II antigen-processing endocytic pathway after first fusing with the host cell membrane. Human  $CD4^+$  T cell cytolytic activity probably is mediated mainly by the perforin/granzyme pathway.<sup>777</sup> Potential target cells include not only professional MHC class II-bearing APCs (e.g., mononuclear phagocytes, B cells, DCs) but many other cell types that can express MHC class II and, in most cases, present antigen after their exposure to IFN- $\gamma$ , GM-CSF, or TNF- $\alpha$ . Substantial  $CD8^+$  T cell responses to HSV are generated in humans, however, and HSV-specific  $CD8^+$  T cells compose a prominent part of the viral response in tissues, such as the skin and cervix; these findings raise questions about how important  $CD4^+$  T cell-mediated cytotoxicity is in the local control of infection.

**$CD8^+$  T Cells.** The efficient clearance of most viral infections depends on  $CD8^+$  T cell-mediated cytotoxicity, in which infected target cells are induced to undergo apoptosis by the secretion of perforin and granzymes or the engagement of Fas by Fas ligand (see Fig. 4-7). Direct evidence for the importance of  $CD8^+$  T cells in the control of herpesvirus infections in humans comes from studies showing that the adoptive transfer of donor-derived  $CD8^+$  T cells against CMV or EBV provides protection of hematopoietic cell transplant recipients from primary infection with these viruses.<sup>1273,1274</sup> In animal models,  $CD8^+$  T cells also appear key in resolving HSV lytic infection of neuronal ganglia during primary infection,<sup>1275</sup> and in preventing reactivation of virus from latency in sensory neurons, possibly by an IFN- $\gamma$ -dependent mechanism.<sup>1276</sup> Direct recognition of infected ganglion cells by  $CD8^+$  T cells is likely, because HSV infection induces detectable MHC class I expression by sensory neurons.<sup>1277</sup> Noncytolytic mechanisms,<sup>1278</sup> such as IFN- $\gamma$  production<sup>1276</sup> or the secretion of granzyme A,<sup>1279</sup> may be key for  $CD8^+$  T cells to maintain latency and to prevent viral spread. Cytolytic mechanisms, such as the perforin/granzyme system, may not be necessary for control of HSV infection at particular tissue sites, such as the cornea, and instead contribute to inflammatory disease.<sup>1280</sup>  $CD8^+$  T cells with high levels of direct cytolytic activity are found at sites of focal temporal lobe lesions in mice with experimental HSV encephalitis,<sup>1281</sup> and such cytolytic activity might well contribute to neuronal destruction as part of viral clearance.

In adults with chronic infection, HSV-specific  $CD8^+$  T cells that can lyse HSV-infected targets are found mainly at sites of local recurrence of virus, such as the skin adjacent to

the genital tract, the cervix,<sup>1253,1262,1264,1269,1282</sup> and cornea.<sup>1283</sup> By contrast, HSV-specific  $CD8^+$  T cells are not detectable in the circulation with use of standard techniques, such as intracellular cytokine staining after stimulation with whole HSV,<sup>1261</sup> but can be expanded *in vitro* from the blood of HSV-immune donors.<sup>1284,1285</sup> The human  $CD8^+$  T cell response appears to be dominated by HSV proteins that are internal structural components of the virion, such as those of the tegument and nucleocapsid, or that are rapidly induced on viral entry, such as proteins encoded by immediate-early genes.<sup>1286,1287</sup> These proteins apparently can be processed into peptides and presented on MHC class I molecules before the inhibitory effects of certain viral proteins, which are discussed later on. Viral glycoproteins of the HSV lipid envelope do not appear to be important antigens for MHC class I-restricted responses, perhaps because they fuse with the host cell membrane and do not enter in the cytoplasm in substantial amounts.<sup>1288</sup> The  $CD8^+$  T cell immune response to primary HSV infection infections has not been characterized.

**Viral Inhibition of Antigen Presentation and Effect on the T Cell Immune Response.** In view of the importance of MHC class I antigen presentation in antiviral control, it is not surprising that many herpesviruses, including HSV and CMV, have accumulated multiple gene products to inhibit MHC class I antigen presentation.<sup>1289</sup> Inhibition of the MHC class I pathway limits not only  $CD8^+$  T cell-mediated cytotoxicity but also the generation of CTL from naïve  $CD8^+$  T cells, although the presence of HSV-specific  $CD8^+$  T cells at sites of infection shows that this inhibition is overcome, at least eventually. Human CMV also encodes proteins that inhibit MHC class II antigen presentation (reviewed by Mocarski<sup>1290</sup>). Although specific proteins in HSV that inhibit MHC class II antigen presentation have not been identified, they may well exist: Infection of mice with virulent HSV strains results in CNS lesions in which MHC class II expression remains intracellular, thereby avoiding any chance of detection by  $CD4^+$  T cells.<sup>1291</sup>

Two HSV proteins, the viral host shutoff protein and the ICP47 immediate-early protein, are particularly important for the inhibition of the MHC class I pathway. The viral host shutoff protein is required for viral pathogenicity<sup>1242</sup> and increases destruction of cellular mRNA and decreases host cell protein synthesis, including MHC class I molecules.<sup>1288</sup> This down regulation of MHC class I limits  $CD8^+$  T cell-mediated cytotoxicity of HSV-infected target cells, such as fibroblasts and keratinocytes.<sup>1292</sup> The ICP47 protein binds to the TAP transporter and prevents the loading of peptides onto MHC class I molecules and the transport of MHC class I molecules to the cell surface.<sup>1288,1293-1296</sup>

The importance of selective inhibition of MHC class I antigen presentation in the pathogenicity of HSV and CMV has not yet been formally tested *in vivo*, but of note, NK cells and HSV antigen-specific  $CD4^+$  T cells are detected earlier than antigen-specific  $CD8^+$  T cells in lesions of adult humans with recurrent HSV-2 disease.<sup>1262</sup> IFN- $\gamma$  produced by infiltrating NK and  $CD4^+$  T cells may help override the inhibitory effects of ICP47 on MHC class I expression,<sup>1288,1297</sup> thereby allowing the subsequent eradication of virus by  $CD8^+$  T cells, which increase in lesions around the time of viral clearance.<sup>1253,1262</sup> This model is supported by the observation

that patients with selective CD4<sup>+</sup> lymphopenia, such as HIV infection, have a lower frequency of circulating HSV antigen-specific CD8<sup>+</sup> CTL precursors and more frequent and severe recurrences of genital disease.<sup>1282</sup> Once HSV-specific CD8<sup>+</sup> T cells arrive at local sites of infection, such as the cervix, they may persist,<sup>1264</sup> providing relative resistance to reinfection.

The ability to address the role of CD4<sup>+</sup> versus CD8<sup>+</sup> T cells in the control of primary HSV infection using murine models is partly compromised by the fact that HSV ICP47 inhibits murine TAP poorly,<sup>1295</sup> which may explain the greater ease with which anti-HSV CD8<sup>+</sup> cytolytic T cells have been detected in mice compared with humans.<sup>1252,1253,1262,1298-1300</sup> This species difference also raises a concern that murine models may not faithfully replicate the role of a particular mechanism for the control of the virus in humans. Many HSV gene products are dispensable *in vitro*, suggesting an *in vivo* role that has yet to be defined, such as immunoevasion or immunomodulation. We currently lack a complete knowledge of HSV-encoded immunoevasive functions, and of any differences between humans and mice in such functions. This point is important to keep in mind when applying the results of murine models to human HSV disease.

**Chemotactic and Homing Receptor Expression by Viral Antigen-Specific T Cells.** In established HSV infection, most recurrences of viral replication occur in keratinocytes found at epithelial sites, such as the skin and genitourinary mucosa. During these recurrences, virus-specific CD4<sup>+</sup> T cells and NK cells may infiltrate the sites by 48 hours after the appearance of lesions. Infiltration by these cells is followed several days later by the appearance of virus-specific CD8<sup>+</sup> T cells, which is associated with viral clearance.<sup>1262</sup> Consistent with the importance of CD8<sup>+</sup> T cell immunity at these local sites of replication, a majority of CD8<sup>+</sup> T cells that recognize a particular HSV peptide, as assessed by staining with viral peptide-MHC class I tetramers, express CLA,<sup>1263</sup> an adhesion molecule that is involved in homing of T cells to skin and other tissues that contain keratinocytes. It is likely that HSV-specific T cells that enter other sites of viral replication, such as the CNS during HSV encephalitis, utilize a distinct combination of homing and chemotactic receptors to achieve selective trafficking. Based on studies of other neurotropic viruses, the expression of CCR2 and CCR5 by CD8<sup>+</sup> T cells may be important for entry into the CNS.<sup>1301</sup> Other chemokine and homing receptor combinations are likely to be involved in trafficking of HSV-specific T cells to the liver and gastrointestinal tract in cases of disseminated disease.

### **B Cells, Antibody, Antibody-Dependent Cellular Cytotoxicity, and Complement**

Although preexisting antibody (e.g., that induced by vaccination) can prevent certain viral infections, antibody probably plays a relatively limited role in the control of viral infections that are established. This limitation probably also applies to human herpesvirus infections, because patients with X-linked agammaglobulinemia, who lack mature B cells and antibody production, generally are not more susceptible to these pathogens. Nonetheless, antibody may serve an auxiliary role in HSV host defense, particularly when cellular components of the response are deficient, such

as in the human neonate. Antibody also may be important for prevention of dissemination of viral infections to the CNS, as has been well documented in agammaglobulinemic or hypogammaglobulinemic patients, who can develop paralytic poliomyelitis or severe chronic encephalitis with echoviruses or coxsackieviruses.<sup>1302</sup>

In contrast with these observations regarding human HSV disease, murine models suggest a more important role of B cells and antibody in host defense. In the cutaneous HSV model, mice lacking B cells as a result of selective gene targeting have been reported to be markedly more susceptible to infection and to have impaired T<sub>H</sub>1 responses.<sup>1303</sup> This finding of decreased T<sub>H</sub>1 responses is particularly surprising in view of the normal or even increased T<sub>H</sub>1 immunity seen in humans with X-linked agammaglobulinemia.<sup>578</sup> B cell-deficient mice also have more local inflammation and viremia than are seen in wild-type mice following intravaginal challenge with attenuated strains.<sup>1304</sup> Of interest, serum from nonimmune wild-type mice transferred into B cell-deficient mice was found to decrease vaginal HSV shedding, suggesting that natural antibody may inhibit viral replication.<sup>1304</sup> Whether such antibody activity is found in the human circulation is unknown.

Human HSV infection results in the induction of antibodies against a diverse set of HSV proteins, including the surface glycoproteins involved in cell attachment and entry.<sup>1305</sup> The production of most HSV-specific antibodies by B cells is T cell dependent. If antibody is passively acquired, as in the case of maternal-to-fetal transfer, humoral immunity may exist independently of T cell immunity. Enveloped viruses, including HSV, can be lysed by antibody and complement *in vitro*, but lysis is unlikely to be an important mechanism *in vivo* because of the high concentrations of antibody required.<sup>1306</sup> Under relatively physiologic conditions, IgG and alternative pathway complement components can coat the surfaces of some viruses, including HSV, thereby effectively neutralizing their infectivity, possibly by preventing their attachment or fusion with cell membranes.<sup>1306,1307</sup> Antibodies also can react with viral proteins found on the surface of infected cells, and IgG and complement components can lyse *in vitro* human cells infected with a number of different viruses, including HSV. The importance of complement in viral host defense in humans is uncertain, however, because serious viral infection is not a feature seen in patients with severe inherited complement deficiency<sup>1308</sup> or in animals made acutely hypocomplementemic.<sup>1309</sup> The apparent limited impact of antibody and complement on HSV infection in humans may reflect viral immunoevasion mechanisms that hamper antibody effector functions. For example, the HSV gC protein is an inhibitor of the complement cascade, especially through the alternative pathway,<sup>1310</sup> and acts by directly binding C3.<sup>1311</sup> The gE-gI heterodimer also binds the Fc portion of antibody molecules and ablates their neutralization activity.<sup>1312</sup> It is possible that these or other HSV-encoded inhibitory mechanisms that block viral neutralization may not be as effective in mice as in humans, analogous with ICP47 inhibition of TAP. Thus, species-specific difference in host-virus interactions might also contribute to the strikingly different roles of B cells in control of HSV in humans versus mice.

A potentially more effective system for the elimination of virus-infected cells by specific antibody is by ADCC, with

NK cells probably being the most efficient ADCC effector cells.<sup>1313</sup> As discussed previously (see section on ADCC), the specificity of cytotoxicity is due to the specific recognition by antibody of viral antigens present on the infected cell surface. In vitro ADCC requires relatively low concentrations of antibody and occurs rapidly (within hours),<sup>1314</sup> making it less likely that the virus will have had sufficient time to produce infectious particles. ADCC mediated by all types of effector cells is upregulated by cytokines, such as IFN- $\gamma$ , type I IFN, IL-12, and IL-15.<sup>1315-1317</sup> In vitro ADCC activity correlates in some cases with protection against serious viral infections in humans and in animal models, but it remains uncertain to what extent this protection is due to ADCC occurring in vivo.

### Neonatal Defenses

HSV infection is severe in term infants infected at the time of parturition, as well as in the uncommon cases when it is acquired in utero. Characteristically, HSV infection in neonates spreads rapidly to produce either disseminated or CNS disease. Enteroviral infections also are severe and may be fatal when acquired in the perinatal period, and, like HSV infections, have a propensity to produce disseminated or CNS disease. Another similarity between HSV and enteroviral infections is that infection acquired after the neonatal period (after age 4 weeks) is typically effectively controlled, suggesting that common developmental limitations in antiviral immunity are responsible. Deficiencies in the function of neonatal NK cells and DCs probably are important contributors to poor early control of infection by the innate immune response. Neonates also may develop critical antigen-specific T cell responses to the virus too slowly to prevent the virus from producing irreparable tissue injury or death. The following discussion focuses mainly on limitations in cellular innate and adaptive antiviral immune mechanisms of the neonate, because these are the best characterized. Neonatal DC function is discussed in the context of the role of this cell as the key APC for naïve T cell activation.

**Innate Immunity: Cytokine Production.** Relatively little is known concerning the innate immune response during primary HSV infection in neonates. In an early study, type I IFN production by neonatal lymphocytes and monocytes was equivalent to that in adult cells for a variety of inducers, including HSV and other viruses.<sup>82</sup> A more recent study,<sup>83</sup> however, found that type I IFN production by PBMCs and the frequency of IFN- $\alpha$ -producing cells (assayed by the ELISPOT technique) in response to fixed HSV were diminished compared with that in adults, particularly for prematurely born infants. It is likely that the major cell type that produces type I IFN in this assay is the plasmacytoid DC (DC2), and that IFN secretion is TLR-9 dependent, but direct comparisons of type I IFN production by neonatal and adult plasmacytoid DCs have not been reported. There are also no studies in which neonatal and adult myeloid DCs have been evaluated for their function in response to HSV.

The in vitro production of other cytokines by cells of the innate immune system that might play a role in enhancing NK cell and T<sub>H</sub>1 T cell responses may be decreased in neonates. For example, IL-12 and IL-15 production by mononuclear cells (presumably mainly by monocytes) from term neonates after stimulation with LPS was approximately 25%

of that by adult cells.<sup>85,891</sup> Whether such cytokines are produced in amounts sufficient to limit NK cell or T cell immunity in neonates with HSV infection is not known. Of note, such reduced responses are highly stimulus dependent. For example, neonatal and adult blood mononuclear cells stimulated with *S. aureus* produce equivalent amounts of IL-12,<sup>85-87,891</sup> and only slightly less IL-18 is produced by adult cells in response to group B streptococci.<sup>1093</sup> Freshly isolated neonatal and adult monocytes also express similar low levels of CD40,<sup>1097</sup> but whether they have similar capacity to produce cytokines in response to CD40 ligand engagement remains unclear. The capacity of neonatal mononuclear phagocytes to produce more recently identified cytokines of the IL-12 family, such as IL-23 and IL-27, is unknown.

**Natural Killer Cells.** As discussed earlier in the section on fetal and neonatal NK cell-mediated cytotoxicity, fetal and neonatal NK cells have reduced cytotoxic activity compared with those of adults, including against HSV-infected<sup>830,907,908</sup> or CMV-infected target cells.<sup>909</sup> Paralleling the reduction in natural cytotoxic activity of neonatal cells, ADCC of neonatal mononuclear cells is approximately 50% of that of adult mononuclear cells, including against HSV-infected targets.<sup>906</sup> Decreased ADCC mediated by purified neonatal NK cells appears to be caused in part by an adhesion defect in the presence of antibody.<sup>894</sup> Whether differences exist between the neonate and the adult for cytokine-primed NK cell cytotoxicity against targets infected with HSV or other herpesviruses is unclear. Cytokine production by NK cells is another potentially important mechanism of host defense against HSV. Neonatal NK cells produce IFN- $\gamma$  as effectively as adult NK cells in response to exogenous IL-2 and HSV<sup>924</sup> or to polyclonal stimulation with ionomycin and PMA.<sup>354</sup> The adequacy of neonatal NK cell production of these and other cytokines in response to physiologic stimulation (e.g., with HSV-infected cell targets in the absence of exogenous cytokines) is not known.

Regardless of the precise mechanism, reduced NK cell cytolytic activity may be an important contributor to the pathogenesis of neonatal HSV infection. In a murine model, the age-related maturation of NK cell function parallels the development of resistance to HSV,<sup>1076,1188</sup> and neonatal mice, which, like human neonates, are more susceptible to HSV infection, can be protected by adoptive transfer of human blood mononuclear cells from adults but not from neonates. Addition of IL-2 augments protection mediated by cells from adults but not by cells from neonates, and protection is dependent on IFN- $\gamma$  production by the transferred cells. The failure of human neonatal cells to transfer resistance in this model also can be corrected by the addition of IFN- $\gamma$ , a cytokine produced poorly by neonatal CD4<sup>+</sup> T cells, as discussed later on. This finding suggests that lack of IFN- $\gamma$  production may be one important difference between adult and neonatal cells. Whether deficits in NK cell IFN- $\gamma$  production and cytotoxicity may contribute to the failure of neonatal mononuclear cells to confer protection in this model is uncertain. It also is important to point out that the role of IFN- $\gamma$  in controlling HSV infections in humans is uncertain, because severe HSV infection has not been reported as a major complication of patients with deficiency of IFN- $\gamma$  receptors. The potential limitations of these murine models, which also apply to those that include the adoptive

transfer of human cells, have been discussed earlier in the section on viral inhibition of antigen presentation and effect on the T cell immune response.

Of importance, no studies have directly compared NK cell function against HSV targets in neonates versus adults with primary HSV infection, including after treatment with various immunostimulatory cytokines. Nor have there been measurements of systemic or cell-associated levels of cytokines that could be useful for augmenting NK cell function in this infection. It is also unknown if neonatal NK cell activity is reduced against enteroviruses.

### **Adaptive Immunity: Antigen Presentation**

In addition to its well-known inhibition of MHC class I antigen presentation, HSV infection of neonatal monocytes,<sup>1318</sup> monocyte-derived DCs,<sup>1236</sup> or B cells<sup>1319</sup> can block the ability of these cells to activate CD4<sup>+</sup> T cells. As discussed previously, however, the extent to which HSV directly infects DCs and other APCs in vivo remains unclear.

**CD4<sup>+</sup> T Cells.** In two studies in which T cell responses in neonates and adults with primary HSV infection were compared,<sup>553,554</sup> HSV-specific proliferation of peripheral blood mononuclear cells and production of IFN- $\gamma$  and TNF- $\alpha$  were markedly diminished and delayed in the neonates compared with these measures in the adults. The neonates did not achieve adult levels of these responses for 3 to 6 weeks after clinical presentation, whereas the adults developed robust responses within 1 week. In both studies, HSV antigen-specific responses by peripheral blood mononuclear cells used viral antigen preparations that are processed mainly by the MHC class II rather than the class I pathway, mainly assaying CD4<sup>+</sup> T cell function. Other reports indicate that antigen-specific CD4<sup>+</sup> T cell responses commonly are slow to develop in neonates infected perinatally or in utero with CMV.<sup>539</sup> Delayed CD4<sup>+</sup> T cell responses to primary CMV infection also have been observed for older infants and young children compared with such responses in adults,<sup>226</sup> suggesting that limitations in developing CD4<sup>+</sup> T cell responses to at least some herpesviruses may continue beyond the neonatal period. Because, as discussed above, CD4<sup>+</sup> T cells provide multiple effector functions that may be critical for the resolution of HSV infection—including direct antiviral cytokine production and help for CD8<sup>+</sup> T cells and B cells—this marked lag in development of HSV-specific CD4<sup>+</sup> T cell responses in neonates could be an important contributor to the tendency of neonatal HSV infection to disseminate and to cause prolonged disease.

The basis for the delayed development of HSV antigen-specific CD4<sup>+</sup> T cells in neonates is not known; the delay could reflect limitations intrinsic to these cells or limitations in APC function. For example, because immature DCs are primed for efficient antigen presentation by engagement of their CD40 molecule by CD40 ligand expressed by activated T cells, or by exposure to microbes or inflammatory cytokines induced by microbes, lack of prior exposure to microbes, which occurs in a cumulative manner after birth, might contribute to the increased susceptibility of the neonate to infection with HSV. A recent study showing reduced basal DC function in adult mice lacking functional TLR-4 supports the idea that postnatal exposure to microbial products may contribute to the maturation of DC function.<sup>1320</sup>

Intrinsic limitations in CD4<sup>+</sup> T cell function might also contribute to the reduced and delayed HSV-specific CD4<sup>+</sup> T cell immune response. Neonatal naïve CD4<sup>+</sup> T cells have a substantially reduced capacity to express CD40 ligand compared with adult naïve CD4<sup>+</sup> T cells after activation in vitro with allogeneic DCs, a condition that should closely mimic physiologic activation by foreign antigen.<sup>356</sup> The importance of CD40 ligand–CD40 interactions in the accumulation of memory CD4<sup>+</sup> T cells with T<sub>H</sub>1 activity has already been mentioned.<sup>1257</sup> Compared with analogous adult cells, neonatal naïve CD4<sup>+</sup> T cells also have decreased capacity to generate key intracellular signals after activation, such as elevation of [Ca<sup>2+</sup>]<sub>i</sub>,<sup>364</sup> reduced expression of certain transcription factors involved in cytokine production,<sup>372,373</sup> and greater methylation of certain cytokine genes.<sup>368</sup> These mechanisms may contribute to the tendency of activated neonatal CD4<sup>+</sup> T cells to become anergic rather than develop into effector cells,<sup>330,388,389</sup> and to the delay in the appearance of IFN- $\gamma$  production by antigen-specific CD4<sup>+</sup> T cells following infection with HSV (and CMV) in the neonatal period.

Neonates also have been reported to have a lower frequency of precursor T cells capable of responding to HSV and CMV.<sup>1321</sup> This finding is unlikely to be due to a limitation in the diversity of the  $\alpha\beta$ -TCR repertoire,<sup>265-267</sup> however, and is more likely to be an artifact of in vitro culture conditions that may favor the survival of adult rather than neonatal T cells.

**CD8<sup>+</sup> T Cells.** There are, to the best of our knowledge, no published studies of antigen-specific cytotoxic T cell responses in the fetus, neonate, or young infant in response to HSV. This lack reflects, in part, the technical difficulties of performing classic cytotoxicity assays, which require HLA-matched or autologous virally infected target cells. This limitation might be overcome by newer approaches, such as flow cytometric detection of intracellular perforin in viral antigen-specific CD8<sup>+</sup> T cells identified using HSV peptide–class I HLA tetramers.

As discussed in detail in the section on T cell response to congenital infection, a recent study of congenital CMV infection using CMV peptide–HLA-A2 tetramers found a robust response in the fetus, neonate, and young infant in terms of both frequency of CD8<sup>+</sup> T cells and their function.<sup>429</sup> Although this finding suggests that strong stimulation, particularly if persistent, may induce virus-specific CD8<sup>+</sup> T cell responses in the fetus, it does not exclude a potential lag in the appearance of CD8<sup>+</sup> T cells in the fetus or perinatally infected infant compared with adults with primary CMV. Evidence from perinatal HIV-1 infection also suggests such a lag in the appearance of CD8<sup>+</sup> T cell-mediated cytotoxicity and cytokine production, recognizing a diverse repertoire of viral antigens compared with that in adults with primary HIV-1 infection.<sup>560-562</sup> A caveat is that this delay may be attributable to the immunosuppressive properties of HIV-1, rather than a deficit specific to neonates. The potential for a general lag in CD8<sup>+</sup> T cell immunity also is suggested by older studies that have found that naïve CD8<sup>+</sup> T cells of the fetus and neonate generate less CTL activity than analogous adult cells after activation and culture in vitro (see section on fetal and neonatal T cell-mediated cytotoxicity). As indicated by the data on HSV-specific CD4<sup>+</sup> T cell responses, even a lag of days to weeks in the develop-

ment of HSV-specific CD8<sup>+</sup> T cell immunity after primary infection would likely be a major contributor to the morbidity of this infection in neonates.

**T Cell Chemotactic and Homing Receptor Expression.** Human neonatal naïve T cells differ from those of adults in that they do not increase CXCR3 expression and decrease CCR7 expression after activation by anti-CD3 and anti-CD28 monoclonal antibodies.<sup>282,402</sup> CXCR3 facilitates T cell trafficking to inflamed tissues that have been exposed to IFN- $\gamma$ , whereas CCR7 mediates entry into lymphoid tissues in response to the CCL19 and CCL21 chemokines.<sup>403</sup> These findings suggest that activated neonatal T cells may be limited in their capacity to traffic to nonlymphoid sites of inflammation, such as sites of HSV infection.

**B Cells, Antibody, Antibody-Dependent Cellular Cytotoxicity, and Complement.** Neonates have a modestly reduced antibody response, particularly for IgG, than older infants to most protein neoantigens, whereas IgM responses are similar. These decreased responses and isotype switching may be due, at least in part, to decreased expression of CD40 ligand by neonatal naïve CD4<sup>+</sup> T cells during their initial interaction with APCs.<sup>356,364</sup> Although these limitations in antibody response to T cell-dependent antigens may resolve by early infancy, they probably apply to HSV-specific antibodies made in response to neonatal HSV infection. Thus, assuming that HSV-specific antibody that is neutralizing or involved in ADCC contributes to the control of primary HSV infection in humans, it is possible that limitations in isotype switching from IgM to IgG or a slower rate of somatic hypermutation of IgG responses could contribute to the severity of neonatal infection.

The neonate also is partially protected from infection by passive maternal IgG antibody, transferred predominantly during the latter third of pregnancy. Fetal IgG concentrations are equal to or higher than maternal concentrations after 34 weeks of gestation, reflecting active transport mechanisms. In newborns with gestational age less than 38 weeks, a greater fraction of this maternally derived HSV-specific IgG may enter into the CNS,<sup>1322</sup> reflecting a generally less effective blood-brain barrier. The risk of transmission of HSV from mother to infant in cases of primary or initial maternal infection is much higher (approximately 35%) than in cases of recurrent maternal infection. This difference may reflect, in part, lesser amounts of virus in the maternal genital tract in recurrent infection but also may be due to protection by passively acquired HSV type-specific antibody, particularly to glycoprotein G.<sup>1323</sup> Kohl and colleagues<sup>1324</sup> also have shown that of HSV-infected infants, those with greater concentrations of ADCC antibody had less severe disease. In otherwise healthy adults and older children with primary HSV infection, who by definition lack antibody to HSV, however, severe disease does not develop, as it does in neonates with primary infection. This finding indicates that the deficits intrinsic to the neonate are the important factors predisposing to severe infection. Nevertheless, passively acquired antibody may play a role in decreasing transmission or ameliorating disease severity.

### **Adjunctive Therapy of Herpesvirus Infections**

The foregoing studies raise the possibility that neonates could be passively protected by administration of antibody to HSV,

particularly antibody that would facilitate ADCC. In vitro studies also suggest that polyclonal antibodies or mAbs could potentially be protective by directly blocking HSV transmission from neurons to epithelial cells.<sup>1325</sup> Passive antibody can even provide substantial protection from a low-inoculum HSV challenge in the absence of both type I IFN signaling and T and B cells, by IL-12- and IFN- $\gamma$ -dependent mechanisms,<sup>1326</sup> at least in mice. Human mAb, murine mAb that have been humanized, or specific hyperimmunoglobulin could potentially be employed for this purpose. The phage display technique recently has been used to select human mAb with an ability to effectively neutralize either HSV-1 or HSV-2 at a relatively low concentration in vitro,<sup>1327</sup> but it remains to be seen if these or related antibodies will be efficacious in limiting the extent of primary HSV infection in humans. The unique capacity of IFN- $\gamma$  to endow human neonatal blood mononuclear cells with the ability to protect neonatal mice from infection suggests that exogenous IFN- $\gamma$  also may be a potentially useful means to enhance the human neonate's resistance to HSV. In the experimental models described by Kohl,<sup>1188</sup> however, passive immunotherapy must be given before or at the time of infection. This requirement raises the concern that such therapy, if administered once infection is established, may be less effective, at least in controlling virally induced tissue damage. In addition, unanticipated fatal toxicity from administration of IL-12 to adult cancer patients<sup>1328</sup> indicates caution in the use of exogenous cytokine therapy in the seriously ill neonate. It should be emphasized again that there is as yet no direct evidence that the initial innate immune response of the neonate to HSV infection is deficient in terms of cytokine production (e.g., for IL-12, TNF- $\alpha$ , and IFN- $\gamma$ ) derived from cells other than T cells.

Facilitating the more rapid development of antigen-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells with appropriate effector function might be a more physiologic approach, allowing these cells and the cytokines they produce to properly localize to the sites of infection. Further elucidation of the cellular and molecular mechanisms that underlie the lag in the development of antigen-specific immunity in the neonate in response to HSV may help in devising therapies to overcome these limitations in host defenses. Neonatal CD4<sup>+</sup> T cells, if polyclonally activated under conditions that favor repeated cell division (strong activation stimuli in common with the provision of exogenous IL-2), are similar to naïve adult T cells in efficiently acquiring the characteristics of effector cells, including the capacity to produce cytokines, such as IFN- $\gamma$  and TNF- $\alpha$ .<sup>342</sup> This finding suggests that such approaches applied in vivo (e.g., IL-2 immunotherapy) might similarly enhance neonatal T cell clonal expansion and differentiation.

### **Herpes Simplex Virus Vaccines**

HSV-2 vaccines employing recombinant glycoproteins, such as glycoproteins B and D in combination,<sup>1199,1329</sup> or glycoprotein D alone,<sup>1330</sup> with various adjuvants have had limited efficacy in preventing infection in persons who are HSV-2 seronegative, and in providing substantial clinical benefit to those who are already HSV-2 infected. Although these vaccines have induced high levels of IgG antibodies against the glycoprotein immunogens, these antibodies may not efficiently mediate ADCC.<sup>1331</sup> Thus, if ADCC is important in

preventing maternal-to-neonatal HSV transmission, these vaccines are not unlikely to be beneficial in reducing neonatal HSV disease.<sup>1332</sup> Further efforts to develop a vaccine that will prevent or at least ameliorate disease in adults and in neonates are indicated. Following the failure of the recombinant glycoprotein vaccines, a number of other strategies are being considered, including replication-defective HSV vaccines (e.g., using gD-deficient HSV viruses that can undergo only one round of productive infection or other viruses that encode HSV proteins).<sup>1211,1333</sup> It also will be important to define which immunologic parameters most closely correlate with reduced disease and with reduced viral shedding in adults as well as in children, to help focus on the appropriate goals of vaccination.

## Nonviral Intracellular Pathogens

### Overview of Host Defense Mechanisms

In addition to viruses, certain nonviral intracellular pathogens can replicate within cells and cause severe fetal or neonatal infection. These include *Salmonella* spp., *L. monocytogenes*, and *M. tuberculosis*, which are facultative intracellular pathogens, and *T. gondii* (hereafter referred to as *Toxoplasma*) and *Chlamydia trachomatis*, which are obligate intracellular pathogens. Unlike pyogenic bacteria, for which phagocytosis usually results in death, phagocytosis for these pathogens is a means of entry into an intracellular haven. Each of these pathogens readily infects tissue macrophages of the reticulo-endothelial system. In addition, *Toxoplasma* can infect virtually any nucleated mammalian cell type, and this non-specificity has important consequences for the pathogenesis of toxoplasmosis. The following discussion of host defense mechanisms focuses primarily on *Toxoplasma*. Relevant information from studies of *L. monocytogenes* and the protozoan *Leishmania major*, an extensively studied obligate intracellular pathogen in rodents, is included.

During acute toxoplasmosis in humans, the replicating form, the tachyzoite, is found both extracellularly and intracellularly. A 30-kDa tachyzoite surface protein, P30, appears to be involved in the initial attachment of *Toxoplasma* to host cells.<sup>1334</sup> Antibodies frequently are made against this protein after infection and constitute a basis for serodiagnosis.<sup>1334,1335</sup> Intracellular *Toxoplasma* organisms are found principally in specialized parasitophorous vacuoles, which are derived from the host cell membrane but lack the features normally associated with phagocytic or endocytic vacuoles.<sup>1336</sup> These vacuoles, from which lysosomal components and host plasma membrane proteins are excluded, allow the free exchange of nutrients with the host cell cytoplasm, facilitating parasite replication.<sup>1337</sup> Cellular invasion by tachyzoites occurs without generating a respiratory burst in human macrophages<sup>1338</sup> or activating microbicidal nitric oxide production in murine macrophages.<sup>1339</sup> In response to adverse intracellular conditions that slow its replication,<sup>1340</sup> the tachyzoite is somehow induced to convert into a less metabolically active form, the bradyzoite. Bradyzoites can persist in many tissues for years or decades in the form of cysts. As discussed later, limiting chronic *Toxoplasma* infection to this quiescent state depends on antigen-specific cellular immunity; acquired T cell immunodeficiency, such as pharmacologic immunosuppression or HIV infection, may

allow bradyzoites to reconvert to tachyzoites that resume invasive infection.

Murine studies suggest that the control of acute infection by *Toxoplasma* and other nonviral intracellular pathogens, such as *L. monocytogenes* and *L. major*, involves an initial innate response involving DCs, NK cells, and mononuclear phagocytes, followed by an antigen-specific response in which T cell immunity is critical.<sup>1341-1343</sup>  $\alpha\beta$  T cells are particularly important for the chronic maintenance of *Toxoplasma* organisms in a quiescent state within infected host cells. The distinctiveness of the early innate response compared with the later antigen-specific response in mice is demonstrated by the observation that genetic susceptibility of common laboratory strains to acute *Toxoplasma* infection does not correlate with susceptibility to chronic infection.<sup>1344</sup>

A model for how cytokines link the activity of innate and antigen-specific immune mechanisms (see Fig. 4-12) in acute toxoplasmosis and during infection with other nonviral intracellular pathogens is described next. This model is based largely on studies in mice utilizing spontaneously occurring or genetically manipulated immunodeficient strains, antibody treatment, or both to deplete particular cell types or to neutralize cytokine and cytokine receptors: *Toxoplasma* tachyzoites, or products they secrete, induce DCs or mononuclear phagocytes to produce cytokines, including IL-1, IL-12, IL-15, IL-18, and TNF- $\alpha$ .<sup>1345-1349</sup> These cytokines, in conjunction with *Toxoplasma* organism-derived products, induce NK cells to produce IFN- $\gamma$ ; NK cell-derived IFN- $\gamma$ , in turn, increases toxoplasma activity within mononuclear phagocytes, helping limit the initial extent of infection.<sup>1343, 1345, 1350</sup> IFN- $\gamma$ , IL-12, IL-18, and TNF- $\alpha$  produced by innate (i.e., NK cells, DCs, and monocytes) rather than antigen-specific (i.e., T cells) mechanisms appear essential for the initial control of acute infection.<sup>1345, 1349, 1350</sup> IFN- $\gamma$  produced by NK cells, in conjunction with IL-12 and IL-18 produced by mononuclear phagocytes and DCs, also favors the differentiation of antigen-specific CD4<sup>+</sup> T cells into T<sub>H</sub>1 effector T cells that secrete large amounts of IFN- $\gamma$ . T<sub>H</sub>1 effector T cells, in turn, produce IFN- $\gamma$  that contains the parasite during the late phase of acute infection and helps limit the spread of infection in tissues should *Toxoplasma* cysts reactivate into tachyzoites. T cells, the IFN- $\gamma$  they produce, and IL-12, IL-15, and IL-23 produced by non-T cells that sustain T<sub>H</sub>1 responses all appear to be essential for the lifelong control of reactivation, as shown from studies in chronically infected mice.<sup>1342, 1343, 1347, 1348, 1351</sup>

Although the foregoing model as outlined emphasizes the role of proinflammatory and T<sub>H</sub>1-type cytokines in controlling *Toxoplasma* infection, it is important to note that *Toxoplasma* actively inhibits this process in several ways. *Toxoplasma* inhibits signaling pathways involved in the induction of IL-12 and TNF- $\alpha$ , including nuclear translocation of NF- $\kappa$ B and STAT-1.<sup>1352</sup> This inhibition may account for the observation that infection of human mononuclear phagocytes and DCs with *Toxoplasma* induces very little IL-12, whereas the production of IL-12 can be markedly upregulated by engagement of CD40 on these cells by CD40 ligand on activated T cells.<sup>1352-1354</sup> Inhibition of IL-12 and TNF- $\alpha$  production by *Toxoplasma* may allow it to evade initial activation of protective immunity or may be an important mechanism by which the organism avoids inducing an excessive and potentially lethal inflammatory response to the infection.<sup>1352, 1355</sup> Consistent with the latter possibility, in mice *Toxoplasma*

counters the induction of proinflammatory cytokines by inducing the anti-inflammatory cytokine IL-10. This capability is biologically important, because mice that are genetically deficient in IL-10 generate excessive amounts of IL-12, TNF- $\alpha$ , and IFN- $\gamma$  in response to acute *Toxoplasma* infection and die with inflammatory liver necrosis.<sup>1356</sup>

Some cytokines may mediate both positive and negative roles in the immune response to *Toxoplasma* organisms. For example, IL-4 production occurs relatively late in primary murine toxoplasmosis and, in this context, may enhance, rather than inhibit, the differentiation of protective IFN- $\gamma$ -producing T<sub>H</sub>1 effector T cells.<sup>1357</sup> With *Leishmania* infection in certain mouse strains, IL-4 that is produced early inhibits T<sub>H</sub>1 effector T cell generation.<sup>179</sup> By contrast, IL-4 produced during the chronic phase of murine infection appears to inhibit the host's ability to control *Toxoplasma* cyst replication within the CNS.<sup>1358</sup> These observations emphasize the importance of the temporal sequence of cytokine expression for appropriate immunoregulation.

### Innate Immunity

**Natural Killer Cells.** Most murine studies support a role for NK cells as a link between the initial innate response and the development of antigen-specific immunity to *Toxoplasma*: NK cell depletion or neutralization of NK cell-derived IFN- $\gamma$  prevents the development of a protective immune response after vaccination with attenuated *Toxoplasma* in mice that have CD4<sup>+</sup> T cells but are genetically deficient in CD8<sup>+</sup>  $\alpha\beta$  T cells and NK T cells.<sup>1359</sup> This pathway may be less important in the fully immunocompetent host, however, because experiments with wild-type mice depleted of NK cells have yielded conflicting results regarding whether NK cells are important for the control of early primary *Toxoplasma* infection.<sup>1360</sup>

Cytokines produced by nonlymphoid cells during the early phase of toxoplasmosis may play a critical role in the early control of infection by multiple mechanisms, including the stimulation of NK cells and NK T cells to produce IFN- $\gamma$ , enhancement of T<sub>H</sub>1 effector cell generation, and activation of mononuclear phagocyte microbicidal activity. Although mononuclear phagocytes are a potent source of cytokines, such as IL-12, when incubated in vitro with *Toxoplasma* organisms or their products, DCs also are a major source of IL-12 in the early response to *Toxoplasma* in vivo.<sup>1354</sup> This finding suggests that mononuclear phagocytes may act downstream of DCs in the innate phase of the immune response to infection.

**Mononuclear Phagocytes.** The critical role of macrophages in resistance to intracellular nonviral pathogens was first demonstrated in animal studies of *L. monocytogenes* in which depletion of macrophages increased susceptibility.<sup>1361</sup> In the first days of infection, the rate at which monocytes are recruited to the site of infection and the microbicidal activity of these cells correlate with the control of *Toxoplasma* in animals.<sup>1362</sup> As discussed in the section on mononuclear phagocytes, monocyte entry into infected tissues requires the coordinated interaction of selectins, integrins (particularly those of the  $\beta_1$  group), and CC chemokine receptors on the monocyte with counterligands on the endothelium and extracellular matrix. Transcripts for CCL3 (MIP-1 $\alpha$ ) are present in the CNS of SCID mice with *Toxoplasma* encephalitis, suggesting that CCL3 attracts mononuclear phagocytes in

vivo.<sup>1350</sup> Infection of human monocytes by *Toxoplasma* tachyzoites also results in the induction of CD80 and increased expression of CD86.<sup>1353</sup> The increased expression of these co-stimulatory molecules may enhance proliferation and IFN- $\gamma$  production by T cells early in *Toxoplasma* infection and may assist in the differentiation of T<sub>H</sub>1 effector cells from naïve T cells.<sup>1353</sup>

In general, the microbicidal activity of human monocytes against *Toxoplasma* is greater than that of macrophages.<sup>1363,1364</sup> In vitro studies with mononuclear phagocytes or microglial cells, which are mononuclear phagocytes of the CNS, demonstrate that both oxidative and nonoxidative mechanisms are involved in limiting intracellular *Toxoplasma* replication. The ability of human monocytes to kill *Toxoplasma* organisms in the absence of exogenous cytokines depends mainly on oxidative mechanisms,<sup>1363</sup> whereas human macrophages, including those from lung alveoli and peritoneum, kill *Toxoplasma* by a nonoxidative mechanism.<sup>1365,1366</sup> Phagocytosis and killing of *Toxoplasma* by monocyte-derived human macrophages are substantially reduced when these cells are infected in vitro with HIV-1. This effect appears to be due to the induction of PGE<sub>2</sub> by HIV-1, a mechanism that could contribute to the reactivation of *Toxoplasma* observed in HIV-1-infected patients.<sup>1367</sup>

Cytokines are critical regulators of mononuclear phagocyte activity. IFN- $\gamma$  produced by activated T cells or NK cells is the most important activator of macrophages for toxoplasma-cidal activity.<sup>1343,1350</sup> In vitro studies have demonstrated that macrophages first primed by treatment with IFN- $\gamma$  can be triggered for toxoplasma-cidal activity by incubation with TNF- $\alpha$ ; treatment with IFN- $\gamma$  alone is ineffective.<sup>1368</sup> IFN- $\gamma$  is able to induce toxoplasma-cidal activity in monocytes or monocyte-derived macrophages from patients with chronic granulomatous disease, confirming the existence of cytokine-dependent, nonoxidative killing.<sup>1363</sup> One such mechanism is the induction of the enzyme indoleamine 2,3-dioxygenase, which catalyzes the first step in tryptophan degradation and deprives replicating *Toxoplasma* of this essential nutrient.<sup>1369,1370</sup> Indoleamine 2,3-dioxygenase is induced by IFN- $\gamma$  in human and murine cells, and the failure of IFN- $\gamma$ -deficient mice to upregulate its expression in response to *Toxoplasma* infection has been correlated with their markedly greater susceptibility.<sup>1371</sup> The relative importance of indoleamine 2,3-dioxygenase in the control of *Toxoplasma* in vivo remains to be shown, however.

Experiments with gene knockout mice lacking iNOS indicate that this enzyme is required for the control of persistent *Toxoplasma* infection in rodents.<sup>1342</sup> Pharmacologic blockade of iNOS activity also results in exacerbation of chronic infection in mice. As discussed in the section on mononuclear phagocytes, iNOS is a nitric oxide-producing enzyme expressed mainly by mononuclear phagocytes. In murine toxoplasmosis, the induction of iNOS appears to be dependent on the production of IFN- $\gamma$  and TNF- $\alpha$ , both of which can directly activate mononuclear phagocytes for increased iNOS expression.<sup>1342</sup> The mechanism by which iNOS mediates an antitoxoplasma effect in vivo remains unclear. In most cytokine-activated human mononuclear phagocyte populations, iNOS activity has been low or undetectable, with the exception of alveolar macrophages from patients with tuberculosis, and the importance of iNOS in limiting *Toxoplasma* or other intracellular pathogens in humans remains unclear.<sup>1024</sup>

## Adaptive Immunity

**Alpha-Beta T Cells.** The importance of T lymphocytes in protection of humans from *Toxoplasma* infection is suggested by the marked increase in the incidence of severe infection in HIV-1-infected patients who have quantitative and qualitative CD4<sup>+</sup> T cell deficiency. This critical role for T cells in controlling toxoplasmosis is supported by the marked susceptibility of rodents with genetic T cell immunodeficiencies (e.g., nude or SCID rodents), and by the ability of splenocytes or T cells from immune animals to transfer resistance adoptively to susceptible recipients.<sup>1350,1351</sup> The importance of CD4<sup>+</sup> and CD8<sup>+</sup> T cells in protection depends on the phase of infection. In acute infection, CD8<sup>+</sup> T cells appear to be more protective than CD4<sup>+</sup> T cells, although both subsets afford some protection to unvaccinated rodents.<sup>1372</sup> CD4<sup>+</sup> and CD8<sup>+</sup> T cells both are necessary to limit the extent of CNS infection in the brain,<sup>1373</sup> and CD4<sup>+</sup> T cells are required for the development of long-term protective immunity.<sup>1374</sup> By contrast, once protective immunity has developed, CD4<sup>+</sup> or CD8<sup>+</sup> T cells can independently limit acute reactivation of chronic *Toxoplasma* infection—this protection requires the secretion of IFN- $\gamma$ .<sup>1375</sup>

Studies with perforin knockout mice suggest that the perforin/granzyme cytotoxicity mechanism is more important in the control of chronic toxoplasmosis, particularly in the brain, than in the control of acute infection.<sup>1376</sup> Such cytotoxicity is more likely to be mediated by T cells than by NK cells, although this preferential effect remains to be shown. Human CD4<sup>+</sup> and CD8<sup>+</sup> T cells can lyse *Toxoplasma*-infected cells,<sup>1377</sup> and in the case of CD4<sup>+</sup> T cells, this cytotoxicity is MHC class II restricted.<sup>1378</sup> Whether lysis results in the intracellular death of *Toxoplasma* organisms is unclear, however; if it does not, whether any released viable tachyzoites are cleared by mononuclear phagocytes or through direct lysis by antibody and complement, or both, also remains unclear. If such released tachyzoites were able to infect new cellular targets, such cytotoxicity might be detrimental to the host. *Toxoplasma* also may inhibit lysis of infected cells by NK and T cells, limiting the efficacy of cell-mediated cytotoxic mechanisms.<sup>603</sup>

The production of IFN- $\gamma$  and other cytokines by T<sub>H</sub>1 effector and memory T cells, which have undergone clonal expansion from naïve precursors, is essential for the control of acute toxoplasmosis and to prevent reactivation of chronic infection.<sup>1341,1343</sup> This also is true for protection against other intracellular bacterial and protozoal pathogens that survive and replicate within phagocytic vacuoles, such as *Salmonella* spp. and *M. tuberculosis*. An additional novel pathway for inducing IFN- $\gamma$  production by naïve CD45RA<sup>hi</sup>CD45RO<sup>lo</sup>  $\alpha\beta$  T cells has been identified for *Toxoplasma*. Cells with this phenotype obtained from *Toxoplasma*-seronegative donors, including neonates, produce IFN- $\gamma$  and proliferate in response to autologous monocytes infected with *Toxoplasma* tachyzoites.<sup>1353</sup> This response appears to utilize MHC class II antigen presentation and is dependent on the upregulation of CD80 and CD86 molecules and the production of IL-12 by infected monocytes, which in turn are dependent on the engagement of CD40 on APCs by CD40 ligand on activated T cells. This response does not have the restricted V $\beta$  repertoire characteristic of responses to a superantigen, but whether an antigenic peptide or non-protein antigen is involved remains unclear. Notably, this

response is not observed with dead parasites or with low concentrations of parasites, both of which are sufficient to activate memory T cells in seropositive persons. Thus, the activation of naïve T cells is likely to occur only when large numbers of infected mononuclear phagocytes or DCs are present in the T cell zones of secondary lymphoid tissues, as might be the case early in an acute infection or in immunocompromised patients. It not known whether this type of response occurs in vivo in infected humans or mice.

**Gamma-Delta T Cells.** Gamma-delta T cells, mainly those encoding V $\gamma$ 2V $\delta$ 2 TCRs, are increased in the circulation of children with postnatally acquired primary toxoplasmosis.<sup>1379,1380</sup> These cells are predominantly CD45RA<sup>lo</sup>-CD45RO<sup>hi</sup>, suggesting that they have been activated in vivo.<sup>1380</sup> This expansion appears to be a direct effect of *Toxoplasma* organisms on this cell population, because V $\gamma$ 2V $\delta$ 2-bearing T cells, when incubated with peripheral blood mononuclear cells that have internalized killed parasites, are activated to secrete cytokines (IL-2, IFN- $\delta$ , and TNF- $\alpha$ ) and to proliferate.<sup>1381</sup> Of interest, lysis of *Toxoplasma*-infected cells by these V $\gamma$ 2V $\delta$ 2 T cells occurs in an MHC-unrestricted manner and does not require previous infection of the donor by *Toxoplasma*.<sup>1381</sup>

The role of  $\gamma\delta$  T cells in host defense against *Toxoplasma* remains controversial. *Toxoplasma* infection induces increased numbers of  $\gamma\delta$  T cells in the spleen and peritoneum, and mice depleted of  $\gamma\delta$  T cells by mAb treatment die more rapidly than controls when challenged with high numbers of *Toxoplasma* bradyzoites.<sup>1382</sup> Gamma-delta T cells also undergo expansion in mice lacking  $\alpha\beta$  T cells, and the transfer of  $\gamma\delta$  T cells into mice lacking CD4<sup>+</sup> and CD8<sup>+</sup> T cells, NK T cells, and NK cells affords protection.<sup>1383</sup> These  $\gamma\delta$  T cells produce IFN- $\gamma$  and lyse autologous *Toxoplasma*-infected macrophages. It is unclear whether  $\gamma\delta$  T cells improve the outcome of infection in these systems by the secretion of cytokines, cell-mediated cytotoxicity, or other mechanisms. In contrast with these studies, Sayles and colleagues,<sup>1384</sup> using a lower inoculum of bradyzoites, found no evidence either for the in vivo expansion of  $\gamma\delta$  T cells in wild-type mice or for any deleterious effects of  $\gamma\delta$  T cell depletion.

**B Cells and Antibody.** In contrast with *L. monocytogenes*, in which antibodies appear to contribute minimally to host resistance to infection,<sup>1361,1385</sup> antibodies probably make some contribution to defense against *Toxoplasma*. Mice that cannot mount an antibody response are slightly more susceptible to late death from *Toxoplasma* infection than are normal mice, and antiserum from convalescent animals has only a slight protective effect.<sup>1386</sup> Antibody and complement lyse extracellular *Toxoplasma*, and this effect is the basis of the Sabin-Feldman dye assay for anti-*Toxoplasma* antibodies. Antibody-coated *Toxoplasma* organisms also are killed by resting mouse and human macrophages, probably through Fc receptor-mediated entry into an intracellular vacuole that, unlike the parasitophorous vacuole, fuses with lysosomes.<sup>1387</sup> Antibody alone provides minimal protection in adult and newborn mice, but it enhances protection by activated macrophages.<sup>1388</sup> T cell-deficient mice are much more susceptible than are antibody-deficient animals, however, and are not protected by antibody. The fact that *Toxoplasma* encephalitis in adult patients with acquired immunodeficiency syndrome (AIDS) typically develops by recrudescence of latent infection

despite the presence of preexisting anti-*Toxoplasma* antibodies<sup>1389</sup> underscores the importance of T cells rather than B cells in the control of chronic infection with this pathogen.

### Fetal and Neonatal Defenses

Information regarding initial aspects of the immune response by the human fetus and neonate to *Toxoplasma* is limited. Neonatal monocytes can ingest and kill *Toxoplasma*<sup>1070,1071</sup> and *L. monocytogenes* (C. Wilson, unpublished data, 1980), and monocyte-derived and placental macrophages from human neonates are activated by IFN- $\gamma$  to kill or restrict the growth of *Toxoplasma* as effectively as are cells from adults.<sup>1070,1390</sup>

Nonetheless, it is likely that other limitations in responses by mononuclear phagocytes, and limitations in the response by NK cells and T cells, contribute to the increased susceptibility of the human fetus to *Toxoplasma* infection. Limitations in cytokine production, particularly IFN- $\gamma$ , TNF- $\alpha$ , and IL-12, would be expected to be deleterious. Studies in neonatal rodents, which are highly susceptible to infection with *L. monocytogenes*, support the idea that reduced cytokine production or responsiveness may limit neonatal immunity. In neonatal mice and rats, administration of recombinant IFN- $\gamma$  before or at the time of infection protects from acute infection and allows the development of protective immunity.<sup>1077,1391</sup> In adult animals, TNF- $\alpha$ , or agents that induce TNF- $\alpha$ , enhance resistance, whereas this effect is not observed in neonates. Co-administration of suboptimal doses of IFN- $\gamma$  and TNF- $\alpha$  protects neonatal rats. Acquisition of resistance to infection correlates with acquisition of adult competence for TNF- $\alpha$  production<sup>1077</sup> and also is likely to correlate with competence for IFN- $\gamma$  production, but whether it does so has not been evaluated. During fetal *Toxoplasma* infection, the ability of NK cells to produce IFN- $\gamma$  and TNF- $\alpha$  and of mononuclear phagocytes to produce TNF- $\alpha$  and other proinflammatory cytokines is unknown.

*Toxoplasma*, like many congenital viral pathogens, such as CMV, is much more likely to produce severe untoward infection when the mother acquires primary infection early in pregnancy. The most severely damaged infants are likely to have acquired infection during the first trimester, when their numbers of T cells and their  $\alpha\beta$ -TCR repertoire for antigen recognition are limited compared with those of the fetus in the latter half of gestation. Nonetheless,  $\alpha\beta$ -TCR repertoire limitations are unlikely to be an important mechanism in most cases of fetal toxoplasmosis, because severe sequelae may result in infants infected during mid- to late gestation, and in most infants infected at any time during gestation, sequelae ultimately develop. Similarly, *L. cytogenes* infection occurring in infants in the latter part of gestation usually is severe. This line of evidence suggests that mechanisms acting to contain *Toxoplasma* and *L. monocytogenes* infection are still immature in late gestation and at term relative to those of older persons.

*Toxoplasma*-specific memory CD4<sup>+</sup> T cell responses, which are evident in response to low concentrations of soluble antigen, often are delayed in their appearance in congenital toxoplasmosis and may not be detectable until weeks or months after birth. McLeod and colleagues found that lymphocyte proliferation in response to *Toxoplasma* antigens, which primarily detects responses by CD4<sup>+</sup> T cells, was below the limit of detection in 11 of 25 congenitally infected

infants younger than 1 year of age.<sup>543</sup> The most severely affected infants were more likely to have undetectable or low antigen-specific T cell responses. Furthermore, when memory T cells were first detected by lymphocyte proliferation assays in congenitally infected children, their capacity to produce IL-2 and IFN- $\gamma$  often was less than that of memory T cells from adults with postnatal *Toxoplasma* infection.<sup>543</sup> Fatoohi and colleagues also found that anti-*Toxoplasma* T cell responses (determined using a different and less standardized assay) were lower in eight congenitally infected infants younger than 1 year of age than in persons with acquired *Toxoplasma* infection and congenitally infected children studied when they were older than 1 year of age.<sup>1392</sup> Nonetheless, anti-*Toxoplasma* T cell responses were detectable in most of the congenitally infected infants younger than 1 year of age by this assay. Why Peyron and colleagues detected responses in a larger fraction of infants than those studied by McLeod and associates is unknown. The larger number might merely reflect differences in experimental technique or differences in their patient populations, or both.

McLeod and colleagues<sup>543</sup> evaluated a referral population in which the children were more severely affected, did not receive early treatment and were born to mothers who did not receive treatment, whereas early treatment and less severe disease were typical for the children studied by Peyron and associates.<sup>1392</sup> Together, these data suggest that antigen-specific CD4<sup>+</sup> T cell responses may develop more slowly or be diminished in congenitally infected infants, particularly those with more severe disease, compared with such responses in older patients. No published information is available regarding antigen-specific CD8<sup>+</sup> T cell responses in neonates with congenital *Toxoplasma* infection.

A similar impairment, lag, or both in the development of antigen-specific CD4<sup>+</sup> T cell responses has been observed in infants with congenital infection due to *T. pallidum*, CMV, VZV, or rubella virus<sup>538-542,1393,1394</sup> and, as discussed earlier, in neonates infected postnatally with HSV.<sup>553,554</sup> Similarly, Tu and colleagues found that antigen-specific CD4<sup>+</sup> T cell responses may be low in infants and young children with postnatally acquired CMV infection until active viral replication ceases, whereas antigen-specific CD8<sup>+</sup> T cell responses are detectable much earlier.<sup>226</sup> Whether the initial poor CD4<sup>+</sup> T cell response, lag in its appearance, or both are due to (1) failure of antigen presentation sufficient to induce activation of naïve antigen-specific T cells (immunologic ignorance), (2) limited proliferation of activated antigen-specific T cells, (3) sequestration of antigen-specific effector T cells at sites of infection, or (4) the induction of anergy (long-term unresponsiveness) or deletion of antigen-specific T cells, as has been observed with in vitro priming of neonatal T cells with alloantigens<sup>391</sup> or superantigens,<sup>330</sup> or to some combination of these mechanisms, is not known. Regardless of the precise mechanisms, these findings suggest that infection of the immunologically immature fetus may in some cases lead to complete or partial antigen-specific unresponsiveness that may persist for some time after birth.

At least some neonates and young infants with congenital *Toxoplasma* infection demonstrate increased expansion of the V $\gamma$ 2V $\delta$ 2-bearing  $\gamma\delta$  T cell population, most of which express a CD45RA<sup>lo</sup>CD45RO<sup>hi</sup> surface phenotype, indicating prior activation in vivo.<sup>552</sup> An analysis of a very limited number of patients has found that the  $\gamma\delta$  T cell population

in the congenitally infected neonate demonstrate a poor proliferative response to stimulation by peripheral blood mononuclear cells infected with viable or irradiated *Toxoplasma* organisms.<sup>552</sup> Other functions, such as the secretion of cytokines by these cells, were not assessed, however, and rigorous age-matched controls were not employed. These results, which need to be confirmed, raise the possibility of an anergic state in  $\gamma\delta$  T cells in infants with congenital toxoplasmosis.

As noted, naïve CD45RA<sup>hi</sup>CD45RO<sup>lo</sup> CD4<sup>+</sup> T cells from donors who have not been infected with *Toxoplasma* can proliferate in response to autologous *Toxoplasma*-infected mononuclear cells.<sup>1353</sup> CD4<sup>+</sup> T cells from neonates, however, proliferate less well in response to autologous *Toxoplasma*-infected mononuclear cells than do phenotypically naïve CD4<sup>+</sup> T cells from adults. As noted previously, the relevance of this novel in vitro response to protection against infection in vivo remains to be defined.

Although the foregoing results suggest that multiple aspects of cell-mediated immunity against *Toxoplasma* organisms are compromised in the human fetus and neonate, particularly in early gestation, antigen-specific antibody responses to *Toxoplasma* are commonly detectable (see Chapter 31 for more details). For example, antibodies to the P30 *Toxoplasma* antigen are frequently detectable in the fetus and neonate after congenital infection and are useful for serodiagnosis. Anti-P30 IgA antibodies are found in most neonates after congenital infection, whereas anti-P30 IgM antibodies are found in a minority.<sup>1335,1395</sup> *Toxoplasma*-specific IgE antibodies also are frequently present within the first 2 months of life in congenitally infected infants.<sup>1396</sup> Anti-P30 IgA and IgE antibodies are not unique to the fetus and neonate but also are common in older persons with acquired toxoplasmosis. Together, these results suggest that isotype switching of antibodies from IgM to the IgA and IgE isotypes can occur in utero, particularly in the face of continuing antigenic stimulation. Because IL-4 or IL-13 produced by CD4<sup>+</sup> T cells is likely to be required for the production of protein antigen-specific IgE antibodies, these results also suggest that the CD4<sup>+</sup> T cell response to *Toxoplasma* organisms in the fetus may include the production of these cytokines.

### **Implications for Immunologic Intervention**

The findings in human neonates, in concert with the results of studies in rodents, suggest that correction of the deficits in NK cell function, cytokine production, and T cell responses could facilitate treatment of infections with intracellular pathogens, such as *Toxoplasma*. Several limitations are apparent, however. For example, treatment of neonatal rats with IFN- $\gamma$  or IFN- $\alpha$  after establishment of infection with *L. monocytogenes* is not effective, whereas concomitant therapy or pretreatment is effective.<sup>1397</sup> These findings are perhaps not surprising in view of the evidence that IFN- $\gamma$  is important only in the early phase of this infection. In the case of congenital infection with *Toxoplasma*, therapy would need to be initiated and maintained in utero, when maternal infection is often asymptomatic, and there is no obvious way by which this could be safely targeted to the fetus. In fact, data in mouse models suggest that increased production of IFN- $\gamma$  during maternal infection may contribute to fetal loss as a result of maternal rejection of the fetus as a foreign

allograft.<sup>1398</sup> After birth, it may be possible to provide exogenous IFN- $\gamma$  (or perhaps TNF- $\alpha$ , IL-12, or IL-15), but the same caveats noted for treatment in cases of viral infection would apply. If studies in other patient populations (e.g., those with HIV infection) provide evidence that IFN- $\gamma$ , TNF- $\alpha$ , IL-12, or IL-15 alone or in some combination can contribute to resolution of established infections, their use in conjunction with antimicrobial therapy for the treatment of neonates with congenital toxoplasmosis might be considered. Alternatively, approaches that seek to modify the deficit in development of antigen-specific effector T cells may prove to be more effective.

A live-attenuated *Toxoplasma* vaccine has been developed for veterinary use in sheep.<sup>1399</sup> Although this vaccine reduces the rate of abortion due to *Toxoplasma* infection of pregnant dams, it does not prevent transmission of infection from mother to fetus. Live *Toxoplasma* vaccines in humans that result in latent infection are not desirable, because they pose the risk of reactivation and dissemination in the immunocompromised person. Immunization with certain recombinant *Toxoplasma* proteins, with DNA vaccines in which such proteins are encoded, and with these in combination with various adjuvants or recombinant cytokines has been tried in rodents.<sup>1347</sup> For example, immunization with the immunodominant tachyzoite surface antigen SAG-1 induces protection in adult mice, but its ability to reduce the risk of mother-to-pup transmission resulting in congenital infection is inconsistent.<sup>1400,1401</sup> No vaccine is likely to be available in the near future for the prevention of congenital *Toxoplasma* infection.

## **IMMUNOPROPHYLAXIS IN THE NEONATE**

### **Passive Immunization**

There is currently no established use for IVIG in the immunoprophylaxis or adjunctive treatment of infection in the neonate. Intramuscular immune globulin (0.02 mL/kg) is indicated for prophylaxis of exposure to hepatitis A, as soon as possible after exposure.<sup>1402</sup> Immune globulin (0.25 mL/kg) may also be given to prevent or modify measles in neonates when the mother has active infection. Specific human hyperimmune globulin preparations are indicated in some situations. Hyperimmune hepatitis B immune globulin (HBIG) is indicated in conjunction with hepatitis B vaccine in infants born to mothers who are hepatitis B surface antigen positive. HBIG is given at a dose of 0.5 mL at a site different from that used for vaccine administration. Both HBIG and hepatitis B vaccine should be given as soon as possible, preferably within 12 hours after birth.<sup>1402</sup> Infants with neonatal tetanus or at risk for it may be given tetanus immune globulin. Precise dosages for treatment in this age group are not established; in older persons, generally a dose of 3000 to 6000 U is given, whereas dosages of 500 U may be effective for the neonate.<sup>1402</sup>

Varicella-zoster immune globulin (VZIG), which is given intramuscularly, is available from local distribution centers and is indicated (in a dose of 125 units [1.25 mL]) for the prophylaxis of infection in those cases in which clinical maternal chickenpox develops between 5 days before and 48 hours after the time of delivery.<sup>1402</sup> Infants born to mothers who have hypogammaglobulinemia may benefit from prophylactic administration of immune globulin in cases in

which mothers have not received adequate immune globulin replacement therapy near term and when IgG levels in the neonate are documented to be low or are likely to be so.

Palivizumab (Synagis) is a humanized monoclonal antibody to RSV, which is indicated for the prevention of RSV infection in high-risk infants and children. High-risk groups include children with chronic lung disease or hemodynamically significant heart disease, or who were born at less than 32 weeks of gestation; those born at 32 to 35 weeks should receive treatment only if there are additional risk factors. Palivizumab is administered intramuscularly in a dose of 15 mg/kg monthly.<sup>1403</sup> A hyperimmune RSV immune globulin (RespiGam) also is available for use but is less convenient and should not be used in those with hemodynamically significant heart disease; it is given intravenously at a dose of 15 mL/kg monthly.

### Active Immunization

The rationale for and against immunization in the neonatal period is described more fully in the sections on B cells and immunoglobulin and on T cell reactivity to specific antigens. The only vaccines commonly administered to neonates are hepatitis B, BCG, and live oral poliovirus vaccine (OPV) vaccines. In the United States, hepatitis B vaccine is recommended for neonates, but the other two vaccines are not used. Although neonatal immunization is preferred, hepatitis B vaccination also may be started at 2 months of age unless the neonate may have been exposed to the virus during delivery, in which case vaccination and treatment with HBIG within 12 hours of birth are indicated.<sup>1403</sup> Most other vaccines that induce T cell–dependent antibody responses, such as whole-cell or acellular pertussis, *H. influenzae* type b polysaccharide–protein conjugate, diphtheria–tetanus, and inactivated poliovirus vaccine, are routinely begun at approximately age 2 months.<sup>1403</sup> Premature or small-for-gestational-age infants also may be immunized with these vaccines at this age. Although immunization at birth is attractive from a public health point of view, there is concern that responses to some vaccines may be lower (with diphtheria vaccine) or that long-term responses may be reduced (with whole-cell pertussis vaccine)<sup>773</sup> compared with immunization given at age 2 months. Nonetheless, the potential benefits of neonatal vaccination, particularly in the developing world, are such that further studies in this area are warranted.

### Recognition of Primary Immunodeficiency in the Neonate

Recognition of primary immunodeficiency in the neonate often is possible. Several syndromes have characteristic clinical findings that permit early diagnosis—for example, thrombocytopenia with low mean platelet volume in Wiskott–Aldrich syndrome; hypocalcemia, unusual facies, and congenital heart disease in DiGeorge and velocardiofacial syndromes; and skeletal dwarfism in cartilage–hair hypoplasia. Other affected children may present with laboratory abnormalities in the neonatal period that are suggestive of the diagnosis, such as marked elevations of IgE level in some patients with hyperimmunoglobulin E syndrome, and elevated IgE and

hypereosinophilia in patients with Omenn’s syndrome, which is a form of SCID due to partial RAG deficiency. Patients with leukocyte adhesion defect (LAD) due to CD18 deficiency may have omphalitis or other soft tissue infection and late (after 3 weeks of age) separation of the umbilical cord. The diagnosis of CD18 deficiency can readily be made by flow cytometric analysis of leukocytes. Delayed cord separation as an isolated clinical finding rarely is due to LAD; therefore, a complete blood count may be useful in such a situation—children with LAD commonly have persistent leukocytosis due to elevated numbers of neutrophils even when they are clinically uninfected. Chronic granulomatous disease may manifest in the neonatal period and should be considered in a term neonate who experiences severe bacterial infection with catalase-positive bacteria or with fungi and who does not have other risk factors for these. Patients with SCID may present with severe or recalcitrant mucocutaneous candidiasis, protracted diarrhea, *P. jiroveci* pneumonia, severe eczema, or any combination of these symptoms. SCID is often associated with lymphopenia. A family history of immunodeficiency or early, unexplained death is suggestive. HIV infection, particularly when congenitally acquired, should always be considered in the differential diagnosis in neonates who appear to have SCID, particularly if lymphadenopathy or splenomegaly is present. In general, unusually severe, recalcitrant, or recurrent infections, especially if due to organisms of low virulence and without other predisposing factors (such as extreme prematurity, multiple courses of empirical antibiotic therapy, multiple catheters, or other aspects of prolonged intensive care) should prompt consideration of primary immunodeficiency.

Normal term neonates lack cutaneous delayed-type hypersensitivity responses to antigens, have IgG values similar to those of their mother, and have little or no circulating IgM and IgA. Thus, these common screening tests for immunodeficiency in older children are of little value in the neonate. Depending on the presenting features, useful tests might include (1) chest radiograph or computed tomography for thymus size (useful only if secondary causes of thymic involution, e.g., stress, can be excluded); (2) a total lymphocyte count, which is helpful when low (fewer than 1500 lymphocytes per mm<sup>3</sup>), although a normal count does not exclude immunodeficiency; (3) enumeration of T, B, and NK cell numbers by flow cytometry; (4) analysis of lymphocyte proliferation to mitogens, superantigens, anti-CD3 plus anti-CD28 mAbs, or allogeneic cells; (5) assessment of lymphocyte effector responses, including cytotoxicity and lymphokine release; (6) staining for CD11a, CD11b, and CD18 when leukocyte adhesion deficiency is strongly suspected; and (7) tests to screen for defects in the neutrophil oxidative burst, the cause of chronic granulomatous disease, which include an analysis of neutrophil hydrogen peroxide generation by flow cytometry (e.g., dihydrorhodamine test) and the nitroblue tetrazolium (NBT) test. More detailed discussion of the evaluation of neonates for primary immunodeficiency is available.<sup>1404</sup> Early, aggressive antimicrobial therapy, appropriate isolation, and early specific treatment of the immunologic disorder (e.g., IVIG for SCID and B cell immunodeficiency) are indicated whenever possible.

**Current Trends in Breast-Feeding 233****Summary and Conclusions 234**

Mother's milk delivered naturally through breast-feeding has been the sole source of infant nutrition in mammalian species for millions of years. Since human beings learned to domesticate cattle about 10,000 years ago, nonhuman mammalian milk also has been used to supplement or replace maternal milk in the human infant. The development and widespread use of commercially prepared infant formula products have been phenomena of the 20th century and notably of the past 6 decades. Additional information acquired during the last several years has reinforced existing concepts on the role of breast-feeding in protecting the infant against infections, in providing an ideal source of infant nutrition, in modulating infectious immune responses, and in suppressing the evolution of neoplasms and autoimmune disease later in life.<sup>1</sup>

Over the past few decades, the immune responses on intestinal and respiratory mucosal surfaces to local infections have been intensely studied. These investigations have led to the development of concepts of immunity on mucosal surfaces of gastrointestinal, respiratory, and genitourinary tracts and identification of mucosa-associated lymphoid tissue (MALT) and local mechanisms of defense that are distinct from the internal (systemic) immune system.

This chapter reviews existing information on major aspects of the physiologic, nutritional, immunologic, and anti-infective components of the products of lactation. Also discussed is the most recent evidence on the contribution of human milk to the development of immunologic integrity in the infant and its influence on the outcome of infections and other host-antigen interactions in the neonate.

\*This chapter is dedicated to Lars A. Hansen, MD, PhD, the discoverer of sIgA in human milk, the father of modern "mother's milk feeding practices," and a remarkable human being.

**PHYSIOLOGY OF LACTATION****Developmental Anatomy of the Mammary Gland**

The rudimentary mammary tissue undergoes several developmental changes during morphogenesis and lactogenesis: In the 4-mm human embryo, the breast tissue appears as a tiny mammary band on the chest wall<sup>2,3</sup>; by the 7-mm embryonic stage, the mammary band develops into the mammary line, along which eventually develops the true mammary anlage; by the 12-mm stage, a primitive epithelial nodule develops; by the 30-mm stage, the primitive mammary bud appears. These initial phases of development take place in both genders (Table 5-1). Further development in the male, however, appears to be limited by androgenic or other male-associated substances.<sup>4,5</sup> Castration in male rat embryos early in gestation leads to female breast development, whereas ovariectomy in the female does not alter the course of development of the mammary anlage. Toward the end of pregnancy, initial phases of fetal mammary differentiation seem to occur under the influence of placental and transplacentally acquired maternal hormones, with transient development of the excretory and lactiferous ductular systems. Such growth, differentiation, and secretory activities are transient and regress soon after birth.<sup>5,6</sup>

At thelarche, and later on at menarche, true mammary growth and development begin in association with rapidly increasing levels of estrogens, progesterone, growth hormone, insulin, adrenocorticosteroids, and prolactin.<sup>6,7</sup> Estrogens appear to be important for the growth and development of the ductular system, and progestins, for lobuloalveolar development (see Table 5-1). Final differentiation of the breast associated with growth and proliferation of the acinar lobes and alveoli continues to be influenced by the levels of estrogen and progesterone. Other peptide hormones, such as prolactin, insulin, and placental chorionic somatomammotropin, appear to be far more important for the subsequent induction and maintenance of lactation (see Table 5-1).

It appears that prolactin secretion from the pituitary gland is under neural control and that the increasing innervation of the breast observed throughout pregnancy is regulated by estrogens.<sup>7</sup> Intense neural input in virgin and parturient but not in currently pregnant mammals has been shown to result in lactation. For example, lactation in goats can be induced by milking maneuvers. Adoptive breast-feeding also is well documented in primitive human societies. Sudden and permanent cessation of suckling can result in the termination of milk secretion and involution of the breast to the prepregnant state as the concentrations of prolactin decline. Estrogen and progesterone also may amplify the direct effects of prolactin or may induce additional receptors for this peptide hormone on appropriate target tissues in the breast.

**Table 5–1 Possible Endocrine Factors in Growth of Human Female Mammary Glands**

Clinical State	Growth Characteristics	Maturational Hormones
Prenatal	Rudimentary	None
Infancy	Rudimentary	None
Puberty	Growth and budding of milk ducts	Growth hormone, prolactin-estrogen, adrenocortical steroids, prolactin (high doses)
Pregnancy	Growth of acinar lobules and alveoli	Estrogen, progesterone, prolactin, growth hormone, adrenocortical steroids
Parturition	Alveolar growth	Prolactin, adrenocortical steroids
Lactational growth of tissue	None	None
Secretory products	Casein, $\alpha$ -lactalbumin	Prolactin, insulin, adrenocortical steroids

### Endocrine Control of Mammary Gland Function

Breast tissue is responsive to hormones, even as a rudimentary structure, as illustrated by the secretion of “witch’s milk” by both male and female newborns in response to exposure to maternal secretion of placental lactogen, estrogens, and progesterone.<sup>3</sup> The secretion of this early milk ceases after exposure to maternal hormones has waned. Sexual differentiation, marked by puberty, is the next major stage in mammary development. As pointed out earlier, androgens inhibit the development of mammary tissue in the male, whereas the development of mammary tissue in the female is dependent on estrogen, progesterone, and pituitary hormones.<sup>8</sup> The postpubertal mammary gland undergoes cyclical changes in response to the release of hormones that takes place during the menstrual cycle. The last stage of development occurs during menopause, when the decline in estrogen secretion results in some atrophy of mammary tissue.

During the menstrual cycle, the mammary gland responds to the sequential release of estrogen and progesterone with a hyperplasia of the ductal system that continues through the secretory phase and declines with the onset of menstruation. The concentration of prolactin modestly increases during the follicular stage of the menstrual cycle but remains constant during the secretory phase.<sup>9</sup> Prolactin secretion appears to be held in readiness for the induction and maintenance of lactation.

**Initiation and Maintenance of Lactation.** Pregnancy is marked by profound hormonal changes reflecting major secretory contributions from the placenta, the hypothalamus, and the pituitary gland, with contributions from a number of other endocrine glands (e.g., the pancreas, thyroid, and parathyroid). Increased estrogen and progesterone levels during pregnancy stimulate secretion of prolactin from the pituitary, whereas placental lactogen appears to inhibit the release of a prolactin-inhibiting factor from the hypothalamus. Prolactin, lactogen, estrogen, and progesterone all aid in preparing the mammary gland for lactation. Initially in gestation, an increased growth of ductule and alveolobular tissue occurs in response to estrogen and progesterone. In the beginning of the second trimester, secretory material begins to appear in the luminal cells. By the middle of the second trimester, mammary development has proceeded sufficiently to permit lactation to occur should parturition take place.

Once the infant is delivered, a major regulatory factor, the placenta, is lost, and new regulatory factors including the maternal-infant interaction and neuroendocrine regulation are gained for control of lactation. Loss of placental hormone secretion results in an endocrine hypothalamic stimulation of prolactin release from the anterior pituitary gland, as well as neural stimulation of oxytocin from the posterior pituitary. The stimulation of the nipple by suckling activates a neural pathway that results in release of both prolactin and oxytocin. Prolactin is responsible for stimulating milk production, whereas oxytocin stimulates milk ejection (the combination is known as the *let-down reflex*). Oxytocin also stimulates uterine contractions, which the mother may feel while she is breast-feeding; this response helps to restore the uterus to prepregnancy tone.

Milk production and ejection are thus dependent on the complex interaction of stimulation by the infant’s suckling, neural reflex of the hypothalamus to such stimulation, release of hormones from the anterior and posterior pituitary, and response of the mammary gland to these hormones to complete the cycle.

**Milk Secretion.** Milk is produced as the result of synthetic mechanisms within the mammary gland, as well as the transport of components from blood. Milk-specific proteins are synthesized in the mammary secretory cells, packaged in secretory vesicles, and exocytosed into the alveolar lumen. Lactose is secreted into the milk in a similar manner, whereas many monovalent ions, such as sodium, potassium, and chloride, are dependent on active transport systems based on sodium-potassium adenosine triphosphatases ( $\text{Na}^+$ ,  $\text{K}^+$ -ATPases). In some situations, the mammary epithelium, which may behave as a “mammary barrier” between interstitial fluid derived from blood and the milk because of the lack of space between these cells, may “leak,” permitting direct diffusion of components into the milk. This barrier results in the formation of different pools or compartments of milk components within the mammary gland and is responsible for maintaining gradients of these components from the blood to the milk.

Lipid droplets can be observed within the secretory cells of the mammary gland and are surrounded by a milk fat globule membrane. These fat droplets appear to fuse with the apical membrane of the secretory cells and then to be either exocytosed or “pinched off” into the milk.<sup>8</sup> Some whole cells also are found in milk, including leukocytes,

macrophages, lymphocytes, and broken or shed mammary epithelial cells. The mechanisms by which these cells enter the milk are complex and include, among others, specific cellular receptor-mediated homing of antigen sensitized lymphocytes.

As the structure of the mammary gland is compartmentalized, so is that of the milk. The gross composition of milk consists of cytoplasm encased by cellular membranes in milk fat globule membranes (fat compartments made up of fat droplets), a soluble compartment containing water-soluble constituents, a casein-micelle compartment containing acid-precipitable proteins with calcium and lactose, and a cellular compartment. The relative amounts of these components change during the course of lactation, generally with less fat and more protein in early lactation than in late lactation. Thus, the infant consumes a dynamic complex solution that has physical properties permitting unique separation of different functional constituents from one another, presumably in forms that best support growth and development.

**Lactation Performance.** Successful lactation performance depends on continued effective contributions from the neural, endocrine, and maternal-infant interactions that were initiated at the time of delivery. The part of this complex behavior most liable to inhibition is the mother-child interaction. An early attachment of the infant to the breast is mandatory to begin stimulation of the neural pathways essential to maintaining prolactin and oxytocin release.

A healthy newborn infant placed between the mother's breasts will locate a nipple and begin to suck spontaneously within the first hour of birth.<sup>10</sup> This rapid attachment to the mother may reflect olfactory stimuli from the breast received by the infant at birth.<sup>11</sup> Frequent feedings are necessary for the mother to maintain an appropriate level of milk production for the infant's proper growth and development. Programs to support lactation performance must emphasize proper maternal-infant bonding, relaxation of the mother, support for the mother, technical assistance to initiate breast-feeding properly and to cope with problems, and reduction of environmental hindrances. Such hindrances may include lack of rooming-in in the hospital, use of extra formula feeds, and lack of convenient day care for working mothers.

Lactation ceases when suckling stops; therefore, any behavior that reduces the amount of suckling by the infant initiates weaning or the end of lactation. Introduction of water in bottles or of 1 or 2 bottles of formula a day may begin the weaning process regardless of the time after parturition but can be most damaging to the process when the mother-infant dyad is first establishing lactation.

### Secretory Products of Lactation: Nutritional Components of Human Colostrum and Milk

Colostrum and milk contain a rich diversity of nutrients, including electrolytes, vitamins, minerals, and trace metals; nitrogenous products; enzymes; and immunologically specific cellular and soluble products. The distribution and relative content of various nutritional substances found in human milk are presented in Table 5-2. The chemical composition often exhibits considerable variation among lactating women and in the same woman at different times

**Table 5-2 Distribution of Secretory Products in Human Colostrum and Milk<sup>a</sup>**

<b>Water 86%-87.5%; Total Solids 11.5 g</b>
<b>Nutritional Components</b>
Lactose 6.9-7.2 g
Fat 3.0-4.4 g
Protein 0.9-1.03 g
α-Lactalbumin 150-170 mg
β-Lactoglobulin trace
Serum albumin 50 mg
<b>Electrolytes, Minerals, Trace Metals</b>
Sodium 15-17.5 mg
Potassium 51-55 mg
Calcium 32-43 mg
Phosphorus 14-15 mg
Chloride 38-40 mg
Magnesium 3 mg
Iron 0.03 mg
Zinc 0.17 mg
Copper 15-105 μg
Iodine 4.5 μg
Manganese 1.5-2.4 μg
Fluoride 5-25 μg
Selenium 1.8-3.2 μg
Boron 8-10 μg
<b>Nitrogen Products Total 0.15-2 g</b>
Whey protein nitrogen 75-78 mg
Casein protein nitrogen 38-41 mg
Nonprotein nitrogen 25% of total nitrogen
Urea 0.027 g
Creatinine 0.021 g
Glucosamine 0.112 g
<b>Vitamins</b>
C 4.5-5.5 mg
Thiamine (B <sub>1</sub> ) 12-15 μg
Niacin 183.7 μg
B <sub>6</sub> 11-14 μg
B <sub>12</sub> <0.05 μg
Biotin 0.6-0.9 μg
Folic acid 4.1-5.2 μg
Choline 8-9 mg
Inositol 40-46 mg
Pantothenic acid 200-240 μg
A (retinol) 54-56 μg
D <0.42 IU
E 0.56 μg
K 1.5 μg

<sup>a</sup>Estimates based on amount per deciliter.

of lactation,<sup>12</sup> as well as between samples obtained from mothers of low-birth-weight infants and from mothers of full-term infants.<sup>13,14</sup> Mature milk contains the following average amounts of major chemical constituents per deciliter: total solids, 11.3 g; fat, 3.0 g; protein, 0.9 g; whey protein nitrogen, 760 mg; casein nitrogen, 410 mg; α-lactalbumin, 150 mg; serum albumin, 50 mg; lactose, 7.2 g; lactoferrin, 150 mg; and lysozyme, 50 mg. Human milk contains relatively low amounts of vitamins D and E (see Table 5-2) and little or no β-lactoglobulin (the major whey protein in bovine milk). The fat globule membrane appears to have a high content of oleic acid, linoleic acid, phosphatidylpeptides, and inositol.<sup>15</sup> In addition, a binding ligand that promotes absorption of zinc has been identified in human milk.<sup>16,17</sup> Temporal studies have indicated that concentrations of many

chemical components, especially nitrogen, calcium, and sodium, decrease significantly as the duration of lactation increases.<sup>18,19</sup> Several components, however, have been found to change in concentration as a function of water content, because their total daily output appears to be remarkably constant, at least during the first 8 weeks of lactation.<sup>20,21</sup>

Milk production progresses through three distinct phases, characterized by the secretion of colostrum, transitional (early) milk, and mature milk. Colostrum comprises lactational products detected just before and for the first 3 to 4 days of lactation. It consists of yellowish, thick fluid, with a mean energy value of greater than 66 kilocalories (kcal)/dL, and contains high concentrations of immunoglobulin, protein, fat, fat-soluble vitamins, and ash. Transitional milk usually is observed between days 5 and 14 of lactation, and mature milk is found thereafter. The concentrations of many nutritional components decline as milk production progresses to synthesis of mature milk. The content of fat-soluble vitamins and proteins decreases as the water content of milk increases. Conversely, levels of lactose, fat, and water-soluble vitamins and total caloric content have been shown to increase as lactation matures.<sup>22,23</sup>

As the result of several manufacturing errors, the nutrient composition of infant formulas has been legislated,<sup>24</sup> resulting in the paradoxical situation that human milk may not always meet the recommended standards for some nutrients, whereas infant formulas may exceed the recommendation. Human milk nutrient composition varies with time of lactation (colostrum versus early milk versus mature milk) and, to some extent, maternal nutritional status. The appropriate amounts of each nutrient must be considered within these constraints.

**Minerals.** The mineral content of human milk is low relative to that of infant formulas and very low compared with that of cow's milk, from which most formulas are prepared, so that although human milk is sufficient to support growth and development, it also represents a fairly low solute load to the developing kidney. The levels of major minerals tend to decline during lactation, with the exception of that of magnesium, but with considerable variability among women tested.<sup>25</sup> Sodium, potassium, chloride, calcium, zinc, and phosphorus all appear to be more bioavailable in human milk than in infant formulas, reflecting their lower concentrations in human milk. Iron is readily bioavailable to the infant from human milk but may have to be supplemented later in lactation.<sup>26,27</sup> Preterm infants fed human milk may need supplements of calcium and sodium.<sup>28</sup>

**Vitamins.** Human milk contains sufficient vitamins to maintain infant growth and development, with the caveat that water-soluble vitamins are particularly dependent on maternal intake of these nutrients.<sup>29</sup> The preterm infant may require supplements of vitamins D, E, and K when fed human milk.<sup>30,31</sup> The low content of vitamin D in human milk has been related to the development of rickets in a few breast-fed infants, as discussed later.<sup>32</sup> Vitamin D deficiency may be a particular problem in breast-fed infants who are not exposed to at least 30 minutes of sunshine per week.<sup>33</sup>

**Carbohydrates and Energy.** Lactose is the primary sugar found in human milk and usually is the carbohydrate chosen for the preparation of commercial formulas. Lactose supplies

approximately half the energy (of a total 67 kcal/dL) taken in by the infant from human milk. Lactose (a disaccharide of glucose and galactose) also may be important to the neonate as a carrier of galactose, which may be more readily incorporated into gangliosides in the central nervous system than galactose derived from glucose in the neonate.<sup>34</sup> Also, glycogen may be synthesized more efficiently from galactose than from glucose in the neonate because of the relatively low activity of glucokinase in early development.<sup>35</sup> Human milk also contains other sugars, including glucose and galactose and more than 100 different oligosaccharides.<sup>36</sup> These oligosaccharides may have protective functions for the infant, especially with respect to their ability to bind to gastrointestinal pathogens.<sup>37</sup>

**Lipids.** Fats provide almost half of the calories in human milk, primarily in the form of triacylglycerols (triglycerides).<sup>38</sup> These lipids are supplied in the form of fat globules enclosed in plasma membranes derived from the mammary epithelial cells.<sup>39</sup> The essential fatty acid, linoleic acid, supplies about 10% of the calories derived from the lipid fraction. The triacylglycerols serve as precursors for prostaglandins, steroids, and phospholipids and as carriers for fat-soluble vitamins. The lipid profiles of human milk differ dramatically from those of commercial formulas, and despite considerable adaptation of such formulas, human milk lipids are absorbed more efficiently by the infant.

Cholesterol, an important lipid constituent of human milk (12 mg/dL), usually is found in only trace amounts in commercial formulas. It has been suggested that cholesterol may be an essential nutrient for the neonate.<sup>40</sup> A lack of cholesterol in early development may result in turning on of cholesterol-synthetic mechanisms that are difficult to turn off later in life, influencing induction of hypercholesterolemia.<sup>41</sup> Some studies suggest that breast-feeding of the neonate is associated with lowered adult serum cholesterol levels and reduced deaths from ischemic heart disease.<sup>42</sup>

Recently, interest has increased in the role that long-chain polyunsaturated fatty acids (LC-PUFAs) may play in human milk, especially docosahexaenoic acid (DHA) and arachidonic acid (AA). These LC-PUFAs are not found in unsupplemented infant formulas but are present in human milk. They are structural components of brain and retinal membranes and thus may be important for both cognitive and visual development. In addition, they may have a role in preventing atopy.<sup>43</sup> Numerous studies have found that infants fed formula without DHA or AA have reduced red blood cell amounts of these fatty acids<sup>44,45</sup>; however, findings in visual and cognitive functional studies in term infants have been inconsistent.<sup>46,47</sup> These studies have been complicated by the finding of slower growth in some preterm infants fed LC-PUFA-supplemented formulas.<sup>48</sup> The inconsistent findings in supplemented formula-fed babies may reflect the difficulty in determining the optimal amounts of DHA to AA, and their precursors linoleic and linolenic acids, in such supplemented formulas. Thus, these lipids appear to be best delivered from human milk.

**Protein and Nonprotein Nitrogen.** The exact protein content of mature human milk is variable but falls close to 1.0 g/dL, in contrast with that of infant formulas, which usually contain 1.5 g/dL; the milk from mothers who deliver preterm infants may have slightly more protein.<sup>49</sup> The

nutritionally available protein may be even less than 1.0 g/dL—as low as 0.8 g/dL—as a result of the proportion of proteins that is utilized for non-nutritional purposes. In addition, human milk contains a considerably greater percentage of nonprotein nitrogen (25% of the total nitrogen) when compared with formulas (5% of the total nitrogen).<sup>50</sup>

Human milk protein is primarily whey predominant (acid-soluble protein), whereas formulas prepared from bovine milk classically reflect the 18% whey–82% casein protein composition in that species. The whey-to-casein protein ratio in humans may change during lactation, with the whey component ranging from 90% (early milk) to 60% (mature milk) to 50% (late milk).<sup>51</sup> Formulas for preterm infants have been reconstituted from bovine milk to provide 60% whey and 40% casein proteins; all of the major formulas for term infants in the United States are now bovine whey protein–predominant preparations, in an attempt to make them closer to human milk in composition. These differences in protein quality are reflected by differences in the plasma and urine amino acid responses of infants fed human milk or formulas that are casein protein predominant or whey protein predominant.<sup>52–54</sup> In general, however, term infants do not respond with the dramatic differences seen in preterm infants when fed formulas with different protein quality.<sup>55–58</sup>

The nonprotein nitrogen component of human milk contains a variety of compounds that may be of importance to the development of the neonate: polyamines, nucleotides, creatinine, urea, free amino acids, carnitine, and taurine.<sup>59</sup> The significance of the presence of these components is not always clear, but when they are not fed, as in the case of infant formulas that contain little taurine<sup>52</sup> or of soy formulas that contain little carnitine,<sup>60</sup> apparent deficiencies that may influence the development of the infant occur. Taurine is important for bile salt conjugation, as well as for support of appropriate development of the brain and retina,<sup>40</sup> whereas carnitine appears to be important for appropriate fatty acid metabolism.<sup>61</sup>

Nucleotides, in particular, appear to bridge the gap between the nutritional and the immunologic roles of human milk components. Human milk contains a majority of these compounds in the form of polymeric nucleotides or nucleic acids,<sup>62,63</sup> whereas formulas contain nucleotides (when they are supplemented) only in the monomeric forms (Table 5-3). Nucleotides appear to enhance intestinal development, promote iron absorption, and modify lipid metabolism in their nutritional role.<sup>64</sup> On the other hand, these compounds perform an immunologic function by promoting killer cell cytotoxicity and interleukin-2 (IL-2) production by stimulated

mononuclear cells from infants either breast-fed or fed nucleotide-supplemented formulas.<sup>65</sup> Nucleotide supplementation also has been reported to reduce the number of episodes of infant diarrhea in a group of lower-socioeconomic-status infants in Chile, in a manner analogous to that for protection afforded by human milk.<sup>66</sup> In 1998 it was reported that nucleotide-supplemented formulas promote the immune response of infants to *Haemophilus influenzae* type b polysaccharide immunization at 7 months of age, and a similar response was observed for diphtheria immunization.<sup>67</sup> Infants fed human milk for more than 6 months demonstrated a similar response and also exhibited an enhanced titer response to oral polio vaccine; this latter response was not observed in the nucleotide-supplemented formula-fed group.<sup>67</sup> Thus, nucleotides are emerging as both nutritional and immunologic components of human milk.

**Nutritional Proteins.** As noted, the nutritional proteins in human milk are classified as either whey (acid-soluble) or casein (acid-precipitable). Within these two classes of proteins, several specific proteins are responsible for supporting the nutritional needs of the infant.

Human casein is made up primarily of  $\beta$ - and  $\kappa$ -casein, although the actual distribution of these two proteins is not clear.<sup>68</sup> By contrast, bovine milk contains  $\alpha_{s1}$ - and  $\alpha_{s2}$ -casein (neither of which is found in human milk), in addition to  $\beta$ - and  $\kappa$ -casein.<sup>69</sup> These two human milk casein proteins appear to account for approximately 30% of the protein found in human milk, in contrast with the earlier calculation of 40% (the amount commonly used to prepare reconstituted, so-called humanized formulas from bovine milk, which normally contains 82% casein proteins).

The whey protein fraction contains all of the proposed functional proteins in human milk (immunoglobulins, lysozyme, lactoferrin, enzymes, cytokines, peptide hormones), in addition to the major nutritional protein,  $\alpha$ -lactalbumin. The whey proteins make up approximately 70% of human milk proteins, in contrast with 18% in bovine milk. Whereas  $\alpha$ -lactalbumin is the major whey protein in human milk,  $\beta$ -lactoglobulin is the major whey protein in bovine milk (and is not found in human milk).<sup>50</sup> A consistent fraction of human milk whey protein is made up of serum albumin. Its source remains unclear; some evidence indicates that it may be synthesized in the mammary gland.<sup>70</sup> Most of the serum albumin, however, probably is synthesized outside the mammary gland.

Thus, milk proteins are characterized by their site of synthesis, as well as being species specific. Therefore, proteins such as  $\alpha$ -lactalbumin and  $\beta$ -lactoglobulin are species and organ specific, whereas proteins such as serum albumin are species specific but not organ specific.<sup>71</sup> The net result of these differences in proteins utilized for nutrition by the neonate is that different amounts of amino acids are ingested by the neonate, depending on the source of milk; even reconstitution of the whey and casein classes of proteins from one species in a ratio similar to that of another species does not result in an identical amino acid intake. These differences are reflected in plasma amino acid profiles of infants fed commercial milks versus human milk, regardless of the ratios of reconstitution.<sup>54</sup>

**Bioactive Proteins and Peptides.** Whereas a major proportion of human milk protein is composed of the nutritional

<sup>b</sup>See ref. 63.

proteins just described, a significant number of the remaining proteins subserve a variety of functions, either other than or in addition to the nutritional support of the neonate. These proteins include carrier proteins, enzymes, hormones, growth factors, immunoglobulins, and cytokines (the latter two are discussed later under "Resistance to Infection"). Whether these proteins are still functional once they have been ingested by the neonate has not always been established, but it is clear that human milk supplies a mixture that is potentially far more complex than just nutritional substrate.

**Carrier Proteins.** A number of nutrients are supplied to the neonate bound to proteins found in human milk. This binding may play an important role in making these nutrients bioavailable. Lactoferrin is an iron-binding protein (a property that also may play a role in its bacteriostatic action) that is apparently absorbed intact by the infant.<sup>72</sup> Lactoferrin may be important in the improved absorption of iron by the infant from human milk compared with that from cow's milk preparations, which contain little lactoferrin.<sup>26</sup> Lactoferrin also may bind other minerals, including zinc and manganese, although the preferred mineral form appears to be the ferric ion.

A number of other proteins appear to be important as carriers of vitamins and hormones. Folate-binding, vitamin B<sub>12</sub>-binding, and vitamin D-binding proteins all have been identified in human milk. These proteins appear to have some resistance to proteolysis, especially when they are saturated with the appropriate vitamin ligand.<sup>73</sup> Serum albumin acts as a carrier of a number of ligands, whereas  $\alpha$ -lactalbumin acts as a carrier for calcium. Finally, proteins that bind thyroid hormone and corticosteroids have been reported to be present in human milk,<sup>74,75</sup> although serum albumin may in part fulfill this function.

**Enzymes.** The activity of more than 30 enzymes has been detected in human milk.<sup>76</sup> Most of these enzymes appear to originate from the blood, with a few originating from secretory epithelial cells of the mammary gland. Little is known about the role of these enzymes, other than lysozyme and the lipases, in human milk. The enzymes found in human milk range from ATPases to antioxidant enzymes, such as catalase, to phosphatases and glycolytic enzymes. Although these enzymes have important roles in normal body metabolism, it is not clear how many of them either function in the milk itself or survive ingestion by the infant to function in the neonate.

Lysozyme appears to have a part in the antibacterial function of human milk, whereas the lipases have a more nutrient-related role in modulating fat metabolism for the neonate. Two lipases have been identified in human milk, a lipoprotein lipase and a bile salt-stimulated lipase.<sup>77</sup> Lipoprotein lipase appears to be involved in determining the pattern of lipids found in human milk by regulating uptake into milk at the level of the mammary gland. Human milk bile salt-stimulated lipase is an acid-stable protein that compensates for the low activity of lipases secreted into the digestive tract during early development.<sup>78</sup> Thus, these two enzymes regulate both the amount and the pattern of lipid that appears in milk as well as the extremely efficient absorption of lipid by the infant. Human milk lipid is absorbed much more readily than lipid from commercial milk formulas despite the many adaptations that have been made to improve absorption, illustrating the effective mechanisms supported by the lipases.

**Hormones and Growth Factors.** Both peptide and steroid hormones, as well as growth factors, have been identified in trace amounts in human milk, although as with most of the enzymes, it is not clear to what degree they function in the neonate to whom they have been supplied. As discussed previously, binding proteins for corticosteroids and thyroxine have been identified in milk and, by extrapolation from observations of other milk components, may play a role in making these bioactive compounds more readily available to the infant.

Among the hormones identified in human milk are insulin, oxytocin, calcitonin, and prolactin. Most of these hormones appear to be absorbed by the infant, but their role in *in vivo* function remains unclear.<sup>79</sup> Breast-fed infants appear to have a different endocrine response from that of formula-fed infants, presumably reflecting the intake of hormones from human milk.<sup>80</sup> The advantages or disadvantages to the infant of these responses, however, are unknown.

Human milk also contains a rich mixture of growth factors, including epidermal growth factor (EGF) and nerve growth factor.<sup>81</sup> In addition, a variety of gastrointestinal peptides have been identified in human milk. Presumably, the supply of these various factors to the infant through the milk compensates for their possible deficiency in the infant during early development.

The composition of human milk provides a complex and complete nutritional substrate to the neonate. Human milk supplies not only individual nutrients but also enzymes involved in metabolism, carriers to improve absorption, and hormones that may regulate metabolic rates. Commercial formulas have not yet been developed to the point that they can provide an analogous complete nutritional system.

## RESISTANCE TO INFECTION

### Component Mechanisms of Defense: Origin and Distribution

Fresh human milk contains a wealth of components that provide specific, as well as nonspecific, defenses against infectious agents and environmental macromolecules (Table 5-4). These component factors include cells, such as T and B lymphocytes, polymorphonuclear neutrophils (PMNs) (i.e., polymorphonuclear leukocytes), and macrophages; soluble products, especially immunoglobulins; secretory immunoglobulin A (sIgA); immunomodulatory cytokines and cytokine receptors; components of the complement system; several carrier proteins; enzymes; and a number of endocrine hormones or hormone-like substances. Additional soluble factors that are active against streptococci, staphylococci, and tumor viruses also have been identified.<sup>22</sup> Other soluble milk factors with potential implications in host defense include the bifidus factor, which promotes growth of bifidobacteria, and an EGF, which promotes growth of mucosal epithelium and maturation of intestinal brush border. The developmental characteristics of sIgA have been studied more extensively than those of other components.<sup>82-84</sup>

On the basis of available information, it is clear that a majority of IgA-producing cells observed in milk have their origin in the precursor immunocompetent cells in the gut-associated lymphoid tissue (GALT) and bronchus-associated

lymphoid tissue (BALT). Exposure of IgA precursor B lymphocytes in the GALT or BALT to microbial and dietary antigens in the mucosal lumen is an important prerequisite for their initial activation and proliferation. Such antigen-sensitized cells eventually are transported through the systemic circulation to other mucosal surfaces, including the mammary glands and, as plasma cells, initiate the synthesis of immunoglobulin against specific antigens previously experienced in the mucosa of the respiratory or alimentary

tract.<sup>82,83</sup> It has been proposed that T cells observed in the milk also may be derived from GALT and BALT in a manner similar to that of IgA-producing cells. Little or no information is available regarding the site of origin of other cellular or soluble immunologic components normally present in human milk. Specific antibody and cellular immune reactivity against many respiratory and enteric bacterial and viral pathogens and ingested food proteins also are present in human breast milk (Table 5-5).

### Soluble Products

**Immunoglobulin A.** As observed in other peripheral mucosal sites, the major class of immunoglobulin in human colostrum and milk is the 11S sIgA. Other isotypes—namely, 7S IgA, IgG, IgM, IgD, and IgE—also are present. The IgA exists as a dimer of two 7S IgA molecules linked together by a polypeptide chain, the J-chain, and is associated with a nonimmunoglobulin protein referred to as the secretory component. The sIgA protein constitutes about 75% of the total nitrogen content of human milk. The IgA dimers produced by plasma cells at the basal surface of the mammary epithelium are transported to specialized columnar epithelial cells, where they acquire the secretory component before their discharge into the alveolar spaces.<sup>83,84</sup>

Sequential quantitation of class-specific immunoglobulin in human colostrum and milk has demonstrated that the highest levels of sIgA and IgM are present during the first few days of lactation (Fig. 5-1). Levels of IgA are 4 to 5 times greater than those of IgM, 20 to 30 times greater than those of IgG, and 5 to 6 times greater than those of serum IgA.<sup>84</sup> As lactation progresses, IgA declines to levels that range from 20 to 27 mg per gram of protein, and IgM levels decline to 3.5 to 4.1 mg/g. IgG levels do not show any significant change during early and late lactation and usually are maintained in the range of 1.4 to 4.9 mg/g (see Fig. 5-1). Although a dramatic and rapid decline in milk IgA and IgM occurs during the first week of life, this decrease is more than balanced by an increase in the volume of milk produced as the process of lactation becomes established (see Fig. 5-1).

**Figure 5-1** Comparison of the mean levels of IgG, IgA, and IgM in colostrum and milk at different intervals after the onset of lactation in mothers who were breast-feeding. (Data from Ogra SS, Ogra PL. *Immunologic aspects of human colostrum and milk. II. Characteristics of lymphocyte reactivity and distribution of E-rosette forming cells at different times after the onset of lactation.* J Pediatr 92:550-555, 1978.)

IgA antibodies found in milk possess specificity for infectious agents endemic to or pathogenic for the intestinal and respiratory tracts (see Table 5-4). These antibodies may be present in the milk in the absence of specific circulating IgA. In a study in which pregnant women were given oral feedings of *Escherichia coli* 083, development of IgA antibody in human milk was evident in the absence of detectable serum antibody-specific responses.<sup>85</sup> In another study, investigators have observed similar responses in animal models using intrabronchial immunization with *Streptococcus pneumoniae*. These and other studies<sup>86-89</sup> have strongly supported the concept of a bronchomammary, as well as an enteromammary, axis of immunologic reactivity in the breast.

Despite the elegance of studies that have defined the mechanisms of IgA cell trafficking from GALT and BALT to the mammary glands, it is clear that the actual number of B cells or IgA plasma cells in the mammary glands is sparse. At the same time, colostrum and milk may contain large amounts of IgA (as much as 11 g in colostrum and as much as 1 to 3 g per day in later milk), as shown in Table 5-6. The reasons underlying the apparent disparity between the content of immunoglobulin-producing cells and concentrations of immunoglobulin are not known. It may be related to the unique hormonal environment of the mammary glands. The hormones that have been consistently observed in human milk are listed in Table 5-4.

The effect of pregnancy- and lactation-related hormones on regulation of immunologic reactivity present in the resting and lactating breast has been examined.<sup>90</sup> In a study on immunoglobulin production in the nonlactating human breast, several interesting findings were noted.<sup>91</sup> Few mononuclear cells were present in the nonlactating breast of nulliparous and of parous women, although IgA-containing cells predominated. Synthesis of IgA appeared to be slightly increased in the parous women. IgA was found in the mammary tissues during the proliferative stage of the menstrual cycle in the nulliparous women and during the luteal phase in the parous women. The number of IgA-producing cells in the nonlactating breast was observed to increase with parity. These findings suggest that the immunologic makeup of the nonlactating, as well as the lactating, breast may be significantly influenced by the hormonal milieu. In another study of virgin mice given exogenously administered hormones,<sup>92</sup> an extended exposure to estrogen, progesterone, and prolactin was necessary for maximal increments in IgA-producing plasma cells in the breast. Similarly, castrated males exposed to these hormones became moderately receptive to mammary gland homing of cells specific for IgA synthesis. As would be expected, testosterone eliminated female breast receptivity to these cells. These studies suggest the existence of a hormonally determined homing mechanism in the mammary gland for class-specific, immunoglobulin-producing cells.

More recent studies have proposed another possible influence of lactational hormones on immunocompetent cells. In limited observations, combinations of prolactin with estrogen and progesterone (in concentrations observed normally at the beginning of parturition) appeared to have an amplifying effect on the synthesis and secretion of IgA from peripheral blood lymphocytes.<sup>93</sup> This observation raises the possibility that the high levels of sIgA observed in colostrum and milk may be the result of selective, hormonally mediated proliferation of antigen-sensitized IgA cells in the

peripheral blood. The immunoglobulin could acquire secretory component during its passage through the mammary epithelium and eventually appear in the colostrum or milk as mature sIgA. Although the appearance of sIgA antibody in milk characteristically follows antigenic exposure in the GALT or BALT, the precise nature of the IgA content in milk appears to be determined by a variety of other factors operating in the mucosal lymphoid tissue. These include the regulatory T cell network in the GALT and possibly in the BALT,<sup>94</sup> the nature of antigens (soluble proteins versus particulate microbial agents),<sup>95</sup> and the route of primary versus secondary antigenic exposure.<sup>96</sup>

It has been estimated that the breast-fed infant may consistently receive an amount of about 1 g of IgA each day. Approximately  $\frac{1}{100}$  of this amount each day is IgM and IgG.<sup>97,98</sup> The estimates of lactational immunoglobulin delivered to the breast-fed infant at different periods of lactation are presented in Table 5-6. Most ingested IgA is eliminated in the feces, although up to 10% may be absorbed from the intestine into the circulation within the first 18 to 24 hours after birth. Approximately 70% to 75% of ingested milk IgA survives passage through the gut and is excreted in the feces.<sup>99</sup> Feces of breast-fed infants contain functional antibodies present in the ingested milk.<sup>100</sup> Other studies also support the finding of prolonged survival of milk IgA in the gastrointestinal tract. Infants fed human milk have demonstrated the presence of all immunoglobulin classes in the feces. Fecal IgA content was three to four times greater than that of IgM after human milk feeding. Comparative studies on survival of human milk IgA and bovine IgG in the neonatal intestinal tract have suggested that the fecal content of IgA may be 14 to 20 times greater after human milk feeding than that of bovine IgG after feeding of bovine immune globulin.<sup>101</sup>

Direct information about the role of milk IgA in antimicrobial defense is available in several studies. Secretory IgA interferes with bacterial adherence to cell surfaces.<sup>102</sup> Colostrum and milk can inhibit the activity of *E. coli* and *Vibrio cholerae* enterotoxins in experimental settings.<sup>103</sup> The antitoxic activity of human milk appears to correlate well with its IgA content but not with its IgM and IgG content. Precoating of *V. cholerae* with specific sIgA protects infant mice from disease.<sup>104</sup> Similar results have been obtained by using specific purified milk sIgA in preventing *E. coli*- and *Shigella dysenteriae*-induced disease in rabbits.<sup>105</sup> Less definite, but suggestive, is a study conducted with human

milk feeding relative to the intestinal implantation of orally administered live poliovirus vaccine.<sup>106</sup> This study found that breast-feeding may reduce the degree of seroconversion for poliovirus antibody in the vaccinated infants. Because antipolio IgA is present in human milk and colostrum, the investigators concluded that specific IgA may bind poliovirus and influence viral replication in the intestinal mucosa. Extensive experience with oral polio immunization worldwide, however, has not found an association between breast-feeding and live vaccine failures. Other studies have clearly shown that the magnitude of poliovirus replication in the intestine is determined by the presence and level of pre-existing sIgA antibody. With high levels of intestinal IgA antibody, little or no replication of vaccine virus was observed in the gut. With lower levels, varying degrees of viral replication could be demonstrated.<sup>107</sup>

Indirect evidence, obtained from a more clinical perspective, suggests a protective role for milk against a variety of mucosal infections. Breast-feeding has been strongly implicated in supporting gastrointestinal homeostasis in the neonate and in establishing normal gut flora. Observations have shown the absence of diarrheal disease in breast-fed infants, even in the face of contamination of the fed milk with *E. coli* and *Shigella* species.<sup>108</sup> A preventive and therapeutic role for breast-feeding also has been suggested in nursery outbreaks of such disease due to enteropathogenic strains of *E. coli*<sup>109</sup> and diarrhea associated with rotavirus.<sup>110</sup> Breast-feeding plays an inhibitory role in the appearance of *E. coli* O83 agglutinins found in the feces of colonized infants. A decrease in the incidence of neonatal sepsis, specifically that associated with gram-negative bacilli and *E. coli* K1 serotypes, also has been linked to breast-feeding.<sup>111,112</sup> Milk IgA, possibly by limiting ingestion of foreign antigens by the neonate, or by binding of foreign proteins with specific antibodies to prevent absorption, or by both processes, may decrease the incidence of atopic-allergic diseases.<sup>113-115</sup> The frequency of IgE skin test-positive results has been described as being lower among breast-fed infants, possibly because of decreased exposure to cow's milk proteins or presence of maternal blocking antibodies.<sup>116</sup> Indirect epidemiologic data suggest that breast-feeding is protective against certain respiratory bacterial and viral infections.<sup>117,118</sup> Whereas the epidemiologic studies strongly support a protective role of breast-feeding, it is not possible in these studies to dissect the relative contribution of sIgA from that of other soluble or cellular components present in colostrum and milk.

**Table 5-6 Level of Immunoglobulins in Colostrum and Milk and Estimates of Delivery of Lactational Immunoglobulins to the Breast-Feeding Neonate<sup>a</sup>**

Day Post Partum	Percentage of Total Proteins Represented by Immunoglobulin			Output of Immunoglobulin (mg/24 hr)

<50	1-2	0.5-1	10-15	10	10	1000

<sup>a</sup>Estimates based on the available data for total immunoglobulin and daily protein synthesis (see references 6, 83, 84).

**Immunoglobulin G and Immunoglobulin M.** Normal neonates exhibit characteristic paucity or lack of IgA during the first 7 to 10 days after birth. At that time, the presence of IgM and IgG in milk may be important to compensate for immunologic functions not present in the mucosal sites. For example, both IgG and IgM participate in complement fixation and specific bactericidal activity, functions not associated with IgA. Studies carried out after oral feeding of immune serum globulin (mostly IgG) have suggested that IgG may survive in the gastrointestinal tract of low-birth-weight infants.<sup>119</sup> Thus, other immunoglobulin isotypes in milk also may be able to serve as effective substitutes for IgA in the neonates of IgA-deficient mothers in prevention of infection with enteric or respiratory pathogens.

**Immunoglobulin E and Immunoglobulin D.** Studies on the distribution and role of IgE or IgD in colostrum and milk are few. Normal cord blood contains little or no IgE or IgD. The highest IgE concentrations observed in normal neonates usually are less than 5 ng/mL. Investigations have failed to demonstrate local synthesis of IgE in the breast.<sup>120-122</sup> Although IgE may be detected in up to 40% of colostrum and milk samples, the concentrations are extremely low, and many samples of colostrum and milk contain no IgE activity when paired samples of serum contain high IgE levels. On the other hand, IgD has been detected in most colostrum and milk samples. It has been suggested that nursing women with high serum IgD levels are more likely to have high IgD concentrations in their milk. The possibility of some local production of both IgE and IgD cannot be ruled out.<sup>122</sup>

### Cellular Elements

Human colostrum and milk contain lymphocytes, monocytes-macrophages, neutrophils, and epithelial cells.<sup>123</sup> Early colostrum contains the highest concentration of cells, approximately  $1 \times 10^6$  to  $3 \times 10^6$  cells per mL. By the end of the first week of lactation, cell concentration is of the order of  $10^5$  cells per mL. Total cell numbers delivered to the newborn throughout lactation may, however, remain constant when adjustments are made for the increase in volume of milk produced.<sup>124</sup> The two major cell populations in human milk are difficult to distinguish by common staining methods because of the large number of intracytoplasmic inclusions, neutrophils, and macrophages. More accurate estimates made by flow cytometry analysis suggest that the relative percentages of neutrophils, macrophages, and lymphocytes in early milk samples are approximately 80%, 15%, and 4%, respectively.<sup>125,126</sup> The remaining cells are present in smaller amounts, especially in the absence of active suckling, engorgement, or local breast infection.

**Macrophages.** Histochemically, the milk macrophage differs from the blood monocyte in demonstrating decreased peroxidase staining, with increased lysosomes and significant amounts of immunoglobulin, especially IgA, in the cytoplasm.<sup>127-129</sup> The intracellular immunoglobulin in macrophages represents up to 10% of milk IgA.<sup>130</sup> Kinetic studies on the release of IgA by human milk macrophages suggest that immunoglobulin release by macrophages, unlike that by other phagocytic cells, is a time-dependent phenomenon and is not significantly influenced by the use of secretagogues or stimulants, such as phorbol myristate acetate.<sup>130</sup> Active phagocytosis, however, is associated with significant increase

in release of IgA.<sup>131</sup> In other studies, milk macrophages have been found to be efficient in release of superoxide anions after in vitro stimulation with phorbol myristate acetate.<sup>132,133</sup> Milk macrophages have the capacity to be primed by appropriate stimulation for greater release of superoxide anions.<sup>133</sup> It has been shown that milk macrophages obtained from preterm-delivered lactating mothers have a significantly higher phagocytic index than that for the macrophages in term milk. The bactericidal activity appears to be similar in pre- and full-term milk macrophages, however.<sup>132</sup> In neutrophils, milk macrophages appear to be activated, as demonstrated by the increased expression of CD11b and decreased expression of L-selectin.<sup>125</sup>

The precise functions of macrophages in colostrum or milk have not been fully explored. These cells have been suggested as potential transport vehicles for IgA.<sup>128,129</sup> Milk macrophages possess phagocytic activity against *Staphylococcus aureus*, *E. coli*, and *Candida albicans*, with possible cytotoxic activity against the first two organisms.<sup>134</sup> Milk macrophages participate in antibody-dependent, cell-mediated cytotoxicity for herpes simplex virus type 1-infected cells.<sup>135</sup> Infection of milk macrophages by respiratory syncytial virus results in the production of the pro-inflammatory cytokines IL-1 $\beta$ , IL-6, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).<sup>136</sup> These cells also are involved in a variety of other biosynthetic and excretory activities, including production of lactoferrin, lysozyme,<sup>137</sup> components of complement,<sup>138</sup> properdin factor B, epithelial growth factor(s), and T lymphocyte-suppressive factor(s).<sup>82</sup> Milk macrophages also have been suggested to be important in regulation of T cell function.<sup>139,140</sup>

**Lymphocytes.** Milk contains a small number of lymphocytes, 80% of which are T cells and 4% to 6% of which are B cells.<sup>126</sup> The small number of B cells reflects the sessile nature of these cells, which enter the lamina propria of the mammary gland to transform into plasma cells. Although several investigators have been unable to show in vitro antibody synthesis by milk lymphocytes, studies performed with colostrum B cells transformed by Epstein-Barr virus have shown production of IgG, as well as J-chain-containing IgM and IgA.<sup>141</sup> A small population of CD16<sup>+</sup> natural killer (NK) cells also can be identified in most milk samples but cannot be accurately quantitated.<sup>126</sup> In functional studies, however, colostrum cells exhibit NK cytotoxicity, which is enhanced by interferon and IL-2. Colostrum cells also elicit antibody- and lectin-dependent cellular cytotoxic responses. The NK, as well as the antibody- and lectin-dependent, responses in colostrum cells, however, have been observed to be significantly lower than those of autologous peripheral blood cells. Reduced cellular cytotoxicity of colostrum cells also has been observed against virus-infected targets and certain bacteria. In fact, with several specific virus-infected targets, colostrum and milk cells conspicuously lack cellular cytotoxicity when compared with autologous peripheral blood cells. There is also an apparent exclusion of cytolytic T cells in the milk that are specific for certain human leukocyte antigen (HLA) phenotypes.<sup>142,143</sup>

A majority of T lymphocytes in colostrum and milk are mature CD3<sup>+</sup> cells. Both CD4<sup>+</sup> (helper) and CD8<sup>+</sup> (cytotoxic and suppressor) populations are present in human milk, with a proportion of CD8<sup>+</sup> T cells higher than that found in human blood (Table 5-7). The CD4<sup>+</sup>/CD8<sup>+</sup> ratio in milk is

**Table 5-7 Lymphocyte Subpopulations in Human Milk and Autologous Blood<sup>a</sup>**

Lymphocyte Subpopulation	Human Milk	Blood
CD3 <sup>+</sup> <sup>b</sup>	83 ± 11	75 ± 7
CD3 <sup>+</sup> CD4 <sup>+</sup> <sup>b</sup>	36 ± 13	44 ± 6
CD3 <sup>+</sup> CD8 <sup>+</sup> <sup>b</sup>	43 ± 12	27 ± 4
CD4 <sup>+</sup> /CD8 <sup>+</sup> <sup>c</sup>	0.88 ± 0.35	1.70 ± 0.45
CD19 <sup>+</sup> <sup>b</sup>	6 ± 4	14 ± 5

<sup>a</sup>Expressed as mean ± standard deviation (SD).

<sup>b</sup>Expressed as percentage of total lymphocytes.

<sup>c</sup>Ratio of CD3<sup>+</sup>/CD4<sup>+</sup> to CD3<sup>+</sup>/CD8<sup>+</sup> lymphocytes.

significantly lower than that observed in peripheral blood and is not due to an increase of CD8<sup>+</sup> cells in the peripheral blood of women during the postpartum period. Colostral and milk T lymphocytes manifest in vitro proliferative responses on stimulation with a number of mitogens and antigens. Several studies have shown a selectivity in lymphocyte stimulation responses in colostrum and milk lymphocytes to various antigens when compared with peripheral blood lymphocyte responses.<sup>124,144</sup> Antigens such as rubella virus stimulate T lymphocytes in secretory sites and milk, as well as in systemic sites.<sup>124</sup> By contrast, *E. coli* K1 antigen whose exposure is limited to mucosal sites produces stimulation of lymphoproliferative responses only in milk lymphocytes. These findings support the concept of select T cell populations in the mammary gland.

In addition to antigen selectivity, a general hyporesponsiveness to mitogenic stimulation of milk lymphocytes relative to peripheral blood lymphocytes has been observed.<sup>124,140</sup> The decreased reactivity of milk lymphocytes to phytohemagglutinin (PHA) may be partly the result of a relative deficiency of certain populations of T cells in milk. Macrophage-T cell interactions also have been postulated as being responsible for this relative hyporesponsiveness,<sup>84</sup> although it is not known whether the effects are the result of decreased helper or increased suppressor function. Recent studies have shown that milk lymphocytes exhibit reduced responses to allogeneic cells but display good ability to stimulate alloreactivity.<sup>142</sup> Treatment of milk lymphocytes with monoclonal antibodies cytotoxic for T lymphocytes or with anti-HLA class II antigen-specific monoclonal antibodies has resulted in a substantial reduction in in vitro proliferative responses to bacterial antigens. It appears that, in general, the T cell proliferative responses to PHA and tetanus toxoid in breast-fed infants are significantly higher than those in bottle-fed infants, possibly secondary to the presence of maternally derived cell growth factors and other lymphokines present in human milk.<sup>140,145</sup>

Virtually all CD4<sup>+</sup> and CD8<sup>+</sup> T cells in milk bear the CD45 isoform CD45RO that is associated with immunologic memory.<sup>126,146</sup> In addition, the proportion of T cells that display other phenotypic markers of activation, including CD25 (IL-2R) and HLA-DR, is much greater than that in blood.<sup>126,147</sup> Consistent with their memory phenotype, T cells in human milk produce interferon- $\gamma$  (IFN- $\gamma$ ).<sup>146</sup>

Furthermore, a significantly greater number of CD4<sup>+</sup> T cells in colostrum express the CD40 ligand (CD40L) compared with autologous or heterologous blood T cells.<sup>148</sup> Cognate interaction between the CD40L on T cells and the CD40 on B cells is a necessary step for antibody production in vivo and is congenitally deficient in the newborn. The function of these memory T cells in the recipient human infant is currently unknown, however. Mucous membrane sites in the alimentary or respiratory tract, or both, of the recipient infant would seem to be potential entry sites for human milk leukocytes. Of considerable interest, very small numbers of memory T cells are detected in blood in infancy.<sup>149</sup> Thus, it is possible that maternal memory T cells in milk compensate for the developmental delay in their production in the infant. In this regard, the proportion of T lymphocytes bearing the T cell receptor- $\gamma\delta$  (TCR- $\gamma\delta$ ) is approximately two times greater in colostrum than in blood.<sup>150,151</sup> Human TCR- $\gamma\delta$ <sup>+</sup> cells populate organized lymphoid tissues and represent half of the intraepithelial lymphocytes in the gut.<sup>152</sup> Thus, the intestinal epithelia may have a selective affinity for TCR- $\gamma\delta$ <sup>+</sup> cells and provide a favorable environment for maternal T cells in milk to be transferred to the breast-fed infant. Evidence from experimental animal studies indicates that milk lymphocytes enter tissues of the neonate,<sup>153-156</sup> but this has not been demonstrated in humans. In addition, the possible transfer of histocompatibility antigens and T cells to the neonate through breast-feeding has been examined by determining the fate of skin grafts in suckling rats fed by allogeneic mothers.<sup>157</sup> Such foster feeding of milk may result not only in increased allogeneic graft survival but also in development of "runt" syndrome, possibly as a result of a graft-versus-host-type reaction in the breast-fed animal. Effects of the transfer may be related to dosage of ingested allogeneic cells, in that increasing cell numbers transferred may prolong skin graft survival but may also increase the likelihood of a graft-versus-host reaction. Of note, the suckling rat gut has a higher degree of permeability to whole proteins than that characteristic of the human intestine. Furthermore, clinical experience in immunodeficient neonates has never supported the development of graft-versus-host reaction-like disease in the breast-fed human infant. In humans, possible transfer of maternal T cell reactivity to tuberculin protein from the mother to the neonate through the process of breast-feeding has been observed.<sup>99,158,159</sup> The implications of these observations are that maternal cellular products or soluble mediators of cellular reactivity may be transferred passively to the neonate through breast-feeding. Admittedly, however, the occurrence of such phenomena in humans has not been studied carefully. Thus, it must be emphasized that at present, evidence to suggest any T cell-mediated immunologic risks associated with breast-feeding in humans is lacking. On the other hand, it is still unknown whether milk T cells, either TCR- $\alpha\beta$ <sup>+</sup> or TCR- $\gamma\delta$ <sup>+</sup>, play a role in the transfer of adoptive immunoprotection to the recipient infant.

**Neutrophils.** Milk contains large numbers of neutrophils. Although the absolute counts in actively nursing mothers exhibit considerable variability between different samples, highest numbers are generally observed during the first 3 to 4 days of lactation. The numbers of neutrophils decrease significantly after 3 to 4 weeks of lactation, and only rare

neutrophils are observed in samples collected after 60 to 80 days post partum. Leukocytes in human milk appear to be metabolically activated. Indeed, although the neutrophils are phagocytic and produce toxic oxygen radicals, they do not respond well to chemoattractants by increasing their adherence, polarity, or directed migration in *in vitro* systems.<sup>160</sup> This diminished response was found to be due to prior activation in that the neutrophils in milk displayed a phenotypic pattern that is typical of activated neutrophils. The expression of CD11b, the  $\alpha$  chain subunit of Mac-1, was increased, and the expression of L-selectin was decreased.<sup>125</sup>

**Epithelial Cells.** On the basis of their anatomic distribution, epithelial cells in the human mammary gland can be classified into two main types: myoepithelial and luminal. Epithelial cells of both types, however, appear to be more heterogeneous on histologic and physicochemical testing.<sup>142,161,162</sup> They include secretory cells, which contain abundant rough endoplasmic reticulum, lipid droplets, and Golgi apparatus. The secretory cells appear to produce casein micelle. The squamous epithelial cells usually are seen in the regions of the cutaneous junction of the nipples, especially near the galactophores. The ductal or luminal cells, which exist in clusters, have many short microvilli, tight junctions, and remnants of desmosomes.<sup>161,162</sup> Studies using monoclonal antibodies have shown that in rodents, as many as 10 different types of epithelial cells in the adult mammary glands may exist. These cell types probably represent various stages of differentiation of mammary gland epithelium. These include, in the mammary end buds, the distinct cell types of the tip and the main compartment peripheral cell types I and II and, in alveoli as well as in the ducts of the mammary glands, the luminal cell types I and II and myoepithelial cells.<sup>161</sup> It is not known, however, whether similar epithelial cell differentiation occurs in the human mammary gland.

In human milk, relatively few epithelial cells are observed in the early phases of lactation. Most epithelial cells appear after 2 to 3 weeks and are seen in appreciable numbers, even as long as 180 to 200 days after the onset of lactation. With the possible exception of the synthesis of secretory component and casein and possibly other products, with which secretory epithelial cells have been associated in the stroma of the mammary gland, the role of epithelial cells in the milk remains to be defined.

**Possible Functional Roles for Cellular Elements.** The information reviewed thus far provides strong evidence for the existence of a number of dynamic cellular reactions in the mammary gland, colostrum, and milk. Unfortunately, the specific functional role, collectively or individually, for the epithelial cells, monocytes, neutrophils, or lymphocytes in the mammary gland or the milk remains to be defined. In view of the high degree of selectivity and the differences in the quantitative and functional distribution of cellular elements, it is suggested that the mammary gland, like mucosal surfaces, may function somewhat partitioned from the cellular elements in peripheral blood, in a manner similar to that for other peripheral sites (such as the genital tract) of the common mucosal system. It is, however, not known whether the characteristic proportions of macrophages, T lymphocytes, other cytotoxic cells, or epithelial cells are designed for any specific functions localized to the mammary

gland in the lactating mother or to epithelium or lumen of the intestinal or respiratory mucosa of the breast-feeding infant, or both. The observations on the transfer of delayed hypersensitivity reactions in human neonates and of graft-versus-host reactivity in the rat raise the possibility that milk cells may function as important vehicles in transfer of maternal immunity to neonates. The potential beneficial and harmful roles of such cell-mediated transfer through the mucosal routes, however, need to be investigated further. The paucity of NK and other cytotoxic cells in the colostrum may have a role for the breast-feeding neonate, especially in influencing the antigen processing and uptake of replicating microorganisms and their immune response at systemic or mucosal levels or both. Although colostrum cells await further elucidation of their function in the mammary glands and the suckling neonate, it is likely that their presence in the milk represents a highly selective phenomenon and not a mere contamination with peripheral blood cells.

### Other Possible Defense Factors

Human colostrum and milk contain all components of the complement system. Active production of C3 has been reported *in vitro* in breast milk cell cultures.<sup>163,164</sup> Interferon,<sup>165</sup> migration inhibition factor,<sup>158</sup> and  $\alpha$ -fetoprotein<sup>148</sup> also are present in human milk, although their roles have not yet been fully elucidated (see Table 5-4).

Iron-binding proteins present in colostrum and milk, such as lactoferrin,<sup>166</sup> have bacteriostatic activity *in vitro* against *E. coli*, *S. aureus*, and *C. albicans*.<sup>137</sup> Some evidence suggests enhanced bactericidal activity of lactoferrin in association with IgA. Lysozyme and bifidus factor (a collection of glycosamides that promote growth of *Lactobacillus* and bifidobacterial species, whose growth in turn inhibits growth of enteric gram-negative aerobic bacilli) may function as ancillary inhibitors of gut and skin pathogens. Anti-staphylococcal factors appear to be active against experimental staphylococcal infections and may be important for local mammary gland protection.<sup>166,167</sup> Of particular interest is the demonstration of certain oligosaccharides that prevent attachment of *S. pneumoniae* to human epithelial cells<sup>168</sup> and of high-molecular-weight substances that inhibit virulence of enterotoxins of Enterobacteriaceae organisms (see Table 5-4).

Nonimmunoglobulin antiviral factors have been demonstrated in lipid and aqueous phases of human milk. These factors have shown activity against influenza A and B viruses, herpes simplex virus, Semliki Forest virus, Japanese B encephalitis virus, rubella virus, rhinovirus, and rotavirus (see Table 5-4). The milk-associated antiviral factors have been shown to have inhibitory functions only *in vitro*. Their *in vivo* role in neonatal and maternal infections remains to be elucidated. Recent studies also have demonstrated the presence of other substances in human milk that promote growth and maturation of intestinal epithelial tissue<sup>169</sup> and uptake of folate by the intestinal cells.<sup>170</sup>

Several recent studies have generated interest in the potential role of nonantibody proteins, bile salt lipases, whey proteins, and trace metals present in human milk in the control of enteric infections.<sup>171-174</sup> Several species of gram-positive and gram-negative bacteria frequently can be killed by incubation with human milk whey but not commercial infant formula.<sup>171</sup> The mechanisms responsible for such antibacterial activity are not known. The synergistic inter-

action among IgA, lactoferrin, and iron has been suggested to play a role in such defense.<sup>171-172</sup>

Concentrations of free fatty acid and possibly monoglycerides seem to increase during storage of milk because of spontaneous lipolysis generated by lipoprotein lipase.<sup>175,176</sup> Antibody-independent antiparasitic effect of stored, but not fresh, human milk against *Giardia lamblia* or *Entamoeba histolytica* has been attributed to such free fatty acids.<sup>177</sup> In additional studies conducted in vitro, bile salt-stimulated lipase, the major lipase in human milk, has been found to cause hydrolysis of milk triglycerides. It remains to be seen whether free fatty acids induce significant in vivo protection in the intestine against intestinal parasites. On the other hand, bile salts themselves may stimulate the growth of *G. lamblia*.<sup>173</sup>

Nonantibody proteins, several carrier proteins, and cellular enzyme proteins are present in milk in high concentrations. Concentrations of lysozyme range from 30 to 50 mg/100 mL in early colostrum to 5 to 10 mg/100 mL in late milk. The susceptibility of an organism to lysozyme depends on the availability of the peptidoglycan substrate. In certain situations in which the peptidoglycan may be blocked by lipoproteins, the organisms are relatively resistant to lysozymes.<sup>173,174</sup>

#### DIRECT-ACTING ANTIMICROBIAL AGENTS

**General Features.** The defense agents in human milk, although biochemically diverse, share certain features: (1) They usually are common to mucosal sites. (2) They are adapted to resist digestion in the gastrointestinal tract of the recipient infant. (3) They protect by noninflammatory mechanisms. (4) They act synergistically with each other or with factors produced by the infant. (5) Most components of the immune system in human milk are produced throughout lactation and during gradual weaning, but (6) there is often an inverse relationship between the production of these factors in the mammary gland and their production by the infant during the same time frames of lactation and postnatal development. Indeed, as lactation proceeds, the concentration of many factors in human milk declines. Concomitantly, the mucosal production of these factors rises in the developing infant. It is unclear whether the inverse relationship between these processes is due to feedback mechanisms or whether the processes are independent.

**Carbohydrate Components.** Human milk contains several oligosaccharides and glycoconjugates, including monosialogangliosides that are receptor analogues for heat-labile toxins produced by *V. cholerae* and *E. coli*<sup>178</sup>; fucose-containing oligosaccharides that inhibit the hemagglutinin activity of the classic strain of *V. cholerae*<sup>179</sup>; enterosylated oligosaccharides that protect against heat-stable enterotoxin of *E. coli*<sup>180</sup>; mannose-containing high-molecular-weight glycoproteins that block the binding of the El Tor strain of *V. cholerae*<sup>178</sup>; and glycoproteins and glycolipids that interfere with the binding of colonization factor (CFA/II) fimbriae on enterotoxigenic *E. coli*.<sup>181</sup> The inhibition of toxin binding is associated with acidic glycolipids containing sialic acid (gangliosides). Although the quantities of total gangliosides in human and in bovine milk are similar, the relative frequencies of each type of ganglioside in milk from these two species are distinct. More than 50 types of monosialylated

oligosaccharides have been identified in human milk, and new types are still being recognized.<sup>182</sup> Monosialoganglioside 3 constitutes about 74% of total gangliosides in human milk, but the percentage is much lower in bovine milk.<sup>183,184</sup> Also, the level of the enterotoxin receptor ganglioside G<sub>M1</sub> is 10 times greater in human than in bovine milk.<sup>184</sup> This difference may be of clinical importance because G<sub>M1</sub> inhibits enterotoxins of *E. coli* and *V. cholerae*.<sup>185</sup> It also is of interest that intact human milk fat globules, as well as the mucin from the membranes of these structures, inhibit the binding of S-fimbriated *E. coli* to human buccal epithelial cells.<sup>186</sup>

Oligosaccharides in human milk also interfere with the attachment of *H. influenzae* and *S. pneumoniae*.<sup>187</sup> In this regard, *N*-acetylglucosamine (G1cNAc) (1-3)Gal-disaccharide subunits block the attachment of *S. pneumoniae* to respiratory epithelium. Moreover, recent evidence indicates that human milk interferes with the binding of human immunodeficiency virus (HIV) envelope antigen gp120 to CD4 molecules on T cells.<sup>188</sup> Some evidence from animal models suggests that the oligosaccharides and glycoconjugates in human milk protect in vivo,<sup>189-191</sup> but relevant clinical data are scarce.<sup>192</sup>

In addition to the direct antimicrobial effects of the carbohydrates in human milk, nitrogen-containing oligosaccharides in human milk are growth promoters for *Lactobacillus bifidus* var. *pennsylvanicus*,<sup>193</sup> glycoproteins, and glycopeptides.<sup>194,195</sup> The bifidus growth promoter activity associated with caseins may reside in the oligosaccharide moiety of those complex molecules.<sup>196</sup> It appears that these factors are responsible to a great extent for the predominance of *Lactobacillus* species in the bacterial flora of the large intestine of the breast-fed infant. These bacteria produce large amounts of acetic acid, which aids in suppressing the multiplication of enteropathogens. It also has been reported that *Lactobacillus* species strain GG aids in the recovery from acute rotavirus infections<sup>197</sup> and may enhance the formation of circulating cells that produce specific antibodies of the IgG, IgA, and IgM isotypes, as well as serum levels of those antibodies.<sup>198</sup>

**Generation of Antiviral, Antiparasitic Lipids from Substrata in Human Milk.** Human milk supplies defense agents from fat as it is partially digested in the recipient's alimentary tract. Fatty acids and monoglycerides produced from milk fats by bile salt-stimulated lipase or lipoprotein lipase in human milk,<sup>199</sup> lingual/gastric lipase from the recipient from birth,<sup>200</sup> or pancreatic lipase after a few weeks of age are able to disrupt enveloped viruses.<sup>201-205</sup> These antiviral lipids may aid in preventing coronavirus infections of the intestinal tract<sup>206</sup> and also may defend against intestinal parasites such as *G. lamblia* and *E. histolytica*.<sup>207,208</sup>

**Proteins.** The principal proteins in human milk that have direct antimicrobial properties include the following.

**$\alpha$ -Lactalbumin.**  $\alpha$ -Lactalbumin is a major component of the milk proteins and may possess some important functions of immunologic defense. This protein appears as large complexes of several  $\alpha$ -lactalbumin molecules, which can induce apoptosis in transformed embryonic and lymphoid cell lines. A lower number of such aggregated  $\alpha$ -lactalbumin molecules binding oleic acid as a co-factor can induce cytolysis of several types of malignant cells. Such preparations of human  $\alpha$ -lactalbumin made lethal to tumor

cells (HAMLET) are highly effective in inducing apoptosis. The antitumor cytolytic activity with HAMLET also has been observed against large numbers of human tumors.

**Lactoferrin.** Lactoferrin, the dominant whey protein in human milk, is a single-chain glycoprotein with two globular lobes, both of which display a site that binds ferric iron.<sup>209</sup> More than 90% of the lactoferrin in human milk is in the form of apolactoferrin (i.e., it does not contain ferric iron),<sup>210</sup> which competes with siderophilic bacteria and fungi for ferric iron<sup>211-215</sup> and thus disrupts the proliferation of these microbial pathogens. The epithelial growth-promoting activities of lactoferrin in human milk also may aid in the defense of the recipient infant.<sup>216</sup> The mean concentration of lactoferrin in human colostrum is between 5 and 6 mg/mL.<sup>217</sup> As the volume of milk production increases, the concentration falls to about 1 mg/mL at 2 to 3 months of lactation.<sup>218,219</sup>

Because of its resistance to proteolysis,<sup>220-222</sup> the excretion of lactoferrin in stool is higher in human milk-fed than in cow's milk-fed infants.<sup>72,223-225</sup> The mean intake of milk lactoferrin per day in healthy breast-fed, full-term infants is about 260 mg/kg at 1 month of lactation and 125 mg/kg by 4 months.<sup>223</sup> The quantity of lactoferrin excreted in the stools of low-birth-weight infants fed human milk is approximately 185 times that in stools of infants fed a cow's milk formula.<sup>226</sup> That estimate, however, may be too high because of the presence of immunoreactive fragments of lactoferrin in the stools of human milk-fed infants.<sup>227</sup>

In addition, a significant increment in the urinary excretion of intact and fragmented lactoferrin occurs as a result of human milk feedings.<sup>227-229</sup> Recent stable isotope studies suggest that the increments in urinary lactoferrin and its fragments are principally from ingested human milk lactoferrin.<sup>230</sup>

**Lysozyme.** Relatively high concentrations of lysozyme single-chain protein are present in human milk.<sup>218,219,231-235</sup> This 15-kDa agent lyses susceptible bacteria by hydrolyzing  $\beta$ -1,4 linkages between *N*-acetylmuramic acid and 2-acetylamino-2-deoxy-D-glucose residues in cell walls.<sup>236</sup> Lysozyme is relatively resistant to digestion by trypsin or denaturation due to acid. The mean concentration of lysozyme is about 70  $\mu$ g/mL in colostrum,<sup>218</sup> about 20  $\mu$ g/mL at 1 month of lactation, and 250  $\mu$ g/mL by 6 months.<sup>219</sup> The approximate mean daily intake of milk lysozyme in healthy, full-term, completely breast-fed infants is 3 to 4 mg/kg at 1 month of lactation and 6 mg/kg by 4 months.<sup>223</sup>

Few studies have been conducted to examine the fate of human milk lysozyme ingested by the infant. The amount of lysozyme excreted in the stools of low-birth-weight infants fed human milk is approximately eight times that found in the stools of infants fed a cow's milk formula,<sup>226</sup> but the urinary excretion of this protein does not increase as a result of human milk feedings.

**Fibronectin.** Fibronectin, a high-molecular-weight protein that facilitates the uptake of many types of particulates by mononuclear phagocytic cells, is present in human milk (mean concentration in colostrum, 13.4 mg/L).<sup>237</sup> The in vivo effects and fate of this broad-spectrum opsonin in human milk are not known.

**Complement Components.** The components of the classical and alternative pathways of complement are present in

human milk, but the concentrations of these components, except C3, are exceptionally low.<sup>163,164</sup>

#### ANTI-INFLAMMATORY AGENTS

Although a direct anti-inflammatory effect of human milk has not been demonstrated in vivo, a number of clinical observations suggest that breast-feeding protects the recipient infant from injury to the intestinal or respiratory mucosa.<sup>238,239</sup> This protection may be due in part to the more rapid elimination or neutralization of microbial pathogens in the lumen of the gastrointestinal tract by specific or broad-spectrum defense agents from human milk, but other features of human milk suggest that this is not the sole explanation. Phlogistic agents and the systems that give rise to them are poorly represented in human milk.<sup>240</sup> By contrast, human milk contains a host of anti-inflammatory agents,<sup>241</sup> including a heterogeneous group of growth factors with cytoprotective and trophic activity for the mucosal epithelium, antioxidants, antiproteases, cytokines and cytokine receptors and antagonists, and other bioactive agents that inhibit inflammatory mediators or block the selected activation of leukocytes. Like the antimicrobial factors, some of these factors are well adapted to operate in the hostile environment of the recipient's alimentary tract.

Growth factors in human milk include EGF,<sup>169,242</sup> the transforming growth factors TGF- $\alpha$ <sup>243</sup> and TGF- $\beta$ ,<sup>244</sup> lactoferrin,<sup>216</sup> mammary gland-derived growth factor,<sup>245</sup> and polyamines.<sup>246,247</sup> These and a host of hormones,<sup>248</sup> including insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), growth hormone-releasing factor (GHF), hepatocyte growth factor (HGF), prolactin, leptin, and cortisol,<sup>249</sup> may affect the growth and maturation of epithelial barriers, limit the penetration of pathogenic microorganisms and free antigens, and prevent allergic sensitization. Corticosterone, a glucocorticoid that is present in high concentrations in rat milk, speeds gut closure in the neonatal rat.<sup>250</sup> Although macromolecular absorption does not appear to be as marked in the human neonate,<sup>251-253</sup> the function of the mucosal barrier system in early infancy is important to host defense, and this system may be affected by factors in human milk. In this regard, the maturation of the intestinal tract as measured by mucosal mass, DNA, and protein content of the small intestinal tract appears to be influenced by milk, particularly early milk secretions.<sup>254</sup>

Antioxidant activity in colostrum has been shown to be associated with an ascorbate compound and uric acid.<sup>255</sup> In addition, two other antioxidants present in human milk,  $\alpha$ -tocopherol<sup>256,257</sup> and  $\beta$ -carotene,<sup>257</sup> are absorbed into the circulation by the recipient gastrointestinal mucosa. Serum vitamin E concentrations rise in breast-fed infants from a mean of 0.3 mg/mL at birth to approximately 0.9 mg/mL on the fourth day of life.<sup>256</sup>

The pleiotropic cytokine IL-10, a potent suppresser of macrophage, T cell, and NK cell function, has been demonstrated at very high concentrations in samples of human milk collected during the first 80 hours of lactation.<sup>258</sup> IL-10 is present not only in the aqueous phase of the milk but also in the lipid layer. Its bioactive properties were confirmed by the finding that human milk samples inhibited blood lymphocyte proliferation and that this property was greatly reduced by treatment with anti-IL-10 antibody. Of interest, mice with a targeted disruption in the IL-10 gene, when

raised under conventional housing conditions, spontaneously develop a generalized enterocolitis that becomes apparent at the age of 4 to 8 weeks (time of weaning).<sup>259</sup> These observations suggest that IL-10 in human milk may play a critical role in the homeostasis of the immature intestinal barrier by regulating aberrant immune responses to foreign antigens. Soluble receptors and cytokine receptor antagonists also are potent anti-inflammatory agents. Human colostrum and mature milk have been shown to contain biologically active levels of IL-1 receptor antagonist (IL-1Ra) and soluble TNF- $\alpha$  receptors I and II (sTNF- $\alpha$ RI and sTNF- $\alpha$ RII).<sup>260</sup> The in vivo relevance of these observations also has been confirmed in a chemically induced colitis model of rats. Animals with colitis fed human milk had significantly lower neutrophilic inflammation than animals fed either chow or infant formula.<sup>261</sup> Similar “protective” effects were seen in rats with colitis fed an infant formula supplemented with IL-1Ra,<sup>261</sup> suggesting that this anti-inflammatory agent present in milk may contribute to the broad protection against different injuries provided by human milk feeding.

The presence in human milk of platelet-activating factor acetylhydrolase (PAF-AH), the enzyme that catalyzes the degradation and inactivation of PAF, is intriguing.<sup>262</sup> Indeed, elevated serum concentrations of PAF have been found in rat and human neonates with necrotizing enterocolitis (NEC), whereas the concentrations of PAF-AH were found to be significantly lower than in control (unaffected) neonates.<sup>263,264</sup> It also is of interest that serum concentrations of PAF-AH at birth are below those in adults and then gradually rise.<sup>265</sup> The enzyme is actively transferred from the mucosal to the serosal fluid in intestine of neonatal rats, particularly in the earliest postnatal period.<sup>266</sup> Other anti-inflammatory factors present in human milk include an IgE-binding factor, related antigenically to the Fc $\epsilon$ RII (the lower-affinity receptor for IgE), that suppresses the in vitro synthesis of human IgE,<sup>267</sup> and the glycoposphoinositol-containing molecule protectin (CD59) that inhibits insertion of the complement membrane attack complex (MAC) to cell targets.<sup>268</sup> The in vivo fate and effects of these anti-inflammatory factors in human milk are still poorly understood.

#### MODULATORS OF THE IMMUNE SYSTEM

Several seemingly unrelated types of observations suggest that breast-feeding modulates the development of the immune system of the recipient infant:

- Both prospective and retrospective epidemiologic studies have shown that breast-fed infants are at less risk for development of certain chronic immunologically mediated disorders later in childhood, including allergic diseases,<sup>269</sup> Crohn's disease,<sup>270</sup> ulcerative colitis,<sup>271</sup> insulin-dependent diabetes mellitus,<sup>272</sup> and some lymphomas.<sup>273</sup>
- Humoral and cellular immune responses to specific antigens (i.e., vaccines) given during the first year of life appear to develop differently in breast-fed and in formula-fed infants. Several studies have reported increased serum antibody titers to *H. influenzae* type b polysaccharide,<sup>274</sup> oral poliovirus,<sup>275</sup> tetanus,<sup>276</sup> and diphtheria toxoid<sup>277</sup> immunizations in breast-fed infants. In regard to cell-mediated immunity, breast-

fed infants given bacille Calmette-Guérin (BCG) vaccine either at birth or later show a significantly higher lymphocyte transformation response to purified protein derivative (PPD) than that in infants who were never breast-fed.<sup>277</sup> Moreover, maternal renal allografts survive better in persons who were breast-fed than in those who were not.<sup>278-280</sup> In this respect, the in vitro allogeneic responses between the blood lymphocytes of mothers (stimulating cells) and their infants (responding cells), as measured by an analysis of the frequencies of cytotoxic T lymphocyte (CTL) precursors directed against HLA alloantigens (CTL allorepertoire), are low in breast-fed infants.<sup>281</sup>

- Increased levels of certain immune factors in breast-fed infants, which could not be explained simply by passive transfer of those substances, also suggest an immunomodulatory activity of human milk. Breast-fed infants produce higher blood levels of interferon in response to respiratory syncytial virus infection.<sup>282</sup> It also was found that the increments in blood levels of fibronectin that were achieved by breast-feeding could not be due to the amounts of that protein in human milk.<sup>237</sup> In addition, it was found that human milk feeding led to a more rapid development in the appearance of sIgA in external secretions,<sup>226,228,229,276,283</sup> some of which, such as urine, are far removed anatomically from the route of ingestion.<sup>228,229</sup>

These and other observations suggest that the ability of human milk to modulate the development of the infant's own mucosal and systemic immune systems may be associated with immunoregulatory factors present in colostrum and in more mature milk. Several different types of immunomodulatory agents can be identified in human milk.<sup>241</sup> Among the numerous substances with proven or potential ability to modulate the infant immune response are prolactin,<sup>284</sup>  $\alpha$ -tocopherol,<sup>256</sup> lactoferrin,<sup>285</sup> nucleotides,<sup>67</sup> anti-idiotypic sIgA,<sup>286</sup> and cytokines.<sup>287</sup> It is evident that many of these factors in milk have other primary biologic functions, as in the case of hormones or growth factors, and that their potential as immune regulatory agents overlaps with their antimicrobial or anti-inflammatory properties.<sup>241</sup>

**Cytokines in Human Milk.** In the 1990s, several cytokines, chemokines, and growth factors that mediate the effector phases of natural and specific immunity were discovered in human milk. These include IL-1 $\beta$ , IL-6, IL-7, IL-10, IL-12, IL-8, growth-related peptide- $\alpha$  (GRO- $\alpha$ ), monocyte chemoattractant protein-1 (MCP-1), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), and TGF- $\beta$  (Table 5-8). Human milk displays a number of cytokine-characteristic biologic activities, including the stimulation of growth, differentiation of immunoglobulin production by B cells,<sup>288-290</sup> enhancement of thymocyte proliferation,<sup>291</sup> inhibition of IL-2 production by T cells,<sup>292</sup> and suppression of IgE production.<sup>267</sup> IL-1 $\beta$ <sup>293</sup> and TNF- $\alpha$ <sup>294</sup> were the first two cytokines quantified in human milk. In colostrum, TNF- $\alpha$  is present mainly in fractions of molecular weight between 80 and 195 kDa, probably bound to its soluble receptors.<sup>260</sup> Milk TNF- $\alpha$  is secreted both by milk macrophages<sup>294,295</sup> and by the mammary epithelium.<sup>296</sup> IL-6 was first demonstrated in human milk by a specific bioassay.<sup>297</sup> In this study, anti-IL-6-neutralizing antibodies

**Table 5-8 Cytokines, Chemokines, and Colony-Stimulating Factors in Human Milk**

Cytokines	Chemokines	Colony-Stimulating Factors
IL-1 $\beta$	IL-8	G-CSF
IL-6	GRO- $\alpha$	M-CSF
IL-7		
IL-8		
IL-10	MCP-1	GM-CSF
IL-16 <sup>a</sup>		TGF- $\beta$
IFN- $\gamma$	RANTES	
TNF- $\alpha$	Eotaxin <sup>a</sup>	

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GRO- $\alpha$ , growth-related peptide- $\alpha$ ; IL, interleukin; MCP-1, monocyte chemoattractant protein-1; M-CSF, monocyte colony-stimulating factor; RANTES, regulated upon activation, normal T cell expressed and secreted; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ .

inhibited IgA production by colostrum mononuclear cells, suggesting that IL-6 may be involved in the production of IgA in the mammary gland. The presence of IL-6 in milk also has been demonstrated by immunoassays.<sup>294,296,298,299</sup> In like manner, IL-6 is localized in high-molecular-weight fractions of human milk.<sup>298</sup> The association of IL-6 with its own receptor has not been studied in milk, although the expression of IL-6 receptor by the mammary epithelium<sup>296</sup> and in secreted form in the milk<sup>260</sup> may explain the high molecular weight of this cytokine in human milk. The expression of IL-6 messenger ribonucleic acid (mRNA) and protein in milk cells and in the mammary gland epithelium suggests that both milk mononuclear cells and the mammary gland are likely major sources of this cytokine.<sup>295,296,300</sup> The presence of IFN- $\gamma$  in human milk also has been reported,<sup>151,296,299</sup> although some investigators have found significant levels of IFN- $\gamma$  only in milk samples obtained from mothers whose infants had been delivered by cesarean section. The significance of this observation is not clear at present. IFN- $\gamma$  bioactivity as well as its association with specific subsets of milk T cells also remains to be determined.<sup>151</sup> (The presence and possible function of IL-10 in human milk are discussed in the section "Anti-inflammatory Agents.")

Chemokines are a novel class of small cytokines with discrete target cell selectivity that are able to recruit and activate different populations of leukocytes.<sup>301</sup> Two major subfamilies, the CXC and the CC chemokines, are defined by the splicing of the conserved cysteine residues, which are separated by either one amino acid (CXC chemokines) or adjacent amino acids (CC chemokines). IL-8 and GRO- $\alpha$  belong to the CXC family and are mainly chemotactic factors for neutrophils. On the other hand, CC chemokines, which include MCP-1, macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ), and RANTES (regulated upon activation, normal T cell expressed and secreted), are chemotactic factors for monocytes, basophils and eosinophils, and T lymphocytes.<sup>302</sup> The presence of both CXC and CC chemokines has been described in human milk (see Table 5-8).

IL-8 concentration was first determined in a small group of milk samples by Basolo and colleagues.<sup>296</sup> These investigators identified the expression and secretion of IL-8 by mammary epithelial cells, although milk cells also appear to produce this chemokine.<sup>295,300</sup> Another member of the CXC chemokine found in human milk is GRO- $\alpha$ , along with the two CC chemokines MCP-1 and RANTES.<sup>300</sup> Expression of MCP-1 and, to a lesser extent, RANTES mRNA was confirmed in studies of milk cells.<sup>300</sup> Recently, high levels of the CC chemokine eotaxin, a potent and specific chemotactic factor for eosinophils and subtype 2 helper T cells (T<sub>H2</sub>), also have been demonstrated in human milk.<sup>303</sup>

Colony-stimulating factors—highly specific protein factors that regulate cell proliferation and differentiation in the process of hematopoiesis—were discovered relatively recently in human milk. Although colony-stimulating activity was demonstrated in milk in 1983,<sup>304</sup> G-CSF, M-CSF, and granulocyte-macrophage colony-stimulating factor (GM-CSF) were not specifically identified and measured in human milk until the 1990s.<sup>151,305-307</sup> The concentrations of M-CSF in particular appear to be 10- to 100-fold those in serum, and M-CSF evidently is produced by epithelial cells of the ducts and alveoli of the mammary gland under the regulatory activity of female sex hormones.<sup>306</sup>

Although it is tempting to speculate that cytokines present in milk may be able to interact with mucosal tissues in the respiratory and alimentary tracts of the recipient infant, the functional expression of specific receptors for cytokines on epithelial or lymphoid cells in the airway and gastrointestinal mucosa has not been fully explored.<sup>241</sup> A receptor-independent mechanism of cytokine uptake by the gastrointestinal mucosa during the neonatal period has not been demonstrated to date.

### **Milk and Altered Pregnancy**

Several investigators have examined the effects of prematurity, early weaning, galactorrhea, and maternal malnutrition on the process of lactation. The immunologic aspects of these studies have focused largely on evaluation of the total content of sIgA and specific antibody activity. As described previously, the mammary secretions of nonlactating breast contain sIgA, although the amount appears to be much lower than in the lactating breast.<sup>308</sup> Mammary secretions of patients with galactorrhea appear to contain sIgA in concentrations similar to those of normal postpartum colostrum.<sup>309</sup> Although malnutrition has been associated with reduced secretory antibody response in other external secretions, maternal malnutrition does not seem to affect the total sIgA concentration or antimicrobial-specific antibody activity in the milk.<sup>310</sup>

The nutritional as well as immunologic composition of milk from mothers of premature infants appears to be significantly different from that of milk from mothers of infants born at term.<sup>14,219,311,312</sup> Comparative studies conducted during the first 12 weeks of lactation suggest that the mean concentrations of lactoferrin and lysozyme are higher in preterm than in term milk. Secretory IgA is the predominant immunoglobulin in preterm as well as in term milk, although the sIgA concentration appears to be significantly higher in preterm milk collected during the first 8 to 12 weeks of lactation. Secretory IgA antibody activity against certain organisms (*E. coli* somatic antigen) in the

preterm milk was observed to be somewhat less than, or at best similar to, that found in term milk. In addition, the number of lymphocytes and macrophages in milk appears to be lower at 2 weeks but significantly higher at 12 weeks in milk from mothers with preterm (born at 34 to 38 weeks of gestational age) infants than in milk from those with full-term infants.<sup>311</sup> The authors of these investigations have proposed that some of the observed changes may reflect the lower volume of milk produced by mothers delivered of preterm infants. The possibility remains that changes in the immunologic profile of preterm milk may be a consequence of inadequate stimulation by the preterm infant, alterations in the maternal hormonal milieu, or other factors underlying premature delivery itself.

## BENEFITS AND RISKS OF HUMAN MILK

### Benefits

#### *Gastrointestinal Homeostasis and Prevention of Diarrhea*

Development of mucosal integrity in the gut appears to depend on maturation of the mucosal tissue itself and the establishment of a normal gut flora. The former represents an anatomic and enzymatic blockage to invasion of microorganisms and antigens, and the latter, an inhibition of colonization by pathogenic bacteria. Although permeability of the neonatal gut to immunoglobulin is rather short-lived or incompletely developed, unprotected or damaged neonatal gut is permeable to a host of other proteins and macromolecules for several weeks or longer. Large milk protein peptides and bovine serum albumin have been shown to enter the circulation and produce a circulating antibody response. The inflamed or ischemic gut is even more porous to both antigens and pathogens. A variety of proven and presumed mechanisms for the role of both IgA and the normal flora have been proposed to compensate for these temporary inadequacies. Evidence for gut-trophic substances in humans is still preliminary. Ample epidemiologic evidence exists for a positive effect of breast-feeding in establishing the normal gut flora. Most compelling are the observations in rural Guatemala of gross contamination of milk by potentially pathogenic aerobic, gram-negative bacilli, including *E. coli* and *Shigella* species, with an absence both of diarrheal illness and of significant numbers of these organisms in the feces of infants during the period of lactation. In addition, the diverse serotypes of aerobic, gram-negative bacilli present in the oropharynx and the gastrointestinal tract of the neonate may serve as a source of antigen to boost the presensitized mammary glands, leading to a further modulation of specific bacterial growth in the mucosa.<sup>313</sup> The precise role of antibody that blocks adherence of these pathogens to the gut and the effects of other factors, such as lactoperoxidase, lactoferrin, lysozyme, and *Bifidobacterium bifidum*, in those situations are undetermined.

Extensive epidemiologic evidence supports the "prophylactic value" of breast-feeding in the prevention or amelioration of diarrheal disease and is summarized in several reviews.<sup>22,82,314,315</sup> Ample experimental animal data on the value of specific colostral antibody in preventing diarrheal illness are available from studies of colostral deprivation.

These include colibacteriosis associated with *E. coli* K88 in swine; rotaviral gastroenteritis in cattle, swine, and sheep; and diarrheal illness associated with transmissible gastroenteritis of swine.<sup>316</sup> In humans, cholera is rare in infancy, especially in endemic areas where the prevalence of breast-feeding is high. The experience with an outbreak of cholera in the Persian Gulf lends support to the possibility that the absence of breast-feeding is an important variable in increasing the risk of cholera in infancy.

A few reports have claimed that nursery outbreaks of diarrhea associated with enteropathogenic strains of *E. coli* can be interrupted by use of breast milk. Conflicting data exist regarding prevention of human rotaviral infection and disease. Evaluation of nursery outbreaks of rotaviral disease has suggested that the incidence both of infection and of illness was lower in breast-fed infants, but the incidence of symptoms in formula-fed infants also was very low. Studies carried out in Japan have noted a fivefold decrease in incidence of rotaviral infection among breast-fed infants younger than 6 months of age. It must be emphasized that most rotavirus infections in neonates are asymptomatic, regardless of breast- or bottle-feeding.<sup>317-321</sup> On the basis of careful clinical observations, Bishop and co-workers<sup>322</sup> in Australia first questioned the positive effects of breast-feeding in rotavirus infection. More recent case-control studies of enteric viral infections in breast-fed infants have suggested that breast-feeding may protect infants from hospitalization rather than from infection itself.<sup>323,324</sup> Longitudinal follow-up of a large cohort of infants during a community outbreak of rotavirus has shown that attack rates of rotavirus infection were similar in breast-fed and in bottle-fed infants. The frequency of clinical disease with diarrhea, however, appeared to be significantly lower in breast-fed infants. Of interest, the protection observed in these patients was more a reflection of altered microbial flora from breast-feeding than of specific immunologic protection against rotavirus. Thus, it appears that breast-feeding provides significant protection against diarrheal disease, although the mechanism of such protection remains to be defined.<sup>323,324</sup>

#### *Necrotizing Enterocolitis*

NEC is a complex illness of the stressed premature infant, often associated with hypoxia, gut mucosal ischemia, and necrolysis and death.<sup>325,326</sup> Clinical manifestations have, on a few occasions, been associated with bacteremia and invasion by gram-negative bacilli, particularly *Klebsiella pneumoniae*, into the intestinal submucosa. Clinical manifestations include abdominal distention, gastric retention, and bloody diarrhea. Classic radiographic findings include air in the bowel wall (pneumatosis intestinalis), air in the portal system, and free infradiaphragmatic air (signifying perforation). Treatment involves decompression, systemic antibiotics, and, often, surgery.<sup>327-329</sup>

A number of studies have suggested a beneficial role of breast milk in preventing or modifying the development of NEC in high-risk human infants. Some pediatric centers have claimed virtual absence of NEC in breast-fed infants; however, many instances of the failure of milk feeding to prevent human NEC also have been reported. In fact, outbreaks of NEC related to *Klebsiella* and *Salmonella* species secondary to banked human milk feedings have been docu-

mented.<sup>127,330,331</sup> In an asphyxiated neonatal rat model of NEC, the entire syndrome could be prevented with feeding of maternal milk. The crucial factor in the milk appeared to be the cells, probably the macrophages.<sup>127</sup> It also is possible that antibody and nonspecific factors play a role, as does establishment of a gut flora. Prophylactic oral administration of immunoglobulin has been found to have a profound influence on the outcome of NEC in well-controlled studies.<sup>331</sup> Penetration of the gut by pathogens and antigens is increased with ischemic damage, and noncellular elements of milk may aid in blockage of this transit.<sup>332</sup>

The role of enteric anaerobic organisms has been seriously considered in the pathogenesis of NEC. Cytolytic toxins of *Clostridium difficile* and other clostridial species have been demonstrated in infants with NEC, often significantly more frequently than in normal infants.<sup>333-336</sup>

Clearly, NEC is a complex disease entity whose pathogenesis and cause remain to be defined. Although breast-feeding may be protective, a number of other factors are clearly related to the mechanism of mucosal injury and the pathogenesis of this syndrome.

### Neonatal Sepsis

The incidence of bacteremia among premature infants fed breast milk has been suggested to be significantly lower than that among those receiving formula feedings or no feeding.<sup>337-339</sup> It has been shown that a high percentage of cases of neonatal bacteremia and meningitis caused by gram-negative bacilli are associated with the *E. coli* K1 serotype. Both antibody and compartmentalized cellular reactivity to this serotype have been demonstrated in human colostrum. High colostrum antibody titers are associated most often with the colonization by the organism in the maternal gut. Other studies have, however, failed to demonstrate clear evidence of protection against systemic infection in breast-fed infants.<sup>340-342</sup>

### Prevention of Atopy and Asthma

One of the most challenging developments in human milk research has been the demonstration in breast-fed infants of a reduced incidence of diseases with auto- or dysregulated immunity, long after the termination of breast-feeding.<sup>269-273</sup> Since the first report in 1936,<sup>343</sup> numerous published studies have addressed the effect of infant feeding on the development of atopic disease and asthma. Beneficial results of breast-feeding as prophylaxis against atopy have been observed in most of the studies; in others, however, beneficial effects were reported only in infants with a genetically determined risk for atopic disease. Finally, no beneficial effect at all or even an increased risk has been suggested in some breast-fed infants. Kramer, in an extensive meta-analysis of 50 studies published before 1986 that focused on infant feeding and atopic disease, has attempted to shed some light on the controversy.<sup>344</sup> Seven of the 13 studies on asthma included in this analysis claimed a protective effect of breast-feeding, whereas 6 claimed no protection. Several serious methodologic drawbacks, however, have been noted in this analysis. In a number of the studies analyzed, early infant feeding history was obtained months or years after the feeding period, ascertainment of the infant feeding history was obtained by interviewers who were aware of the disease outcome, or insufficient duration

and exclusivity of breast-feeding were documented; all were confounding variables that considered inappropriate "exposure standards." Nonblind ascertainment of disease outcome was found to be the most common violation of the "outcome standards."

Kramer's analysis also found that failure to control for confounding variables was a common violation in "statistical analysis standards" identified in several studies. Indeed, the effect of infant feeding on subsequent asthma may be confounded by other variables that are associated both with infant feeding and with unique investigational conditions. Factors that seem to have the greatest potential for confounding effects include the family history of atopic disease, socioeconomic status, and parental cigarette smoking. Only 1 of 13 studies on asthma included in the meta-analysis adequately controlled for these confounding factors. Moreover, 3 of the studies that did not demonstrate a protective effect of breast-feeding on asthma had inadequate statistical power. The effect of infant feeding on the severity of outcome and on the age at onset of the disease was virtually ignored in most of the studies.<sup>344</sup>

Although this extensive meta-analysis may suggest some uncertainty about the prophylactic benefit of breast-feeding, two recent studies strongly support a positive effect of breast-feeding on the development of atopic disease and asthma. The first study<sup>269</sup> consisted of prospective, long-term evaluation from infancy until the age of 17 years; the prevalence of atopy was significantly higher in those infants with short-duration (less than 1 month) or no breast-feeding, which increased to a demonstrable difference by the age of 17 years, than in the infants with intermediate-duration (1 to 6 months) or prolonged (longer than 6 months) breast-feeding. The differences in the prevalence of atopy persisted when the groups were divided according to positive or negative atopic heredity. Furthermore, the atopy manifestations in the different infant feeding groups did not remain constant with age. In particular, respiratory allergy, including asthma, increased greatly in prevalence up to the age of 17 years, with a prevalence as high as 64% in the group with short-duration or no breast-feeding.<sup>269</sup> In the second study, a prospective, longitudinal study of the prevalence and risk factors for acute and chronic respiratory illness in childhood, the investigators examined the relationship of infant feeding to recurrent wheezing at age 6 years and the association with lower respiratory tract illnesses associated with wheezing early in life.<sup>345</sup> Children who were never breast-fed had significantly higher rates of recurrent wheezing at 6 years of age. Increasing duration of breast-feeding beyond 1 month was not associated with significantly lower rates of recurrent wheezing. The effect of breast-feeding was apparent for children both with and without wheezing lower respiratory tract illnesses in the first 6 months of life. In contrast with the findings of the first study, however, the effect of breast-feeding was significant only among nonatopic children.<sup>345</sup>

The exact mechanisms by which breast-feeding seems to confer long-lasting protection against allergic sensitization are poorly understood. It is likely, however, that multiple synergistic mechanisms may be responsible for this effect, including (1) maturation of the recipient gastrointestinal and airway mucosa, promoted by growth factors present in human milk<sup>242-244</sup>; (2) inhibition of antigen absorption by

milk sIgA<sup>346</sup>; (3) reduced incidence of mucosal infections and consequent sensitization to bystander antigens<sup>347</sup>; (4) changes in the microbial flora of the intestine of breast-fed infants<sup>325</sup>; and (5) direct immunomodulatory activity of human milk components on the recipient infant.<sup>241</sup> A number of earlier and more recent studies have greatly contributed to the understanding of macromolecular transport across the immature gut and its consequences in terms of the generation of circulating antibody or immune complexes, the processes that are blocked predominantly by sIgA, the glycocalyx, and the intestinal enzymes. These mucosal immunologic events have been the basis for the concept of immune exclusion. Immune exclusion is not absolute, however, because uptake of some antigens across the gut may be enhanced rather than blocked by interaction with antibody at the mucosal surface. Beginning with the observations of IgA-deficient patients, it has become clear that the absence of the IgA barrier in the gut is associated with both an increased incidence of circulating antibodies directed against many food antigens and an increased occurrence of atopic-allergic diseases.<sup>346</sup> Some studies have noted complement activation in serum after feeding of bovine milk to children with cow's milk allergy. The neonate is similar in some respects to the IgA-deficient patient,<sup>348</sup> and increased trans-intestinal uptake of food antigen with consequent circulating antibody formation in the premature infant has been reported.<sup>349</sup> Other studies have suggested that early breast-feeding, even of short duration, is associated with a decreased serum antibody response to cow's milk proteins.<sup>253</sup> Prolonged breast-feeding not only may partially exclude foreign antigens through immune exclusion but may also, because the mother's milk is the infant's sole food, prevent their ingestion.<sup>350</sup> It must, however, be emphasized that intact bovine milk proteins and other food antigens and antibodies have been observed in samples of colostrum and milk.<sup>6</sup>

### Other Benefits

As described previously, epidemiologic evidence suggests that bacterial and viral respiratory infections are less frequent and less severe among breast-fed infants in a variety of cultures and socioeconomic settings. Antibodies and immunologic reactivity directed against herpes simplex virus, respiratory syncytial virus, and other infectious agents<sup>86,95,118,351,352</sup> have been quantitated in colostrum and milk. Adoptive experiments in suckling ferrets have shown that protection of the young against respiratory syncytial virus can be transferred in colostrum containing specific antibody. The neonatal ferret gut, however, is quite permeable to macromolecules and permits passage of large quantities of virus-specific IgG. In the absence of either documented antibody or cellular transfer in the human neonate across the mucosa, any mechanisms of protection against respiratory syncytial virus and other respiratory pathogens remain obscure.

Data are lacking in humans regarding passive protection on other mucosal surfaces, such as the eye, ear, or genitourinary tract. Some epidemiologic evidence suggests that recurrence of otitis media with effusion is strongly associated with early bottle-feeding and that breast-feeding may confer protection against otitis media with effusion for the first 3 years of life.<sup>353</sup> Foster feeding-acquired antibody to herpes simplex virus has been found to result in

significant protection against reinfection challenge in experimental animal studies.<sup>351</sup>

A number of other benefits have been associated with breast-feeding, including natural contraception during active nursing<sup>354</sup> and protection against sudden infant death syndrome,<sup>355</sup> diabetes,<sup>356</sup> obesity,<sup>357</sup> and high cholesterol level and ischemic heart disease later in life.<sup>42</sup> Of particular recent interest has been the association of breast-feeding with improved intellectual performance in older children. Several studies have demonstrated enhanced cognitive outcome in breast-fed children, although controversy exists regarding the mechanisms by which such improved performance may occur.<sup>358-360</sup> Health benefits for the mother also may be associated with breast-feeding: A reduced incidence of breast cancer has been noted in women who have lactated.<sup>361</sup>

## Potential Risks

### Noninfectious Risks

Several potentially harmful effects have been associated with breast-feeding. Some provocative data suggest that non-autologous human milk may, under certain conditions, be nutritionally inadequate for the premature infant.<sup>22,23</sup> The concentration of anti-Rhesus factor (anti-Rh) antibodies in milk appears to be too low to pose any threat to the incompatible neonate. Variable concentrations of medicinal products and their metabolites are excreted in colostrum and milk (Table 5-9). Environmental contaminants such as dichlorodiphenyl trichloroethane (DDT), polychlorinated biphenyls (PCBs), and mercury have been demonstrated in high concentrations in human milk.<sup>22,362</sup>

The failure to initiate lactation properly during early breast-feeding may present a risk of dehydration to the infant, because insufficient fluids may be ingested. Inappropriate introduction of bottles and pacifiers also may interfere with proper induction of lactation. Later in lactation, introduction of bottles may induce premature weaning as the result of a reduction in the milk supply.

Although human milk is the optimal form of nutrition for most healthy term infants, some circumstances have been identified in which breast-feeding is contraindicated and some in which continued breast-feeding should be conducted with caution to protect the infant. Infants with inherited metabolic diseases may be best nourished by treatment with alternative forms of nutrition. In particular, neonates with diagnosed galactosemia need to have galactose removed from their diet; in other words, they need to be switched to a milk containing lactose-free carbohydrate (because lactose is a glucose-galactose disaccharide). Infants diagnosed with phenylketonuria may receive some human milk to support their requirement for phenylalanine but often may be better managed by use of specially prepared commercial milks.

Management of hyperbilirubinemia associated with breast-feeding, so-called breast milk jaundice, has been an area of some controversy. The mechanism responsible for this form of jaundice is unknown but has been suggested to reflect inhibitors of glucuronidation, deficiency of related enzymes, excessive lipid breakdown, and insufficient milk intake.<sup>363,364</sup> Recent recommendations suggest that a more laissez-faire approach to this problem is appropriate.<sup>365</sup> Increasing milk

**Table 5-9 Drugs in Maternal Circulation Known to Pose Potential Health Problems for the Breast-Feeding Infant**

Drugs	Drugs	Environmental Contaminants
Anticoagulants	Autonomic drugs	Dichlorodiphenyl trichloroethane (DDT)
Ethyl biscoumacetate	Atropine	Polybromated biphenyls (PBBs)
Phenindione	Laxatives	Polychlorinated biphenyls (PCBs)
Anticonvulsants	Anthraquinone derivatives	Heptachlor
Mysoline	(Dialose Plus, Dorbane, Doxidon,	Mirex
Phenobarbital	Peri-Colace)	Lead
Phenytoin (diphenylhydantoin)	Aloe	Radioisotopes
Carbamazepine	Calomel	Caffeine
Antidepressants	Cascara	Food proteins
Lithium	Narcotics	Nicotine
Antihypertensives	Heroin	Cadmium
Reserpine	Methadone	Alcohol
Antimetabolites	Oral contraceptives	
Cyclophosphamide	Pain killers	
Methotrexate	Propoxyphene (Darvon)	
Antimicrobials	Sedatives	
Chloramphenicol	Barbiturates	
(Chloromycetin)	Bromides	
Metronidazole (Flagyl)	Chloral hydrate	
Tinidazole	Diazepam (Valium)	
Nalidixic acid	Steroids	
Nitrofurantoin <sup>a</sup>	Prednisone	
Sulfonamides <sup>a</sup>	Prednisolone	
Antithyroid drugs	Miscellaneous	
Iodide	Dihydrotachysterol (DHT)	
Thiouracil	Ergot alkaloids	
Radioactive iodine	Gold thioglucose	

<sup>a</sup>This drug causes problems mainly in infants suffering from the inherited deficiency of glucose-6-phosphate dehydrogenase.

volume by increasing the number of feedings may be the most appropriate approach to breast milk jaundice; however, severe cases may necessitate phototherapy. Increased intake of fluids in breast-feeding infants appears to be effective in many cases.<sup>366</sup>

Several instances of specific nutrient deficiencies in breast-fed infants have been described, specifically related to lack of vitamin K, vitamin D, vitamin B<sub>12</sub>, folic acid, vitamin C, and carnitine. In each of these instances, several case reports have appeared warning against deficiencies that have resulted in clinical consequences to the neonate. For example, hemorrhagic disease reported in a few breast-fed infants was successfully treated with vitamin K.<sup>367</sup> These infants did not receive vitamin K at birth. Mothers who practice unusual dietary habits, such as strict vegetarianism, may have reduced levels of vitamin B<sub>12</sub> and folic acid in their milk, and deficiencies in breast-fed infants of such mothers have been reported.<sup>368,369</sup> Cases of rickets in breast-fed infants have been reported, particularly during winter among infants not exposed to the sun.<sup>32,370</sup> Deficiency of carnitine, a nutrient responsible for modulating fat absorption, also has been reported to result in clinical symptoms in breast-fed infants in mothers ingesting unusual diets.<sup>61,371</sup>

These various clinical expressions of nutrient deficiency in milk are of concern, but they also should be put in the context of nutrient deficiencies observed in formula-fed infants. Clearly, millions of infants in developing countries are at severe risk of malnutrition when they are formula-fed because of the economic stress of supplying sufficient

formula. Even in developed countries, large numbers of nutrient deficiencies and associated clinical symptoms have occurred as a result of accidents in the manufacture of formulas.<sup>372</sup> The most notable of these accidents have taught us the effects of early vitamin B<sub>6</sub> deficiency, folic acid deficiency, and chloride deficiency. Formula feeding also has been associated with an increased incidence of diabetes.<sup>373</sup>

Thus, some situations arise in which breast-feeding must be carefully considered as an appropriate feeding modality for the infant. Commercial formulas also represent risks, however. The infant is best served by observant pediatricians and mothers who promptly respond to any clinical signs in the neonate.

### **Infectious Risks**

The presence of microbial contamination in milk is of serious concern. Contaminated milk has been implicated in neonatal infection with *S. aureus*, group B hemolytic streptococci, mycobacteria, and, possibly, *Salmonella* species (Table 5-10). Mastitis and breast abscess have been associated with the presence of bacterial pathogens in human milk. Such inflammation of the breast will often resolve even with continued breast-feeding. Resolution of the inflammation may be related to the presence of antisecretory factor (AF), a factor induced in the milk by enterotoxin-producing bacteria that appears to promote recovery from acute bacterial mastitis. In general, feeding an infant from a breast affected by an abscess is not recommended.<sup>1</sup> Infant feeding on the affected breast may be resumed, however, once the mother

Table 5-10 Spectrum of Infectious Agents<sup>a</sup> Recovered in Human Milk and Their Possible Role in Infections in the Neonate

HTLV, human T-lymphotropic virus.

has received adequate treatment. Furthermore, breast-feeding may continue on the unaffected breast. Mothers with active tuberculosis should refrain from breast-feeding for at least 2 weeks or longer after institution of appropriate treatment if they are considered contagious.<sup>1</sup>

Viral contaminants of maternal origin in the milk include rubella virus, herpes simplex virus, hepatitis B virus (HBV), cytomegalovirus (CMV), HIV-1, human T-lymphotropic virus type 1 (HTLV-1), and, possibly, HTLV-2 (see Table 5-10). For most viruses, although transmission has been documented as evidenced by seroconversion, no serious illness in the neonate, with the possible exception of CMV infection-related illness secondary to breast-feeding, has been reported.<sup>22,314</sup> Occasional reports of possible neonatal herpes simplex virus infection associated with presence of the virus in the mother's milk may just as easily have been caused by an infant-to-mammary gland rather than a mammary gland-to-infant route of inoculation.<sup>374</sup> Both the RNA-dependent DNA polymerase and structural proteins of C-type tumor viruses, possibly related to mouse mammary tumor and Mason-Pfizer viruses, have been identified in human breast tissue and products of lactation.<sup>82</sup> An association between breast-feeding of female infants and the development of breast cancer has been hypothesized in families with a strong history of carcinoma of the breast. Epidemiologic evidence to support such an association is lacking, however. Breast-feeding may in fact be a protective factor relative to maternal risk of such neoplastic disease.<sup>375</sup> Therefore, with adherence to reasonable maternal hygiene and in the absence of intense chemical contamination, generally few proven or well-defined contraindications to natural breast-feeding exist. Current recommendations regarding the transmission of infectious virus in human

milk and their implications for the breast-fed infant are summarized next.

**Human Immunodeficiency Virus Infection.** Recently, serious concern has been voiced regarding the potential risk of the transmission of HIV from infected mothers to their suckling neonates through the process of breast-feeding. The possibility of postnatal transmission of this virus from mother to child has been considered in a large number of infants breast-fed in the United States and in other parts of the world. In some of these infants, breast-feeding has been implicated as one of the major risk factors for acquisition of HIV infection. Since 1985, small but significant numbers of infants with HIV infection possibly acquired through the process of breast-feeding have been reported.<sup>376</sup> In virtually all reported cases, maternal seroconversion for HIV antibody probably occurred after delivery of the infant. More than 50% of these mothers acquired the infection through heterosexual transmission, and about 30% through blood transfusion. Few of the mothers were judged to be intravenous drug users. Although acquisition of HIV infection before delivery cannot be ruled out with certainty, the likely route of transmission in these infants has been presumed to be through breast-feeding. The most convincing observations are based on several maternal-infant pairs in whom maternal seroconversion to HIV antibody occurred 4 months or longer after delivery.<sup>377</sup>

A number of studies have demonstrated HIV in milk.<sup>378-382</sup> The findings include isolation of HIV from milk supernatants collected from symptom-free women and from cellular fractions of maternal milk, recovery of HIV virions in the histiocytes and cell-free extracts of milk by electron microscopy, and detection of viral DNA by polymerase chain

reaction (PCR) assay in greater than 70% of samples from HIV-seropositive lactating women. Limited epidemiologic studies carried out to date, however, have failed to demonstrate the magnitude of risk of HIV infection in breast-fed infants. Cohort studies<sup>383</sup> in different populations have suggested increased, reduced, or similar transmission rates in breast-feeding and in non-breast-feeding (bottle-feeding) infants of seropositive mothers (Table 5-11). Thus, it appears that although precise epidemiologic data are still lacking, a majority of breast-fed infants born to HIV-seropositive mothers remain uninfected despite the presence of HIV DNA in the milk in a high proportion of such mothers. Nevertheless, the risk of acquisition of HIV infection through breast-feeding must not be ignored. On the basis of meta-analysis of available data, it has been estimated that the additional risk of HIV infection through breast-feeding may be as high as 22%.<sup>384</sup> Some studies have suggested that breast-feeding contributes up to a 50% increase in the overall vertical transmission of HIV infection.<sup>385</sup>

Despite the potential risk of HIV infection in infants of HIV-infected breast-feeding mothers, consideration of cessation of breast-feeding must be balanced against other beneficial effects as outlined in this chapter. In a 1990 study, breast-fed HIV-infected children progressed to acquired immunodeficiency syndrome (AIDS) at a slower rate than that noted for bottle-fed children.<sup>386</sup>

Current estimates indicate the overall risk of acquiring HIV infection from breast-feeding to be about 16%. Of all HIV-infected infants, 47% may be infected by means of breast-feeding. Among those breast-fed for 3 months or longer, the rate of infection was estimated to be approximately 21%, and among those breast-fed for 2 months or less, the rate of infection was approximately 13%.<sup>1</sup> It is, however, important to realize that a number of other risk factors contribute to the increased transfer of HIV through breast-feeding. Associated maternal factors include younger age, multiple deliveries, high virus load, lower number of CD4<sup>+</sup> lymphocytes, and maternal mastitis. Other risk factors associated with the maternal milk include high viral load in the milk, long duration of breast-feeding, especially mixed formula feeding and breast-feeding, low levels of antiviral

factor in the milk (low CTL, sIgA, lactoferrin, lysozyme). Evidence of oral candidiasis in the breast-feeding neonate also appears to be a risk factor for development of breast-feeding-associated HIV infection.<sup>1</sup>

Current recommendations from the American Academy of Pediatrics state that in populations such as that of the United States, in which the risk of death from infectious diseases and malnutrition is low and in which safe and effective alternative sources of feeding are readily available, HIV-infected women should be counseled not to breast-feed their infants nor to donate milk. All pregnant women in the United States should be counseled and encouraged to be tested for HIV infection. Data are not available about the safety of breast-feeding by mothers receiving highly active antiretroviral therapy (HAART).

In geographic areas in which infectious diseases and malnutrition are important causes of death early in life, the feeding decision may be more complex. The World Health Organization (WHO) states that if a mother is infected with HIV, replacement of human milk to decrease the risk of HIV transmission may be preferable to breast-feeding, provided that the risk associated with replacement feeding is less than the potential risk of HIV transmission. Implementation of this suggestion has many obstacles. The WHO policy stresses the need for continued support for breast-feeding by mothers who are HIV negative or of unknown HIV serostatus, improved access to HIV counseling and testing, and government efforts to ensure uninterrupted access to nutritionally adequate human milk substitutes.<sup>1</sup>

**Cytomegalovirus Infection.** CMV infection is a common perinatal infection. The virus is shed in the milk in about 25% of infected mothers. Although breast-feeding from infected mothers may result in seroconversion in up to 70% of breast-feeding neonates, the infection often is not associated with clinical symptoms of disease. Low-birth-weight infants (born at less than 1500 g), however, may exhibit evidence of clinical disease, with thrombocytopenia, neutropenia, or hepatosplenomegaly seen in 50% of breast-feeding-infected babies. The decision to breast-feed a premature baby by an infected mother should be based on weighing the potential benefits of human milk versus the risk of CMV transmission.<sup>1</sup>

**Hepatitis B Virus Infection.** Hepatitis B surface antigen (HBsAg) has been detected in milk of HBV-infected mothers. Nevertheless, breast-feeding does not increase the risk of HBV infection among these infants. Infants born to HBV-positive mothers should receive hepatitis B immune globulin (HBIG) and the recommended series of hepatitis B vaccine without any delay in the institution of breast-feeding.<sup>1</sup>

**Hepatitis C Virus Infection.** The RNA of hepatitis C virus (HCV) and antibody to HCV have been detected in the milk from infected mothers. Transmission by means of breast-feeding, however, has not been documented in anti-HCV-positive, anti-HIV-negative mother. According to current guidelines, HCV infection does not contraindicate breast-feeding.<sup>1</sup>

**Rubella.** Rubella virus has been recovered from milk after natural as well as vaccine-associated infection. It has not been associated with significant disease in infants, however,

although transient seroconversion has been frequently demonstrated. No contraindication to breast-feeding exists in women recently immunized with currently licensed rubella vaccines.

**West Nile Virus Infection.** The RNA of west Nile virus has been detected in human milk, and seroconversion in breast-feeding infants also has been observed. Although West Nile virus can be transmitted in milk, its extent of transmission in humans remains to be determined. Most infants and children infected with the virus to date have been asymptomatic or have had minimal disease.<sup>1</sup>

**Infection Due to Human T-Lymphotropic Viruses 1 and 2.** Epidemiologic studies strongly suggest the possibility of mother-to-infant transmission of HTLV-1 by breast-feeding. In the United States, currently it is recommended that HTLV-1-infected women should not breast-feed. On the other hand, the status of maternal-infant transmission of HTLV-2 through the process of breast-feeding has not been well established, and until additional information is available, breast-feeding should not be recommended in seropositive women.<sup>1</sup>

### Summary

It is apparent that human colostrum and milk are richly endowed with a wide variety of cellular and soluble components that participate in many nutritional, immunologic, and anti-infective processes of specific benefit to the neonate. The function of the products of lactation and maternal breast-feeding best characterized to date is nutritional support, and modulation and/or compensation for the transient mucosal immune deficiency against infectious and dietary macromolecules in the autologous infant.

In general, it is quite safe for the mother to collect her milk for later feeding or to directly breast-feed her own neonate. Nevertheless, increasing concerns regarding contamination of human milk by infectious agents have resulted in the limited use of either milk banks or wet nursing. Because of the transfer of infectious agents from maternal blood to milk (see Table 5-10), several national advisory committees have recommended that patients who have known transmissible infectious viral or bacterial diseases should not breast-feed.<sup>388</sup>

Other clinical situations in which withholding breast-feeding is appropriate because of high metabolite content in the milk include presence of galactosemia (galactose from lactose), phenylketonuria (phenylalanine), and other amino acid disorders in the infant.

As shown in Tables 5-9 and 5-10, many drugs, infectious agents, and environmental agents can be transferred to the infant in maternal milk. Rather than stopping breast-feeding, a nursing mother should avoid use of any drug unless it is absolutely essential. Many organohalides and fat-soluble environmental products, such as DDT and PCBs, may be present in higher concentrations in human milk.<sup>22</sup> Although not much is known about their risk to the infant, it is generally agreed that unless the degree of exposure in the mother is extremely high, the benefits of breast-feeding outweigh the possible risks associated with environmental contaminants. Caffeine, alcohol, and nicotine also present potential hazards to the infant (see Table 5-9). It is advisable to reduce or preferably discontinue the intake of tobacco,

caffeine-containing products, and alcoholic beverages during lactation and nursing.

## CURRENT TRENDS IN BREAST-FEEDING

Both international<sup>389</sup> and national<sup>1,390,391</sup> organizations have endorsed breast-feeding as the optimal means of feeding for the healthy term infant. In general, the percentage of mothers initiating breast-feeding in developing countries is 80% or higher and often 90% or more.<sup>392</sup> The health and economic consequences for bottle-fed infants in these countries are severe, however. In the United States, at one point in the early 1970s, the rate of breast-feeding initiation was as low as 25%. This low point was followed by an increase to a high of 61.9% in 1982. After 1982 a slow decline was observed (to 52.2% in 1989), after which a modest increase has been observed since the early 1990s.<sup>393</sup>

The pattern of breast-feeding initiation is accompanied by concomitant changes in maintenance of breast-feeding to 6 months, from 24% (1984) to 18% (1989) to 21.6% (1995).<sup>393,394</sup> These changes took place despite goals set by the U.S. Surgeon General for 75% of infants to be breast-feeding in the first week of life and 35% at 6 months.<sup>395</sup> These goals were reestablished for the year 2000.<sup>396</sup>

Within the United States, a variety of demographic patterns appear to be associated with breast-feeding behavior. Older mothers, mothers with a college education, and higher-income mothers all are more likely to breast-feed. By contrast, black and Hispanic mothers, mothers of lower socioeconomic status who are participants in the Women, Infants, and Children (WIC) program of the U.S. Department of Health and Human Services and mothers who live in the southern regions of the United States are much less likely to breast-feed. The low rate of breast-feeding for mothers enrolled in WIC is of particular concern, as that agency has a specific policy to encourage breast-feeding. Many states, however, now depend on formula manufacturer rebates to fund part of their WIC programs, creating something of a conflict of interest. The disturbing part of the demographic pattern of breast-feeding in the United States is that the infants of lower-socioeconomic-status mothers, who would accrue the greatest health and economic benefits from breast-feeding, are those least likely to be breast-fed.

Although demographic studies indicate who is breast-feeding, they do not explain the behavioral differences among groups of mothers. One of the more complete models designed to explain breast-feeding behavior includes components that address maternal attitudes and family, societal, cultural, and environmental variables.<sup>397</sup> Individual studies have shown that the maternal decision-making process is closely related to the social support and influence that come from the family members surrounding the mother.<sup>398</sup> The husband in particular appears to have a strong positive influence, whereas the mother's mother may have a negative influence on the breast-feeding decision. Social support appears to be different among ethnic groups, as are maternal attitudes; such differences may provide one explanation for differences in breast-feeding behavior among ethnic groups.<sup>399,400</sup>

## SUMMARY AND CONCLUSIONS

Clearly, human milk contains a wide variety of soluble and cellular components with a diverse spectrum of biologic functions. The major milk components identified to date exhibit antimicrobial, anti-inflammatory, pro-inflammatory, and/or immunoregulatory functions; cytotoxicity for tumor cells; ability to repair tissue damage; and receptor analogue functions, as well as other metabolic effects. The relative contributions of different milk components to these biologic effects are summarized in Table 5-12.

The bulk of antimicrobial effects are associated with milk immunoglobulin, especially the sIgA isotype, which makes up to 80% of all immunoglobulins in the human body. Clinical observations have demonstrated that milk antibodies protect against a large number of intestinal pathogens such as *Campylobacter*, *Shigella*, *E. coli*, *V. cholerae*, *Giardia*, rotavirus, and respiratory pathogens such as respiratory syncytial virus. The milk antibodies also effectively neutralize toxins and a variety of human viruses. The role of small amounts of IgG and IgM in milk has not been fully examined. Recently, it has been suggested that milk IgG may hydrolyze nucleotides and DNA.<sup>401</sup> In general, milk IgA antibodies induce antimicrobial protection in the absence of any inflammation, a characteristic of other complement-binding immunoglobulins such as IgG and IgM.

Significant numbers of PMNs, macrophages, and epithelial cells are observed in the milk. Their precise function in the milk remains to be determined. It is possible that their primary task is the defense of the mammary gland itself. The lymphocytes present in the milk transfer immunologic information and may offer significant T cell-mediated immunologic defense to the suckling neonate. Breast-fed infants seem to become tolerant to their mothers' HLA, which may have important implications regarding immune responsiveness and allograft rejection.<sup>402</sup>

Lactoferrin, a major milk protein, also may play an important role in antimicrobial defense. It can kill bacteria, fungi, and viruses without causing inflammation. Lactoferrin also has been found to block mechanisms that result in the expression of pro-inflammatory cytokines (TNF- $\alpha$ , IL-6, IL-1 $\beta$ ) by inhibiting nuclear transcription factor (NF $\kappa$ B) activation mechanisms.<sup>403</sup>

Recent observations have suggested that  $\alpha$ -lactalbumin may exist in human milk as large complexes binding to oleic acid. Such complexes, referred to as human  $\alpha$ -lactalbumin made lethal to tumor cells (HAMLET), induce apoptosis of all malignant cells tested to date. These complexes have remarkably little to no effect on normal cells.<sup>404,405</sup>

Additional recent studies have suggested that milk contains large numbers of cytokines, chemokines, and growth factors. Although their precise role in the milk remains to be determined, some of these may act as signals for recruitment of pro-inflammatory and or immunoregulatory cells to the mucosal sites. TGF- $\beta$  may be important in downregulating immune response and induction of tolerance, thereby decreasing the risk of allergic disease. IL-7 may promote development of a  $\gamma\delta$  T cell population in cryptopatches which are small aggregates of lymphocytes in the intestinal crypts, and in the maintenance of thymus size.<sup>406,407</sup> It also has been shown that increased levels of IL-1 $\beta$ , TNF- $\alpha$ , IL-6,

and possibly other cytokines increase the level of leptin, an appetite-regulating hormone that is present in significant quantities in mammary epithelial cells, milk fat globules, and milk.<sup>407,408</sup> Leptin has several immunologic effects, including differentiation and proliferation of hematopoietic cells and regulation of monocyte-macrophage function. It also influences T cell response by enhancing IL-2 and IFN- $\gamma$  production (for T<sub>H</sub>1 cells) and IL-4 and IL-10 production (for T<sub>H</sub>2 cells). Leptin is absorbed by the breast-feeding infant<sup>408,409</sup> and may be associated with prevention of obesity observed in breast-fed infants.

Another important recent observation with milk relates to the presence of antisecretory factor (AF). It has been observed in samples of milk, possibly induced by exposure to enterotoxin-producing bacteria.<sup>410</sup> It possesses significant effect on intestinal fluid secretions. The precise function of AF remains to be determined. Preliminary observations, however, suggest that AF may be highly effective in treatment of inflammatory bowel disease.<sup>411,412</sup>

Human milk has been found to possess large quantities of soluble CD14 and soluble Toll-like receptors TLR-2 and TLR-4, important elements for innate immunity.<sup>413,414</sup> CD14 promotes differentiation in expression of B cell function and anti-inflammatory effect of lactoferrin. Intestinal epithelium does not possess CD14, and it is possible that milk CD14 facilitates phagocytosis of organisms that require expression of this ligand. The TLR-2 and TLR-4 bind to a variety of microorganisms and may play an important role in down-regulating inflammatory responses in the mucosal sites.

It is beyond the scope of this chapter to explore in any detail the reasons for and possible benefits of the evolution of mammalian life forms. Nevertheless, the passive transfer of the diversity of maternal biologic experiences to the neonate through the process of breast-feeding represents an essential component of the survival mechanism in the mammalian neonate. For millions of years, maternal products of lactation delivered through the process of breast-feeding have been the sole source of nutrition and immunity during the neonatal period and early infancy for all mammals, including the human infant. During the past 150 to 300 years, however, the human societal culture has undergone remarkable changes in rapid succession, which have had a major impact on the basic mechanisms of maternal-neonatal interaction and breast-feeding. Such changes include introduction of sanitation and nonhuman milk and formula feeds for neonatal nutrition, use of antimicrobial agents, introduction of processed foods, and exposure to newer environmental macromolecules and dietary antigens. The introduction of such manmade changes in the neonatal environment has had a profound impact on human homeostatic mechanisms and at the same time allowed new insights into the role of breast-feeding in the developing human neonate.

Comparative analysis of natural (traditional) forms of breast-feeding and artificial feeding modalities of modern times has demonstrated clearly that natural breast-feeding is associated with significant reduction in infant mortality and morbidity, protection against acute infectious diseases (both in the acute phase of the disease and with long-term re-exposure), and possible protection against allergic disorders and autoimmune disease, acute and chronic inflammatory disorders, obesity, diabetes mellitus and other metabolic

disorders, allograft rejection, and development of a number of malignant conditions in childhood or later in life. Newer evidence suggests a protective role of breast-feeding in modulating many respiratory, intestinal, and urinary tract infections, otitis media, and NEC in the neonate. This information has been recently reviewed by Hanson in an elegant monograph.<sup>415</sup> Despite the overwhelmingly protective role attributed to natural breast-feeding and the evolutionary advantages related to the development of lactation, several infectious agents have acquired, during the course of evolution, the ability to evade immunologic factors in milk and to use milk as the vehicle for maternal-to-infant transmission. The potential for the acquisition of infections such as those due to HIV, HTLV, CMV, and possibly other pathogens highlights potential hazards of breast-feeding in some clinical situations.

Thus, it is reasonable to conclude that the development of lactation, the hallmark of mammalian evolution, is designed to enhance the survival of the neonate of the species, and that breast-feeding may have a remarkable spectrum of immediate and long-term protective functions.

 Fever in the First Month of Life

Bacterial sepsis in the neonate is a clinical syndrome characterized by systemic signs of infection and accompanied by bacteremia in the first month of life. Meningitis in the neonate usually is a sequela of bacteremia and is discussed in this chapter because meningitis and sepsis typically share a common cause and pathogenesis. Infections of the bones, joints, and soft tissues and of the respiratory, genitourinary, and gastrointestinal tracts can be accompanied by bacteremia, but the cause, clinical features, diagnosis, and management of these infections are sufficiently different to warrant separate discussions. Sepsis and meningitis caused by group B *Streptococcus*, *Staphylococcus aureus*, *Neisseria gonorrhoeae*, *Listeria monocytogenes*, *Salmonella* species, and *Mycobacterium tuberculosis* are described in other chapters.

The two patterns of disease, early-onset and late-onset, have been associated with systemic bacterial infections during the first month of life (Table 6-1). Early-onset disease typically presents as a fulminant, systemic illness during the first 24 hours of life, with most other cases presenting on the second day of life. Infants with early-onset disease can have a history of one or more obstetric complications, including premature or prolonged rupture of maternal membranes, preterm onset of labor, chorioamnionitis, and peripartum maternal fever, and many of the infants are premature or of low birth weight. Bacteria responsible for early-onset disease are acquired hours before delivery from overt or occult rupture of membranes or from the birth canal during delivery. The mortality rate varies from 3% to as high as 50% in some series, especially with gram-negative pathogens. Late-onset disease is variably defined as occurring after 72 hours to 6 days (e.g., group B *Streptococcus*) of life. Very late onset infection due to group B *Streptococcus* (disease in infants older than 3 months) is discussed in Chapter 13. Term infants with late-onset infections can have a history of obstetric complications, but these are less characteristic than in early-

onset sepsis or meningitis. Bacteria responsible for late-onset sepsis and meningitis include those acquired from the maternal genital tract and organisms acquired after birth from human contacts or infrequently from contaminated hospital equipment or materials where prolonged intensive care is needed for a neonate. The mortality rate usually is lower than that for early-onset sepsis but can vary between 2% and 40%, with the latter figure typically for very low birth weight (VLBW) infants with gram-negative sepsis. Because different microorganisms are responsible for disease by age at onset, the choice of antimicrobial agents also differs. Some organisms, such as *Escherichia coli*, groups A and B

streptococci, and *L. monocytogenes*, can be responsible for early-onset and late-onset infections, whereas others, such as *S. aureus*, coagulase-negative staphylococci, and *Pseudomonas aeruginosa*, rarely cause early-onset and typically are associated with late-onset disease. The survival of VLBW infants with prolonged stays in the neonatal intensive care unit has been accompanied by increased risk for nosocomial or hospital-associated infections and for very late onset disease<sup>1</sup> (see Chapter 35).

## BACTERIOLOGY

The changing pattern of organisms responsible for neonatal sepsis is reflected in a series of reports by pediatricians at the Yale–New Haven Hospital covering the period of 1928 to 1999<sup>2-7</sup> (Table 6-2). Before development of the sulfonamides, gram-positive cocci caused most cases of neonatal sepsis. With the introduction of antimicrobial agents, gram-negative enteric bacilli, particularly *E. coli*, became the predominant cause of serious infection in the newborn. *S. aureus* was a major pathogen between 1950 and 1963 but subsequently diminished in importance for reasons that remain unclear. Reports for the periods of 1966 to 1978 and 1979 to 1988 indicate the importance of group B streptococci, *E. coli*, and coagulase-negative staphylococcal (CoNS) species, predominantly *Staphylococcus epidermidis*, in neonatal sepsis. The latest reports also document the problem of sepsis in very premature and low-birth-weight infants who have survived with the aid of sophisticated life-support equipment and advances in neonatal intensive care.

The etiologic pattern of microbial infection observed at Yale Medical Center also has been reported in studies of neonatal sepsis carried out at other centers during the same intervals (Table 6-3). Studies indicate that group B streptococci and gram-negative enteric bacilli, predominantly

**Table 6-1 Characteristics of Early-Onset and Late-Onset Neonatal Sepsis**

Characteristic	Early-Onset <sup>a</sup>	Late-Onset <sup>b</sup>
Time of onset (days)	0-6	7-90
Complications of pregnancy or delivery		
Source of organism	+	±
	Mother's genital tract	Mother's genital tract; postnatal environment
Usual clinical presentation	Fulminant	Slowly progressive or fulminant
	Multisystem	Focal
	Pneumonia frequent	Meningitis frequent
Mortality rate (%)	3-50 <sup>c</sup>	2-40

<sup>a</sup>Many studies define early-onset sepsis as that which occurs in the first 72 hours of life; others in the first 5 or 6 days of life.

<sup>b</sup>Very small premature infants may have late-onset sepsis beyond 90 days of life.

<sup>c</sup>Higher mortality rates in earlier studies.

*E. coli*, were the most frequent pathogens for sepsis, but other organisms were prominent in some centers. *S. aureus* was an important cause of sepsis in the mid-1980s in Finland<sup>20</sup> and East Africa<sup>32</sup> and a more recently significant pathogen in Connecticut<sup>7</sup> and southern Israel<sup>31</sup>; *Streptococcus viridans* was the most frequent isolate from neonatal blood cultures in Philadelphia<sup>14</sup>; *S. epidermidis* was responsible for 53% of cases in Liverpool,<sup>22</sup> and CoNS account for 35% to 48% of all late-onset sepsis in VLBW infants across the

United States<sup>17,18</sup> and in Israel<sup>37</sup>; and *Klebsiella* and *Enterobacter* species were the most common bacterial pathogens in Tel Aviv.<sup>30</sup> Sepsis and focal infections in neonates in developing countries are further discussed in Chapter 2.

The survey of five university hospitals in Finland<sup>20</sup> provides data about the association of the etiologic agent and mortality based on age at onset of sepsis (Table 6-4) and birth weight (Table 6-5). Infants with sepsis onset during the first 24 hours of life and weighing less than 1500 g at birth had the highest mortality rate.

The mortality rates for neonatal sepsis over time are documented in the Yale Medical Center reports. In the pre-antibiotic era, neonatal sepsis usually was fatal. Even with the introduction of penicillins and aminoglycosides in the reports from 1944 to 1965, death resulted from sepsis in most infants. Concurrent with the introduction of neonatal intensive care units and technologic support for cardiorespiratory and metabolic functions beginning in the early 1970s, the mortality rate was reduced to 16%.

The Yale data also provide information about the microorganisms responsible for early-onset and late-onset sepsis (Table 6-6). Group B streptococci were responsible for most early-onset disease. *E. coli* and CoNS were the major pathogens of late-onset disease, with the latter afflicting VLBW infants almost exclusively. A wide variety of gram-positive cocci and gram-negative bacilli caused disease after age 30 days.

Survival of VLBW infants (<1500 g) has been accompanied by an increased risk for invasive, nosocomial, or health care-associated bacterial infection as a cause of morbidity and mortality. The danger of sepsis is documented in a multicenter trial that enrolled 2416 VLBW infants in a study of the efficacy of intravenous immunoglobulin in preventing nosocomial infections.<sup>16</sup> Sixteen percent of the VLBW infants developed septicemia at a median age of 17 days, with an overall mortality rate of 21% and a hospital stay that averaged 98 days; infants without sepsis had an overall mortality rate of 9% and 58-day average length of stay.

Organisms responsible for bacterial meningitis in the newborn are listed in Table 6-7, which summarizes data collected from 1932 to 1997 at neonatal centers in the United States,<sup>38-41,44</sup> The Netherlands,<sup>42</sup> Great Britain,<sup>43,45</sup> and Israel.<sup>31</sup> Gram-negative enteric bacilli and group B streptococci currently are responsible for most cases. Organisms that cause acute bacterial meningitis in older children and adults—*Streptococcus pneumoniae*, *Neisseria meningitidis*, and non-

typeable *Haemophilus influenzae*—are relatively infrequent causes of meningitis in the neonate.<sup>46</sup> A nationwide survey of causative agents of neonatal meningitis in Sweden between 1976 and 1983 indicated a shift from bacterial to viral or unidentified microorganisms, with lower attributable mortality rates.<sup>47</sup>

### Group B Streptococci

Group B  $\beta$ -hemolytic streptococci were implicated in human disease shortly after the precipitin-grouping technique was described.<sup>48</sup> Neonatal sepsis caused by this organism was recognized, but only a few sporadic cases were reported.<sup>3,49</sup> For the past 3 decades, group B streptococci have been the most common organisms causing invasive disease in neonates throughout the United States and western Europe (see Chapter 13).

*Streptococcus agalactiae*, the species designation of group B streptococci, has a characteristic colonial morphology on suitable solid media. The organism produces a mucoid

colony with a narrow zone of  $\beta$ -hemolysis on sheep blood agar media. The group B streptococci can be differentiated immunochemically on the basis of their type-specific polysaccharides. Ten capsular types Ia, Ib, II, III, IV, V, IV, VI, VII, and VIII have been characterized, and most invasive human isolates can be classified as one of these types.

Group B streptococci have been isolated from various sites and body fluids, including throat, skin, wounds, exudates, stool, urine, cervix, vagina, blood, joint, pleural or peritoneal fluids, and cerebrospinal fluid (CSF). The organisms frequently are found in the lower gastrointestinal and genital tracts of adult women and men and in the lower gastrointestinal and upper respiratory tracts of newborns. Patterns of early-onset, late-onset, and very late onset disease have been associated with group B streptococci (see Table 6-1). Early-onset disease presents as a multisystem illness with rapid onset typically during the first day or two of life and is frequently characterized by severe respiratory distress. The pathogenesis is presumed to be similar to that of other forms of early-onset sepsis of neonates. Isolates may belong to any

<sup>b</sup>Survey of 16 newborn nurseries participating in neonatal meningitis study of intrathecal gentamicin under the direction of Dr. George McCracken, Jr.

<sup>c</sup>Authors report an additional nine cases of gram-positive and six cases of gram-negative meningitis with organisms not otherwise specified.

<sup>d</sup>Authors report 16 cases related to enteric bacteria, including *E. coli*, *Proteus* species, and *Klebsiella-Enterobacter* group.

of the serotypes of group B streptococci, but types Ia, III, and V predominate. The mortality rate is estimated at 8% but was as high as 50% in the 1970s.<sup>50</sup>

Clinical manifestations of late-onset neonatal sepsis are more insidious than those of early-onset disease, and meningitis is frequently a part of the clinical picture. However, some infants with meningitis have a fulminant onset with rapid progression to centrally mediated apnea. Many of the infants are products of a normal pregnancy and delivery and have no problems in the nursery. It is uncertain whether group B streptococcal infection was acquired at the time of birth and carried until disease developed, was acquired after delivery from the mother or other household contacts, or was acquired from other infants or personnel in the nursery. Nearly 80% of strains belong to serotype III. The mortality rate, estimated at 3%, is lower than that for early-onset disease. With increasing survival of extremely low birth weight (ELBW) (<1000 g) infants, very late onset disease (>89 days) has been described in the past decade.<sup>37</sup>

In addition to sepsis and meningitis, other manifestations of neonatal disease caused by group B streptococci include pneumonia, empyema, facial cellulitis, ethmoiditis, orbital cellulitis, conjunctivitis, necrotizing fasciitis, osteomyelitis, suppurative arthritis, and impetigo. Bacteremia without systemic or focal signs of sepsis can occur. Group B streptococcal infection in pregnant women can result in peripartum infections, including septic abortion, chorioamnionitis, peripartum bacteremia, septic pelvic thrombophlebitis, meningitis, and toxic shock syndrome.<sup>51</sup>

### Group A Streptococci

Streptococcal puerperal sepsis has been recognized as a cause of morbidity and mortality among parturient women since the 16th century.<sup>52-56</sup> Neonatal group A streptococcal infection now is reported infrequently<sup>57-68</sup> but can occur rarely in epidemic form in nurseries.<sup>57-61</sup> The reemergence of virulent group A streptococcal infections, including invasive disease and toxic shock syndrome, has been reflected in more case reports of severe disease in the pregnant woman and the newborn.

Group A streptococcal disease in the mother can affect the fetus or newborn in three clinical patterns. Maternal streptococcal bacteremia during pregnancy can lead to in utero infection resulting in fetal loss or stillbirth; the fetus can be affected by transplacentally transmitted group A streptococcal toxins resulting from maternal infection; and acquisition of group A streptococci from the maternal genital tract can cause early-onset neonatal sepsis similar to early-onset group B streptococcal disease. In the first form of disease, previously healthy pregnant women with influenza-like signs and symptoms have been reported. This presentation rapidly progressed to disseminated intravascular coagulopathy and shock; four of five women died; stillbirth or fetal loss occurred in three cases; one neonate developed group A streptococcal sepsis and recovered; and a fifth infant was unaffected.<sup>69-71</sup>

The second manifestation of fetal or neonatal group A streptococcal disease is caused by production of toxins transferred across the placenta to the fetus. Babl and colleagues (personal communication, 1999) described a woman who had bacteremia due to group A *Streptococcus* at term,

extensive infection of the placenta, and toxic shock syndrome leading to disseminated intravascular coagulopathy. A severely depressed but uninfected infant was delivered by cesarean section with resulting hypoxic encephalopathy. Presumably, the infant was affected by transplacental passage of streptococcal toxins. The virulence factors produced by group A streptococci that are important in the systemic toxicity characteristic of streptococcal toxic shock syndromes are largely the extracellular toxins, such as pyrogenic exotoxin A, B, and C; mitogenic factor; and streptococcal superantigen. These toxins have the ability to induce cytokine production by monocytes and lymphocytes. The result is T cell proliferation with production of interleukin-2, interferon- $\gamma$ , and tumor necrosis factor- $\beta$ .<sup>72-75</sup> It remains unclear whether the immune system of a fetus or neonate is sufficiently mature to respond to superantigens with subsequent cytokine production or whether the effect on the fetus results from cytokines produced on the maternal side of the placenta and passed to the fetal circulation. In the third form of disease, early-onset group A streptococcal infection in the neonate was acquired from maternal genitalia or pharynx and frequently was fatal. A review by Greenberg and colleagues<sup>76</sup> of 15 cases of neonatal sepsis due to group A streptococci reported between 1976 and 1999 identified nine cases of early-onset sepsis (three deaths) and six cases of late-onset sepsis (one death).

In addition to sepsis, meningitis, and toxin-mediated disease in the neonate, focal infections, including cellulitis, omphalitis, Ludwig's angina,<sup>77</sup> pneumonia, and osteomyelitis, have been reported. Because all group A streptococci are susceptible to  $\beta$ -lactam antibiotics, the current strategy for prevention or treatment of infections due to group B streptococci also could apply to infections caused by group A streptococci.

### Streptococci Other than Groups A and B

Group C streptococci have been associated with puerperal sepsis, but neonatal sepsis or meningitis related to these organisms is rare.<sup>78-80</sup> Group G streptococci are an infrequent cause of neonatal sepsis and pneumonia.<sup>81-85</sup> Maternal intrapartum transmission was the likely source for most cases,<sup>83</sup> and concurrent endometritis and bacteremia in the mother and sepsis in the neonate have been reported.<sup>84</sup> Dyson and Read<sup>83</sup> found very high rates of colonization in neonates born at New York Hospital in a 1-year survey of discharge cultures in 1979; the monthly incidence of cultures of group G streptococci from the nose and umbilicus varied between 41% and 70%. During this period, group B streptococcal colonization was only 1% to 11%.<sup>83</sup> Auckenthaler and colleagues<sup>85</sup> have reviewed group G streptococcal bacteremia, and their review includes invasive disease in newborns.

*Enterococcus* now is considered taxonomically distinct from group D streptococci and a unique genus. However, much of the earlier literature about neonatal sepsis combined enterococci (i.e., *Streptococcus faecalis* and *Streptococcus faecium*) and nonenterococci (i.e., *Streptococcus bovis* and *Streptococcus mitis*), and because of this historical context, the two groups are combined in this section. Enterococci are differentiated from nonenterococci by their ability to grow in 6.5% NaCl broth and to withstand heating at 60°C for 30 minutes.

In general, *Enterococcus* species are resistant to cephalosporins, are only moderately susceptible to penicillin G and ampicillin, and require the synergistic activity of penicillin at high dosage and an aminoglycoside for maximal bactericidal action; nonenterococcal strains are susceptible to penicillin G, ampicillin, and most cephalosporins. Vancomycin-resistant *Enterococcus* (VRE) has been reported from neonatal intensive care units and raises concerns about the efficacy of antimicrobial agents currently approved for use in neonates.<sup>86</sup> Use of high doses of ampicillin is one option, but other drugs may be suggested by the susceptibility pattern (see Chapter 37). New agents, such as the streptogramin combination of quinupristin and dalbapristin and the oxazolidinone linezolid are effective against VRE infections in adults. However, limited pharmacokinetic data are available to guide use of these agents in neonates.<sup>87</sup>

Most cases of group D streptococcal sepsis in the neonate are caused by *Enterococcus faecalis*, with a smaller number caused by *Enterococcus faecium* and *S. bovis*<sup>88-93</sup>; rare cases due to *S. mitis* have been reported.<sup>94,95</sup> In the 4 years beginning in 1974, 37 neonates with group D streptococcal sepsis (including 30 related to enterococci and 7 to nonenterococcal isolates) occurred among 30,059 deliveries at Parkland Memorial Hospital in Dallas.<sup>88</sup> During this period, group D streptococci were second only to group B streptococci (99 cases) and were more common than *E. coli* (27 cases) as a cause of neonatal sepsis. The clinical presentation in most cases was similar to that of early-onset sepsis of any cause.<sup>90</sup> Among infants with respiratory distress as a prominent sign of infection, the chest radiographs were similar to those demonstrating the hyaline membrane-appearing pattern of group B streptococcal infection. Enterococcal bacteremia during the 10 years beginning January 1977 was reported in 56 neonates from the Jefferson Davis Hospital in Houston, Texas.<sup>96</sup> These 56 infants had the three clinical syndromes: early-onset disease was a mild illness with respiratory distress or diarrhea; late-onset infection often was severe with apnea, bradycardia, shock, and increased requirement for oxygen and mechanical ventilation; many cases were nosocomial.<sup>96</sup> Case series of neonatal sepsis or meningitis, or both, due to group D streptococci (including enterococci) also have been reported from Children's Hospital Medical Center of Cincinnati (13 cases from 1970 to 1976),<sup>97</sup> the Hospital for Sick Children in Toronto (9 cases from 1985 to 1989),<sup>98</sup> and New York Hospital/Cornell Medical Center (138 episodes of enterococcal bacteremia from 1974 to 1993).<sup>86</sup> Group D enterococci also have been recovered from CSF<sup>88,92</sup> and urine<sup>88</sup> of infants with sepsis. Outbreaks of bacteremia and meningitis related to *E. faecium* were reported from the neonatal intensive care units at the Medical College of Virginia<sup>99</sup> and Children's Hospital of Denver.<sup>100</sup>

Viridans streptococci are a heterogeneous group of  $\alpha$ -hemolytic and nonhemolytic streptococci that are constituents of the normal flora of the respiratory and gastrointestinal tracts of infants, children, and adults. There are several classification schemata for these streptococci, and they may bear different designations in the literature. Viridans streptococci accounted for 23% of isolates from cultures of blood and CSF obtained from neonates at the Jefferson Davis Hospital, Houston.<sup>101</sup> Only group B streptococci were more common (28%) as a cause of neonatal sepsis. Most infants had early-onset infection with

clinical features similar to those of sepsis caused by other pathogens, but 22.6% had no signs of infection. One infant had meningitis. The case-fatality rate was 8.8%. Sepsis related to viridans streptococci also has been reported from Finland,<sup>20</sup> Liverpool,<sup>22</sup> Indianapolis,<sup>13</sup> and Montreal.<sup>19</sup> It is clear from these studies that isolation of viridans streptococci from the blood culture of a neonate suspected to have sepsis cannot be considered a contaminant, as is the case in many other patient populations.

### ***Staphylococcus aureus* and *Staphylococcus epidermidis***

*S. aureus* and CoNS, especially *S. epidermidis*, colonize skin and mucosa. Isolation of *S. aureus* from tissue, blood, or other body fluid usually is clearly associated with disease. Most episodes of sepsis due to *S. aureus* are hospital acquired, and mortality remains high (23% among 216 Swedish neonates with *S. aureus* bacteremia during the years 1967 to 1984), with low birth weight as the most important risk factor.<sup>102</sup> Disease in newborn infants caused by *S. aureus* and CoNS is discussed in Chapter 17.

The apparent increased incidence of CoNS sepsis<sup>13,16-18,37</sup> has been associated with increased survival of VLBW and ELBW infants with developmentally immature immune systems and with the introduction of invasive procedures for maintenance and monitoring of the infants, including long-term vascular access devices. Because CoNS are present on the skin, isolation of these organisms from a single culture of blood can represent skin contamination but also can indicate bloodstream invasion. Collection of two cultures of blood at separate sites can assist in differentiating skin or blood culture bottle contamination from bloodstream invasion in the infant with suspected late-onset sepsis.<sup>103</sup> The significance of a positive blood culture yielding CoNS is discussed in "Microbiologic Techniques."

Many episodes of sepsis caused by CoNS are associated with the use of vascular catheters. *S. epidermidis* and other CoNS species can adhere to and grow on surfaces of synthetic polymers used in the manufacture of catheters. Strains obtained from infected ventricular shunts or intravenous catheters produce a mucoid substance (i.e., slime or glycocalyx) that stimulates adherence of microcolonies to various surfaces in the environment and on epithelial surfaces.<sup>104</sup> In addition to this adhesin function, the slime may protect staphylococci against antibiotics and host defense mechanisms such as opsonophagocytosis. Parenteral nutrition with a lipid emulsion administered through a venous catheter with organisms adherent to the polymer provides nutrients for growth of the bacteria, leading to invasion of the bloodstream when the organisms reach an inoculum of sufficient size.<sup>105</sup>

Three cases of fatal sepsis caused by CoNS occurred in VLBW infants with cytomegalovirus infection. At autopsy, the bacteria were cultured from the blood, spleen, and meninges. These cases suggest that concurrent cytomegalovirus infection may further suppress immune functions in the neonate and lead to increased virulence of the bacterial infection.<sup>106</sup>

### ***Listeria monocytogenes***

The prevalence of *L. monocytogenes* in packaged meat, dairy, or other food products and the danger to immunocompro-

mised patients and pregnant women was documented in a 2002 outbreak involving 46 patients in eight states. This outbreak was caused by isolates of *L. monocytogenes* sharing a relatively uncommon pulsed-field gel electrophoresis pattern; the cases included seven deaths of adults and miscarriages or stillbirths in three pregnant women.<sup>107</sup> *Listeria* can be found in unprocessed animal products, including milk, meat, poultry, cheese, ice cream, and processed meats, and on fresh fruits and vegetables. Most people exposed to *L. monocytogenes* do not develop illness, but the pregnant woman can suffer pregnancy loss, and the neonate can develop early or late-onset sepsis and meningitis. Neonatal disease due to *Listeria* is discussed in Chapter 14.

### ***Escherichia coli***

Coliform organisms are prevalent in the maternal birth canal, and most infants are colonized in their lower gastrointestinal or respiratory tracts during or just before delivery. The antigenic structure of *E. coli* is complex; members of this species account for more than 145 different somatic (O) antigens, approximately 50 flagellar (H) antigens, and 80 different capsular (K) antigens. Although there is a wide genetic diversity of human commensal isolates of *E. coli*, strains causing neonatal pathology are derived from a limited number of clones.<sup>108</sup>

One of the capsular antigens of *E. coli*, K1, is uniquely associated with neonatal meningitis.<sup>109-111</sup> K1 antigen is an acidic polysaccharide that is immunochemically identical to the capsular antigen of group B *N. meningitidis*. McCracken and co-workers<sup>109</sup> found K1 strains in the blood or CSF of most (65 of 77) neonates with meningitis related to *E. coli*. These strains also were cultured from the blood of some infants (14 of 36) and adults (43 of 301) with sepsis but without meningitis. The K1 capsular antigen was present in 88% of 132 strains from neonates with *E. coli* meningitis reported from The Netherlands.<sup>42</sup> K1 antigen was related to invasive disease and to a more severe outcome. Infants with meningitis caused by K1 strains had significantly higher mortality and morbidity rates than did infants with meningitis caused by non-K1 *E. coli* strains.<sup>110</sup> The severity of disease was directly related to the presence, amount, and persistence of K1 antigen in the CSF. Strains of *E. coli* with K1 antigen were isolated from cultures of stool of 7% to 38% (varying with time and location of the study) of healthy newborns and from approximately 50% of nurses and mothers of the infants.<sup>111,112</sup> The K1 strains have been present in the birth canal of mothers and subsequently in cultures from their newborns, indicating that these newborn infants acquired the organisms vertically from their mothers.<sup>112,113</sup> However, high rates of carriage of K1 strains by nursery personnel indicate that postnatal acquisition of the K1 strains in the nursery also may occur.<sup>111,112</sup>

Pili or fimbriae are filamentous surface appendages that may play a role in the pathogenesis of disease caused by *E. coli*.<sup>114</sup> Pili assist adherence of *E. coli* to epithelial cell surfaces, an initial step in the development of invasive disease. Fimbriated strains of *E. coli* have been associated with infections of the urinary tract in infants (see Chapter 9). The epidemiology of fimbriated *E. coli* and the relationship of these strains to fecal colonization of neonates and development of extraintestinal infections are discussed in a monograph by Tullus.<sup>115</sup>

### ***Klebsiella* Species and *Enterobacter* Species**

*Klebsiella* is a genus of Enterobacteriaceae that has emerged as a significant nosocomial pathogen in neonates.<sup>31,44,116,117</sup> The four recognized species include *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Klebsiella terrigena*, and *Klebsiella planticola*. *K. pneumoniae*, the most common human pathogen, and *K. oxytoca* cause neonatal infections of the bloodstream, urinary tract, central nervous system, lung, skin, and soft tissues.<sup>118-120</sup> Previously thought to be a nonpathogenic organism inhabiting soil and water, *K. planticola* has been implicated as a cause of neonatal sepsis.<sup>121,122</sup>

In a 4-year retrospective study from Israel,<sup>123</sup> *Klebsiella* species caused 31% of late-onset neonatal sepsis. Greenberg and colleagues<sup>31</sup> performed an 8-year prospective study of neonatal sepsis and meningitis at Soroka University Medical Center during the years 1986 to 1994; 49 (20%) of 250 cases were caused by *K. pneumoniae*, with a mortality rate of 29%. Risk factors for infection included preterm, VLBW, prolonged rupture of membranes (>24 hours), and cesarean section or instrument delivery.

The reservoirs for transmission of *Klebsiella* infections include the hands of health care workers and the gastrointestinal tracts of hospitalized infants. Multidrug resistance, in the form of extended spectrum  $\beta$ -lactamase production, of *Klebsiella* strains causing neonatal infections and nursery outbreaks has become a substantial problem in some nurseries and is associated with increased morbidity and mortality.<sup>124-126</sup> Enhanced infection control measures and changes in use of routine broad-spectrum antibiotics can reduce the frequency of these serious infections.

Among the *Enterobacter aerogenes* (i.e., *Aerobacter aerogenes*) species, *Enterobacter cloacae*, *Enterobacter sakazakii*, and *Enterobacter hormaechei* have caused sepsis and a severe form of necrotizing meningitis in neonates.<sup>127-132</sup> *Enterobacter* septicemia was the most common nosocomial infection in neonates at the Ondokuz Mayıs University Hospital in Samsun, Turkey, from 1988 to 1992.<sup>133</sup> Willis and Robinson<sup>128</sup> reviewed 17 cases of neonatal meningitis caused by *E. sakazakii*; cerebral abscess or cyst formation developed in 77% of the infants, and 50% of the infants died. Bonadio and colleagues<sup>129</sup> reviewed 30 cases of *E. cloacae* bacteremia in children, including 10 infants younger than 2 months old. Of importance was the high frequency of multidrug resistance among isolates from patients in the neonatal intensive care units that was attributed to routine extended spectrum cephalosporin usage.<sup>134</sup>

In addition to the gastrointestinal tracts of hospitalized infants and hands of health care personnel, sources and modes of transmission of *Enterobacter* infections in the neonate include contaminated infant formula,<sup>135,136</sup> contaminated total parenteral nutrition fluid,<sup>137,138</sup> bladder catheterization devices,<sup>137</sup> and contaminated saline.<sup>139</sup> Effective infection control measures require reinforcement of procedures, including proper hand hygiene, aseptic technique, isolation protocols, and disinfection of environmental surfaces.

### ***Citrobacter* Species**

Organisms of the genus *Citrobacter* are gram-negative bacilli that are occasional inhabitants of the gastrointestinal tract and are responsible for disease in neonates and debilitated or immunocompromised patients. The genus has undergone

frequent changes in nomenclature, making it difficult to relate the types identified in reports of newborn disease over the years. For example, in 1990, *Citrobacter koseri* replaced *Citrobacter diversus*.<sup>140</sup> For the purposes of this chapter, *C. koseri* replaces *C. diversus*, even though the original article may refer to the latter name.

*Citrobacter* species are responsible for sporadic and epidemic clusters of neonatal sepsis and meningitis, and *C. koseri* is uniquely associated with brain abscesses.<sup>140-148</sup> Neonatal disease can occur as early-onset or late-onset presentations. Outbreaks of *C. koseri* in neonatal intensive care units resulting in sepsis and meningitis, septic arthritis, and skin and soft tissue infections were reviewed by Doran.<sup>140</sup> Other focal infections in neonates due to *Citrobacter* species include bone, pulmonary, and urinary tract infections.<sup>140</sup>

During the period of 1960 to 1980, 74 cases of meningitis caused by *Citrobacter* species were reported to the Centers for Disease Control and Prevention (CDC) of the U.S. Public Health Service.<sup>141</sup> In 1999, Doran reviewed an additional 56 cases of neonatal meningitis due to *Citrobacter* species.<sup>140</sup> Combining results from the two studies, brain abscess developed in 73 (76%) of 96 patients for whom information was available. The pathogenesis of brain abscess caused by *C. koseri* is uncertain; cerebral vasculitis with infarction and bacterial invasion of necrotic tissues is the likely explanation.<sup>146</sup> Persistence of *C. koseri* in the central nervous system is suggested by a case report of recovery of the organism from the CSF during a surgical procedure 4 years after treatment of neonatal meningitis.<sup>145</sup> The mortality rate for meningitis due to *Citrobacter* species was about 30%; most of the infants who survived had some degree of mental retardation. A review of 110 survivors of *Citrobacter* meningitis revealed only 20 infants who were believed to have structurally intact brains and development that was age appropriate.<sup>140</sup>

*Citrobacter* species usually are resistant to ampicillin and variably susceptible to aminoglycosides. Historically, most infants were treated with a combination of penicillin or cephalosporin plus an aminoglycoside. Surgical drainage has been used in some cases with variable success. Choosing antimicrobial agents with the most advantageous susceptibility pattern and selected surgical drainage appears to be the most promising approach to therapy, but no one regimen has been found to be more successful than another. Plasmid profiles, biotypes, serotypes, and chromosomal restriction endonuclease digests are useful as epidemiologic markers for the study of isolates of *C. koseri*. Morris and colleagues<sup>147</sup> used these markers to investigate an outbreak of six cases of neonatal meningitis caused by *C. koseri* in three Baltimore hospitals between 1983 and 1985. Identification of a specific outer membrane protein associated with strains isolated from CSF but uncommon elsewhere can provide a marker for virulent strains of *C. koseri* according to some investigators.<sup>148</sup>

### ***Serratia marcescens* and *Pseudomonas* Species**

Like other members of Enterobacteriaceae, *Serratia marcescens* increasingly is associated with hospital-acquired infections among infants in the neonatal intensive care unit.<sup>149-151</sup> Late-onset sepsis has occurred in infants infected from health care equipment,<sup>151-153</sup> the hands of health care workers,<sup>154</sup> milk bottles,<sup>150</sup> aqueous solutions such as theophylline,<sup>150</sup> hand

hygiene washes,<sup>151</sup> and lipid parenteral feeds.<sup>153</sup> The gastrointestinal tracts of hospitalized infants provide a reservoir for transmission and infection.<sup>152</sup>

In a review of neonatal bacteremia and meningitis caused by *S. marcescens* by Campbell and colleagues,<sup>155</sup> 11 (29%) of 38 infants had meningitis as a complication of their bacteremia. Mean gestational age and birth weight were 28 weeks and 1099 g, respectively. All patients required mechanical ventilation, 90% had central venous catheters in situ, 90% had received prior antibiotics, 50% had a prior intraventricular hemorrhage, 40% had a hemodynamically significant patent ductus arteriosus treated medically or surgically, and 20% had necrotizing enterocolitis with perforation. All patients were treated for a minimum of 21 days with combination antimicrobial therapy that included a third-generation cephalosporin or a ureidopenicillin and an aminoglycoside, typically gentamicin. Three of 10 patients died. Four of the seven survivors developed severe hydrocephalus requiring ventriculoperitoneal shunt placement and had poor neurologic outcome. Poor neurologic outcome also was documented in a report of *S. marcescens* brain abscess resulting in multicystic encephalomalacia and severe developmental retardation.<sup>156</sup>

*P. aeruginosa* usually is a cause of late-onset disease in infants who are presumably infected from their endogenous flora or from equipment, from aqueous solutions, or occasionally from the hands of health care workers. Stevens and colleagues<sup>14</sup> reported nine infants with *Pseudomonas* sepsis, four of whom presented in the first 72 hours of life. In three of these infants, the initial signs were those of respiratory distress, and chest radiographs were consistent with hyaline membrane disease. Noma (i.e., gangrenous lesions of the nose, lips, and mouth) in a neonate has been associated with bacteremia caused by *P. aeruginosa*.<sup>157</sup>

A retrospective review of sepsis in infants admitted over the 10-year period from 1988 through 1997 to the neonatal intensive care unit at Children's Hospital of the King's Daughters in Norfolk, Virginia, identified 825 cases of late-onset sepsis.<sup>17</sup> Infants with *Pseudomonas* sepsis had the highest frequency of clinically fulminant onset (56%), and 20 (56%) of the 36 (56%) infants with *Pseudomonas* sepsis died within 48 hours of blood culture collection.

*P. aeruginosa* conjunctivitis in the neonate is a danger because it is rapidly destructive to the tissues of the eye and because it may lead to sepsis and meningitis. Shah and Gallagher<sup>158</sup> reviewed the course of 18 infants at Yale–New Haven Hospital newborn intensive care unit who had *P. aeruginosa* isolated from cultures of the conjunctiva during the 10 years beginning in 1986. Five infants developed bacteremia, including three with meningitis, and two infants died.

### ***Salmonella* Species**

Nontyphi *Salmonella* infection is an uncommon cause of sepsis and meningitis in neonates, but a significant proportion of cases of *Salmonella* meningitis occur in young infants. The CDC observed that approximately one third of 290 *Salmonella* isolates from CSF reported during 1968 to 1979 were from patients younger than 3 months of age, and more than one half were from infants younger than 1 year of age.<sup>159</sup> A 21-year review of gram-negative enteric meningitis

in Dallas beginning in 1969 identified *Salmonella* as the cause in 4 of 72 cases.<sup>44</sup> Investigators from Turkey reported seven cases of neonatal meningitis caused by *Salmonella* during the years 1995 to 2001.<sup>160</sup> Two of the five survivors developed communicating hydrocephalus, and one had a subdural empyema.

Reed and Klugman<sup>161</sup> reviewed 10 cases of neonatal typhoid that occurred in a rural African hospital. Six of the infants had early-onset sepsis with acquisition of the organism from the maternal genital tract, and four had late-onset infection with acquisition from a carrier or an environmental source. Two neonates developed meningitis, and three died.

### ***Neisseria meningitidis***

Although *N. meningitidis* is a leading cause of bacterial sepsis and meningitis among children and adolescents, it rarely is associated with invasive infection in neonates.<sup>31,45,162</sup> *N. meningitidis* may colonize the female genital tract<sup>163-165</sup> and has been associated with pelvic inflammatory disease.<sup>166</sup> The infant can be infected at delivery by organisms present in the maternal genital tract, or intrauterine infection can result during maternal meningococcemia.<sup>167</sup> Meningococcal sepsis is rare in the neonate, but more than 50 cases (including 13 from the preantibiotic era) have been described.<sup>168-170</sup> Early-onset and late-onset forms<sup>163,164,170</sup> of meningococcal sepsis in neonates have been reported. Purpura similar to that of meningococcemia in older children has been observed in a 15-day-old<sup>171</sup> and a 25-day-old infant.<sup>172</sup>

Shepard and colleagues<sup>170</sup> from the CDC reported 22 neonates with invasive meningococcal disease from a 10-year active, population-based surveillance of 10 states with diverse populations and more than 31 million persons. The average annual incidence was 9 cases per 100,000 people (versus 973.8 per 100,000 for group B *Streptococcus*). Sixteen patients had meningitis, and 6 of these also had meningococcemia. Six patients had early-onset disease. The overall mortality rate was 14%. Ten isolates were serogroup B, four were serogroup C, three were serogroup Y, one was non-groupable, and four were unavailable.

### ***Haemophilus influenzae***

Because of the introduction of *H. influenzae* type b conjugate vaccines in 1988, there has been a substantial decrease in the incidence in *H. influenzae* type b disease in infants and children in the United States and many other countries.<sup>173-175</sup> Given the estimated proportion of individuals that are completely immunized, the decrease in *H. influenzae* type b invasive disease has exceeded expectations. The reduction in *H. influenzae* carriage associated with vaccination and the consequent decreased transmission from immunized children to unimmunized infants and children likely explains this effect.<sup>176-178</sup>

Despite increased reporting of invasive infections caused by nontypeable *H. influenzae* in adults and older children,<sup>179-181</sup> such infections in neonates remain uncommon.<sup>182-185</sup> Four clinical syndromes have been associated with neonatal disease caused by *H. influenzae*: sepsis or respiratory distress syndrome; meningitis; soft tissue or joint infection; and otitis media or mastoiditis. The overall mortality rate was 5.5% for 45 cases reviewed by Friesen and Cho<sup>186</sup>; the

mortality rate was 90% for 20 infants with a gestation lasting less than 30 weeks. Clinical and epidemiologic characteristics were similar to those of neonatal disease caused by group B streptococci, including early-onset (within 24 hours of birth) and late-onset presentations, signs simulating respiratory distress syndrome, and a high mortality rate. Autopsy of infants with bacteremia related to nontypeable *H. influenzae* and signs of respiratory distress syndrome revealed hyaline membranes with gram-negative coccobacilli within the membranes, similar to findings of hyaline membranes due to group B streptococci.<sup>187</sup> Examination of placentas from mothers of infants with sepsis caused by nontypeable *H. influenzae* revealed acute chorioamnionitis and acute villitis in some.<sup>183</sup> *H. influenzae* also has been responsible for maternal disease, including bacteremia, chorioamnionitis,<sup>188</sup> acute or chronic salpingitis, and tubo-ovarian abscess.<sup>184</sup>

Neonatal sepsis caused by *Haemophilus parainfluenzae*<sup>189-191</sup> and *Haemophilus aphrophilus*<sup>192</sup> has been reported.

### ***Streptococcus pneumoniae***

Although pneumococci rarely are isolated from cultures from the cervix or vagina of gynecologic patients or pregnant women, cases of early-onset pneumococcal sepsis in neonates have been reported.<sup>193-198</sup> Bortolussi and colleagues<sup>193</sup> reported five infants with pneumococcal sepsis who had respiratory distress and clinical signs of infection on the first day of life. Three infants died, two within 12 hours of onset. *S. pneumoniae* was isolated from the vaginas of three of the mothers. Radiographic features were consistent with hyaline membrane disease or pneumonia, or both. The clinical features were strikingly similar to those of early-onset group B streptococcal infection, including the association of prolonged interval after rupture of membranes, early-onset respiratory distress, abnormal chest roentgenograms, hypotension, leukopenia, and rapid deterioration. Fatal pneumococcal bacteremia in a mother 4 weeks postpartum, and the same disease and outcome in her healthy term infant who died at 6 weeks of age, suggested an absence of protective antibody in mother and child.<sup>194</sup>

Hoffman and colleagues from the United States Multi-center Pneumococcal Surveillance Group<sup>198</sup> reported 20 cases of neonatal *S. pneumoniae* sepsis or meningitis in a review of 4428 episodes of pneumococcal infection at eight children's hospitals from 1993 to 2001. Ninety percent of the infants were born at term, with a mean age at the onset of infection of 18.1 days. Only two of the mothers had clinically apparent infections at the time of delivery. Eight neonates had meningitis and 12 had bacteremia; four of the bacteremic neonates also had pneumonia. The most common infecting pneumococcal serotypes were 19 (32%), 9 (18%), and 18 (11%). Penicillin and ceftriaxone nonsusceptibility were observed in 21.4% and 3.6% of isolates, respectively. Three deaths (15%) occurred, all within 36 hours of presentation.

### **Anaerobic Bacteria**

Improvements in techniques for isolation and identification of the various genera and species of anaerobic bacteria have provided a better understanding of the anaerobic flora of humans and their role in disease.<sup>199</sup> With the exception of *Clostridium tetani* and *Clostridium botulinum*, all of the

anaerobic bacteria belong to the normal flora of humans. Anaerobes are present on the skin, in the mouth, in the intestines, and in the genital tract. They account for the greatest proportion of the bacteria of the stool. All are present in the intestines, and have been isolated from the external genitalia or vagina of pregnant and nonpregnant women.<sup>200-202</sup> Newborns are colonized with these organisms during or just before delivery. A review of the literature on neonatal bacteremia due to anaerobic bacteria by Brook<sup>203</sup> in 1990 included 179 cases, with a mortality rate of 26%. *Bacteroides* and *Clostridium* species were the most common isolates. Predisposing factors for infection included premature rupture of membranes, preterm delivery, and necrotizing enterocolitis.

Anaerobic bacteria have been isolated from the blood of newborns with sepsis,<sup>204-206</sup> from various organs at autopsy,<sup>204</sup> from an infant with an adrenal abscess,<sup>207</sup> from an infant with an infected cephalhematoma,<sup>208</sup> and from infants with necrotizing fasciitis of the scalp associated with placement of a scalp electrode.<sup>209</sup> Feder<sup>210</sup> reviewed meningitis caused by *Bacteroides fragilis*; seven of nine reported cases occurred in neonates.

The incidence of neonatal sepsis caused by anaerobic bacteria remains uncertain, but recent data are available from some surveys that suggest the incidence is low (<5%).<sup>17,31,203</sup> Noel and colleagues<sup>205</sup> identified 29 episodes of anaerobic bacteremia in neonates in the intensive care unit at New York Hospital during 18 years. Chow and co-workers<sup>204</sup> analyzed 59 cases of neonatal sepsis associated with anaerobic pathogens and classified them into four groups: transient bacteremia after premature rupture of membranes and maternal amnionitis; sepsis after postoperative complications; fulminant septicemia (in the case of clostridial infections); and intrauterine death associated with septic abortion. The mortality rate associated with neonatal anaerobic sepsis reported in the literature ranges from 4% to 38%.<sup>204,211,212</sup>

Infections caused by *Clostridium* species can be localized, as in the case of omphalitis,<sup>213</sup> cellulitis, and necrotizing fasciitis,<sup>214</sup> or can manifest as sepsis or meningitis.<sup>215</sup> Disease in neonates has been related to *Clostridium perfringens*, *Clostridium septicum*, *Clostridium sordellii*, *Clostridium butyricum*, *Clostridium tertium*, and *Clostridium paraputrificum*.<sup>216</sup> The presenting signs usually are similar to those of other forms of bacterial sepsis. Chaney<sup>215</sup> reported a case of bacteremia caused by *C. perfringens* in mother and child in which the neonate had classic features of adult clostridial sepsis, including active hemolysis, hyperbilirubinemia, and hemoglobinuria. Motz and colleagues<sup>217</sup> reviewed five cases of clostridial meningitis due to *C. butyricum* and *C. perfringens*. Clostridial sepsis is accompanied by a high mortality rate.<sup>215</sup>

Neonatal tetanus is caused by the gram-positive anaerobic spore-forming bacillus, *C. tetani*. The organism is present in soil and can be present in human and animal feces. Infection usually occurs after contamination of the umbilical stump. In the United States, tetanus in the newborn is rare.<sup>218</sup> Since 1984, only three cases of neonatal tetanus have been reported.<sup>218-220</sup> The most recent case, reported from Montana in 1998, was an infant born to an unimmunized mother; the parents used a *C. tetani*-contaminated clay powder to accelerate drying of the umbilical cord. The use of this product had been promoted on an Internet site on "cord care" for use by midwives.<sup>221</sup>

In contrast to the United States, most cases of tetanus worldwide occur in neonates. In developing countries, the incidence and mortality of neonatal tetanus remain high.<sup>222-224</sup> Mustafa and colleagues<sup>225</sup> conducted a retrospective neonatal tetanus survey among rural and displaced communities in the East Nile Province in the Sudan and observed that neonatal tetanus was a major cause of neonatal mortality. The incidence in the displaced community was 7.1 cases per 1000 livebirths, more than double that reported from the stable rural community (3.2 per 1000). In both communities, coverage with two doses of tetanus toxoid was about 58%.

The mortality rate for neonatal tetanus in Djakarta in 1982 was 6.9 deaths per 1000 livebirths; in the island provinces of Indonesia, it was 10.7 deaths per 1000 livebirths.<sup>226</sup> The mortality rate for neonates with tetanus in Lima, Peru, was 45% and was not improved with use of intrathecal tetanus antitoxin.<sup>227</sup> However, a meta-analysis of intrathecal therapy in tetanus suggested benefit in adults but not in neonates.<sup>228</sup>

Application of contaminated materials to the umbilical cord is associated with deep-rooted customs and rituals in developing countries. A case-control study to identify risk factors for neonatal tetanus in rural Pakistan identified application of ghee (i.e., clarified butter from the milk of water buffaloes or cows) to the umbilical wound as the single most important risk factor.<sup>229</sup> Although commercial ghee is available in Pakistan, the ghee used in rural areas is made at home from unpasteurized milk. Oudesluys-Murphy<sup>230</sup> observed that application of some materials, including ghee and a stone wrapped in wet cloth, increased the risk of neonatal tetanus among Yoruba women but that other practices of cord care decreased the incidence, including searing of the cord with heat in China during the Ming dynasty and use of a candle flame to scar the cord in Guatemala. Neonatal tetanus is a preventable disease; use of hygienic techniques at delivery and a program of tetanus toxoid immunization of children and young adults, particularly of pregnant women, are effective in eliminating this lethal disease.<sup>230-233.</sup>

## Commensal Organisms

Species of bacteria and fungi that are normal flora of skin and mucous membranes can invade the bloodstream of neonates under certain circumstances. The bacteria include coagulase-negative *Staphylococcus* species, gram-positive rods other than *Listeria*, gram-negative cocci other than *N. meningitidis* and *N. gonorrhoeae*, and gram-positive anaerobes. The clinical significance of a blood culture positive for a commensal species often is obscure. Interpretation of culture results that identify commensal species and the management of infants with positive cultures are discussed later in "Diagnosis."

## Mixed Infections

Multiple organisms frequently are present in brain, liver, or lung abscesses; aspiration in the lung after pneumonia; or pleural empyema but infrequently are found in cultures of the blood or CSF. When several species are found, the significance of each is uncertain because it is possible that one or more of the organisms in a mixed culture is a contaminant.

Bacteremia with more than one organism occurs in patients with immunodeficiency, major congenital abnor-

malities, or contamination of a body fluid with multiple organisms, as is present in peritonitis typically as a sequela of severe necrotizing enterocolitis in the VLBW infant. Neonatal meningitis due to *S. pneumoniae* and *Acinetobacter calcoaceticus*<sup>234</sup> and sepsis due to *P. aeruginosa* and *Yersinia enterocolitica*<sup>235</sup> have been reported. Although included in a series of cases of neonatal sepsis by some investigators, mixed cultures are not identified by most. Mixed infections were reported by Tessin and co-workers<sup>24</sup> in 5% of 231 Swedish neonates, by Vesikari and associates<sup>21</sup> in 4% of 377 Finnish infants, and by Bruun and Paerregaard<sup>28</sup> in 7% of 81 Danish neonates. Faix and Kovarik<sup>236</sup> reviewed the records of 385 specimens of blood or CSF submitted to the microbiology laboratories at the University of Michigan Medical Center for the period of September 1971 to June 1986. More than one organism was present in 38 specimens from 385 infants in the neonatal intensive care unit; 15 (3.9%) infants had multiple pathogens associated with clinical signs of sepsis or meningitis. The mortality was high (60%). Factors predisposing to mixed infection included prolonged rupture of membranes (>24 hours), total parenteral nutrition, necrotizing enterocolitis, presence of an intravascular catheter or ventriculostomy, and entities associated with multiple pathogens, including peritonitis, pseudomembranous colitis, and hepatic necrosis. Chow and colleagues<sup>204</sup> reported polymicrobial bacteremia in eight newborns with anaerobic co-isolates or aerobic and anaerobic organisms in combination. An outbreak of polymicrobial bacteremia caused by *K. pneumoniae* and *E. cloacae* associated with use of a contaminated lipid emulsion was reported by Jarvis and colleagues.<sup>237</sup>

Mixed infections also can include bacteria and viruses or bacteria and fungi, typically *Candida*, in the situation of intravascular central catheter or peritoneal infections associated with bowel perforation. Sferra and Pacini<sup>238</sup> reported mixed viral-bacterial meningitis in five patients, including neonates with CSF isolates of enterovirus and group B *Streptococcus* in a 10-day-old child and enterovirus and *Salmonella* in a 12-day-old child.

### Uncommon Bacterial Pathogens

Uncommon bacterial pathogens responsible for neonatal sepsis and meningitis are listed in Table 6-8 with their references, and they are reviewed by Giaconia.<sup>239</sup>

## EPIDEMIOLOGY

### Incidence of Sepsis and Meningitis

The reported incidence of neonatal sepsis varies from less than 1 to 8.1 cases per 1000 livebirths.<sup>12,24,27,31,116,123,309-312</sup> A 2-year study of 64,858 infants from the Atlanta metropolitan area beginning in January 1982 (Table 6-9) reported an incidence of early-onset group B streptococcal disease of 1.09 per 1000 livebirths and 0.57 per 1000 livebirths for late-onset disease.<sup>310</sup> The increased usage of intrapartum antibiotic prophylaxis for women with group B streptococcal colonization with or without other risk factors associated with neonatal group B streptococcal disease has been associated with a 70% reduction in the incidence of early-onset group B streptococcal sepsis to 0.44 per 1000 livebirths in

**Table 6-9 Incidence and Mortality of Group B Streptococcal Disease by Birth Weight, Atlanta 1982-1983**

Birth Weight	Total Births	Early Onset		Late Onset	
		Cases (Deaths)	Cases/1000	Cases (Deaths)	Cases/1000
<1500 g	835	5 (1)	5.99	0	0
1500-2499 g	4,380	11 (2)	2.51	6 (0)	1.37
>2500 g	59,303	53 (5)	0.89	23 (0)	0.39

1999, a rate comparable to that of late-onset sepsis<sup>7</sup> (see Chapter 13).

The incidence of meningitis usually is a fraction of the number of neonates with early-onset sepsis. During the 8-year period from 1986 to 1994 at the Soroka University Medical Center in southern Israel, Greenberg and colleagues<sup>31</sup> found incidences of neonatal bacterial sepsis and meningitis of 3.2 cases and 0.5 case per 1000 livebirths, respectively. Certain pathogens that cause bloodstream invasion, such as group B streptococci, *E. coli*, and *L. monocytogenes*, are more likely to be accompanied by meningeal invasion than others (e.g., *S. aureus*). Meningitis is more frequent during the first month of life than in any subsequent period (see Table 6-6).

### Characteristics of Infants Who Develop Sepsis

Host susceptibility, socioeconomic factors, obstetric and nursery practices, and the health and nutrition of mothers are important in the pathogenesis of neonatal sepsis and meningitis. Infants who develop sepsis, particularly early-onset disease, usually have a history of one or more risk factors associated with the pregnancy and delivery that significantly increase the risk for neonatal infection. These factors include preterm delivery or low birth weight, premature rupture of membranes (i.e., rupture before the onset of labor), prolonged time of rupture of membranes, maternal peripartum infection, septic or traumatic delivery, and fetal hypoxia.

#### Birth Weight

The factor associated most significantly with enhanced risk for bacterial sepsis and meningitis in neonates is low birth weight<sup>16,31,313-315</sup> (see Tables 6-5 and 6-9). Infection is the most common cause of death in VLBW infants.<sup>314,315</sup> However, with the exception of infection caused by group B streptococci, it is unusual for a term infant to develop early-onset sepsis after an uneventful pregnancy and delivery. In a study in England and Wales, neonates weighing less than 2000 g at birth acquired meningitis six times more frequently than did infants weighing more than 2000 g.<sup>45</sup> The lower the infant's birth weight, the higher is the incidence of sepsis (see Table 6-5). An Israeli study of 5555 VLBW infants documented the increased risk of late-onset sepsis with decreasing birth weight; late-onset sepsis occurred in 16.8% of neonates with a birth weight of 1250 to 1500 g, 30.6% of neonates weighing 1000 to 1249 g, 46.4% of those weighing 750 to 999 g, and 53% of those weighing less than 750 g at birth.<sup>37</sup> In a study

**Table 6-10 Relationship of Attack Rates and Fatalities of Neonatal Group B Streptococcal Early-Onset Disease to Perinatal Characteristics**

Characteristic	Attack Rate per 1000 Livebirths	Mortality Rate (%)
Birth weight (g)		
<1000	26	90
1001-1500	8	25
1501-2000	9	29

Data from Boyer KM, Gadzala CA, Burd LI, et al. Selective intrapartum chemoprophylaxis of neonatal group B streptococcal early-onset disease: I. Epidemiologic rationale. *J Infect Dis* 148:795-801, 1983.

of infants in Atlanta (see Table 6-9), the importance of birth weight was identified as a predisposing factor for development of early-onset and late-onset sepsis. If VLBW infants survived the first days of life, rates of sepsis decreased but remained elevated<sup>310</sup>; 16% of 2416 infants with birth weights of 501 to 1500 g who were enrolled in a study sponsored by the National Institute of Child Health developed sepsis at a median of 17 days of age.<sup>16</sup>

#### Risk Factors of Infant and Mother

The relative importance of other factors associated with systemic infection in the newborn is more difficult to define. Greenberg and co-workers<sup>31</sup> found that certain conditions were common in their prospective study of 229 infants with sepsis and meningitis: 130 (57%) were premature (<37 weeks' gestation); 64 (28%) were delivered by cesarean section or instrumental delivery; 43 (19%) had an Apgar score of less than 7 at 5 minutes; and 27 (2%) had a prolonged (>24 hours) interval after rupture of maternal membranes. Investigators in Pakistan<sup>316</sup> found that maternal urinary tract infection, maternal fever, vaginal discharge and vaginal examinations during labor were maternal factors significantly associated with neonatal early-onset sepsis, whereas low Apgar scores at birth and the need for endotracheal intubation were significant neonatal risk factors.

Attack rates for early-onset group B streptococcal sepsis in a study from Chicago<sup>317</sup> were affected by birth weight, duration of rupture of membranes, and occurrence of maternal peripartum fever. Infants with one or more of these perinatal risk factors had an attack rate of 8 per 1000 livebirths and a mortality rate of 33%, compared with infants without such risk factors, who had an attack rate of 0.6 per 1000 livebirths and a mortality rate of 6% (Table 6-10).

**Table 6-11 Selected Characteristics of Women,<sup>a</sup> Their Pregnancies, and Newborns in the Collaborative Perinatal Study of the National Institute of Neurological Diseases and Stroke**

Characteristic	Percent with Characteristics	
	White Women	Black Women
Premature rupture of membranes: time from rupture to onset of labor		
<8 hr	70.9	56.7
8-23 hr	18.3	21.9
24-48 hr	5.4	11.7
49 + hr	5.4	9.7
Puerperal infection	3.6	4.1
Type of delivery		
Vaginal vertex	91.7	92.4
Vaginal breech	3.3	2.6
Cesarean section	4.9	5.0
Birth weight <2500 g	7.1	13.4
Neutrophilic infiltration of		
Amnion	9.0	7.9
Chorion	13.1	15.6
Umbilical vein	14.6	7.5

<sup>a</sup>Approximately 18,700 white women and 19,800 black women were evaluated. Data from reference 319.

Maternal fever during labor or after delivery suggests a concurrent infectious event in mother and infant, but non-infectious events may be responsible for maternal fever. Use of epidural analgesia for pain relief during labor is associated with increases in maternal temperature. Intrapartum fever of more than 38° C (100.4° F) occurred an average of 6 hours after initiation of the epidural anesthesia in 14.5% of women receiving an epidural anesthetic compared with 1.0% of women not receiving an epidural agent; the rate of fever increased from 7% in women with labors of less than 6 hours to 36% for labors lasting longer than 18 hours. There was no difference in the incidence of neonatal sepsis in the infants born to 1045 women who received epidural analgesia (0.3%) compared with infants born to women who did not have epidural analgesia (0.2%).<sup>318</sup> Fetal core temperature may be elevated during maternal temperature elevation, and increased temperature may be present transiently in the neonate after delivery.

### Ethnicity

The Collaborative Perinatal Research Study provides historical information on 38,500 pregnancies<sup>319</sup>; selected data for white and black women are presented in Table 6-11. Black women had a higher rate of premature rupture of membranes lasting more than 24 hours (21.4%) compared with white women (10.8%); black women had a higher rate of puerperal infection (4.1%) compared with white women (3.6%); and more black infants weighed less than 2500 g at birth (13.4%) compared with white infants (7.1%). Recent published data concurs with that observed 30 years ago. The National Center for Health Statistics reports continued dis-

**Table 6-12 Incidence of Fetal and Neonatal Infections by Sex**

Data based on a review of the literature and study of Johns Hopkins Hospital case records, 1930-1963.<sup>323</sup>

parities between blacks and whites in maternal and infant health indicators.<sup>320</sup> In 1996, significant differences were found between blacks and the general population in terms of neonatal mortality (9.6 versus 4.8 deaths per 1000 livebirths), low birth weight (13% versus 7.4%), and severe complications of pregnancy (23 versus 14 complications per 100 deliveries). A review of the literature from 1966 to 1994 reported significantly increased rates of severe histologic chorioamnionitis, maternal fever during labor, prolonged rupture of membranes and early neonatal mortality from sepsis in blacks compared with whites.<sup>321</sup>

In a study of group B streptococcal disease in infants from the Atlanta metropolitan area,<sup>310</sup> black infants had a higher incidence than nonblack infants of early-onset disease; the risk of late-onset disease was 35 times greater in black than in white infants. Thirty percent of early-onset disease and 92% of late-onset disease could be attributed to black race after controlling for other significant risk factors, such as low birth weight and maternal age younger than 20 years. The increased incidence of group B streptococcal disease in blacks of all ages was observed in a survey by the CDC in selected counties in California, Georgia, and Tennessee and the entire state of Oklahoma. The rate of disease of 13.5 cases per 100,000 blacks was significantly higher than the 4.5 cases per 100,000 whites. In neonates with early-onset infection, 2.7 cases per 1000 livebirths occurred in blacks and 1.3 cases per 1000 livebirths occurred in whites.<sup>322</sup> Maternal factors such as socioeconomic status, nutrition, recently acquired sexually transmitted diseases, or racial differences in maternally acquired protective antibodies may result in the increased risk of group B streptococcal disease among blacks.

### Gender

Historical data have suggested that there is a predominance of male neonates affected by sepsis and meningitis but not by in utero infections<sup>323,324</sup> (Table 6-12). This difference partially may reflect the fact that female infants had lower rates of respiratory distress syndrome (i.e., hyaline membrane disease) than did male infants. Torday and colleagues<sup>325</sup> studied fetal pulmonary maturity by determining lecithin-

to-sphingomyelin ratios and concentrations of saturated phosphatidylcholine and cortisol in amniotic fluid of fetuses between 28 and 40 weeks' gestation. Female infants had higher indices of pulmonary maturity than did male infants. These data provide a biochemical basis for the increased risk of respiratory distress syndrome in male infants and the possible role of these factors of pulmonary maturation in the development of pulmonary infection. Later studies failed to confirm a significant increased risk for bacterial sepsis and meningitis among male infants.<sup>31,326-328</sup>

### Geographic Factors

The cause of neonatal sepsis varies from hospital to hospital and from one community to another. These differences probably reflect characteristics of the population served, including unique cultural features and sexual practices, local obstetric and nursery practices, and patterns of antimicrobial agent usage. The bacteriology of neonatal sepsis and meningitis in western Europe<sup>20-28</sup> (see Table 6-3) and Jamaica<sup>329</sup> is generally similar to that in the United States. In tropical areas, a somewhat different pattern can be observed.<sup>330-332</sup> In Riyadh, Saudi Arabia, from 1980 through 1984, *E. coli*, *Klebsiella*, and *Serratia* species were the dominant causes of neonatal sepsis; group B *Streptococcus* was an infrequent cause.<sup>332</sup> However, later data from this geographic location revealed *E. coli* and CoNS, respectively, were the most common pathogens causing early-onset and late-onset sepsis.<sup>333</sup>

At Obafemi Awolowo University in Nigeria between 1994 and 1995, 59 cases of neonatal septicemia were reported.<sup>330</sup> Gram-positive bacteria were isolated from 60% of cases, with *S. aureus* accounting for 34% and *S. epidermidis* for 8%. *L. monocytogenes*, previously uncommon in this region, accounted for 14% of cases. Of the 40% of neonates with bloodstream infection caused by gram-negative organisms, *P. aeruginosa* was isolated from 25%, *K. pneumoniae* from 14%, and *E. coli* from 7%. Twenty-four bacterial isolates were cultured from CSF; 92% of these were gram-negative enteric bacilli. *P. aeruginosa* (32%), *K. pneumoniae* (23%), *Citrobacter freundii* (23%), and *E. coli* (14%) were most commonly isolated from CSF.

In a prospective survey from 1995 to 1996 of neonatal sepsis in South India,<sup>331</sup> 131 episodes of sepsis occurred among 125 newborn infants. Thirty (24%) infants had early-onset sepsis, and 95 (76%) had late-onset sepsis. *E. coli* and *E. faecalis* were the predominant pathogens in early-onset sepsis, whereas *Klebsiella* species and *E. faecalis* most commonly caused late-onset sepsis. Group B *Streptococcus* accounted for only two cases of early-onset disease. *Klebsiella* also was the most frequent cause of sepsis (43 of 176 positive blood cultures) in the neonatal unit at Chris Hani Baraqwanath Hospital in Johannesburg, South Africa, in the year beginning March 1996.<sup>34</sup> Group B *Streptococcus* was the next most frequent pathogen, accounting for 26 cases, and group A streptococcal sepsis occurred in 12 infants.

The rates and risk factors of maternal and neonatal group B streptococcal (GBS) colonization vary in different communities.<sup>334-336</sup> Amin and colleagues in the United Arab Emirates<sup>334</sup> evaluated 563 pregnant women from similar socioeconomic and ethnic backgrounds and reported a GBS colonization rate of 10.1%. In Athens, Greece, maternal and neonatal colonization rates were 6.6% and 2.4%, respectively, with a vertical transmission rate of 22.5%.<sup>335</sup> Middle-class

women followed in the private setting were more frequently colonized with GBS than those followed in a public hospital. No association was found between colonization with GBS and maternal age, nationality, marital status, previous obstetric history, cesarean section, infant birth weight, or preterm birth.

Stoll and Schuchat<sup>336</sup> reviewed data on female genital colonization with GBS from 34 reports in the literature and emphasized the importance of appropriate specimen collection and inoculation into selective (antibiotic containing) broth media in the ascertainment of accurate colonization rates. Analysis of data from studies employing adequate methods revealed regional GBS colonization rates of 12% in India and Pakistan, 19% in Asian and Pacific countries, 19% in sub-Saharan Africa, 22% in the Middle East and North Africa, and 14% in the Americas. A comparison of studies that did and did not use selective broth media revealed significantly higher GBS colonization rates in the populations where selective broth media was employed to assess colonization. Other reasons for varying rates of GBS colonization and disease may include socioeconomic factors or differences in sexual practices, hygiene, or nutrition.

### Socioeconomic Factors

The lifestyle pattern of mothers, including cultural practices, housing, nutrition, and level of income, appears to be important in determining infants at risk for infection. The most significant factors enhancing risk for neonatal sepsis are low birth weight and prematurity, and the incidence of these is inversely related to socioeconomic status. Various criteria for determining socioeconomic status have been used, but no completely satisfactory and reproducible standard is available. Maternal education, resources, and access to health care can affect the risk of neonatal sepsis. A CDC report<sup>337</sup> evaluating the awareness of perinatal group B streptococcal infection among women of childbearing age in the United States revealed that women with a high school education or less, women with a household income of less than \$25,000, and women reporting black, Asian/Pacific Islander, or other ethnicity had lower awareness of perinatal GBS infections than other women.

### Procedures

Most VLBW infants have one or more procedures that place them at risk for infection. Any disruption of the protective capability of the intact skin or mucosa can be associated with infection. In a multicenter study of neonatal intensive care unit patients, increased risk of bacteremia was associated with parenteral nutrition, mechanical ventilation, peripherally inserted central catheters, peripheral venous catheters, and umbilical artery catheters.<sup>338</sup>

### Nursery Outbreaks or Epidemics

The nursery is a small community of highly susceptible infants where patients have contact with many adults, including parents, physicians, nurses, respiratory therapists, and diagnostic imaging technicians (see Chapter 35). Siblings may enter the nursery or mothers' hospital suites and represent an additional source of infection. In these circumstances, outbreaks or epidemics of respiratory and gastrointestinal illness, most of which is caused by nonbacterial agents, can

occur. Spread of microorganisms to the infant occurs by droplets from the respiratory tracts of parents, nursery personnel, or other infants. Organisms can be transferred from infant to infant by the hands of health care workers. Individuals with open or draining lesions are especially hazardous agents of transmission.

Staphylococcal infection and disease are a concern in many nurseries in the United States (see Chapter 35). Epidemics or outbreaks associated with contamination of nursery equipment and solutions caused by *Proteus* species, *Klebsiella* species, *S. marcescens*, *Pseudomonas* species, and *Flavobacterium* also have been reported. An unusual and unexplained outbreak of early-onset group B streptococcal sepsis with an attack rate of 14 per 1000 livebirths occurred in Kansas City during January through August of 1990.<sup>339</sup>

The availability of molecular techniques to distinguish among bacterial strains provides an important epidemiologic tool in the investigation of nursery outbreaks. Previously, methods to determine strain relatedness relied on antibiotic susceptibility patterns, biochemical profiles, and plasmid or phage analysis.<sup>147,340</sup> More recent techniques permit the discrimination of strains based on bacterial chromosomal polymorphisms. Pulse-field gel electrophoresis, ribotyping, multilocus sequence typing, and polymerase chain reaction-based methods are widely used tools to assign strain identity or relatedness.<sup>341-343</sup>

Antimicrobial agents play a major role in the ecology of the microbial flora in the nursery. Extensive and prolonged use of these drugs eliminates susceptible strains and allows for proliferation of resistant subpopulations of neonatal flora. There is selective pressure toward colonization by microorganisms that are resistant to the antimicrobial agents used in the nurseries and, because of cross-resistance patterns, to similar drugs within an antimicrobial class.

A historical example of the selective pressure of a systemic antimicrobial agent is provided by Gezon and co-workers<sup>58</sup> in their use of benzathine penicillin G to control an outbreak of group A streptococcal disease. All infants entering the nursery during a 3-week period were treated with a single intramuscular dose of penicillin. Before institution of this policy, most strains of *S. aureus* in the nursery were susceptible to penicillin G. One week after initiation of the prophylactic regimen and for the next 2 years, almost all strains of *S. aureus* isolated from newborns in this nursery were resistant to penicillin G.

During a 4-month period in 1997, van der Zwet and colleagues<sup>344</sup> investigated a nosocomial nursery outbreak of gentamicin-resistant *K. pneumoniae* in which 13 neonates became colonized and 3 became infected. Molecular typing of strains revealed clonal similarity of isolates from eight neonates. The nursery outbreak was terminated by the substitution of amikacin for gentamicin in neonates when treatment with an aminoglycoside was believed to be warranted. Development of resistance in gram-negative enteric bacilli also has been documented in an Israeli study after widespread use of aminoglycosides.<sup>345</sup>

Extensive or routine use of third-generation cephalosporins in the nursery, especially for all neonates with suspected sepsis, can lead to more rapid emergence of drug-resistant gram-negative enteric bacilli than occurs with the standard regimen of ampicillin and an aminoglycoside. Investigators in Brazil<sup>124</sup> performed a prospective investigation of extended-

spectrum  $\beta$ -lactamase (ESBL)-producing *K. pneumoniae* colonization and infection during the 2-year period from 1997 to 1999 in the neonatal intensive care unit. A significant independent risk factor for colonization was receipt of a cephalosporin and an aminoglycoside. Previous colonization was an independent risk factor for infection. In India, Jain and co-workers<sup>134</sup> concluded that indiscriminate use of third-generation cephalosporins was responsible for the selection of ESBL-producing, multiresistant strains in their neonatal intensive care unit, where ESBL production was detected in 86.6% of *Klebsiella* species, 73.4% of *Enterobacter* species, and 63.6% of *E. coli* strains. Nosocomial infections in the nursery and their epidemiology and management are further discussed in Chapter 35.

### Unexplained Changes in the Pattern of Microorganisms in the Nursery

New strains of bacteria may appear in a nursery without changes in invasive procedures or techniques, nursery practices, or antimicrobial use. The cause of the worldwide epidemic of *S. aureus* disease in the 1950s is uncertain, as is the reason for its diminished importance in the late 1960s. The incidence of serious infections caused by group B streptococci increased in the 1970s, and there is no ready explanation for the appearance or persistence of this organism as a major cause of neonatal morbidity and mortality.

## PATHOGENESIS

The developing fetus is relatively protected from the microbial flora of the mother. However, procedures disturbing the integrity of the uterine contents, such as amniocentesis,<sup>346</sup> cervical cerclage,<sup>347,348</sup> transcervical chorionic villus sampling,<sup>349</sup> or percutaneous umbilical blood sampling,<sup>346,350</sup> can permit entry of skin or vaginal organisms into the amniotic sac, causing amnionitis and secondary fetal infection.

Initial colonization of the neonate usually takes place after rupture of the maternal membranes.<sup>323,351</sup> In most cases, the infant is colonized with the microflora of the birth canal during delivery. However, if delivery is delayed, vaginal bacteria may ascend the birth canal and, in some cases, produce inflammation of the fetal membranes, umbilical cord, and placenta.<sup>352</sup> Fetal infection can then result from aspiration of infected amniotic fluid,<sup>353</sup> leading to stillbirth, premature delivery, or neonatal sepsis.<sup>346,352,354,355</sup> The organisms most commonly isolated from infected amniotic fluid are group B streptococci, *E. coli* and other enteric bacilli, anaerobic bacteria, and genital mycoplasmas.<sup>346,354</sup>

There are studies reporting that amniotic fluid inhibits the growth of *E. coli* and other bacteria due to the presence of lysozyme, transferrin, immune globulins (IgA and IgG but not IgM), zinc and phosphate, and lipid-rich substances.<sup>355-361</sup> The addition of meconium to amniotic fluid in vitro has resulted in increased growth of *E. coli* and group B streptococci in some studies.<sup>362,363</sup> However, in other in vitro studies of the bacteriostatic activity of amniotic fluid, there is not inhibition of the growth of group B streptococci.<sup>364-366</sup> Further discussion of bacterial inhibition by amniotic fluid is available in Chapter 3.

Infection of the mother at the time of birth, particularly genital infection, can play a significant role in the development of infection in the neonate. Transplacental hematogenous infection during or shortly before delivery (including the period of separation of the placenta) is possible, although it is more likely that the infant is infected just before or during passage through the birth canal. Among reports of concurrent bacteremia in mother and neonate are cases caused by *H. influenzae* type b,<sup>367</sup> *H. parainfluenzae*,<sup>191</sup> *S. pneumoniae*,<sup>368,369</sup> group A *Streptococcus*,<sup>370</sup> *N. meningitidis*,<sup>371</sup> *Citrobacter* species,<sup>372</sup> and *Morganella morgagnii*<sup>373</sup>; and concurrent cases of meningitis have been reported as caused by *S. pneumoniae*,<sup>374</sup> *N. meningitidis*,<sup>371</sup> and group B streptococci.<sup>375</sup> Many neonates are bacteremic at the time of delivery, which indicates that invasive infection occurred antepartum.<sup>376</sup> Infants with signs of sepsis during the first 24 hours of life also have the highest mortality rate.<sup>20</sup> These data suggest the importance of initiating chemoprophylaxis for women with group B streptococcal colonization or other risk factors for invasive disease in the neonate at the time of onset of labor (see Chapter 13).<sup>377</sup>

Microorganisms acquired by the newborn infant just before or during birth colonize the skin and mucosal surfaces, including the conjunctivae, nasopharynx, oropharynx, gastrointestinal tract, umbilical cord, and in the female infant, the external genitalia. Normal skin flora of the newborn includes coagulase-negative staphylococci, diphtheroids, and *E. coli*.<sup>378</sup> In most cases, the microorganisms proliferate at the initial site of attachment without resulting in illness. Occasionally, contiguous areas may be infected by direct extension (e.g., sinusitis and otitis can occasionally occur from upper respiratory tract colonization).

Bacteria can be inoculated into the skin and soft tissue by obstetric forceps, and organisms may infect these tissues if abrasions or congenital defects are present. Scalp abscesses can occur in infants who have electrodes placed during labor for monitoring of heart rate.<sup>379-381</sup> The incidence of this type of infection in the hands of experienced clinicians, however, is generally quite low (0.1% to 5.2%).<sup>382</sup> A 10-year survey of neonatal enterococcal bacteremia detected 6 of 44 infants with scalp abscesses as the probable source of their bacteremia.<sup>380</sup> The investigators were unable from the data available to deduce whether these abscesses were associated with fetal scalp monitoring, intravenous infusion, or other procedures that resulted in loss of the skin barrier.

Transient bacteremia can accompany procedures that traumatize mucosal membranes such as endotracheal suctioning.<sup>383</sup> Invasion of the bloodstream also can follow multiplication of organisms in the upper respiratory tract or other foci. Although the source of bacteremia frequently is inapparent, careful inspection can reveal a focus, such as an infected circumcision site or infection of the umbilical stump, in some neonates. Metastatic foci of infection can follow bacteremia and can involve the lungs, kidney, spleen, bones, or central nervous system.

Most cases of neonatal meningitis result from bacteremia. Fetal meningitis followed by stillbirth<sup>384</sup> or hydrocephalus, presumably because of maternal bacteremia and transplacentally acquired infection, has been described but is exceedingly rare. Although CSF leaks caused by spiral fetal scalp electrodes do occur, no cases of meningitis have been traced to this source.<sup>385-386</sup> After delivery, the meninges can

be invaded directly from an infected skin lesion, with spread through the soft tissues and skull sutures and along thrombosed bridging veins,<sup>351</sup> but in most circumstances, bacteria gain access to the brain through the bloodstream to the choroid plexus during the course of sepsis.<sup>384</sup> Infants with developmental defects such as a midline dermal sinus or myelomeningocele are particularly susceptible to invasion of underlying nervous tissue.<sup>44</sup>

Brain abscesses can result from hematogenous spread of microorganisms (i.e., septic emboli) and proliferation in tissue that is devitalized because of anoxia or vasculitis with hemorrhage or infarction. Certain organisms are more likely than others to invade nervous tissue and cause local or widespread necrosis.<sup>44</sup> Most cases of meningitis related to *C. koseri* (formerly *C. diversus*) and *E. sakazakii* are associated with cyst and abscess formation. Other gram-negative bacilli with potential to cause brain abscesses include *Proteus*, *Pseudomonas*, *S. marcescens*, and occasionally group B streptococci.<sup>148,155,387-389</sup> Volpe comments that bacteria associated with brain abscesses are those that cause meningitis with severe vasculitis.<sup>390</sup>

## Host Factors

Infants with one or more predisposing factors (e.g., low birth weight, premature rupture of membranes, septic or traumatic delivery, fetal hypoxia, maternal peripartum infection) are at increased risk for sepsis. Microbial factors such as inoculum size<sup>391</sup> and virulence properties of the organism<sup>346</sup> undoubtedly are significant. Immature function of phagocytes and decreased inflammatory and immune effector responses are characteristic of very small infants and can contribute to the unique susceptibility of the fetus and newborn (see Chapter 4).

Metabolic factors are likely to be important in increasing risk for sepsis and severity of the disease. Fetal hypoxia and acidosis can impede certain host defense mechanisms or allow localization of organisms in necrotic tissues. Infants with hyperbilirubinemia can suffer impairment of various immune functions, including neutrophil bactericidal activity, antibody response, lymphocyte proliferation, and complement functions (see Chapter 4). The indirect hyperbilirubinemia that commonly occurs with breast-feeding jaundice rarely is associated with neonatal sepsis.<sup>392</sup> Late-onset jaundice and direct hyperbilirubinemia can be the result of an infectious process. Evidence of diffuse hepatocellular damage and bile stasis have been described in such infants.<sup>393,394</sup>

Hypothermia in newborns, generally defined as a rectal temperature equal to or below 35° C (95° F), is associated with a significant increase in the incidence of sepsis, meningitis, pneumonia, and other serious bacterial infections.<sup>395-398</sup> In developing countries, hypothermia is a leading cause of death during the winter. Hypothermia frequently is accompanied by abnormal leukocyte counts, acidosis, and uremia, each of which can interfere with resistance to infection. However, the exact cause of increased morbidity in infants presenting with hypothermia remains poorly understood. In many infants, it is unclear whether hypothermia predisposes to or results from bacterial infection.

Infants with galactosemia have increased susceptibility to sepsis caused by gram-negative enteric bacilli, in particular *E. coli*.<sup>399-401</sup> Among eight infants identified with galactosemia

by routine newborn screening in Massachusetts, four had systemic infection caused by *E. coli*.<sup>400</sup> Three of these four infants died of sepsis and meningitis; the fourth infant, who had a urinary tract infection, survived. A survey of state programs in which newborns are screened for galactosemia revealed that among 32 infants detected, 10 had systemic infection, and 9 died of bacteremia. *E. coli* was the infecting organism in nine of the infants, and group D *Streptococcus* was the pathogen in the 10th infant. It appears that galactosemic neonates have an unusual predisposition to severe infection with *E. coli*, and bacterial sepsis is a significant cause of death among these infants. Depressed neutrophil function due to elevated serum galactose levels is postulated to be a possible cause of their predisposition to sepsis.<sup>402,403</sup>

Other inherited metabolic diseases have not been associated with a higher incidence of neonatal bacterial infection. A poorly documented increase in the relative frequency of sepsis has been observed among infants with hereditary fructose intolerance.<sup>404</sup> Infants with methylmalonic acidemia and other inborn errors of branched-chain amino acid metabolism manifest neutropenia as a result of bone marrow suppression by accumulated metabolites; however, no increased incidence of infection has been described in this group of infants.<sup>405,406</sup> Shurin<sup>402</sup> observed that infants became ill when serum galactose levels were high when glucose levels were likely to be low and that susceptibility to infection diminished when dietary control was initiated.

Iron may have an important role in the susceptibility of neonates to infection, but this continues to be controversial. Iron added to serum *in vitro* enhances the growth of many organisms, including *E. coli*, *Klebsiella* species, *Pseudomonas* species, *Salmonella* species, *L. monocytogenes*, and *S. aureus*. Iron-binding proteins, lactoferrin and transferrin, are present in serum, saliva, and breast milk. However, the newborn has low levels of these proteins.<sup>407</sup> Barry and Reeve<sup>408</sup> demonstrated an increased incidence of sepsis in Polynesian infants who were treated with intramuscular iron. Prophylactic regimens of intramuscular iron dextran were administered to these infants soon after birth because of a high incidence of iron-deficiency anemia. The regimen was shown to be effective in preventing anemia of infancy, but an extraordinary increase in bacterial sepsis occurred. The incidence of sepsis in newborns receiving iron was 17 cases per 1000 livebirths, whereas the incidence of sepsis in infants who did not receive iron was 3 cases per 1000 livebirths; during a comparable period, the rate of sepsis for European infants was 0.6 case per 1000 livebirths. Special features of sepsis in the infants who received iron soon after birth were late-onset, paucity of adverse perinatal factors, and predominance of *E. coli* as the cause of sepsis. During the period studied, *E. coli* was responsible for 26 of 27 cases of sepsis in iron-treated Polynesian infants and for none of three cases of sepsis in the infants who did not receive iron. Results of this study were similar to the experience reported by Farmer<sup>409</sup> for New Zealand infants given intramuscular iron. The incidence of meningitis caused by *E. coli* increased fivefold in infants who received iron and decreased when the use of iron was terminated.

### Infection in Twins

Studies have suggested a higher risk for contracting ascending intrauterine infection in the first than the second

born of twins.<sup>410,411</sup> Pass and colleagues<sup>412</sup> showed that low-birth-weight twins were at higher risk for group B streptococcal infection than were low-birth-weight singletons; infection developed in 3 of 56 twin births, or 53.5 cases per 1000 livebirths, compared with infections in 7 of 603 singleton births, or 11.6 cases per 1000 livebirths. Edwards and colleagues<sup>413</sup> studied group B streptococcal infection in 12 index cases of multiple gestations. Early-onset disease occurred in both twins in one pair and in one twin in five other pairs; late-onset infection occurred in both infants in two pairs and in one twin in four other pairs. Cases of late-onset group B streptococcal disease in twin pairs occurred closely in time to one another: 19 and 20 days in one set and at 28 and 32 days of age in the other set.

In twins, the presence of virulent organisms in the environment, especially the maternal genital tract; their absence of specific maternal antibodies; and their similar genetic heritage probably contribute to the risk for invasive infection. It seems logical that twins, particularly if monochorionic, should have high rates of simultaneous early-onset infection, but it is particularly intriguing that some cases of late-onset disease occur in twins almost simultaneously. Infections in twins, including disease related to *T. pallidum*, echoviruses 18 and 19, and *Toxoplasma gondii*, are discussed in Chapters 18, 24, and 31, respectively. Neonatal infections in twins have been caused by group A streptococci<sup>414</sup> (case report of streptococcal sepsis in a mother and infant twins) and *Salmonella* species,<sup>415</sup> malaria,<sup>416,417</sup> coccidioidomycosis,<sup>418</sup> cytomegalovirus infection,<sup>419-421</sup> and rubella.<sup>422</sup>

### The Umbilical Cord as a Focus of Infection

Historically, the umbilical cord was a particularly common portal of entry for systemic infection in the newborn, and infection by this route can still occur. The devitalized tissue is an excellent medium for bacterial growth, and the recently thrombosed umbilical vessels provide direct access to the bloodstream. Epidemics of erysipelas, staphylococcal disease, tetanus, and gas gangrene of the umbilicus were common in the 19th century. The introduction of simple hygienic measures in cord care resulted in a marked reduction of omphalitis.<sup>423</sup> In 1930, Cruickshank wrote, "in Prague, before antiseptic and aseptic dressing of the cord was introduced, sepsis neonatorum was as common as puerperal sepsis ... after the introduction of cord dressing in the hospital the number of newborn children developing fever sank from 45% to 11.3%."<sup>424,425</sup>

Closure of the umbilical vessels and the subsequent aseptic necrosis of the cord begins soon after the infant takes the first breath; the umbilical arteries contract, the blood flow is interrupted, and the cord tissues, deprived of a blood supply, undergo aseptic necrosis. The umbilical stump acquires a rich flora of microorganisms. Within hours, the umbilical stump is colonized with large numbers of gram-positive cocci, particularly *Staphylococcus* species, and shortly thereafter with fecal organisms.<sup>425,426</sup> These bacteria can invade the open umbilical wound, causing a localized infection with purulent discharge and, as a result of delayed obliteration of the umbilical vessels, bleeding from the umbilical stump. From this site, infection can proceed into the umbilical vessels, along the fascial planes of the abdominal wall, or into the peritoneum<sup>423,425,427,428</sup> (Fig. 6-1).

**Figure 6-1** After birth, the necrotic tissue of the umbilical stump separates. This provokes some inflammation, which is limited by a fibroblastic reaction extending to the inner margin of the coarsely stippled area. The inner half of the media and the intima of the umbilical arteries become necrotic, but this does not stimulate an inflammatory reaction. Arrows indicate routes by which infection may spread beyond the granulation tissue barriers. Organisms invading the thrombus in the vein may disseminate by emboli. (From Morison JE. *Foetal and Neonatal Pathology*, 3rd ed. Washington, DC, Butterworth, 1970.)

Although umbilical discharge or an “oozing” cord is the most common manifestation of omphalitis, periumbilical cellulitis and fasciitis are the conditions most often associated with hospitalization.<sup>427</sup> Infants presenting with fasciitis have a high incidence of bacteremia, intravascular coagulopathy, shock, and death.<sup>427</sup> Septic embolization arising from the infected umbilical vessels is uncommon but can produce metastatic spread to various organs, including the lungs, pancreas, kidneys, and skin.<sup>423</sup> Such emboli can arise from the umbilical arteries and from the umbilical vein, because final closure of the ductus venosus and separation of the portal circulation from the inferior vena cava and the systemic circulation are generally delayed until day 15 to 30 of life.<sup>429</sup>

Complications of omphalitis, now a rare infection in developed countries because of modern umbilical cord care, include a variety of infections such as septic umbilical arteritis,<sup>423,430</sup> suppurative thrombophlebitis of the umbilical or portal veins or the ductus venosus,<sup>430-432</sup> peritonitis,<sup>428,430,431,434</sup> intestinal gangrene,<sup>428</sup> liver abscess, endocarditis, pylephlebitis,<sup>428,435</sup> and subacute necrotizing funisitis.<sup>436</sup> Some of these infections can occur in the absence of signs of omphalitis.<sup>423,430</sup>

### Administration of Drugs to the Mother before Delivery

Almost all antimicrobial agents cross the placenta. Antimicrobial drugs administered to the mother at term can alter

the initial microflora of the neonate and can complicate the diagnosis of infection in the neonate. Chapter 37 reviews the clinical pharmacology of antimicrobial agents administered to the mother.

Several studies have shown that corticosteroid administration to mothers in preterm labor to enhance pulmonary maturation in the fetus resulted in a significant decrease in the incidence and severity of neonatal respiratory distress syndrome but an increase in maternal infection, particularly endometritis, when compared with placebo.<sup>437</sup> A trend toward increased neonatal infection also was described among infants whose mothers received corticosteroid treatment.<sup>437</sup> Many other investigators have found that corticosteroids administered to the mother at term had no effect on maternal or neonatal infections.<sup>437-439</sup>

Substance abuse during pregnancy can affect immune function in the neonate. Significant abnormalities in T cell function and an apparent increased incidence of infections have been found during the first year of life among infants born to alcohol-addicted<sup>440,441</sup> and heroin-addicted<sup>442,443</sup> mothers. The adverse effects of cocaine and opiates on placental function, fetal growth and development, and prematurity also may predispose to a greater likelihood of neonatal infection.<sup>443,444</sup> Unfortunately, drug abuse is a multifactorial problem; it is virtually impossible to separate the consequences of direct pharmacologic effects on the fetus from those due to inadequate nutrition, lack of prenatal care, and infectious medical complications encountered in addicted pregnant women.<sup>443-445</sup>

### Administration of Drugs Other than Antibiotics to the Neonate

Administration of indomethacin to neonates for the closure of a patent ductus arteriosus has been associated with a higher incidence of sepsis and necrotizing enterocolitis in the indomethacin-treated groups compared with infants treated with surgery or other medications.<sup>446-448</sup> The mechanism by which indomethacin predisposes low-birth-weight infants to sepsis is unknown.<sup>448</sup>

O’Shea and colleagues<sup>449</sup> described the outcomes of VLBW (500 to 1250 g) infants given dexamethasone at 15 to 25 days of age for the prevention of chronic lung disease. Among 61 infants treated with tapering doses of dexamethasone for 42 days, there was no increase in the incidence of sepsis or the number of sepsis evaluations in the treatment group when compared with a control population.

A strong association between intravenous lipid administration to newborns and coagulase-negative staphylococcal bacteremia has been confirmed.<sup>105</sup> Although the infants in this study were of low birth weight, ill, and were using non-umbilical central venous catheters for nutrition, administration of lipid emulsion was an independent risk factor for bacteremia. It was postulated that the role of lipid as a growth medium for bacteria, the mechanical blockage of the catheter by deposition of lipid in the lumen, and the effect of lipid emulsions on the function of neutrophils and macrophages each might contribute to the observed increased risk for bacteremia.

The effects of prostaglandins and leukotrienes in the perinatal period have been reviewed by Heymann.<sup>450</sup> Prosta-

glandin E<sub>1</sub> has been used in the management of congenital malformations for which it is critical to maintain the ductus arteriosus in a dilated position. Adverse effects of prostaglandin E<sub>1</sub> that can be confused with sepsis included temperature elevation, hypotension, and jitteriness.

## **PATHOLOGY**

Infants with severe and rapidly fatal sepsis generally have minimal or no histologic indication of an infectious process.<sup>351,451</sup> Findings typical of bacteremia, such as multiple disseminated abscesses of similar size, purulent vasculitis, and intravascular identification of bacteria, are evident in a minority of infants.<sup>451</sup> Shock accompanying sepsis sometimes causes findings such as periventricular leukomalacia and intraventricular hemorrhage, scattered areas of nonzonal hepatic necrosis, renal medullary hemorrhage, renal cortical or acute tubular necrosis, and adrenal hemorrhage and necrosis. Evidence of disseminated intravascular coagulopathy, manifested by strands of interlacing fibrin in the vessels or by a well-demarcated subarachnoid fibrinous hematoma, also can be present.<sup>384,451</sup> The pathology of infections of the respiratory, genitourinary, and gastrointestinal tracts and focal suppurative diseases is discussed in subsequent chapters.

The pathology of neonatal meningitis<sup>384,452,453</sup> and brain abscess<sup>454,455</sup> is similar to that in the older child and adult. The major features are ventriculitis (including inflammation of the choroid plexus), vasculitis, cerebral edema, infarction, cortical neuronal necrosis, and periventricular leukomalacia; chronic pathologic features include hydrocephalus, multicystic encephalomalacia and porencephaly, and cerebral cortical and white matter atrophy.<sup>456</sup> Significant collections of purulent material can be present in the sulci and subarachnoid space, particularly around the basal cisterns, of infants with meningitis. Because the fontanelles are open, exudative material can collect around the base of the brain without a significant increase in intracranial pressure. Hydrocephalus may result from closure of the aqueduct or the foramina of the fourth ventricle by purulent exudate or by means of inflammatory impairment of CSF resorption through the arachnoid channels.<sup>384,457</sup> Ventriculitis has been described in 20% to 90% of cases<sup>44,384,457</sup> and often is the reason for persistence of bacteria in CSF when obstruction ensues and for a slow clinical recovery.<sup>458</sup> Acute inflammatory cells infiltrate the ependymal and subependymal tissues, causing destruction of the epithelial lining of the ventricles. Hemorrhage, venous thrombosis, and subdural effusions often are present.

Brain abscesses and cysts in the neonate are distinguished by the relatively large size of the lesions and relatively poor capsule formation. They occur most frequently in association with meningitis caused by *C. koseri*, *E. sakazakii*, *S. marcescens*, and *Proteus mirabilis* and usually are located in the cerebrum, involving several lobes.<sup>148,155,387,390</sup> These organisms characteristically give rise to a hemorrhagic meningoencephalitis caused by intense bacterial infiltration of cerebral vessels and surrounding tissues. The resulting vascular occlusion is followed by infarction and widespread necrosis of cerebral tissue with liquefaction and formation of multiple loculated abscesses and cysts.<sup>387,390</sup>

## **CLINICAL MANIFESTATIONS**

Signs of fetal distress can be the earliest indication of infection in neonates with sepsis, beginning at or soon after delivery. Fetal tachycardia in the second stage of labor was evaluated as a sign of infection by Schiano and colleagues.<sup>459</sup> Pneumonia or sepsis occurred in 3 of 8 infants with marked fetal tachycardia (>180 beats per minute), in 7 of 32 infants with mild tachycardia (160 to 179 beats per minute), and in 1 of 167 infants with lower heart rates.

A low Apgar score, suggesting distress at or before delivery, also has been correlated with sepsis in the newborn period. Infants delivered vaginally had a 56-fold higher risk of sepsis when the Apgar score was less than 7 at 5 minutes compared with infants with higher Apgar scores.<sup>460</sup> Among infants with rupture of the amniotic membranes for 24 hours or more, St. Geme and colleagues<sup>352</sup> found a significant increase in the risk for perinatal bacterial infection among those with an Apgar score of less than 6 at 5 minutes but found no association with fetal tachycardia (>160 beats per minute).

The Apgar score is well characterized in term infants but less so in premature infants who have the higher attack rates for sepsis. Because low Apgar scores (<3 at 1 minute, <6 at 5 minutes) were significantly associated with low birth weight and shorter gestation, the use of the score is less valuable as an indicator of sepsis in premature than in term infants.<sup>461</sup>

The earliest signs of sepsis often are subtle and non-specific. Poor feeding, diminished activity, or just "not looking well" can be the only early evidence that infection is present. More prominent findings are respiratory distress, apnea, lethargy, fever or hypothermia, jaundice, vomiting, diarrhea, and skin manifestations, including petechiae, abscesses, and sclerema.<sup>462</sup>

The nonspecific and subtle nature of the signs of sepsis in newborns is even more problematic in identifying sepsis in the VLBW infant. In a study by Fanaroff and colleagues,<sup>16</sup> the clinical signs of late-onset sepsis in 325 infants weighing 501 to 1500 g at birth included increasing apnea and bradycardia episodes (55%), increasing oxygen requirement (48%), feeding intolerance, abdominal distention or guaiac-positive stools (46%), lethargy and hypotonia (37%), and temperature instability (10%). Unexplained metabolic acidosis (11%) and hypoglycemia (10%) were the most common laboratory indicators of the metabolic derangement accompanying sepsis.

Bonadio and co-workers<sup>463</sup> attempted to determine the most reliable clinical signs of sepsis in more than 200 febrile infants from birth to 8 weeks old. They found that changes in affect, peripheral perfusion, and respiratory status best identified those infants with serious bacterial infection. Alterations in feeding pattern, level of alertness, level of activity, and muscle tone also were present; however, these signs were less sensitive indicators.

Focal infection involving any organ can occur in infants with sepsis, but most often (excluding pneumonia or meningitis), this occurs in neonates with late-onset rather than early-onset disease. Evaluation of infants with suspected bacteremia must include a careful search for primary or secondary foci such as meningitis, pneumonia, urinary tract infection, septic arthritis, osteomyelitis, peritonitis, or soft tissue infection.

Table 6-13 Clinical Signs of Bacterial Sepsis

Clinical Sign	Percent of Infants with Sign

Data from references 3, 4, 10, and 11.

Serious bacterial infections are uncommon in neonates without any clinical evidence of illness,<sup>463</sup> even among those with maternal risk factors for infection.<sup>464</sup> Occasionally, bacteremia occurs without clinical signs.<sup>465-467</sup> Albers and associates<sup>465</sup> described the case histories of three infants without signs of illness for whom blood cultures were performed as part of a nursery study involving 131 infants. Blood was obtained from peripheral veins at different times during the first 10 days of life. The same pathogen was isolated repeatedly (i.e., three, three, and two times) from the blood of the three infants even though they remained well. The infants subsequently were treated with appropriate antimicrobial agents. Bacteremia caused by group B streptococci can occur with minimal or no systemic or focal signs,<sup>467-469</sup> and it may be sustained over several days.<sup>470</sup> Most healthy-appearing infants with group B streptococcal bacteremia were born at term and had early-onset (<7 days old) infection. Similarly, among 44 neonates with enterococcal bacteremia, 3 (17%) of 18 with early-onset infection but none with late-onset infection appeared well.<sup>96</sup> The incidence of bacteremia without clinical signs is uncertain because few cultures of blood are performed for infants who show no signs of sepsis.

Table 6-13 lists the common clinical signs of neonatal bacterial sepsis. Clinical signs of neonatal bacterial meningitis are given in Table 6-14. Noninfectious conditions that can present with clinical manifestations similar to those of sepsis are shown in Table 6-15.

### Fever and Hypothermia

The temperature of the infant with sepsis may be elevated, depressed, or normal.<sup>468-474</sup> In a multicenter survey of nearly 250 infants with early-onset group B streptococcal bacteremia, approximately 85% had a normal temperature (36°C to 37.2°C [96.8°F to 99°F]) at the time of their admission to the neonatal intensive care unit.<sup>468</sup> In comparing temperatures by gestational age, it was observed that term infants were more likely to have fever than preterm infants (12% versus 1%), whereas preterm infants more frequently had hypothermia (13% versus 3%). Phagocytes of the infant born after an uncomplicated labor can produce adult concentrations of interleukin-1, a potent pyrogen. The phagocytes of infants born after cesarean section have a

Table 6-14 Clinical Signs of Bacterial Meningitis

markedly suppressed ability to produce this pyrogen.<sup>475</sup> In the studies reviewed in Table 6-13, approximately one half of the infants had fever. Hypothermia, which was mentioned in one study, occurred in 15% of the infants.

Fever is variably defined for newborns. A temperature of 38.0°C (100.4°F) measured rectally generally is accepted as the lower limit of the definition of fever. Although some clinical studies indicate that axillary,<sup>476,477</sup> skin-matrix,<sup>476</sup> and infrared tympanic membrane thermometry<sup>477</sup> are accurate and less dangerous than rectal measurements for obtaining core temperature, the reliability of these methods, particularly in febrile infants, has been questioned.<sup>478-481</sup> The current method of choice for determining the presence of fever in neonates is a rectal temperature taken at a depth of 2 to 3 cm past the anal margin. In infants with suspected sepsis without fever, it has been shown that a difference between core (rectal) and skin (sole of the foot) temperature of more than 3.5°C can be a more useful indicator of infection than measurement of core temperature alone.<sup>474</sup>

There is no study of temperatures in neonates that is prospective, assesses all infants (febrile and afebrile), includes rectal and axillary temperatures, includes preterm and term infants, and requires positive cultures of blood or other body fluids to define invasive bacterial infection. However, Voora and colleagues<sup>482</sup> observed 100 term infants in Chicago with an axillary or rectal temperature of 37.8°C (100.1°F) or higher during the first 4 days of life, and Osborn and Bolus<sup>483</sup> conducted a retrospective review of 2656 term infants in Los Angeles. Both groups of investigators reported that temperature elevation in healthy term infants was uncommon. Approximately 1% of neonates born at term had at least one episode of fever, measured as 37.8°C (100.1°F) or higher per axilla.<sup>482</sup> Temperature elevation infrequently was associated with systemic infection when a single evaluation occurred. None of 64 infants in these two studies who had a single episode of fever developed clinical evidence of systemic infection (cultures of blood or other body fluids were not obtained). By contrast, temperature elevation that was sustained for more than 1 hour frequently was associated with infection. Of seven infants with sustained fever in the Osborn and Bolus study,<sup>483</sup> five had proven bacterial or viral infections. Of 65 infants reported by Voora and colleagues,<sup>482</sup> 10 had documented systemic bacterial disease. Temperature elevation without other signs of infection was infrequent. Only one

--	---

infant (with cytomegalovirus infection) of the five Los Angeles infants had fever without other signs. Only two infants (with bacteremia caused by *E. coli* or group B *Streptococcus*, respectively) of the 10 Chicago infants with fever and proven bacterial disease had no other signs of infection.

In addition to infection, fever may be caused by an elevation in ambient temperature, dehydration, retained blood or extensive hematoma, and damage to the temperature-regulating mechanisms of the central nervous system. Less common noninfectious causes of fever are hyperthyroidism,

cystic fibrosis, familial dysautonomia, and ectodermal dysplasia. When thermoregulatory devices that monitor and modify infant temperature are introduced, the use of fever or hypothermia as a diagnostic sign of sepsis sometimes is impeded.

### Respiratory Distress

Signs of respiratory distress, including tachypnea, grunting, flaring of the alae nasi, intercostal retractions, rales, and

decreased breath sounds, are common and important findings in the infant suspected of having sepsis. Respiratory distress syndrome and aspiration pneumonia must be considered in the differential diagnosis. Apnea is one of the most specific signs of sepsis but usually occurs in the setting of a fulminant onset or after other nonspecific signs have been present for hours or days. Clinical signs of cardiovascular dysfunction, including tachycardia, arrhythmia, and poor peripheral perfusion, that occur in the absence of congenital heart disease are sensitive and specific signs of sepsis.

### Jaundice

Jaundice is present in approximately one third of infants with sepsis and is a common finding in infants with urinary tract infection.<sup>484-487</sup> It can develop suddenly or subacutely and occasionally is the only sign of sepsis. Jaundice usually decreases after institution of appropriate antimicrobial therapy. It occurs in septic infants irrespective of the type of bacterial pathogen.

### Organomegaly

The liver edge is palpable in premature infants and can extend to 2 cm below the costal margin in healthy term infants. Ashkenazi and colleagues<sup>488</sup> evaluated liver size in healthy term infants examined within 24 hours of birth and again between 72 and 96 hours. Measurements ranged between 1.6 and 4.0 cm below the costal margin, and there was no significant difference between early and late examinations. Reiff and Osborn<sup>489</sup> suggested that determination of liver span by palpation and percussion is a more reliable technique than identifying the liver projection below the costal margin. Hepatomegaly is a common sign of in utero infections and of some noninfectious conditions such as cardiac failure and metabolic diseases, including galactosemia and glycogen storage disease. Splenomegaly is less common than hepatomegaly and infrequently is mentioned in reports of bacterial sepsis of the newborn.<sup>490</sup>

Lymph nodes infrequently are palpable in newborns unless they are infected with viruses, spirochetes, or protozoa. Bamji and colleagues<sup>491</sup> examined 214 healthy neonates in New York and identified palpable nodes at one or more sites in one third of the infants. Embree and Muriithi<sup>492</sup> examined 66 healthy, term Kenyan neonates during the first 24 hours of life and found palpable axillary nodes (27.7%) but no palpable inguinal nodes. Adenopathy is a sign of congenital infection caused by rubella virus, *T. gondii*, *T. pallidum*, and enteroviruses. Adenitis can occur in drainage areas involved with bacterial soft tissue infection. Although adenopathy is not an important sign of systemic bacterial infection in neonates, cellulitis-adenitis syndrome, a rare clinical manifestation of late-onset group B streptococcal infection in infants, is a condition in which local inflammation can be the only initial sign of sepsis that can include concurrent meningitis.<sup>493-495</sup>

### Gastrointestinal Signs

Gastrointestinal disturbances, including poor feeding, regurgitation or vomiting, large gastric residuals in infants

fed by tube, diarrhea, and abdominal distention, are common and significant early signs of sepsis. The first indications of illness can be a change in feeding pattern or lethargy during feedings.

### Skin Lesions

A variety of skin lesions can accompany bacteremia, including cellulitis, abscess, petechiae, purpuric lesions, sclerema, erythema multiforme, and ecthyma. These lesions are described in Chapter 10.

### Neurologic Signs

The onset of meningitis in the neonate is accompanied by identical signs of illness as observed in infants with sepsis. Meningitis can be heralded by increasing irritability, alteration in consciousness, poor tone, tremors, lip smacking or twitching of facial muscles or an extremity. Seizures were present in 31% of the infants reviewed in Table 6-14, but Volpe<sup>496</sup> identified seizures, in many cases subtle, in 75% of infants with bacterial meningitis. Approximately one half of the seizures were focal, and at their onset, they usually were subtle. Focal signs, including hemiparesis, horizontal deviation of the eyes, and cranial nerve deficits involving the seventh, third, and sixth cranial nerves, in that order of frequency, can be identified.<sup>496</sup> Because cranial sutures in the neonate are open and allow for expansion of the intracranial contents and for increasing head size, a full or bulging fontanelle can be absent.<sup>469,497</sup> The presence of a bulging fontanelle is not related to gestational age. Among 72 newborns with gram-negative enteric bacillary meningitis, a bulging fontanelle was seen in 18% and 17% of term and preterm infants, respectively.<sup>44</sup> Nuchal rigidity, an important sign in older children and adults, is uncommon in neonates.<sup>44</sup>

In addition to the physical findings observed in infants with meningitis, several investigators have reported the occurrence of fluid and electrolyte abnormalities associated with inappropriate antidiuretic hormone secretion, including hyponatremia, decreased urine output, and increased weight gain.<sup>457,460</sup> Occasionally, the onset of meningitis has been followed by a transient or persistent diabetes insipidus.<sup>497</sup>

Early clinical signs of brain abscess in the newborn are subtle and frequently unnoticed by the physician or parent. Presenting signs include those of increased intracranial pressure (e.g., emesis, bulging fontanelle, enlarging head size, separated sutures), focal cerebral signs (e.g., hemiparesis, focal seizures), and acute signs of meningitis. Of six infants with brain abscesses described by Hoffman and colleagues,<sup>454</sup> two were febrile and two had seizures, and five had increased head size.

Other focal infections in the nervous system include pneumococcal endophthalmitis in a neonate with meningitis,<sup>498</sup> pseudomonas endophthalmitis in a premature neonate with late-onset sepsis,<sup>499</sup> and epidural abscess caused by *S. aureus* in 3-week-old,<sup>500</sup> 4-week-old,<sup>501</sup> and 7-week-old infants.<sup>502</sup>

### DIAGNOSIS

The diagnosis of systemic infection in the newborn is difficult to establish on the basis of clinical findings alone. A

history of one or more risk factors for neonatal sepsis associated with the pregnancy and delivery often is associated with early-onset infection, but there can be no clues before the onset of subtle signs in the term infant who develops late-onset sepsis. The extensive list of conditions that must be considered in the differential diagnosis for the various signs that are associated with sepsis or meningitis and noninfectious conditions is given in Table 6-15. Laboratory tests to assist in the diagnosis of sepsis are discussed in Chapter 36.

### Maternal History

Many infants, particularly those born prematurely, who develop systemic infection just before or shortly after delivery, are born to women who have one or more risk features for early-onset sepsis in their infants. These features include preterm labor, premature rupture of the membranes at any time during gestation, prolonged rupture of membranes, chorioamnionitis, prolonged labor, intrauterine scalp electrodes, and traumatic delivery. The following features are identified by the American College of Obstetrics and Gynecology (ACOG) as the basis for identification of women who should receive intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal disease<sup>503,504</sup>:

1. Antenatal colonization with group B *Streptococcus*
2. Unknown group B streptococcal colonization status and
  - a. Preterm labor (less than 37 weeks' gestation)
  - b. Fever during labor (defined by temperature of 38.0° C [100.4° F] or more)
  - c. Rupture of membranes for 18 or more hours
3. A urine culture that grows group B *Streptococcus* during the current pregnancy
4. Prior delivery of a neonate with invasive group B streptococcal infection

### Microbiologic Techniques

Isolation of microorganisms from a usually sterile site, such as the blood, CSF, urine, other body fluids (e.g., peritoneal, pleural, joint, middle ear), or tissues (e.g., bone marrow, liver, spleen) remains the most valid method of diagnosing bacterial sepsis. Infectious agents cultured from the nose, throat, external auditory canal, skin, umbilicus, or stool indicate colonization and can include organisms that cause sepsis, but isolation of a microorganism from these sites does not establish invasive systemic infection. The limited sensitivity, specificity, and predictive value of body surface cultures in a neonatal intensive care unit was documented using a database of 24,584 cultures from 3371 infants by Evans and colleagues.<sup>505</sup> These investigators strongly discouraged the use of cultures from these sites in diagnosing neonatal sepsis because of their poor correlation with the pathogen in the blood and their expense.

#### Culture of Blood

Isolation of a pathogenic microorganism from the blood is the only method to establish the diagnosis of neonatal sepsis.

#### METHODS

Technology has evolved from manually read, broth-based methods to continuously monitored, automated blood

culture systems that use enriched media for processing of blood culture specimens. Automated and semiautomated systems for continuous blood culture monitoring are standard in laboratories in the United States.<sup>507-509</sup> Before the widespread use of automated blood-culturing systems, lysis direct plating was the most often employed method of isolating bacteria. Positive cultures were recognized by growth of colonies on agar and provided a rapid means to obtaining quantitative blood culture results from pediatric patients.<sup>510</sup> St. Geme and colleagues<sup>511</sup> used this technique to investigate the distinction of sepsis from contamination in cultures of blood growing coagulase-negative staphylococci.

#### TIME TO DETECTION OF A POSITIVE BLOOD CULTURE

Bacterial growth is evident in most cultures of blood from neonates within 48 hours.<sup>512,513</sup> With use of conventional culture techniques and subculture at 4 and 14 hours, only 4 of 105 cultures that had positive results (one group B *Streptococcus* and three *S. aureus*) required more than 48 hours of incubation.<sup>512</sup> By use of a radiometric technique (BACTEC 460), 40 of 41 cultures that grew group B *Streptococcus* and 15 of 16 cultures with *E. coli* were identified within 24 hours.<sup>514</sup>

#### OPTIMAL NUMBER OF CULTURES

The optimal number of cultures to obtain for the diagnosis of bacteremia in the newborn remains uncertain. A single blood culture from an infant with sepsis can be negative, but most studies suggest a sensitivity of 90% or slightly more. Sprunt<sup>515</sup> suggested the use of two blood cultures "not primarily to increase the yield of organisms..." but to "minimize the insecurity and debates over the meaning of the findings." The value of one or of multiple site blood cultures to establish the diagnosis of neonatal sepsis is discussed by Wiswell and Hachey.<sup>516</sup> Two or more blood cultures increase the likelihood of identifying a pathogen in a neonate with sepsis by a few percent, but the need to initiate therapy promptly can make this practice difficult.

#### OPTIMAL VOLUME OF BLOOD

The optimal volume of blood needed to detect bacteremia in neonates has not been determined. Neal and colleagues<sup>517</sup> evaluated the volume of neonatal blood submitted for culture by physicians who were unaware of the study and found that the mean blood volume per patient was 1.05 mL. Dietzman and co-workers<sup>518</sup> suggested that 0.2 mL of blood was sufficient to detect bacteremia caused by *E. coli*. The relationship between colony counts of *E. coli* from blood cultures from infants with sepsis and meningitis and mortality was evaluated. Meningitis occurred only in neonates with more than 1000 colonies of *E. coli* per milliliter of blood. These data of Dietzman and associates<sup>518</sup> are supported by experimental results indicating that common pediatric pathogens can be reliably recovered from 0.5 mL of blood even when cultured at blood-to-broth ratios of 1:100.<sup>519,520</sup> However, several more recent studies have found that in the circumstance of low inoculum bacteremia (<10 colony-forming units/mL of blood), the collection of only 0.5 mL of blood proved inadequate for the reliable detection of common pathogens.<sup>521-523</sup> It appears that if one blood culture is to be collected before antimicrobial therapy is initiated, a volume of 1 mL or more will ensure the greatest sensitivity.

#### CULTURES OF BLOOD FROM UMBILICAL VESSELS AND INTRAVASCULAR CATHETERS

Umbilical vessel and intravascular catheters are essential in the care of neonates in the intensive care unit and are preferred blood culture sampling sites.<sup>524-526</sup> Results of cultures of blood obtained from indwelling umbilical or central venous catheters can present ambiguities in interpretation (e.g., contamination versus catheter colonization versus systemic infection). Obtaining blood cultures from a peripheral vessel and catheters in the ill-appearing neonate is useful in the interpretation of results.

#### DISTINGUISHING CLINICALLY IMPORTANT BACTEREMIA FROM BLOOD CULTURE CONTAMINATION

The increased use of intravascular catheters in neonates has resulted in an increase in the incidence of bacteremia, particularly that caused by coagulase-negative staphylococci (CoNS), and uncertainty regarding the significance of some results. Investigators have considered criteria based on clinical signs and microbiologic factors.

Yale investigators<sup>6</sup> used the following criteria to define the role of commensal organisms in neonatal sepsis: one major clinical sign, such as apnea, bradycardia, core temperature greater than 38.0° C or less than 36.5° C documented at the time the blood culture was obtained plus another blood culture positive for the same organism obtained within 24 hours of the first or an intravascular access device in place before major clinical signs occurred. Some microbiologic features can be useful in differentiating sepsis from contamination:

1. Time to growth in conventional media: The longer the time needed to detect growth (>2 to 3 days), the more likely that skin or intravascular line contamination was present.
2. Number of cultures positive: If peripheral and intravascular catheter specimens are positive, the presence of the organism in the blood is likely; if the catheter specimen alone is positive, intravascular line colonization may have occurred; if multiple cultures from an indwelling vascular catheter are positive or if a single culture is positive and the patient has had a clinical deterioration, a bloodstream infection must be presumed.
3. Organism type: Organisms that are part of skin flora (e.g., diphtheroids, nonhemolytic streptococci, CoNS) suggest contamination in certain cases as described previously, whereas known bacterial pathogens must be considered to be associated with sepsis. Contamination is more likely when multiple species grow in one blood culture bottle, different species grow in two bottles, or only one of several cultures before or during antimicrobial therapy is positive.
4. Clinical signs: If the infant is well without use of antibiotics, growth of a commensal organism from a blood culture is more likely to be a contaminant.

In an attempt to resolve the question of sepsis versus contamination, investigators have used multiple site blood cultures,<sup>516</sup> comparisons of results of cultures of blood and cultures of skin at the venipuncture site,<sup>527</sup> and quantitative blood cultures.<sup>511</sup> These techniques are of investigational interest, but the results do not suggest that any one is of sufficient value to be adopted for clinical practice. Healy and colleagues<sup>528</sup> suggest that isolation of CoNS of the same species or antimicrobial susceptibility from more than one blood culture or from one blood culture obtained from an

indwelling catheter or a peripheral vessel and a normally sterile body site represents true infection if the patient is a premature infant with signs of clinical sepsis. At present, management of the sick premature infant, especially the VLBW patient, with a positive blood culture for CoNS requires that the organism be considered a pathogen and managed with appropriate antimicrobial agents. If the infant is well, the microbiologic results given earlier should be considered in the decision to continue or discontinue use of an antimicrobial agent. Another culture of blood should be obtained when the initial culture result is ambiguous.

#### Buffy-Coat Examination

The rapid diagnosis of bacteremia by identification of microorganisms in the buffy leukocyte layer of centrifuged blood is a method used for many years and has been evaluated for use in newborn infants.<sup>529-535</sup> By using Gram and methylene blue stains of the buffy-coat preparation, immediate and accurate information was obtained for 37 (77%) of 48 bacteremic, clinically septic infants in the four studies.<sup>530-532,534</sup> Positive results were found for gram-positive and gram-negative organisms. In contrast to findings reported for adult populations,<sup>536</sup> there were no false-positive results among almost 200 infants with negative blood cultures. Failure to identify organisms was attributed to extreme neutropenia in several patients.

The large inoculum of microorganisms in the blood of neonates with sepsis most probably explains the excellent sensitivity of leukocyte smears. Smears can be positive with as few as 50 colonies per milliliter of *S. aureus* in the peripheral blood; approximately 50% of neonates with *E. coli* bacteremia have higher concentrations.<sup>518</sup> *Candida* and *S. epidermidis* septicemia in young infants also have been diagnosed by this method.<sup>537-539</sup> Strom<sup>540</sup> reported that bacteria were identified in peripheral blood smears in 17 of 19 infants with septicemia. However, Rodwell and associates<sup>541</sup> were able to identify bacteria in direct blood smears for only 4 of 24 bacteremic neonates. In is likely that the disparity in these results reflects differences in patient populations or distribution of etiologic agents or both. The buffy-coat examination of blood smears has become infrequently used in laboratories since the introduction of automated systems for continuous blood culture monitoring.

#### Culture of Urine

Infants with sepsis can have a urinary tract origin or a concomitant urinary tract infection. The yield from culture of urine is low in early-onset sepsis and most often reflects metastatic spread to the bladder from the bacteremia, but in late-onset infection, the yield is substantially higher. Visser and Hall<sup>542</sup> found positive cultures of urine in only 1.6% of infants with early-onset sepsis compared with 7.4% of infants with late-onset sepsis. DiGeronimo<sup>543</sup> performed a chart review of 146 clinically septic infants who had cultures of blood and urine. Of 11 infants with positive blood cultures, only one infant with group B *Streptococcus* bacteremia had a positive urine culture. These data suggest that cultures of urine yield very limited information about the source of infection in infants with signs of sepsis before age 7 days. In contrast, it is apparent that urine should be collected for culture from infants with suspected late-onset sepsis before initiation of antimicrobial therapy.

Because of the difficulty in collecting satisfactory clean-voided specimens of urine from the newborn, bladder catheterization or suprapubic needle aspiration of bladder urine frequently is performed. These methods are simple and safe and suprapubic bladder aspiration avoids the ambiguities inherent in urine obtained by other methods.<sup>544-546</sup> If a suprapubic aspirate cannot be performed for technical or medical reasons, catheterization is a satisfactory method of obtaining urine although ambiguous results can occur because of contamination from the urethra, especially in VLBW neonates.

### **Cultures of Tracheal Aspirates and Pharynx**

Because of the association of pneumonia and bacteremia, investigators have sought to determine the risk of sepsis on the basis of colonization of the upper respiratory tract. Lau and Hey<sup>547</sup> found that among ventilated infants who became septic, the same organism usually was present in cultures of tracheal aspirate and blood. However, growth of a bacterial pathogen from a tracheal aspirate culture does not predict which infants will develop sepsis. Similarly, cultures of the pharynx or trachea do not necessarily predict the causative organism in the blood of a neonate with clinical sepsis.<sup>548</sup> Unless the patient has a change in respiratory status documented clinically and radiographically, routine use of cultures from the pharynx or trachea have very limited diagnostic value.

### **Diagnostic Needle Aspiration and Tissue Biopsy**

Direct aspiration of tissues or body fluids through a needle or catheter is used for the diagnosis of a wide variety of infectious and noninfectious diseases.<sup>549</sup> Aspiration of an infectious focus in lung, pleural space, middle ear, pericardium, bones, joints, abscess, and other sites provides immediate and specific information to guide therapy. Biopsy of the liver or bone marrow can assist in diagnosing occult infections, but this rarely is necessary.

### **Autopsy Microbiology**

Two factors must be considered in interpreting bacterial cultures obtained at autopsy: the frequent isolation of organisms usually considered to be nonpathogenic and the difficulty of isolating fastidious organisms such as anaerobic bacteria. To minimize these problems, it is important that specimens be collected with proper aseptic technique and as early as possible after death.

It is a common belief that organisms in the intestinal and respiratory tracts gain access to tissues after death, but it also is possible that bacteremia occurs shortly before death and is not a postmortem phenomenon. Eisenfeld and colleagues<sup>550</sup> identified the same organisms in specimens obtained before and within 2 hours after death. Confusion in the interpretation of results of bacteriologic cultures often is obviated by the review of slides prepared directly from tissues and fluids. If antimicrobial treatment was administered before death, organisms can be observed on a smear even though they are not viable. Pathogens would be expected to be present in significant numbers and accompanied by inflammatory cells, whereas contaminants or organisms that invade tissues after death, if they are seen, would be present in small numbers with no evidence of an inflammatory process.<sup>551,552</sup>

### **Rapid Techniques for Detection of Bacterial Antigens in Body Fluid Specimens**

In the 1970s, the limulus lysate assay for detection of endotoxin produced by gram-negative bacteria based on a gelation reaction between lysates of *Limulus* (horseshoe crab) amoebocytes and bacterial endotoxin was investigated for diagnosis of neonatal meningitis with equivocal results.<sup>553-557</sup> Counterimmunoelectrophoresis also was used successfully for detecting the capsular polysaccharide antigens of various pathogenic bacteria, including *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and group B streptococci (see Chapter 13) in CSF, serum, and urine. Less complex and more rapid detection methods have replaced these two assays.

Latex agglutination assays, based on specific agglutination of antibody-coated latex particles by bacterial antigens, has been shown to be helpful in early detection of bacterial antigens in the CSF of patients with acute meningitis. This method of antigen detection now is preferred because of its speed, simplicity, and greater sensitivity for selected organisms. Kits designed to detect cell wall or capsular or cell wall antigen released into body fluids are commercially available. Among the prevalent bacterial pathogens in neonatal infections, only group B *Streptococcus* can be detected by latex agglutination. The sensitivity of latex agglutination methods for identifying infants with group B streptococcal meningitis varies between 73% and 100% for CSF and 75% and 84% for urine.<sup>558</sup> Possible cross-reactions have occurred when concentrated urine was tested. The group B *Streptococcus* cell wall antigen can cross react with those from *S. pneumoniae*, coagulase-negative staphylococci, enterococci, and gram-negative enteric bacteria, including *P. mirabilis* and *E. cloacae*. False-positive results in urine for a positive latex agglutination test for group B *Streptococcus* often were caused by contamination of bag specimens of urine with the streptococci from rectal or vaginal colonization.<sup>559</sup> The poor specificity of group B *Streptococcus* antigen detection methods used with urine led to the Food and Drug Administration recommendation in 1996 that these methods not be employed except for testing of CSF and serum.

### **Lumbar Puncture and Examination of Cerebrospinal Fluid**

Because meningitis can accompany sepsis with no clinical signs to differentiate between bacteremia alone and bacteremia with meningitis, a lumbar puncture should be considered for examination of the CSF in any neonate before initiation of therapy. Up to 15% of infants with sepsis have accompanying meningitis. The overall incidence of bacterial meningitis is less than 1 case per 1000 infants, but the incidence for low-birth-weight (<2500 g) infants or premature infants is several-fold higher than that for term infants. For the diagnosis of some noninfectious central nervous system diseases in neonates (e.g., intracranial hemorrhage), cranial ultrasonography and, occasionally, computed tomography or magnetic resonance imaging are the techniques of choice. For infants with hypoxic-ischemic encephalopathy, lumbar puncture should be considered only for those infants in whom meningitis is a possible diagnosis.

Some investigators suggest that too many healthy term infants have a diagnostic evaluation for sepsis, including lumbar puncture, based solely on maternal risk features and that the lumbar puncture rarely provides clinically useful

information. Other investigators have questioned the role of an admission lumbar puncture in the premature infant with respiratory distress and found that the yield of the procedure is very low.<sup>560-562</sup> Of more than 1700 infants with respiratory distress syndrome evaluated for meningitis, bacterial pathogens were identified in the CSF of only 4. Three of the four infants with meningitis were bacteremic with the same pathogen.<sup>560</sup> A large, retrospective study assessed the value of lumbar puncture in the evaluation of suspected sepsis during the first week of life and found that bacteria were isolated from 9 of 728 CSF specimens, but only one infant was believed to have bacterial meningitis.<sup>563</sup> Fielkow and colleagues<sup>564</sup> found no cases of meningitis among 284 healthy-appearing infants who had a lumbar puncture performed because of maternal risk factors, whereas 2.5% of 799 neonates with clinical signs of sepsis had meningitis regardless of maternal risk factors. More recent data regarding the usefulness of lumbar puncture is provided by Wiswell and co-workers.<sup>565</sup> These investigators conclude from their data, collected in the era of maternal intrapartum prophylaxis for the prevention of early-onset group B streptococcal sepsis, that up to 28% of infants with meningitis have sterile blood cultures. In summary, the value of a lumbar puncture has been established for infants with clinical signs of sepsis, but lumbar puncture performed because of maternal risk features in a healthy-appearing neonate is less likely to be useful.

#### METHOD OF LUMBAR PUNCTURE

Lumbar puncture is more difficult to perform in the neonate than in the older child or adult; traumatic lumbar punctures resulting in blood in the CSF are more frequent, and care must be taken in the infant who is in respiratory distress. Gleason and colleagues<sup>566</sup> suggest that the procedure be performed with the infant in the upright position or, if performed in the flexed position, be modified with neck extension. Pinheiro and associates<sup>567</sup> evaluated the role of locally administered lidocaine before lumbar puncture and found that the local anesthesia decreased the degree of struggling of the infant. However, other investigators have concluded that local anesthesia failed to influence physiologic changes in the neonate undergoing lumbar puncture.<sup>568</sup> Fiser and colleagues<sup>569</sup> suggest that the administration of oxygen before lumbar puncture prevents most hypoxemia resulting from this procedure in infants.

The physician can choose to withhold or delay lumbar puncture in some infants who would be placed at risk for cardiac or respiratory compromise by the procedure. Weisman and colleagues<sup>570</sup> observed that transient hypoxemia occurred during lumbar puncture performed in the lateral position (i.e., left side with hips flexed to place knees to chest) but occurred less frequently when the infant was in a sitting position or modified lateral position (i.e., left side with hips flexed to 90 degrees). Reasons for withholding lumbar puncture in older children, such as signs of increased intracranial pressure, signs of a bleeding disorder, and infection in the area that the needle will traverse to obtain CSF, are less likely to be concerns in the neonate.

Ventricular puncture should be considered in the infant with meningitis who does not respond clinically or microbiologically to antimicrobial therapy because of ventriculitis, especially with obstruction between the ventricles and

lumbar CSF. Ventriculitis is diagnosed on the basis of elevated white blood cell count ( $>100$  cells/mm<sup>3</sup>) or identification of bacteria by culture, Gram stain, or antigen detection. Ventricular puncture is a potentially hazardous procedure and should be performed only by a physician who is an expert in the technique.

#### IF A LUMBAR PUNCTURE IS NOT PERFORMED

Is it sufficient to culture only blood and urine for the diagnosis of neonatal bacterial meningitis? Visser and Hall<sup>571</sup> demonstrated that the blood culture was sterile when the CSF yielded a pathogen in 6 (15%) of 39 infants with bacterial meningitis. Franco and colleagues<sup>572</sup> reported that in 26 neonates with bacterial meningitis, only 13 had a positive blood culture. A significant number of infants with meningitis will not have this diagnosis established unless a lumbar puncture is performed.

Ideally, the lumbar puncture should be performed before the initiation of antimicrobial therapy, but there are alternative strategies for infants who may not tolerate the procedure. If the physician believes that lumbar puncture would endanger the infant with presumed sepsis and meningitis, therapy should be initiated after blood (and urine for late-onset illness) is obtained for culture. After the infant is stabilized, lumbar puncture should be performed. Even several days after the start of antibiotic therapy, CSF pleocytosis and abnormal CSF chemistry assays usually should identify the presence or absence of an inflammatory reaction, although CSF culture may be sterile.

#### EXAMINATION OF CEREBROSPINAL FLUID

The cell content and chemistry of the CSF of healthy newborn infants differ from those of older infants, children, and adults (Table 6-16). The values vary widely during the first weeks of life, and the normal range must be considered in evaluation of CSF in infants suspected to have meningitis.<sup>573-582</sup> The cell content in the CSF of a neonate is higher than that in older infants. Polymorphonuclear leukocytes often are present in the CSF of normal newborns, whereas more than a single polymorphonuclear neutrophil in the CSF of older infants or children should be considered abnormal. Similarly, protein concentration is higher in preterm than in term infants and highest in VLBW infants<sup>582</sup> (Table 6-17). In term infants, the total protein concentration decreases with age, reaching values of healthy older infants ( $<40$  mg/dL) before the third month of life. In low-birth-weight or preterm infants, CSF protein concentrations may not fall within normal values for older infants for several months after birth. CSF glucose levels are lower in neonates than in older infants and can be related to the lower concentrations of glucose observed in blood. Healthy term infants can have blood glucose levels as low as 30 mg/dL, and preterm infants may have levels as low as 20 mg/dL.<sup>582</sup> The physiologic basis for the higher concentration of protein and the increased numbers of white blood cells in the CSF of healthy, uninfected preterm and term infants is unknown. The explanations that have been offered include possible mechanical irritation of the meninges during delivery and an increased permeability of the blood-brain barrier.

In nearly all of the studies of the CSF in newborns, *normal* or *healthy* refers to the absence of clinical manifestations at the time of examination of the CSF. Only the

Data from Rodriguez AF, Kaplan SL, Mason EO. Cerebrospinal fluid values in the very low birth weight infant. *J Pediatr* 116:971, 1990.

study by Ahmed and colleagues<sup>576</sup> included in the definition of *normal* the absence of viral infection defined by lack of evidence of cytopathic effect in five cell lines and negative polymerase chain reaction for enteroviruses. None of the studies included information about the health of the infant after the newborn period. It now is recognized that infants with congenital infections, such as rubella, cytomegalovirus infection, toxoplasmosis, acquired immunodeficiency syndrome, and syphilis, can have no signs of illness during the newborn period. Observations of these infants over the course of months or years can reveal abnormalities that are inapparent at birth. Until more data are available, it would appear prudent to observe carefully infants with white blood cells in excess of 20 per mm<sup>3</sup> or a protein level in excess of 100 mg/dL in the CSF and, if clinical signs indicate, to obtain paired serum samples for serologic assays and viral cultures from body fluids or tissues for congenital central nervous system infections (i.e., *T. gondii*, rubella virus, cytomegalovirus, herpes simplex virus, human immunodeficiency virus, and *T. pallidum*).

In newborns with bacterial meningitis, there can be thousands of white blood cells in the CSF, and polymorphonuclear leukocytes predominate early in the course of the disease.<sup>38,574</sup> The number of white blood cells in the CSF can vary greatly in infants with both gram-negative and gram-

positive meningitis. The median number of cells per cubic millimeter in the CSF of 98 infants with gram-negative meningitis was more than 2000 (range, 6 to 40,000), whereas the median number of cells per cubic millimeter in 21 infants with group B streptococcal meningitis was less than 100 (range, 8 to >10,000).<sup>574</sup> The concentration of glucose in CSF usually is less than two thirds of the concentration in blood. The concentration of protein can be low (<30 mg/dL) or very high (>1000 mg/dL). CSF parameters observed in the healthy term neonate can overlap with those observed in the infant with meningitis.

A Gram-stain smear of CSF should be examined for bacteria, and appropriate media should be inoculated with the CSF specimen. Sarff and colleagues<sup>574</sup> detected organisms in Gram-stain smears of CSF in 83% of infants with group B streptococcal meningitis and in 78% of those with gram-negative meningitis. After initiation of appropriate antimicrobial therapy, gram-positive bacteria usually clear from the CSF within 36 hours, whereas in some patients with meningitis caused by gram-negative enteric bacilli cultures can remain positive for many days.<sup>581</sup>

Microorganisms can be isolated from CSF that has normal white blood cell and chemistry test values. Visser and Hall<sup>571</sup> reported normal CSF parameters (cell count < 25; protein level < 200 mg/dL) in 6 (15%) of 39 infants with

culture-proven meningitis. Subsequent examination of the CSF identified an increase in the number of cells and in the protein level. Presumably, the initial lumbar puncture was performed early in the course of meningitis before an inflammatory response occurred. Other investigators reported isolation of enterovirus<sup>583</sup> and *S. pneumoniae*<sup>584</sup> from the CSF of neonates in the absence of pleocytosis.

Identification of bacteremia without meningitis defined by the absence of pleocytosis or isolation of a pathogen from culture of CSF can be followed by meningeal inflammation on subsequent examinations. Sarman and colleagues<sup>585</sup> identified six infants with gram-negative bacteremia and initial normal CSF who developed evidence of meningeal inflammation 18 to 59 hours after the first examination. Although the investigators suggest that a diagnosis of gram-negative bacteremia in the neonate warrants repeat lumbar puncture to identify the optimal duration of therapy, this recommendation could be broadened to include all infants with bacteremia and initial negative studies of CSF. Dissemination of the organisms from the blood to the meninges can occur after the first lumbar puncture before sterilization of the blood by appropriate antimicrobial therapy occurs. This is especially likely to occur in neonates with intense bacteremia where sterilization by  $\beta$ -lactam agents (i.e., third-generation cephalosporins) is inoculum dependent.

Investigators have sought a sensitive and specific CSF metabolic determinant of bacterial meningitis with little success. Among products that have been evaluated and found to be inadequate to distinguish bacterial meningitis from other neurologic disease (including cerebroventricular hemorrhage and asphyxia) are  $\gamma$ -aminobutyric acid,<sup>586</sup> lactate dehydrogenase,<sup>587</sup> and creatine kinase brain isoenzyme.<sup>588</sup> Cyclic-3',5'-adenosine monophosphate was elevated in the CSF of neonates with bacterial meningitis compared with the CSF of infants who had nonbacterial meningitis or a control group.<sup>589</sup> Elevated CSF concentrations of C-reactive protein have been reported for infants older than 4 weeks with bacterial meningitis<sup>590,591</sup>; however, the test was found to be of no value in neonates.<sup>591,592</sup> Current investigations of the pro-inflammatory cytokines interleukin-6 and interleukin-8 indicate that there is a cytokine response in the CSF after birth asphyxia and that these assays are not useful in detecting the infant with meningitis.<sup>593,594</sup>

#### THE TRAUMATIC LUMBAR PUNCTURE

A traumatic lumbar puncture can result in blood in the CSF and can complicate the interpretation of the results for CSF white blood cell count and chemistries. Schwersenski and colleagues<sup>563</sup> found that 13.8% of 712 CSF specimens obtained during the first week of life were bloody and that an additional 14.5% were considered inadequate for testing.

If the total number of white blood cells compared with the number of red blood cells exceeds the value for whole blood, the presence of CSF pleocytosis is suggested. Some investigators have found that the observed white blood cell counts in bloody CSF were lower than would be predicted based on the ratio of white-to-red blood cells in peripheral blood; the white blood cells lyse more rapidly than red blood cells, or the number of white blood cells is decreased for other reasons.<sup>595-598</sup> Several formulas have been used in an attempt to interpret cytologic findings in CSF contaminated

by blood.<sup>599-601</sup> However, none of the corrections applied to bloody CSF can be used with confidence for excluding meningitis in the neonate.<sup>602-604</sup>

Protein in CSF usually is elevated after a traumatic lumbar puncture because of the presence of red blood cells. It has been estimated in older children and adults that an increase of 1 mg/dL in CSF protein occurs for every 1000 red blood cells/ $\mu$ L. The concentration of glucose does not appear to be altered by blood from a traumatic lumbar puncture; a low CSF glucose concentration should be considered an important finding even when associated with a traumatic lumbar puncture.

Because a "bloody tap" is difficult to interpret, it can be valuable to repeat the lumbar puncture 24 to 48 hours later. If the results of the second lumbar puncture reveal a normal white blood cell count, bacterial meningitis can be excluded. Even if performed without trauma or apparent bleeding, CSF occasionally can be ambiguous because white blood cells can be elicited by the irritant effect of blood in the CSF.

#### BRAIN ABSCESS

Brain abscess is a rare entity in the neonate, usually complicating meningitis caused by certain gram-negative bacilli. The CSF in the infant with a brain abscess can demonstrate a pleocytosis of a few hundred cells with a mononuclear predominance and an elevated protein level. Bacteria may not be seen by Gram stain of the CSF if meningitis is not present. Sudden clinical deterioration and the appearance of many cells ( $>1000$  per  $\text{mm}^3$ ), with a majority of polymorphonuclear cells, suggest rupture of the abscess into the CSF.

#### Laboratory Aids

Laboratory aids in the diagnosis of systemic and focal infection in the neonate include peripheral white blood cell and differential counts, platelet counts, acute-phase reactants, blood chemistries, histopathology of the placenta and umbilical cord, smears of gastric or tracheal aspirates, and diagnostic imaging studies. New assays for diagnosis of early-onset sepsis, including serum concentrations of neutrophil CD 11b,<sup>605</sup> granulocyte colony-stimulating factor,<sup>606</sup> interleukin receptor antagonist,<sup>607</sup> interleukin-6,<sup>607-610</sup> and procalcitonin,<sup>611-613</sup> show promise for increased sensitivity and specificity compared with other laboratory assessments, such as white blood cell count, absolute neutrophil count, and acute-phase reactants. However, pro-inflammatory cytokines, including interleukin-1 and interleukin-6 and tumor necrosis factor- $\alpha$ , have been identified in serum and CSF in infants after perinatal asphyxia, raising doubts about the specificity of some of these markers.<sup>593,594,614,615</sup> Mehr and Doyle<sup>616</sup> review the recent literature on cytokines as aids in the diagnosis of neonatal bacterial sepsis. These assays and procedures are discussed in detail in Chapter 36.

#### MANAGEMENT

If the maternal history or infant clinical signs suggest the possibility of neonatal sepsis, blood and CSF (all infants) and cultures of urine and other clinically evident focal sites should be collected (all infants with suspected late-onset infection). If respiratory abnormalities are apparent or

respiratory status has changed, a radiograph of the chest should be performed. Because the clinical manifestations of sepsis can be subtle, the progression of the disease can be rapid, and the mortality rate remains high when compared with that for older infants with serious bacterial infection, empirical treatment should be initiated promptly. Many infants who have a clinical course typical of bacterial sepsis are treated empirically because of the imperfect sensitivity of a single blood culture in the diagnosis of sepsis.

## Choice of Antimicrobial Agents

### Initial Therapy for Presumed Sepsis

The choice of antimicrobial agents for the treatment of suspected sepsis is based on knowledge of the prevalent organisms responsible for neonatal sepsis by age of onset and hospital setting as well as on their patterns of antimicrobial susceptibility. Initial therapy for the infant who develops clinical signs of sepsis during the first few days of life (early-onset disease) must include agents active against gram-positive cocci, particularly group B *Streptococcus*, other streptococci, and *L. monocytogenes*, and gram-negative enteric bacilli. Treatment of the infant who becomes septic while in the nursery after age 6 days (late-onset disease) must include therapy for hospital-acquired organisms, such as *S. aureus*, gram-negative enteric bacilli, CoNS (in the VLBW infant), and occasionally *P. aeruginosa*, as well as for maternally acquired etiologic agents.

Group B streptococci continue to demonstrate uniform in vitro susceptibility to penicillins and cephalosporins. In a study of 231 isolates of group B streptococci from patients with invasive infection, all strains were killed by concentrations of penicillin G of less than 0.25  $\mu\text{g}/\text{mL}$ .<sup>617</sup> Ampicillin, the penicillinase-resistant penicillins, and third-generation cephalosporins also are active in vitro but aminoglycosides are relatively inactive. In vitro studies<sup>618-620</sup> and experimental animal models of bacteremia,<sup>621,622</sup> however, indicate that the bactericidal activity of ampicillin and penicillin against group B streptococci and *L. monocytogenes* is enhanced by the addition of gentamicin (synergy). Some physicians prefer to continue the combination of ampicillin and gentamicin for 48 to 72 hours, but once group B *Streptococcus* is identified as the etiologic agent, the drug of choice for therapy is penicillin administered intravenously for the remainder of the treatment regimen. There are no clinical data to indicate that continuing an aminoglycoside in combination with a penicillin results in more rapid recovery or improved outcome for infected neonates (see Chapter 13).

Most strains of *S. aureus* that cause disease in neonates produce  $\beta$ -lactamase and are resistant to penicillin G and ampicillin. Many of these organisms are susceptible to the penicillinase-resistant penicillins, such as nafcillin, and to first-generation cephalosporins. Methicillin-resistant staphylococci that are resistant to other penicillinase-resistant penicillins and cephalosporins have been encountered in many nurseries in the United States. Antimicrobial susceptibility patterns must be monitored by surveillance of staphylococcal strains causing infection and disease in each neonatal intensive care unit. Bacterial resistance must be considered whenever staphylococcal disease is suspected or confirmed in a patient, and empirical vancomycin therapy

should be initiated until the susceptibility pattern of the organism is known. Virtually all staphylococcal strains isolated from neonates have been susceptible to vancomycin. Synergistic activity is provided by the combination of an aminoglycoside (see Chapter 17). Vancomycin- or glycopeptide-resistant *S. aureus* has been reported from Japan and the United States, but none of these strains has been isolated from neonates.

CoNS can cause systemic infection in VLBW infants and in neonates with or without devices such as an intravascular catheter or a ventriculoperitoneal shunt. Vancomycin is the drug of choice for treatment of serious CoNS infections. If daily cultures from an indwelling device continue to grow CoNS, removal of the foreign material probably will be necessary to cure the infection.

Group D streptococci vary in their susceptibility to penicillins. Nonenterococcal strains, including *S. bovis*, are highly susceptible to penicillin, but *Enterococcus* species are only moderately susceptible to penicillin and highly resistant to cephalosporins. Optimal antimicrobial therapy for neonatal infections caused by *Enterococcus* includes ampicillin or vancomycin in addition to an aminoglycoside, typically gentamicin or tobramycin.

*L. monocytogenes* is susceptible to penicillin and ampicillin and resistant to cephalosporins. Ampicillin is the preferred agent for treating *L. monocytogenes*, although an aminoglycoside can be continued in combination with ampicillin if the patient has meningitis. Specific management of *L. monocytogenes* infection is discussed in Chapter 14.

The choice of antibiotic therapy for infections caused by gram-negative bacilli depends on the pattern of susceptibility for these isolates in the nursery that cares for the neonate. These patterns vary by hospital or community and by time within the same institution or community. Although isolates from neonates should be monitored to determine the emergence of new strains with unique antimicrobial susceptibility patterns, the general pattern of antibiotic susceptibility in the hospital is a good guide to initial therapy for neonates. The aminoglycosides, including gentamicin, tobramycin, netilmicin, and amikacin, are highly active in vitro against virtually all isolates of *E. coli*, *P. aeruginosa*, and *Enterobacter*, *Klebsiella*, and *Proteus* species.

### Role of Third-Generation Cephalosporins

The third-generation cephalosporins, cefotaxime, ceftriaxone, and ceftazidime, possess attractive features for therapy for bacterial sepsis and meningitis in newborns. These features include excellent in vitro activity against group B streptococci and *E. coli* and other gram-negative enteric bacilli. Ceftazidime is highly active in vitro against *P. aeruginosa*. None of the cephalosporins is active against *L. monocytogenes* or *Enterococcus*, and activity against *S. aureus* is variable. These cephalosporins provide concentrations of drug at most sites of infection that greatly exceed the minimum inhibitory concentrations of susceptible pathogens, and there is no dose-related toxicity. Clinical and microbiologic results of studies of sepsis and meningitis in neonates suggest that the third-generation cephalosporins are comparable to the traditional regimens of penicillin and an aminoglycoside (see Chapter 37).<sup>623-626</sup> Because ceftriaxone can displace bilirubin from serum albumin, it is not recommended for

use in neonates unless it is the only agent effective against the bacterial pathogen.

The rapid development of resistance of gram-negative enteric bacilli when cefotaxime is used extensively for presumptive therapy for neonatal sepsis suggests that extensive use of third or fourth-generation cephalosporins can lead to rapid emergence of drug-resistant bacteria in nurseries.<sup>627</sup> Empirical use of cefotaxime in neonates should be restricted to those with evidence of meningitis or with gram-negative sepsis. Continued cefotaxime therapy should be limited to those infants with gram-negative meningitis caused by susceptible organisms or those with ampicillin-resistant enteric infections.<sup>628</sup>

### Current Practice

The combination of ampicillin and an aminoglycoside, usually gentamicin or tobramycin, is suitable for initial treatment of presumed early-onset neonatal sepsis.<sup>629</sup> If there is a concern for endemic or epidemic staphylococcal infection, typically occurring beyond 6 days of age, the initial treatment of late-onset neonatal sepsis should include vancomycin.

The increasing use of antibiotics, particularly in neonatal intensive care units, can result in alterations in antimicrobial susceptibility patterns of bacteria and can necessitate changes in initial empirical therapy. This alteration of the microbial flora in nurseries where the use of broad-spectrum antimicrobial agents is routine supports recommendations from the CDC for the judicious use of antibiotics. The hospital laboratory must regularly monitor isolates of pathogenic bacteria to assist the physician in choosing the most appropriate therapy. The clinical pharmacology and dosage schedules of the various antimicrobial agents considered for neonatal sepsis are provided in Chapter 37.

### Continuation of Therapy When Results of Cultures Are Available

The choice of antimicrobial therapy should be reevaluated when results of cultures and susceptibility tests become available. The duration of therapy depends on the initial response to the appropriate antibiotics but should be 10 days, with sepsis documented by positive culture of blood and minimal or absent focal infection. The usual duration of therapy for infants with meningitis caused by gram-negative enteric bacilli is 21 days. However, in complicated cases of meningitis caused by gram-negative enteric bacilli, group B streptococci, or other pathogens, the duration of therapy is variable and is best determined in consultation with an infectious diseases specialist.

The third-generation cephalosporins cefotaxime, ceftriaxone, and ceftazidime have important theoretical advantages for treatment of sepsis or meningitis compared with therapeutic regimens that include an aminoglycoside. Unlike the aminoglycosides, third-generation cephalosporins are not associated with ototoxicity and nephrotoxicity. However, little toxicity from aminoglycosides occurs when use is brief or, when continued for the duration of therapy, if serum trough levels are maintained at less than 2 µg/mL. Because cephalosporins have no dose-related toxicity, measurements of serum concentrations, obligatory with the use of aminoglycosides beyond 72 hours or in infants with renal

insufficiency, are unnecessary. However, routine use of the cephalosporins for presumptive sepsis therapy in neonates often leads to problems with drug-resistant enteric organisms. Extensive use of the third-generation cephalosporins in the nursery could result in the emergence of resistance caused by de-repression of chromosomally mediated β-lactamases.<sup>630</sup> Cefotaxime is preferred to other third-generation cephalosporins for use in neonates because it has been used more extensively<sup>624-626,631</sup> and because it does not affect the binding of bilirubin.<sup>630,632</sup> Ceftazidime in combination with an aminoglycoside should be used in therapy for *P. aeruginosa* meningitis because of its excellent in vitro activity and its good penetration into the CSF. Use of ceftriaxone in the neonate should be determined on a case-by-case basis because of its ability to displace bilirubin from serum albumin and result in biliary sludging.

### Management of the Infant Whose Mother Received Intrapartum Antimicrobial Agents

Antimicrobial agents commonly are administered to women in labor who have risk factors associated with sepsis in the fetus, including premature delivery, prolonged rupture of membranes, fever, or other signs of chorioamnionitis or group B streptococcal colonization. Antimicrobial agents cross the placenta and achieve concentrations in fetal tissues that are parallel to concentrations achieved in other well-vascularized organs. Placental transport of antibiotics is discussed in more detail in Chapter 37.

Protocols for prevention of group B streptococcal infection in the newborn by administration of a penicillin to the mother were published in 1992 by ACOG<sup>633</sup> and the American Academy of Pediatrics (AAP),<sup>634</sup> These guidelines were revised in 1996 by the CDC,<sup>635</sup> in 1997 by the AAP,<sup>636</sup> and in 2002 by the CDC,<sup>637</sup> AAP, and ACOG.<sup>504</sup> Recent data suggest that nearly 50% of women receive intrapartum chemoprophylaxis because of the presence of one or more risk factors for neonatal sepsis or because of a positive antenatal screening culture for group B *Streptococcus*.<sup>638</sup>

When ampicillin or penicillin is administered to the mother, drug concentrations are achieved in the fetus that are more than 30% of the concentrations in the blood of the mother.<sup>639</sup> Concentrations of penicillin, ampicillin, and cefazolin that are bactericidal for group B streptococci are achieved in the amniotic fluid approximately 3 hours after completion of a maternal intravenous dose. Parenteral antibiotic therapy administered to a mother with signs of chorioamnionitis in labor essentially is treating the fetus early in the course of the intrapartum infection.<sup>640,641</sup> However, for some infected fetuses, the treatment administered in utero is insufficient to prevent signs of early-onset group B streptococcal disease. Although maternal intrapartum prophylaxis has been associated with a 75% decrease in the incidence of early-onset group B streptococcal disease since 1993,<sup>641,642</sup> the regimen has had no impact on the incidence of late-onset disease.<sup>643</sup>

The various algorithms prepared to guide empirical management of the neonate born to a mother with risk factors for group B streptococcal disease who received intrapartum antimicrobial prophylaxis for prevention of early-onset group B streptococcal disease focus on three clinical scenarios<sup>504,637,644,645</sup>:

1. Infants who have signs of sepsis should receive a full diagnostic evaluation and should be treated, typically with ampicillin and gentamicin, until laboratory studies are available.

2. Infants born at 35 or more weeks' gestation who appear healthy and whose mothers received intrapartum prophylaxis with penicillin, ampicillin, or cefazolin for 4 or more hours before delivery do not have to be evaluated or treated but should be observed in the hospital for 48 hours.

3. Infants who are less than 35 weeks' gestation who appear healthy and whose mothers received penicillin, ampicillin, or cefazolin for less than 4 hours before delivery should receive a limited evaluation, including a blood culture and a complete blood cell count with a differential count, and be observed for 48 hours in the hospital. The same management probably is necessary for infants of any gestation whose mothers received vancomycin for prophylaxis because nothing is known about the amniotic fluid penetration of this drug or its efficacy in preventing early-onset group B streptococcal disease.

The first two clinical scenarios are readily identified, but the third category often leads to controversy regarding optimal management. Recent recommendations for prevention and treatment of early-onset group B streptococcal infection are discussed in detail in Chapter 13.

Management of the infant born to a mother who received an antimicrobial agent within hours of delivery must include consideration of the effect of the drug on cultures obtained from the infant after birth. Intrapartum therapy provides some treatment of the infant in utero, and variable concentrations of drug will be present in the infant's body fluids. If the infant is infected and the bacterial pathogen is susceptible to the drug administered to the mother, cultures of the infant can be sterile despite a clinical course suggesting sepsis.

### Treatment of the Infant Whose Bacterial Culture Results Are Negative

Whether or not the mother received antibiotics before delivery, the physician must decide on the subsequent course of therapy for the infant who was treated for presumed sepsis and whose bacterial culture results are negative. If the neonate appears to be well and there is reason to believe that infection was unlikely, treatment can be discontinued at 48 hours. If the clinical condition of the infant remains uncertain and suspicion of an infectious process remains, therapy should be continued as outlined for documented bacterial sepsis unless another diagnosis becomes apparent. Significant bacterial infection can occur without bacteremia. Squire and colleagues<sup>646</sup> found that results of premortem blood cultures were negative in 7 (18%) of 39 infants with unequivocal infection at autopsy. Some infants with significant systemic bacterial infection may not be identified by the usual single blood culture technique. The physician must consider this limitation when determining length of empirical therapy. However, if treatment for infection is deemed necessary, parenteral administration for 10 days is recommended.

### Management of the Infant with Catheter-Associated Infection

Investigators in Connecticut found that multiple catheters, low birth weight, low gestational age at birth, and low Apgar

scores were significant risk factors for late-onset sepsis.<sup>525</sup> Benjamin and colleagues<sup>526</sup> reported a retrospective study at Duke University from 1995 to 1999 of all neonates who had central venous access. The goal of the Duke study was to evaluate the relationship between central venous catheter removal and outcome in bacteremic neonates. Infants bacteremic with *S. aureus* or a gram-negative rod who had their catheter retained beyond 24 hours had a 10-fold higher rate of infection-related complications than those in whom the central catheter was removed promptly. Compared with neonates who had three or fewer positive intravascular catheter blood cultures for coagulase-negative staphylococci, neonates who had four consecutive positive blood cultures were at significantly increased risk for end-organ damage and death. In neonates with central venous catheter-associated infection, prompt removal of the device is advised unless there is rapid clinical improvement and sterilization of blood cultures after initiation of therapy.

### Treatment of Neonatal Meningitis

Because the pathogens responsible for neonatal meningitis are largely the same as those that cause neonatal sepsis, initial therapy and subsequent therapy are similar. Meningitis caused by gram-negative enteric bacilli can pose special management problems. Eradication of the pathogen often is delayed, and serious complications can occur.<sup>44,119,388,631</sup> The persistence of gram-negative bacilli in CSF despite bactericidal levels of the antimicrobial agent led to the evaluation of lumbar intrathecal<sup>647</sup> and intraventricular<sup>648</sup> gentamicin. Mortality and morbidity were not significantly different in infants who received parenteral drug alone or parenteral plus intrathecal therapy.<sup>647</sup> The study of the intraventricular gentamicin was stopped early because of the high mortality in the parenteral plus intraventricular therapy group.<sup>648</sup>

Feigin and colleagues<sup>629</sup> provide a review of the management of meningitis in children, including neonates. Ampicillin or penicillin G, initially with an aminoglycoside, are appropriate antimicrobial agents for treating infection caused by group B streptococci. Cefotaxime has superior *in vitro* and *in vivo* bactericidal activity against many microorganisms.<sup>624</sup> Treatment of enteric gram-negative bacillary meningitis should include cefotaxime and an aminoglycoside until results of susceptibility testing are known.

If meningitis develops in a low-birth-weight infant who has been in the nursery for a prolonged period or in a neonate who has received previous courses of antimicrobial therapy for presumed sepsis, alternative empirical antibiotic regimens should be considered. Enterococci and antibiotic-resistant, gram-negative enteric bacilli are potential pathogens in these settings. A combination of vancomycin, an aminoglycoside, and cefotaxime may be appropriate. Ceftazidime in addition to an aminoglycoside should be considered for *P. aeruginosa* meningitis.

Other antibiotics may be necessary for the treatment of highly resistant organisms. Meropenem,<sup>649</sup> ciprofloxacin,<sup>650-652</sup> or trimethoprim-sulfamethoxazole<sup>270,653</sup> can be the only antimicrobial agents active *in vitro* against bacteria that are highly resistant to broad-spectrum  $\beta$ -lactam antibiotics or aminoglycosides. Some of these drugs require careful monitoring because of toxicity to the newborn (see Chapter 37), and ciprofloxacin has not been approved for use in the United

**Table 6–18 Infectious and Noninfectious Causes of Aseptic Meningitis<sup>a</sup> in the Neonate**

Cause	Disease
Infectious agent	
Bacteria	Partially treated meningitis Parameningeal focus (brain or epidural abscess) Tuberculosis
Viruses	Herpes simplex meningoencephalitis Cytomegalovirus Enteroviruses Rubella Acquired immunodeficiency syndrome Lymphocytic choriomeningitis Varicella
Spirochetes	Syphilis Lyme disease
Parasites	Toxoplasmosis Chagas' disease
Mycoplasma	<i>Mycoplasma hominis</i> infection <i>Ureaplasma urealyticum</i> infection
Fungi	Candidiasis Coccidioidomycosis Cryptococcosis
Noninfectious causes	
Trauma	Subarachnoid hemorrhage Traumatic lumbar puncture
Malignancy	Teratoma Medulloblastoma Choroid plexus papilloma and carcinoma

<sup>a</sup>*Aseptic meningitis* is defined as meningitis in the absence of evidence of bacterial pathogen detectable in cerebrospinal fluid by usual laboratory techniques.

States in infants younger than 3 months. Definitive treatment of meningitis caused by gram-negative enteric bacilli should be determined by in vitro susceptibility tests, and assistance from an infectious diseases specialist can be helpful.

If cultures of blood and CSF for bacterial pathogens by usual laboratory techniques are negative in the neonate with meningitis, the differential diagnosis of aseptic meningitis must be reviewed, particularly in view of diagnosing treatable infections (Table 6-18).

### Management of the Infant with a Brain Abscess

If purulent foci or abscesses are present, they should be drained. However, some brain abscesses resolve with medical therapy alone.<sup>388,654</sup> Brain abscesses can be polymicrobial or result from organisms that uncommonly cause meningitis such as *Citrobacter*,<sup>141,143</sup> *Enterobacter*,<sup>128</sup> *Proteus*,<sup>388</sup> and *Salmonella* species.<sup>652</sup> Aspiration of the abscess provides identification of the pathogens to guide rational antimicrobial therapy.

### Treatment of the Infant with Meningitis Whose Bacterial Culture Results Are Negative

In the absence of a detectable bacterial pathogen, an aggressive diagnostic approach is necessary for the infant with meningitis, defined by CSF pleocytosis and variable changes in the concentration of CSF protein and glucose. The most frequent cause of aseptic or nontuberculous bacterial meningitis in the neonate is prior antimicrobial therapy resulting in negative blood and CSF cultures. Congenital infections need to be excluded. Treatable diseases, such as partially treated bacterial disease, meningoencephalitis due to herpes simplex virus, syphilis, cytomegalovirus, toxoplasmosis, Lyme disease in regions where *Borrelia* is prevalent, tuberculosis, and malignancy, need to be considered in the differential diagnosis. The history of illness and contacts in the mother and family and epidemiologic features, such as animal exposures and recent travel, should be explored. Re-examination of the infant for focal signs of disease, including special techniques such as ophthalmologic examination, and consideration of appropriate diagnostic imaging studies of the long bones, skull, and brain can provide further information in determining the source of infection. Treatment of possible bacterial or nonbacterial causes of aseptic meningitis may be necessary before the results of culture, polymerase chain reaction, or serology tests are available to indicate the diagnosis.

### Treatment of Anaerobic Infections

The importance of anaerobic bacteria as a cause of serious neonatal infection is uncertain. *Clostridium*, *Peptococcus*, and *Peptostreptococcus* are highly sensitive to penicillin G, but *B. fragilis* sp. usually are resistant. If anaerobic organisms are known or suspected to be responsible for infection (as in peritonitis), initiating therapy with a clinically appropriate agent, such as clindamycin, metronidazole, ticarcillin, or piperacillin, is warranted.

### Adjunctive Therapies for Treatment of Neonatal Sepsis

Despite appropriate antimicrobial and optimal supportive therapy, mortality rates resulting from neonatal sepsis remain high, especially for the VLBW infant. With the hope of improving survival and decreasing the severity of sequelae in survivors, investigators have considered adjunctive modes of treatment, including granulocyte transfusion, exchange transfusion, and the use of standard intravenous immune globulin or pathogen-specific polyclonal or monoclonal antibody reagents for deficits in neonatal host defenses. These therapies are discussed in further detail in Chapters 4 and 13. Pentoxifylline has been documented to reduce plasma tumor necrosis factor- $\alpha$  concentrations in premature infants with sepsis and to improve survival, but the number of infants treated (five of five survived) and number of controls (one of four survived) was too small to provide more than a suggestion of efficacy.<sup>655</sup> In neutropenic infants with sepsis, the administration of granulocyte colony-stimulating factor and human granulocyte-macrophage colony-stimulating factor have had variable effects on outcome.<sup>656-659</sup> Although the results of selected studies indicate that some of these

techniques improved survival, the potential adverse effects (e.g., graft-versus-host reaction, pulmonary leukocyte sequestration) are sufficiently concerning to warrant further study in experimental protocols.

Human immunoglobulin preparations for intravenous administration (IGIV) have been assessed for adjunctive therapy for neonatal sepsis based on the hypothesis that infected infants lack circulating antibodies against bacterial pathogens and that IGIV can provide some antibody for protection. Hill<sup>660</sup> reviewed four clinical trials and reported a mortality rate of 15% (9 of 60) in untreated infants and 3% (2 of 59) in IGIV-treated infants. A meta-analysis of studies of IGIV for the treatment of neonates with sepsis showed a sixfold decrease in the mortality rate in infants who received IGIV in addition to standard therapies.<sup>661</sup> In contrast, Noya<sup>662</sup> concluded that IGIV has not been demonstrated conclusively to be effective in the treatment of neonatal sepsis. A multicenter randomized placebo-controlled trial of IGIV therapy for neonatal sepsis in infants with a birth weight greater than 1000 g showed no difference in mortality between the IGIV-treated and untreated groups.<sup>663</sup>

## PROGNOSIS

Before the advent of antibiotics, almost all infants with neonatal sepsis died.<sup>5</sup> Dunham<sup>2</sup> reported that physicians used various treatments, including "erysipelas serum" and transfusions, without altering the course of the disease. The introduction of sulfonamides and penicillin and later introduction of broad-spectrum antibiotics such as chloramphenicol and streptomycin decreased the mortality rate to about 60%.<sup>3,5</sup> During this period, some infants undoubtedly died because of treatment with high dosages of chloramphenicol, which can cause cardiovascular collapse (i.e., gray baby syndrome).

The introduction of the aminoglycosides, first with kanamycin in the early 1960s and gentamicin late in that decade, vastly improved therapy for bacteremia due to gram-negative organisms, the leading cause of sepsis at that time.<sup>664</sup> These therapies, together with an improved understanding of neonatal physiology and advances in life-support systems, combined to result in a steady decrease in neonatal mortality in the United States<sup>664</sup> and in Europe<sup>21,24,665,666</sup> during the period from 1960 to 1985. Mortality rates for sepsis, including infants of all weights and gestational ages, decreased from 40% to 50% in the 1960s<sup>4,664,665,667</sup> to 10% to 20% in the 1970s and 1980s.<sup>20,21,24,468,469,664,666</sup> Population-based surveillance of selected counties in the United States conducted by the CDC from 1993 to 1998 reported 2196 cases of neonatal sepsis due to group B *Streptococcus*, of which 92 (4%) were fatal.<sup>644</sup>

The postnatal age at which infection occurs, once thought to be of prognostic significance, has become less important within the past 2 decades. Fulminant sepsis, with signs of illness present at birth or during the first day of life, has a high mortality rate, varying from 14% to 20%<sup>21,31,330,662</sup> to as high as 70%.<sup>667</sup> However, when infections occurring during the first 24 hours of life, most of which are caused by group B *Streptococcus*, are excluded from the analysis, the percentage of deaths due to early-onset sepsis does not differ significantly from that associated with late-onset

infection.<sup>20,21,24,96,469,664,665</sup> Mortality from sepsis is higher for preterm than for term infants in virtually all published studies<sup>7,16,20,21,24,31,468,469</sup> but is approximately the same for all major bacterial pathogens<sup>20,24</sup> (see Tables 6-4 and 6-5).

In recent surveys, the mortality rate for neonatal meningitis has declined from 25%<sup>20,42,666,668</sup> to 10% to 15%.<sup>31,44,45,669,670</sup> This decrease represents a significant improvement from prior years, when studies reported a case-fatality rate of more than 30%.<sup>39,455,647,648,671</sup> Mortality is greater among preterm than term infants.<sup>31,44,45,497,672</sup>

Significant sequelae develop in 17% to 60% of infants who survive neonatal meningitis caused by gram-negative enteric bacilli or group B streptococci.<sup>44,666,668,673-675</sup> These sequelae include mental and motor disabilities, convulsive disorders, hydrocephalus, hearing loss, and abnormal speech patterns. The most extensive experience with the long-term observation of infants who had group B streptococcal meningitis as neonates was reported by Edwards and colleagues.<sup>674</sup> Sixty-one patients were treated between 1974 and 1979, and 21% died. Of the 38 survivors who were available for evaluation at 3 years of age or older, 29% had severe neurologic sequelae, 21% had minor deficits, and 50% were functioning normally. Presenting factors that were associated with death or severe disability included comatose or semi-comatose state, decreased perfusion, total peripheral white blood cell count less than 5000/mm<sup>3</sup>, absolute neutrophil count less than 1000/mm<sup>3</sup>, and CSF protein level greater than 300 mg/dL. A comparable study evaluating 35 newborns over a period of 3 to 18 years demonstrated more favorable outcomes with 60% of survivors considered normal at the time of follow-up compared with sibling controls, 15% with mild to moderate neurologic residua, and 25% with major sequelae.<sup>671</sup> Franco and co-workers<sup>672</sup> reported the results of frequent and extensive neurologic, developmental, and psychometric assessments on a cohort of 10 group B streptococcal meningitis survivors followed for one to 14 years and found that one child had severe central nervous system damage, five children, including one with hydrocephalus, had mild academic or behavioral problems, and four children were normal.

The neurodevelopmental outcomes described for infants with gram-negative bacillary meningitis are similar to those reported for group B streptococcal meningitis. Unhanand and colleagues<sup>44</sup> reported findings from their 21-year experience with gram-negative meningitis at two hospitals in Dallas, Texas. Among 72 patients less than 28 days old at the onset of symptoms, there were 60 survivors, 43 of whom were followed and evaluated for a period of at least 6 months. Neurologic sequelae, occurring alone or in combination, were described in 56% and included hydrocephalus (≈30%), seizure disorder (≈30%), developmental delay (≈30%), cerebral palsy (25%), and hearing loss (15%). Forty-four percent of the survivors were developmentally normal at follow-up. Among infants with gram-negative bacillary meningitis, thrombocytopenia, CSF white blood cell count greater than 2000/mm<sup>3</sup>, CSF protein greater than 200 mg/dL, CSF glucose-to-blood glucose ratio of less than 0.5, prolonged (>48 hours) positive CSF cultures, and elevated endotoxin and interleukin-1 concentrations in CSF were indicators of a poor outcome.<sup>44,457,676</sup> Investigators in England and Wales<sup>670</sup> found that independent predictors of adverse outcome 12 hours after admission were the presence of seizures, coma, ventilatory support, and leukopenia.

Computed tomography reveals a high incidence of central nervous system residua among newborns with meningitis. McCracken and colleagues<sup>677</sup> report that, among 44 infants with gram-negative bacillary meningitis, only 30% of computed tomographic scans were considered normal. Hydrocephalus was found in 20% of cases; areas of infarct, cerebritis, diffuse encephalomalacia, or cortical atrophy in 30%; brain abscess in about 20%; and subdural effusions in 7%. Two or more abnormalities were detected in about one third of infants.

The prognosis of brain abscess in the neonate is guarded because about one half of these children die, and sequelae such as hydrocephalus are common among survivors. Of 17 children who had brain abscess during the neonatal period and were followed for at least 2 years, only 4 had normal intellect and were free of seizures.<sup>388</sup> In neonates with brain abscess, the poor outcome probably is caused by destruction of brain parenchyma as a result of hemorrhagic infarcts and necrosis.

## PREVENTION

### Obstetric Factors

Improvement in the health of pregnant women with increased use of prenatal care facilities has led to lower rates of prematurity. Increased use of antenatal steroids in pregnant women with preterm labor and of surfactant in their infants has resulted in significantly fewer cases of respiratory distress syndrome. More appropriate management of prolonged interval after rupture of maternal membranes, maternal peripartum infections, and fetal distress has improved infant outcome. Because these factors are associated with sepsis in the newborn, improved care of the mother should decrease the incidence of neonatal infection. The development of neonatal intensive care expertise and units with appropriate equipment has resulted in the survival of VLBW infants. Increasingly, obstetric problems are anticipated, and mothers are transferred to medical centers with neonatal intensive care units before delivery.

### Chemoprophylaxis

The use of antibiotics to prevent infection can be valuable when they are directed against specific microorganisms for a limited time. In the neonate, the use of silver nitrate eye drops or intramuscular ceftriaxone to prevent gonococcal ophthalmia, vaccination with bacillus Calmette-Guérin (BCG) or prophylactic use of isoniazid to reduce morbidity from tuberculosis in infants who must return to endemic areas, and use of hexachlorophene baths to prevent staphylococcal disease have been recognized as effective modes of chemoprophylaxis. The value of using antimicrobial agents against unknown pathogens in infants believed to be at high risk of infection or undergoing invasive procedures is uncertain. Studies of penicillin administered to the mother during labor for prevention of neonatal disease caused by group B streptococci are reviewed earlier and in Chapter 13.

Baier and colleagues<sup>678</sup> investigated daily administration of vancomycin for the prevention of CoNS bacteremia in low-birth-weight infants. Vancomycin was effective in reducing

colonization and bacteremia when added to parenteral nutrition fluids for infants weighing 500 to 1500 g. Infants were randomized to receive vancomycin or no antibiotic for the duration of parenteral nutrition in a study blinded to the investigators. Nine infants in the control group developed bacteremia or fungemia, and one infant in the vancomycin-treated group developed candidemia. All invasive episodes occurred in infants weighing less than 1000 g, and there were no isolates of vancomycin-resistant strains of CoNS. Although the data suggest a beneficial effect for the vancomycin-treated infants, the number of patients studied was too small to verify this conclusion with adequate statistical power and this prophylactic regimen is not recommended.

### Maternal Factors

The antiviral and antibacterial activity of human milk has been recognized for many years<sup>679-682</sup> and is discussed extensively in Chapter 5. Evidence that breast-feeding defends against neonatal sepsis and gram-negative meningitis was reported more than 30 years ago from Sweden.<sup>683</sup> Later studies carried out in Pakistan have shown that even partial breast-feeding appears to be protective among neonates in a resource-limited nation with a high neonatal mortality rate from clinical sepsis.<sup>684</sup> Breast-fed infants have a lower incidence of gastroenteritis, respiratory illness, and otitis media than those who are formula fed. A protective effect of breast-feeding against infections of the urinary tract also has been suggested.<sup>685</sup>

Observations that breast-feeding enhances lymphocyte responses to a purified protein derivative (PPD) of *M. tuberculosis* in infants given BCG vaccination at birth indicates that the effects of breast milk are not limited to those of an antibody-mediated mucosal protection.<sup>686</sup> The clinical significance of this increased specific cellular immune response during the first few weeks of life remains to be determined.

### Immunoprophylaxis

The immaturity of the neonatal immune system is characterized by decreased levels of antibody against common pathogens; decreased complement activity, especially alternative pathway components; diminished polymorphonuclear leukocyte production, mobilization, and function; diminished T lymphocyte cytokine production to many antigens; and reduced concentrations of plasma and cell surface fibronectin.<sup>660</sup> Recognition of these factors has resulted in attempts at therapeutic intervention aimed specifically at each component of the deficient immune response.

Infants are protected from infection by passively transferred maternal IgG. To enhance the infant's ability to ward off severe infections, immunization of pregnant women and women in the childbearing years has been selectively adopted.<sup>687,688</sup> Programs to immunize pregnant women in resource limited countries with tetanus toxoid have markedly decreased the incidence of neonatal tetanus. Investigational programs for immunization of pregnant women with polysaccharide pneumococcal, *H. influenzae* type b and group B streptococcal vaccines aim to provide infants with protection in the first months of life. Studies of safety and immunogenicity of polysaccharide conjugate vaccines for group B

streptococci show promise of a reduction in incidence of late-onset and early-onset disease in newborns.<sup>689</sup> Use of vaccines in pregnant women is discussed in Chapter 1.

Several clinical trials have explored the use of IGIV to correct the antibody deficiency of neonates, particularly very preterm newborns, and thereby reduce the incidence of sepsis. The results of these investigations were reviewed in 1993 by Hill.<sup>660</sup> Two of six studies indicated that IGIV reduced the incidence of late-onset infections, particularly those due to coagulase-negative staphylococci, but did not affect mortality. The remaining four studies failed to demonstrate any effect of IGIV on the incidence of late-onset sepsis, mortality, morbidity, or length of hospital stay. A meta-analysis performed in 1998 by Jenson and Pollack<sup>661</sup> found that prophylactic IGIV was of minimal but demonstrable benefit in preventing sepsis in premature, low-birth-weight infants. A recent prospective, randomized, placebo-controlled, multicenter trial found no effect of prophylactic IGIV on preventing sepsis when administered to neonates who were less than 33 weeks' gestation.<sup>690</sup> The use of hyperimmune IGIV preparations and human monoclonal antibodies to prevent specific infections (e.g., CoNS, *S. aureus*) in high-risk neonates is being explored.

Sidiropoulos and co-workers<sup>691</sup> studied the benefit of low-dose (12 g in 12 hours) or high-dose (24 g daily for 5 days) IGIV given to pregnant women at risk for preterm delivery because of chorioamnionitis. Cord blood IgG levels were doubled in infants older than 32 weeks' gestational age whose mothers received the higher dosage schedule but were unaffected in infants born earlier, suggesting little or no placental transfer of IGIV before the 32nd week of gestation. Among the infants delivered after 32 weeks, 6 (37%) of 16 born to untreated mothers developed clinical, laboratory, or radiologic evidence of infection and required antimicrobial therapy, whereas none of 7 infants born to treated mothers became infected. Although this study suggests that intrauterine fetal prophylaxis can be beneficial in selected cases, widespread use of IGIV for all women having premature onset of labor is not feasible because of timing before delivery, widespread shortages of IGIV, and cost.

The decreased number of circulating polymorphonuclear leukocytes and reduced myeloid reserves in the bone marrow of newborns have been ascribed to impaired production of cytokines, interleukin-3, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, tumor necrosis factor- $\alpha$ , and interferon- $\gamma$ .<sup>692,693</sup> Considerable experience with in vitro myeloid cell cultures and animal models<sup>694,695</sup> and with human trials<sup>696</sup> suggests that cytokine therapy can be an effective aid in preventing sepsis among newborns with hereditary or acquired congenital neutropenia. Treatment of a small number of infants with early signs of sepsis with pentoxifylline to reduce the concentrations of tumor necrosis factor- $\alpha$  showed promise,<sup>655</sup> but there are no studies that have used pentoxifylline for prevention of sepsis. Similarly, preliminary studies of granulocyte colony-stimulating factor in neonates are inconsistent in demonstrating that absolute neutrophil counts are increased or that the incidence of sepsis is reduced.<sup>656,657,696</sup>

Fibronectins are high-molecular-weight glycoproteins, produced primarily by the liver and endothelial cells, that facilitate cell-to-cell and cell-to-substrate adhesion.<sup>697,698</sup> They are involved in numerous functions, including

hemostasis; vascular integrity; tissue repair; T lymphocyte activation; leukocyte migration, adhesion, and phagocytosis; and reticuloendothelial clearance. Plasma fibronectin concentrations in newborns are about one third to one half those of adults, and premature infants have levels significantly lower than those of term infants. These concentrations are further decreased in neonates with perinatal asphyxia, respiratory distress syndrome, and sepsis.<sup>699</sup> Studies in animal models and adults with sepsis suggest that fibronectin administration can be of value in improving host defenses and in reducing the risk of nosocomial infection in neonates.

## Decontamination of Fomites

Because contamination of equipment poses a significant infectious challenge for the newborn, disinfection of all materials that are involved in the care of the newborn is an important responsibility of nursery personnel. The basic mechanisms of large pieces of equipment must be cleaned appropriately or replaced because they have been implicated in nursery epidemics. The use of disposable equipment and materials packaged in individual units, such as containers of sterile water for a nebulization apparatus, are important advances in the prevention of infection. The frequency of catheter-associated CoNS sepsis has led to attempts to prevent bacterial colonization of intravascular catheters through use of attachment-resistant polymeric materials, antibiotic impregnation, and immunotherapy directed against adherence factors.<sup>700</sup> These procedures are reviewed in Chapter 35.

## Epidemiologic Surveillance

### Endemic Infection

Nursery-acquired infections can become apparent days to several months after discharge of the infant. A surveillance system that provides information about infections within the nursery and involves follow-up of infants after discharge should be established. Various techniques can be used for surveillance and are reviewed in Chapter 35.

### Epidemic Infection

The medical and nursing staff must be aware of the possibility of outbreaks or epidemics in the nursery. Prevention of disease is based on the level of awareness of personnel. Infection in previously well infants who lack high-risk factors associated with sepsis must be viewed with suspicion. Several cases of infection occurring within a brief period, caused by the same or an unusual pathogen, and occurring in close physical proximity should raise concern about the possibility of a nursery outbreak. Techniques for management of infection outbreaks in nurseries are discussed in Chapter 35.

## SEPSIS IN THE NEWBORN RECENTLY DISCHARGED FROM THE HOSPITAL

When fever or other signs of systemic infection occur in the first weeks after the newborn is discharged from the nursery, appropriate management requires consideration of the possible sources of infection. Infection acquired at birth or from a household contact is the most likely cause. Congenital

infection can be present with signs of disease that are detected after discharge. Late-onset infection from microorganisms acquired in the nursery can occur weeks or occasionally months after birth. Infection can occur after discharge because of underlying anatomic, physiologic, or metabolic abnormalities.

The newborn is susceptible to infectious agents that colonize or cause disease in other household members. If an infant whose gestation and delivery were uneventful is discharged from the nursery and develops signs of an infectious disease in the first weeks of life, the infection was probably acquired from someone in the infant's environment. Respiratory and gastrointestinal infections are common and can be accompanied by focal disease such as otitis media. A careful history of illnesses in household members can suggest the source of the infant's infection.

### Congenital Infection

Signs of congenital infection can appear or be identified after discharge from the nursery. Hearing impairment caused by congenital rubella or cytomegalovirus infection can be noticed by a parent at home. Hydrocephalus with gradually increasing head circumference caused by congenital toxoplasmosis can be apparent only after serial physical examinations. Chorioretinitis, jaundice, or pneumonia can occur as late manifestations of congenital infection. A lumbar puncture may be performed in the course of a sepsis evaluation. CSF pleocytosis and increased protein concentration can be caused by congenital infection and warrant appropriate diagnostic studies.

### Late-Onset Disease

Late-onset disease can present after the first week to months after birth as sepsis and meningitis or other focal infections. Group B *Streptococcus* (see Chapter 13) is the most frequent cause of late-onset sepsis in the neonate. Organisms acquired in the nursery also can cause late-onset disease. Skin and soft tissue lesions or other focal infections, including osteomyelitis and pneumonia from *S. aureus*, can occur weeks after birth. The pathogenesis of late-onset sepsis is obscure in many cases. The reason why an organism becomes invasive and causes sepsis or meningitis after colonizing the mucous membranes, skin, or upper respiratory, genitourinary, or gastrointestinal tracts remains obscure. Nosocomially acquired or health care-associated organisms are discussed in further detail in Chapter 35.

### Infections in the Household

Infection can be associated with an underlying anatomic defect, physiologic abnormality, or metabolic disease. The infant who fails to thrive or presents with fever can have a urinary tract infection as the first indication of an anatomic abnormality. Infants with lacrimal duct stenosis or choanal atresia can develop focal infection. Sepsis caused by gram-negative enteric bacilli occurs frequently in infants with galactosemia (see "Pathogenesis").

The infected infant can be an important source of infection to family members. In one study in New York,<sup>701</sup> 12.6% of household contacts developed suppurative lesions

during the 10-month period after introduction into the home of an infant with a staphylococcal lesion. The incidence of suppurative infections in household contacts of infants without lesions was less than 2%. Damato and co-workers<sup>702</sup> demonstrated colonization of neonates with enteric organisms possessing R factor-mediated resistance to kanamycin and persistence of these strains for more than 12 months after birth. During the period of observation, one third of the household contacts of the infants became colonized with the same strain.

Infections in infants have been associated with bites or licks from household pets. *Pasteurella multocida* is part of the oral flora of dogs, cats, and rodents. Meningitis caused by *P. multocida* was reported in seven infants younger than 2 months.<sup>703</sup> A 5-week-old infant with *P. multocida* meningitis frequently was licked by the family dog, and the organism was identified in cultures of the dog's mouth but not of the parents' throats. *P. multocida* meningitis in a 3-week-old infant may have resulted from transmission of the organism from the family cat to the mother and then to the infant.<sup>704</sup> The epidemiologic link between cats and dogs and infection in young infants suggests that parents should limit contact between pets and infants.

### Fever in the First Month of Life

Reviews of fever in the first weeks of life indicate that elevation of temperature ( $>38.8^{\circ}\text{C}$  [ $101.8^{\circ}\text{F}$ ])<sup>705-712</sup> is relatively uncommon. However, when fever occurs in the young infant, the incidence of severe disease, including sepsis, meningitis, and pneumonia, is sufficiently high to warrant careful evaluation and conservative management. A careful history of the pregnancy, delivery, nursery experience, interval since discharge from the nursery, and infections in the household should be obtained. Physical examination should establish the presence or absence of signs associated with congenital infection and late-onset diseases. Culture of blood and urine should be performed if no other focus is apparent, and culture of the CSF and a chest radiograph should be considered if the infant is believed to have systemic infection.

Practice guidelines prepared by Baraff and colleagues<sup>705</sup> for the management of infants and children with fever without source state that all febrile infants younger than 28 days should be hospitalized for parenteral antibiotic therapy. The group designated that a rectal temperature of  $38.0^{\circ}\text{C}$  ( $100.4^{\circ}\text{F}$ ) or higher should be used as the definition of fever. The sepsis evaluation includes a culture of blood, urine, and CSF; a complete blood cell and differential count; examination of CSF for cells, glucose, and protein; and a urinalysis.

### Acknowledgment

Dr. S. Michael Marcy was a co-author of this chapter in the first four editions. The authors are indebted to Dr. Marcy for his continued interest in the preparation of this chapter.

## INFECTIONS OF THE ORAL CAVITY AND NASOPHARYNX

### Pharyngitis, Retropharyngeal Cellulitis, and Retropharyngeal Abscess

Neonates with bacterial infection of the oropharynx may present with pharyngeal inflammation with or without exudate or with retropharyngeal cellulitis or abscess. Extension of infection to the surrounding structures may occur, leading to deep neck abscess formation. Microorganisms identified as the etiologic agents of these infections and their manifestations of disease include the following:

*Staphylococcus aureus*. Although many children are colonized in the throat and nasopharynx with *S. aureus*, this organism is rarely a primary agent in the etiology of pharyngitis in infants (or adults). There have, however, been reports of localized abscesses in the oral cavity related to *S. aureus*. Clark and Barysh, in 1936, reported a case of retropharyngeal abscess in a

6-week-old infant.<sup>1</sup> The child was critically ill but recovered after incision and drainage of the abscess. Steinhauer reported a case of cellulitis of the floor of the mouth (Ludwig's angina) in a 12-day-old infant.<sup>2</sup> The child was febrile and toxic; examination of the mouth revealed swelling under the tongue. Purulent material was subsequently drained from this lesion, and *S. aureus* was isolated from the pus. A laceration was noted in the floor of the mouth, and the author considered this wound to be the portal of entry of the infection.

*Streptococcus pyogenes*. Fever and pharyngeal inflammation may result from infection with this organism in the neonate.<sup>3</sup>

*Streptococcus agalactiae*. Retropharyngeal cellulitis has been associated with bacteremia caused by group B streptococci.<sup>4,5</sup> The affected neonates presented with poor feeding, noisy breathing, and widening of the retropharyngeal space on radiographs of the lateral neck. Stridor also may be associated with retropharyngeal abscess, as reported in a 13-day-old infant in Hong Kong.<sup>6</sup> A retropharyngeal abscess caused by group B streptococci occurred in one of three neonates reported in a series of 31 cases of retropharyngeal abscess seen in children in Camperdown, Australia, between 1954 and 1990.<sup>7,8</sup> This infant was found to have a third branchial arch pouch that was subject to recurrent infection until age 5 years.

*Listeria monocytogenes*. Small focal granulomas on the mucous membrane of the posterior pharynx have been observed in neonates with *L. monocytogenes* infection. Necrosis of some of the granulomas results in ulcers on the pharynx and tonsils.

*Treponema pallidum*. Mucous patches occur on the lips, tongue, and palate of congenitally infected infants. Rhinitis may appear after the first week of life.

*Neisseria gonorrhoeae*. A yellow mucoid exudate of the pharynx may be present simultaneously with ophthalmia (A Yu, personal communication, 1981). A case report of in utero gonococcal infection with involvement of multiple tissues included pharyngeal abscess.<sup>9</sup>

*Enterococcus faecalis*. A case of retropharyngeal abscess in which culture of aspirated pus grew *E. faecalis* as well as two strains of coagulase-negative staphylococci occurred in a 2-week-old full-term infant from Australia.<sup>8</sup> The infant was severely ill and had atlanto-axial dislocation resulting in paraplegia. At autopsy the findings included bacterial endocarditis, diffuse bilateral pneumonia, and renal infarcts.

*Escherichia coli*. This organism can be a rare cause of infection of the pharyngeal cavity. Pus from a retropharyngeal abscess in a 1-week-old infant grew two strains of *E. coli*.<sup>8</sup> The infant was afebrile on presentation and had a large midline pharyngeal swelling.

Infants may have coryza and other signs of upper respiratory tract disease due to infection with respiratory viruses. Infections with respiratory viruses may damage the respiratory mucosa, thereby increasing susceptibility to bacterial infection of the respiratory tract. Eichenwald<sup>10</sup> described an apparent synergy of respiratory viruses and staphylococci that produced an upper respiratory tract infection called the "stuffy nose syndrome." The syndrome occurred only when both organisms were present. He and his group also documented increased dissemination of bacteria by newborns carrying staphylococci and echovirus 20 or adenovirus type 2 in the nasopharynx and coined the term *cloud babies* for these infants.<sup>11</sup> These studies have not been repeated by other investigators, and the significance of synergy of two or more microorganisms in neonatal respiratory infections remains uncertain.

## Noma

Noma (cancrum oris) is a destructive gangrenous process that may affect the nose, lips, and mouth. It occurs almost exclusively in malnourished children in developing countries; nutrient deficiencies have been postulated to play a role in its pathogenesis.<sup>12</sup> Although it is usually a chronic, destructive process in older children, in neonates it may be rapidly fatal. Affected neonates are usually premature and of low birth weight. In older children and adults, noma is caused by fusospirochetes such as *Fusobacterium necrophorum*.<sup>13</sup> The disease in neonates is usually due to *Pseudomonas aeruginosa*. Ghosal and co-workers, from Calcutta, reported bacteriologic and histologic findings in 35 cases of noma in neonates.<sup>14</sup> *P. aeruginosa* was isolated from blood or the gangrenous area in more than 90% of the cases. An Israeli full-term infant with bilateral choanal atresia who required an airway developed gangrenous lesions of the cheek on day 11 and palatal lesions that progressed to ulceration and development of an oronasal fistula. Cultures of material from the lesions grew *P. aeruginosa*.<sup>15</sup> Freeman and associates reported the development of noma neonatorum in the third week of life in a 26-week-gestation premature infant; they suggest that this entity represents a neonatal form of ecthyma gangrenosum.<sup>16</sup>

## Epiglottitis

Epiglottitis caused by *S. aureus* in an 8-day-old infant was reported by Baxter in a survey of experience with the disease at Montreal Children's Hospital between 1951 and 1965.<sup>17</sup> A second case of epiglottitis due to *S. aureus* in a 5-day-old infant was reported by Rosenfeld and associates.<sup>18</sup> The infant presented with bradycardia, hoarseness, and inspiratory stridor and had diffuse inflammation of the arytenoids and epiglottis. *S. aureus* was cultured from pus on the epiglottic surface; blood culture was negative. Epiglottitis due to group B streptococci was reported in an 11-week-old infant in 1996.<sup>19</sup>

## Laryngitis

Laryngitis in the newborn is rare. The child with congenital syphilis may have laryngitis and an aphonic cry. Hazard and co-workers described a case of laryngitis caused by *Streptococcus pneumoniae*.<sup>20</sup> A term infant was noted at 12 hours to have a hoarse cry, which progressed to aphonia during the next 3 days. Direct examination of the larynx revealed swelling and redness of the vocal cords. The child was febrile (38.5° C), but the physical examination was unremarkable. *S. pneumoniae* was isolated from the amniotic fluid, the maternal cervix, and the larynx of the infant. The child responded rapidly to treatment with parenteral penicillin G.

## Infection of the Paranasal Sinuses

The paranasal sinuses of the fetus begin to differentiate at about the fourth month of gestation. The sinuses develop by local evagination of nasal mucosa and concurrent resorption of overlying bone. The maxillary and ethmoid sinuses are developed at birth and may be sites for suppurative infection. The sphenoid and frontal sinuses are rudimentary at birth and are not well defined until about 6 years of age.<sup>21,22</sup>

Inflammatory reaction may occur simultaneously in the paranasal sinuses, the middle ears, and the lungs. Autopsy may reveal that purulent exudate and leukocytic infiltration of the mucosa are present at one or more of these sites. Infection of the ethmoid and maxillary sinuses may be severe and life-threatening in the newborn. Clinical manifestations include general signs of infection such as fever, lethargy, irritability, and poor feeding as well as focal signs indicative of sinus involvement (i.e., nasal congestion, purulent drainage from the nostrils, and periorbital redness and swelling). Proptosis may occur in severely affected children. Although any of the organisms responsible for neonatal sepsis may cause sinusitis, *S. aureus* and group A and group B streptococci are responsible for most infections.<sup>23-25</sup> Suppurative infection of the maxillary sinus may progress to osteomyelitis of the superior maxilla (see Chapter 8).<sup>24</sup>

Blood specimens, nasopharyngeal secretions, and purulent drainage material (if present) should be obtained for culture before treatment. Antibacterial therapy must include a penicillinase-resistant penicillin or cephalosporin for activity against *Staphylococcus* and group A and group B streptococci. If no material is available for examination of Gram-stained pus or if results of the preparation are ambiguous, initial therapy should include an aminoglycoside or a third-generation cephalosporin to ensure activity against gram-negative enteric bacilli (see discussion of management in Chapter 6). Surgical drainage of the infected site should be considered. Drainage of the suppurative maxillary sinus should be performed through the nose to avoid scars on the face and damage to the developing teeth.<sup>24</sup>

## Diphtheria

Neonatal diphtheria, although now extremely rare in the United States, was common before the development and extensive use of immunization with diphtheria toxoid.

Outbreaks occurred in hospital nurseries. One of the most striking reports describes three separate epidemics in a “foundling hospital” in Tipperary, Ireland, between 1937 and 1941; 36 infants younger than 1 month of age were afflicted, and 26 died.<sup>26</sup> Goebel and Stroder described 109 infants younger than 1 year of age with diphtheria in Germany during the period extending from the fall of 1945 to the summer of 1947: 59 infants were younger than 1 month of age, and 26 died.<sup>27</sup> In a report from the Communicable Disease Unit of the Los Angeles County Hospital covering the 10-year period ending June 1950, 1433 patients were admitted to the hospital with diphtheria; 19 patients were younger than 1 year of age, but just 2 patients were younger than 1 month of age.<sup>28</sup> Elsewhere, the disease also appears to be on the wane; only three cases of neonatal diphtheria were identified in India between 1974 and 1984 by Mathur and associates.<sup>29</sup>
