The most extensive studies on the epidemiology of gastroenteritis related to *E. coli* have dealt with events that took place during outbreaks in newborn nurseries. Unfortunately, investigations of this sort frequently regard the epidemic as an isolated phenomenon and ignore the strong interdependence that exists between community- and hospital-acquired illness.<sup>280,283,284</sup> Not surprisingly, the direction of spread is most often from the reservoir of disease within the community to the hospital. When the original source of a nursery outbreak can be established, frequently it is an infant born of a carrier mother who recently acquired her EPEC infection from a toddler living in the home. Cross-infection epidemics also can be initiated by infected newborns who have been admitted directly into a clean nursery unit from the surrounding district<sup>270,272,285</sup> or have been transferred from a nearby hospital.<sup>278,280,286</sup>

After a nursery epidemic has begun, it generally follows one of two major patterns. Some are explosive, with rapid involvement of all susceptible infants and a duration that seldom exceeds 2 or 3 months.<sup>264,265,276,287</sup> The case-fatality rate in these epidemics may be very high. Other nursery outbreaks have an insidious onset with a few mild, unrecognized cases; the patients may not even develop illness until

after discharge from the hospital. During the next few days to weeks, neonates with an increased number of loose stools are reported by the nurses; shortly thereafter, the appearance of the first severely ill infants makes it apparent that an epidemic has begun. Unless oral antimicrobial therapy is instituted (see "Therapy"), nursery outbreaks like these may continue for months<sup>266-269</sup> or years,<sup>270</sup> with cycles of illness followed by periods of relative quiescence. This pattern can be caused by multiple strains (of different phage or antibiogram types) sequentially introduced into the nursery.<sup>278,288,289</sup>

The nursery can be a source of infection for the community. The release of infants who are in the incubation stages of their illness or are convalescent carriers about to relapse may lead to secondary cases of diarrheal disease among young siblings living in widely scattered areas.<sup>238,239,243</sup> These children further disseminate infection to neighboring households, involving playmates of their own age, young infants, and mothers.<sup>238,239,242</sup> As the sickest of these contact cases are admitted to different hospitals, they contaminate new susceptible persons, completing the cycle and compounding the outbreak. This feedback mechanism has proved to be a means of spreading infantile gastroenteritis through entire cities,<sup>238,239,242</sup> counties,<sup>239,285,290</sup> and even provinces.<sup>240</sup> One major epidemic of diarrhea related to EPEC O111:B4 that occurred in the metropolitan Chicago and northwestern Indiana region during the winter of 1961 involved more than 1300 children and 29 community hospitals during a period of 9 months.<sup>240,291</sup> Almost all of the patients were younger than 2 years old, and 10% were younger than 1 month, producing an age-specific attack rate of nearly 4% of neonates in the community. The importance of the hospital as a source of cross-infection in this epidemic was demonstrated through interviews with patients' families, indicating that a minimum of 40% of infants had direct or indirect contact with a hospital shortly before the onset of their illness.

It has been suggested, but not proved, that asymptomatic carriers of EPEC in close contact with a newborn infant, such as nursery personnel or family members, might play an important role in its transmission.<sup>280,284,292</sup> Stool culture surveys have shown that at any one time about 1% of adults<sup>242,293</sup> and 1% to 5% of young children<sup>230,238,243</sup> who are free of illness harbor EPEC strains. Higher percentages have been recorded during community epidemics.<sup>238,239,243</sup> Because this intestinal carriage is transitory,<sup>238,280</sup> the number of individuals who excrete EPEC at one time or another during the year is far higher than the 1% figure recorded for single specimens.<sup>280,293</sup>

Nursery personnel feed, bathe, and diaper a constantly changing population of newborns, about 2% to 5% of whom excrete EPEC.<sup>238,280</sup> Despite this constant exposure, intestinal carriage among nursery workers is surprisingly low. Even during outbreaks of diarrheal illness, when dissemination of organisms is most intense, less than 5% of the hospital personnel in direct contact with infected neonates are themselves excreting pathogenic strains of *E. coli*.<sup>291,294,295</sup>

Although adult asymptomatic carriers generally excrete fewer organisms than patients with acute illness do,<sup>272</sup> large numbers of pathogenic bacteria may nevertheless exist in their stools.<sup>242,274</sup> However, no nursery outbreak and few family cases<sup>240</sup> have been traced to a symptomless carrier. Instead, passive transfer of bacteria from infant to infant by the hands of personnel appears to be of primary importance in these outbreaks.

EPEC can be recovered from the throat or nose of 5% to 80% of infants with diarrheal illness<sup>275,294,295</sup> and from about 1% of asymptomatic infants.<sup>232,243</sup> The throat and nasal mucosa may represent a portal of entry or a source of transmission for EPEC. Environmental studies have shown that EPEC is distributed readily and widely in the vicinity of an infant with active diarrheal disease, often within 1 day of admission to the ward.<sup>232,296</sup> Massive numbers of organisms are shed in the diarrheal stool or vomitus of infected infants.<sup>249,296</sup> *E. coli* organisms may survive 2 to 4 weeks in dust<sup>243,296</sup> and can be found in the nursery air when the bedding or diapers of infected infants are disturbed during routine nursing procedures<sup>243,296</sup> or on floors, walls, cupboards, and nursery equipment such as scales, hand towels, bassinets, incubators, and oxygen tents of other infants.<sup>88,243,267</sup> Documentation of the presence of EPEC in nursery air and dust does not establish the importance of this route as a source of cross-infection. One study presented evidence of the respiratory transmission of EPEC; however, even in the cases described, the investigators pointed out that fecal-oral transmission could not be completely ruled out.<sup>238</sup> Additional clinical and experimental data are required to clarify the significance of droplet and environmental infection.

Coliform organisms have also been isolated in significant numbers from human milk,<sup>46,297,298</sup> prebottled infant formulas,<sup>299</sup> and formulas prepared in the home.<sup>292</sup> EPEC in particular has been found in stool cultures obtained from donors of human milk and workers in a nursery formula room.<sup>260</sup> In one instance, EPEC O111:B4 was isolated from a donor, and subsequently, the same serogroup was recovered in massive amounts in almost pure culture from her milk.<sup>260</sup> Pathogenic strains of *E. coli* have also been isolated from raw cow's milk<sup>300</sup> and from drinking water.<sup>301</sup> Likewise, EPEC has been isolated from flies during an epidemic, but this fact has not been shown to be of epidemiologic significance.<sup>211,220</sup>

### Pathogenesis

Infection of the newborn infant with EPEC takes place exclusively by the oral route. Attempts to induce disease in adult volunteers by rectal instillation of infected material have been unsuccessful.<sup>98</sup> There are no reports of disease occurring after transplacental invasion of the fetal bloodstream by enteropathogenic or nonenteropathogenic strains of *E. coli*. Ascending intrauterine infection after prolonged rupture of the membranes has been reported only once; the neonate in this case suffered only from mild diarrhea.<sup>86</sup>

Bacterial cultures of the meconium and feces of newborns indicate that enteropathogenic strains of *E. coli* can colonize effectively the intestinal tract in the first days of life.<sup>85-88</sup> Although *E. coli* may disappear completely from stools of breast-fed children during the ensuing weeks, this disappearance is believed to be related to factors present in the human milk rather than the gastric secretions.<sup>5,302,303</sup> The use of breast-feeding or expressed human milk has even been effective in terminating nursery epidemics caused by EPEC O111:B4, probably by reducing the incidence of cross-infections among infants.<sup>303,304</sup> Although dose-effect studies have not been performed among newborns, severe diarrhea has occurred after ingestion of  $10^8$  EPEC organisms by very young infants.<sup>305,306</sup> The high incidence of cross-infection outbreaks in newborn nurseries suggests that a far lower inoculum can often effect spread in this setting.

The role of circulating immunity in the prevention of gastrointestinal tract disease related to EPEC has not been clearly established. Virtually 100% of maternal sera have been found to contain hemagglutinating,<sup>219,307,308</sup> bactericidal,<sup>305,310</sup> or bacteriostatic<sup>280,312</sup> antibodies against EPEC. The passive transfer of these antibodies across the placenta is extremely inefficient. Titers in blood of newborn infants are, on average, 4 to 100 times lower than those in the corresponding maternal sera. Group-specific hemagglutinating antibodies against the O antigen of EPEC are present in 10% to 20% of cord blood samples,<sup>219,307,308</sup> whereas bactericidal<sup>307,311</sup> or bacteriostatic<sup>311</sup> activity against these organisms can be found much more frequently. Tests for bacterial agglutination, which are relatively insensitive, are positive in only a small percentage of neonates.<sup>219,311</sup>

The importance of circulating antibodies in the susceptibility of infants to EPEC infection is unknown. Experiments with suckling mice have failed to demonstrate any effect of humoral immunity on the establishment or course of duration of intestinal colonization with *E. coli* O127 in mothers or their infants.<sup>313</sup> Similar observations have been made in epidemiologic studies among premature human infants using enteropathogenic (O127:B8)<sup>310</sup> and nonenteropathogenic (O4:H5)<sup>269</sup> strains of *E. coli* as the indicator organisms. In a cohort of 63 mothers and their infants followed from birth to 3 months old, Cooper and associates<sup>85</sup> were able to show a far higher incidence of clinical EPEC disease in infants of EPEC-negative mothers than in infants born of mothers with EPEC isolated from stool cultures. This finding suggested to the investigators the possibility that mothers harboring EPEC in their gastrointestinal tracts transfer specific antibodies to their infants that confer some protection during the first weeks of life.

Protection against enteric infections in humans often correlates more closely with levels of local secretory than serum antibodies. Although it is known that colonization of newborns with *E. coli* leads to the production of coproantibodies against the ingested organisms,<sup>314,315</sup> the clinical significance of this intestinal immunity is uncertain. The previously mentioned experiment with mice showed no effect of active intestinal immunity on enteric colonization.<sup>313</sup> In human infants, the frequency of bacteriologic and clinical relapse related to EPEC of the same serotype<sup>264,265,279</sup> and the capacity of one strain of EPEC to superinfect a patient already harboring a different strain<sup>247,258,268</sup> also cast some doubt on the ability of mucosal antibodies to inhibit or alter the course of intestinal infection. Studies of the protective effects of orally administered EPEC vaccines could help to resolve these questions.<sup>248</sup>

The mechanism by which EPEC causes diarrhea involves a complex array of plasmid and chromosomally encoded traits. EPEC serotypes usually do not make one of the recognized enterotoxins (LT or ST) as usually measured in tissue culture or animal models,<sup>316-320</sup> nor do these serotypes cause a typical invasive colitis or produce a positive Sereny test result.<sup>315,316</sup> Only uncommonly do EPEC strains invade the bloodstream or disseminate.<sup>288</sup> Nevertheless, EPEC strains that test negative in these tests are capable of causing diarrhea; inocula of  $10^{10}$  *E. coli* O142 or O127 organisms caused diarrhea in 8 of 10 adult volunteers.<sup>320</sup>

Some EPEC strains may secrete weak enterotoxins,<sup>321,322</sup> but the consensus opinion is that the attaching and effacing

lesion constitutes the critical secretory virulence phenotype.<sup>98,121</sup> Clinical pathologic reports reveal the characteristic attaching and effacing lesion in the small intestine of infected infants.<sup>324</sup> The lesion is manifested by intimate (about 10 nm) apposition of the EPEC to the enterocytes plasma membrane, with dissolution of the normal brush border and rearrangement of the cytoskeleton.<sup>121,324</sup> In some instances, the bacteria are observed to rise up on pedestal-like structures, which are diagnostic of the infection.<sup>121</sup> Villus blunting, crypt hypertrophy, histiocytic infiltration in the lamina propria, and a reduction in the brush border enzymes may also be observed.<sup>324,325</sup>

Two major EPEC virulence factors have been described; strains with both factors are designated as typical EPEC.<sup>98,99,323</sup> One such factor is the locus of enterocyte effacement (LEE), a type III secretion system encoded by the LEE chromosomal pathogenicity island.<sup>326-328</sup> The LEE secretion apparatus injects proteins directly from the cytoplasm of the infecting bacterium into the cytoplasm of the target enterocytes.<sup>327</sup> The injected proteins constitute cytoskeletal toxins, which together elicit the close apposition of the bacterium to the cell, cause the effacement of microvilli, and most likely give rise to the net secretory state.<sup>98,99,121</sup> One critical secreted protein, called Toll/interleukin-1 receptor (Tir),<sup>120</sup> inserts into the plasma membrane of the epithelial cell, where it serves as the receptor for a LEE-encoded EPEC outer membrane protein called intimin.<sup>121</sup> Animals infected with attaching and effacing pathogens mount antibody responses to intimin and Tir,<sup>329</sup> and both are considered potential immunogens. The lack of protection from EPEC reinfection suggests that natural antibody responses to Tir and intimin are not protective.

The second major virulence factor of typical EPEC is the bundle-forming pilus (BFP),<sup>330</sup> which is encoded on a partially conserved 60 MDa virulence plasmid called EPEC adherence factor (EAF).<sup>331</sup> BFP, a member of the type IV pilus family, mediates aggregation of the bacteria to each other and probably to enterocytes themselves, thereby facilitating mucosal colonization.<sup>332</sup> A BFP mutant was shown to be attenuated in adult volunteers.<sup>333</sup>

### Pathology

The principal pathologic lesion with EPEC is the focal destructive adherence of the organism, effacing the microvillous brush border with villus blunting, crypt hypertrophy, histiocytic infiltration of the lamina propria, and reduced brush border enzymes. Rothbaum and colleagues<sup>324</sup> described similar findings with dissolution of the glycocalyx and flattened microvilli with the nontoxigenic EPEC strain O119:B14. There has been a wide range of pathologic findings reported in infants dying of EPEC gastroenteritis. Most newborns dying with diarrheal disease caused by EPEC show no morphologic changes of the gastrointestinal tract by gross or microscopic examination of tissues.<sup>209,210</sup> Bray<sup>211</sup> described such "meager" changes in the intestinal tract that "the impression received was that the term gastroenteritis is incorrect." At the other extreme, extensive and severe involvement of the intestinal tract, although distinctly unusual among neonates with EPEC diarrhea, has been discussed in several reviews of the pathologic anatomy of this disease.<sup>247,319,334</sup> Changes virtually identical to those found in infants dying with necrotizing enterocolitis have been

reported.<sup>334</sup> Drucker and co-workers<sup>319</sup> found that among 17 infants who were dying of EPEC diarrhea, "intestinal gangrene, and/or perforation, and/or peritonitis were present in five, and intestinal pneumatosis in five."

The reasons for such wide discrepancies in EPEC disease pathology are not clear. The severity of intestinal lesions at the time of death does not correlate with the birth weight of the patient, the age of onset of illness, the serogroup of the infecting strain, or the prior administration of oral or systemic antimicrobial agents. The suggestion that the intensity of inflammatory changes may depend on the duration of the diarrhea<sup>319</sup> cannot be corroborated in autopsy studies<sup>215,264,335</sup> or small intestinal biopsies.<sup>336,337</sup> It is difficult to reconcile such a thesis with the observation that a wide range of intestinal findings can be seen at autopsy among newborns infected by a single serotype of EPEC during an epidemic. The nonspecific pathologic picture described by some researchers includes capillary congestion and edema of the bowel wall and an increase in the number of eosinophils, plasma cells, macrophages, and mononuclear cells in the mucosa and submucosa.<sup>262,319,335</sup> Villous patterns are generally well preserved, although some flattening and broadening of the villi are seen in the more severe cases. Almost complete absence of villi and failure of regeneration of small bowel mucosa have been reported in an extreme case.<sup>338</sup> Edema in and around the myenteric plexuses of Auerbach, a common associated finding, has been suggested as a cause of the gastrointestinal tract dilatation often seen at autopsy in infants with EPEC infections.<sup>247,335,339</sup> In general, the distal small intestine shows the most marked alterations; however, the reported pathologic findings may be found at all levels of the intestinal tract.

Several complications of EPEC infection have been reported. Candidal esophagitis accounted for significant morbidity in two series collected before<sup>210</sup> and during<sup>247</sup> the antibiotic era. Oral thrush has been seen in 50% of EPEC-infected infants treated with oral or systemic antibiotics.<sup>245,264,335</sup> Some degree of fatty metamorphosis of the liver has been reported by several investigators<sup>210,215,335</sup>; however, these changes are nonspecific and probably result from the poor caloric intake associated with persistent diarrhea or vomiting. Some degree of bronchopneumonia, probably a terminal event in most cases, exists in a large proportion of newborns dying of EPEC infection.<sup>210,215,339</sup> In one reported series of infant cases, EPEC was demonstrated by immunofluorescent staining in the bronchi, alveoli, and interalveolar septa.

Mesenteric lymph nodes are often swollen and congested with reactive germinal centers in the lymphoid follicles.<sup>215,262,293</sup> Severe lymphoid depletion, unrelated to the duration or severity of the antecedent illness, also has been described.<sup>285</sup> The kidneys frequently show tubular epithelial toxic changes. Various degrees of tubular degeneration and cloudy swelling of convoluted tubules are common findings.<sup>215,285,335</sup> Renal vein thrombosis or cortical necrosis may be observed in infants with disseminated intravascular coagulation in the terminal phases of the illness. The heart is grossly normal in most instances but may show minimal vacuolar changes of nonspecific toxic myocarditis on microscopic examination.<sup>335,339</sup> Candidal abscesses of the heart<sup>339</sup> and kidneys<sup>285,335,339</sup> have been described. With the exception of mild congestion of the pia arachnoid vessels and some edema of the meninges,

examination of the central nervous system reveals few changes.<sup>215,262</sup> Despite the observation of Bray<sup>211</sup> that “inflammation of the middle ear [is] exceptional,” strains of EPEC have been isolated from a significant number of specimens of the middle ear in case series in which dissection of the temporal bone has been performed.<sup>209,215</sup>

### Clinical Manifestations

Exposure of newborns to EPEC may be followed by one of several possible consequences: no infection, infection without illness, illness with gastroenteritis of variable severity and duration, and rarely, septicemia with or without metastatic foci of infection accompanying gastroenteritis.

When infants are exposed to EPEC, a significant number become colonized as temporary stool<sup>185,88,231</sup> or pharyngeal<sup>238</sup> carriers with no signs of clinical disease. Although Laurell<sup>340</sup> showed that the percentage of asymptomatic infections rises steadily as age increases, this observation has not been confirmed by other investigators.<sup>214,341</sup> Similarly, the suggestion that prematurity per se is associated with a low incidence of inapparent EPEC infection has been documented in several clinical studies<sup>262,264,265</sup> but refuted in others.<sup>252,279</sup> Most neonates who acquire infection with EPEC eventually show some clinical evidence of gastroenteritis. The incubation period is quite variable. Its duration has been calculated mostly from evidence in outbreaks in newborn nurseries, where the time of first exposure can be clearly defined in terms of birth or admission dates. In these circumstances, almost all infants show signs of illness between 2 and 12 days after exposure, and most cases show signs within the first 7 days.<sup>215,231,264</sup> In some naturally acquired<sup>85,86</sup> and experimental<sup>306</sup> infections with heavy exposure, the incubation period may be as short as 24 hours; the stated upper limit is 20 days.<sup>232,343</sup> The first positive stool culture and the earliest recognizable clinical signs of disease occur simultaneously in most infants,<sup>264,266</sup> although colonization may precede symptoms by 7 to 14 days.<sup>265,266,344</sup> The gastroenteritis associated with EPEC infection in the newborn is notable for its marked variation in clinical pattern. Clinical manifestations vary from mild illness manifest only by transient anorexia and failure to gain weight to a sudden explosive fulminating diarrhea causing death within 12 hours of onset. Prematurity, underlying disease, and congenital anomalies often are associated with the more severe forms of illness.<sup>214,233,345,346</sup> Experienced clinicians have observed that the severity of EPEC gastroenteritis has declined markedly during the past 3 decades.<sup>225</sup> The onset of illness usually is insidious, with vague signs of reluctance to feed, lethargy, spitting up of formula, mild abdominal distention, or even weight loss that may occur for 1 or 2 days before the first loose stool is passed. Diarrhea usually begins abruptly. It may be continuous and violent, or in milder infections, it may run an intermittent course with 1 or more days of normal stools followed by 1 or more days of diarrhea. Emesis sometimes is a prominent and persistent early finding. Stools are loose and bright yellow initially, later becoming watery, mucoid, and green. Flecks or streaks of blood, which are commonly seen with enterocolitis caused by *Salmonella*, *Campylobacter*, or *Shigella*, are rarely a feature of EPEC diarrheal disease. A characteristic seminal smell may pervade the environment of infants infected with EPEC O111:B34,<sup>232,262,347</sup> and an odor variously described as “pungent,” “musty,” or “fetid” often surrounds

patients excreting other strains in their stools.<sup>231,256</sup> Because the buttocks are repeatedly covered with liquid stools, excoriation of the perianal skin can be an early and persistent problem. Fever is an inconstant feature, and when it occurs, the patient’s temperature rarely rises above 39° C. Convulsions occur infrequently; their occurrence should alert the clinician to the possible presence of electrolyte disturbances, particularly hypernatremia. Prolonged hematochezia, distention, edema, and jaundice are ominous signs and suggest an unfavorable prognosis.<sup>215,240,285</sup> Most infants receiving antimicrobial agents orally show a cessation of diarrhea, tolerate oral feedings, and resume weight gain within 3 to 7 days after therapy has been started.<sup>242,245</sup> Those with mild illness who receive no treatment can continue to have intermittent loose stools for 1 to 3 weeks. In one outbreak related to EPEC O142:K86, more than one third of the untreated or inappropriately treated infants had diarrhea for more than 14 days in the absence of a recognized enteric pathogen on repeated culturing.<sup>267</sup> Recurrence of diarrhea and vomiting after a period of initial improvement is characteristic of EPEC enteritis.<sup>191,239,240</sup> Although seen most often in newborns who have been treated inadequately or not treated at all, clinical relapses also occur after appropriate therapy. Occasionally, the signs of illness during a relapse can be more severe than those accompanying the initial attack of illness.<sup>215,232,285</sup> Not all clinical relapses result from persistent infection. A significant number of relapses, particularly those that consistently follow attempts at reinstitution of formula feedings,<sup>262,265</sup> are caused by disaccharide intolerance rather than bacterial proliferation. Intestinal superinfections, caused by another serotype of EPEC<sup>283,347,348</sup> or by completely different enteric pathogens, such as *Salmonella* or *Shigella*,<sup>245</sup> also can delay the resolution of symptoms. Rarely, infants suffer a “relapse” caused by an organism from the same O group as the original strain but differing in its H antigen. Unless complete serotyping is performed on all EPEC isolates, such an event easily could be dismissed as being a recurrence rather than a superinfection with a new organism.<sup>258,268</sup>

Antimicrobial agents to which the infecting organisms are susceptible often may not eradicate EPEC,<sup>245,265,267</sup> which may persist for weeks<sup>264,283,344</sup> or months<sup>349</sup> after the acute illness has subsided. Although reinfection cannot always be excluded, a significant number of infants are discharged from the hospital with positive rectal cultures.<sup>231,233</sup> Dehydration is the most common and serious complication of gastroenteritis caused by EPEC or a toxin-producing *E. coli*. Virtually all deaths directly attributable to the intestinal infection are caused by disturbances in fluids and electrolytes. When stools are frequent in number, large in volume, and violent in release, as they often are in severe infections with abrupt onset, a neonate can lose up to 15% of body weight in a few hours.<sup>232,276</sup> Rarely, fluid excretion into the lumen of the bowel proceeds so rapidly that reduction of circulating blood volume and shock may intervene before passage of even a single loose stool.<sup>262</sup> Before the discovery of the etiologic agent, epidemic diarrhea of the newborn was also known by the term *cholera infantum*.

Mild disease, particularly when aggravated by poor fluid intake, can lead to a subtle but serious deterioration of an infant’s metabolic status. Sometimes, a week or more of illness elapses before it becomes apparent that an infant with borderline acidosis and dehydration who seemed to be

responding to oral fluids alone requires parenteral therapy for improvement.<sup>272</sup> It is incumbent on the clinician caring for small infants with gastroenteritis to follow them closely, with particular attention to serial weights, until full recovery can be confirmed.

There are few other complications, with the possible exception of aspiration pneumonia, directly related to EPEC gastroenteritis. Protracted diarrhea and nutritional failure may occur as a consequence of functional damage to the small intestinal mucosa, with secondary intolerance to dietary sugars.<sup>265,338</sup> Necrotizing enterocolitis, which occasionally results in perforation of the bowel and peritonitis, has not been causally related to infection with EPEC.<sup>247,264,266</sup> A review of most of the large clinical series describing EPEC disease in infants who ranged in age from neonates to children aged 2 years revealed only three proven instances of bacteremia,<sup>265,278</sup> one possible urinary tract infection,<sup>265</sup> and one documented case of meningitis in an infant of unspecified age.<sup>351</sup> Focal infections among neonates were limited to several cases of otitis media<sup>247,262</sup> and a subcutaneous abscess<sup>294</sup> from which EPEC was isolated. Additional complications include interstitial pneumonia,<sup>319</sup> gastrointestinal bleeding with or without disseminated intravascular coagulation,<sup>334,352</sup> and methemoglobinemia caused by a mutant of EPEC O127:B8 that was capable of generating large quantities of nitrite from proteins present in the gastrointestinal tract.<sup>353</sup>

### Diagnosis

The gold standard of EPEC diagnostics is identification in the stool of *E. coli* carrying genes for BFP and LEE. Identification of these genes can be accomplished by molecular methods (discussed later), but lack of access to these methods has led many labs to rely on surrogate markers, such as serotyping.<sup>19</sup> Classic EPEC has been recovered from the vomitus, stool, or bowel contents of infected newborns. Isolation from bile<sup>233</sup> and the upper respiratory tract<sup>85,238,239</sup> has been described in those instances in which a specific search has been made. Less commonly, EPEC is isolated from ascetic fluid<sup>252</sup> or purulent exudates<sup>209,215,294</sup>; occasionally, the organism has been recovered from blood cultures,<sup>265,278</sup> urine,<sup>265</sup> and cerebrospinal fluid. Stool cultures generally are more reliable than rectal swabs in detecting the presence of enteric pathogens, although a properly obtained swab should be adequate to demonstrate EPEC in most cases.<sup>217,296,354</sup> Specimens should be obtained as early in the course of the illness as possible because organisms are present in virtually pure culture during the acute phase of the enteritis but diminish in numbers during convalescence. Because of the preponderance of EPEC in diarrheal stools, two cultures are adequate for isolation of these pathogens in almost all cases of active disease. Studies using fluorescent antibody methods for identification of EPEC in stool specimens have demonstrated that during the incubation period of the illness, during convalescence, and among asymptomatic carriers of EPEC, organisms can be excreted in such small numbers that they escape detection by standard bacteriologic methods in a significant proportion of infants.<sup>245,355,356</sup> As many as 3 to 10 specimens may be required to detect EPEC using methods that identify individual EPEC isolates in the stool.<sup>85,346</sup> After a stool specimen is received, it should be plated as quickly as possible onto noninhibiting media or placed in a preservative medium if it is to be held for longer

periods. Deep freezing of specimens preserves viable EPEC when a prolonged delay in isolation is necessary.<sup>218</sup> No selective media, biochemical reactions, or colonial variations permit differentiation of pathogenic and nonpathogenic strains. Certain features may aid in the recognition of two important serogroups. Cultures of serogroups O111:B4 and O55:B5, unlike many other coliforms, are sticky or stringy when picked with a wire loop and are rarely hemolytic on blood agar,<sup>217,219</sup> whereas O111:B4 colonies emit a distinctive evanescent odor commonly described as "seminal."<sup>210,214</sup> This unusual odor first led Bray<sup>347</sup> to suspect that specific strains of *E. coli* might be responsible for infantile gastroenteritis.

Because serotyping is simpler than molecular detection and because EPEC have long been known to belong to certain highly characteristic serotypes, serotyping can be used to identify likely EPEC strains, especially in outbreaks.<sup>216</sup> *E. coli*, like other Enterobacteriaceae members, possesses cell wall somatic antigens (O), envelope or capsular antigens (K), and if motile, flagellar antigens (H). Many of the O groups may be further divided into two or more subgroups (a, b, c), and the K antigens are divisible into at least three varieties (B, L, A) on the basis of their physical behavior. Organisms that do not possess flagellar antigens are nonmotile (designated NM). The EPEC B capsular surface antigen prevents agglutination by antibodies directed against the underlying O antigen. Heating at 100°C for 1 hour inactivates the agglutinability and antigenicity of the B antigen.

Slide agglutination tests with polyvalent O or OB antiserum may be performed on suspensions of colonies typical of *E. coli* that have been isolated from infants with diarrhea, especially in nursery outbreaks. However, because of numerous false-positive "cross-reactions," the O and K (or B) type must be confirmed by titration with the specific antisera.<sup>227</sup> The presence of EPEC does not prove that EPEC is the cause of diarrhea in an individual patient. Mixed cultures with two or three serotypes of EPEC have been demonstrated in 1% to 10% of patients.<sup>244,245,352</sup> This need not mean that two or three serotypes are causative agents. Secondary infection with hospital-acquired strains can occur during convalescence,<sup>173,281,283,380</sup> and some infants may have been asymptomatic carriers of one serotype at the time that another produced diarrheal disease. A similar explanation may pertain to mixed infections with EPEC and *Salmonella* or *Shigella*.<sup>217,220,358</sup> Nelson<sup>245</sup> reported the presence of these pathogens in combination with EPEC in 14% of infants who were cultured as part of an antibiotic therapy trial. *Salmonella* and *Shigella* that had not been identified on cultures obtained at admission were isolated only after institution of oral therapy with neomycin. The investigator postulated that the alteration in bowel flora brought about by the neomycin facilitated the growth of these organisms, which had previously been suppressed and obscured by coliform overgrowth.<sup>245</sup> The importance of seeking all enteric pathogens in primary and follow-up cultures of infantile diarrhea is apparent, particularly when the specimen originates from a patient in a newborn nursery or infants' ward.

Although EPEC gastroenteritis was once considered to be synonymous with "summer diarrhea," community outbreaks have occurred as frequently, if not more frequently, in the colder seasons.<sup>133,160,172</sup> It has been suggested that the increased incidence at that time of year might be related to the heightened chance of contact between infants and toddlers

that is bound to occur when children remain indoors in close contact.<sup>294</sup> Nursery epidemics, which depend on the chance introduction and dissemination of EPEC within a relatively homogeneous population and stable environment, demonstrate no seasonal prevalence. Average relative humidity, temperature, and hours of daylight have no significant effect in determining whether an outbreak will follow the introduction of enteropathogenic strains of *E. coli* into a ward of infants.<sup>243</sup>

There are no clinical studies of the variations in peripheral leukocyte count, urine, or cerebrospinal fluid in neonatal enteritis caused by EPEC. Microscopic examination of stools of infants with acute diarrheal illness caused by these organisms usually has revealed an absence of fecal polymorphonuclear leukocytes,<sup>214,256,320,359</sup> although data on fecal lactoferrin in human volunteers suggest that an inflammatory process may be important in EPEC diarrhea.<sup>360,361</sup> Stool pH can be neutral, acid, or alkaline.<sup>61,341</sup> Serologic methods have not proved to be useful in attempting to establish a retrospective diagnosis of EPEC infection in neonates. Rising or significantly elevated agglutinin titers rarely could be demonstrated in early investigations<sup>210,215,231</sup>; hemagglutinating antibodies showed a significant response in no more than 10% to 20% of cases.<sup>245,297</sup> Fluorescent antibody techniques have shown promise for preliminary identification of EPEC in acute infantile diarrhea. This method is specific, with few false-positive results, and it is more sensitive than conventional plating and isolation techniques.<sup>282,361,362</sup> The rapidity with which determinations can be performed makes them ideally suited for screening ill infants and possible carriers in determining the extent and progression of a nursery<sup>272,282</sup> or community<sup>238,291</sup> outbreak. Because immunofluorescence does not depend on the viability of organisms and is not affected by antibiotics that suppress growth on culture plates, it can be used to advantage in following bacteriologic responses and relapses in patients receiving oral therapy.<sup>210,363</sup> The use of fluorescent antibody techniques offers many advantages in the surveillance and epidemiologic control of EPEC gastroenteritis. Immunofluorescent methods should supplement but not replace standard bacteriologic and serologic methods for identification of enteric pathogens.

Specific gene probes and PCR primers for the BFP adhesin, the intimin-encoding gene (*eae*) and for a cryptic plasmid locus (EAF) are available.<sup>98</sup> Detection of BFP or EAF are superior to detection of *eae*, because many non-EPEC, including nonpathogens, carry the *eae* gene.<sup>98,364</sup> PCR and gene probe analysis can be performed directly on the stools of suspect infants. However, confirmation of infection by the identification of the organism in pure culture should be pursued.

Before widespread use of molecular methods, the HEp-2 cell adherence assay was proposed for EPEC diagnosis.<sup>119</sup> The presence of a focal or localized adherence (LA)<sup>119</sup> pattern on the surface of HEp-2 or HeLa cells after 3-hour co-incubation is a highly sensitive and specific test for detection of EPEC.<sup>365</sup> The requirement for cell culture and expertise in reading this assay limits its utility to the research setting. An ELISA for the BFP has been described but is not readily available.<sup>366</sup> The capacity of LA + EPEC to polymerize F-actin can be detected in tissue culture cells stained with rhodamine-labeled phalloidin.<sup>367</sup> This fluorescence-actin

staining (FAS) test is cumbersome and impractical for routine clinical use.

### Prognosis

The mortality rate recorded previously in epidemics of EPEC gastroenteritis is impressive for its variability. During the 1930s and 1940s, when organisms later recognized as classic enteropathogenic serotypes were infecting infants, the case-fatality ratio among neonates was about 50%.<sup>209,210</sup> During the 1950s and 1960s, many nursery epidemics still claimed about one of every four infected infants, but several outbreaks involving the same serotypes under similar epidemiologic circumstances had fatality rates of less than 3%.<sup>234,241,251</sup> In the 1970s, reports appeared in the literature of a nursery epidemic with a 40% neonatal mortality rate<sup>285</sup> and of an extensive outbreak in a nursery for premature infants with 4% fatalities<sup>265</sup>; another report stated that among "243 consecutive infants admitted to the hospital for EPEC diarrheal disease, none died of diarrheal disease per se."<sup>368</sup>

A significant proportion of the infants who died during or shortly after an episode of gastroenteritis already were compromised by preexisting disease<sup>233,283,330</sup> or by congenital malformations<sup>214,231,240</sup> at the time they acquired their illness. These underlying pathologic conditions appear to exert a strongly unfavorable influence, probably by reducing the infant's ability to respond to the added stresses imposed by the gastrointestinal tract infection. Although prematurity is often mentioned as a factor predisposing to a fatal outcome, the overall mortality rate among premature infants with EPEC gastroenteritis has not differed significantly over the years from that recorded for term infants.<sup>233,262,264</sup>

### Therapy

The management of EPEC gastroenteritis should be directed primarily toward prevention or correction of problems caused by loss of fluids and electrolytes.<sup>198</sup> Most neonates have a relatively mild illness that can be treated with oral rehydration. Infants who appear toxic, those with voluminous diarrhea and persistent vomiting, and those with increasing weight loss should be hospitalized for observation and treatment with parenteral fluids and careful maintenance of fluid and electrolyte balance and possibly with antimicrobial therapy. Clinical studies suggest that slow nasogastric infusion of an elemental diet can be valuable in treating infants who have intractable diarrhea that is unresponsive to standard modes of therapy.<sup>369</sup>

There is no evidence that the use of proprietary formulas containing kaolin or pectin is effective in reducing the number of diarrheal stools in neonates with gastroenteritis. Attempts to suppress the growth of enteric pathogens by feeding lactobacillus to the infant in the form of yogurt, powder, or granules have not been shown to be of value.<sup>370</sup> A trial of cholestyramine in 15 newborns with EPEC gastroenteritis had no effect on the duration or severity of the diarrhea.<sup>265</sup> The use of atropine-like drugs, paregoric, or loperamide to reduce intestinal motility or cramping should be avoided. Inhibition of peristalsis interferes with an efficient protective mechanism designed to rid the body of intestinal pathogens and may lead to fluid retention in the lumen of the bowel that may be sufficient to mask depletion of extracellular fluid and electrolytes.

The value of antimicrobial therapy in management of neonatal EPEC gastroenteritis, if any, is uncertain. There are no adequately controlled studies defining the benefits of any antibiotic in eliminating EPEC from the gastrointestinal tract, reducing the risk of cross-infection in community or nursery outbreaks, or modifying the severity of the illness. Proponents of the use of antimicrobial agents have based their claims for efficacy on anecdotal observations or comparative studies.<sup>245</sup> Nonetheless, several clinical investigations have provided sufficient information to guide the physician faced with the dilemma of deciding whether to treat an individual infant or an entire nursery population suffering from EPEC diarrheal disease. It should be emphasized, however, that these guidelines must be considered tentative until rigidly controlled, double-blind studies have established the efficacy of antibiotics on a more rational and scientific basis.

Oral therapy with neomycin,<sup>234,251</sup> colistin,<sup>363</sup> or chloramphenicol<sup>344</sup> appears to be effective in rapidly reducing the number of susceptible EPEC organisms in the stool of infected infants. Studies comparing the responses of infants treated orally with neomycin,<sup>233</sup> gentamicin,<sup>265</sup> polymyxin,<sup>242</sup> or kanamycin<sup>371</sup> with the responses of infants receiving supportive therapy alone have shown that complete eradication of EPEC occurs more rapidly in those receiving an antimicrobial agent. In most cases, stool cultures are free of EPEC 2 to 4 days after the start of therapy.<sup>245,363</sup> Bacteriologic failure, defined as continued isolation of organisms during or after a course of an antimicrobial agent, can be expected to occur in 15% to 30% of patients.<sup>245,265</sup> Such relapses generally are not associated with a recurrence of symptoms.<sup>231,234,245</sup> The effectiveness of oral antimicrobial therapy in reducing the duration of EPEC excretion serves to diminish environmental contamination and the spread of pathogenic organisms from one infant to another. Breaking the chain of fecal-oral transmission by administering antimicrobial agents simultaneously to all carriers of EPEC and their immediate contacts in the nursery has appeared to be valuable in terminating outbreaks that have failed to respond to more conservative measures.<sup>234,264,372</sup> The apparent reduction in morbidity and mortality associated with oral administration of neomycin,<sup>230,233,234</sup> colistin,<sup>246,267,285</sup> polymyxin,<sup>242</sup> or gentamicin<sup>246</sup> during nursery epidemics has led to the impression that these drugs also exert a beneficial clinical effect in severely or moderately ill infants. Reports describing clinical,<sup>256</sup> bacteriologic,<sup>265</sup> or histopathologic<sup>319</sup> evidence of tissue invasion by EPEC have persuaded some investigators to suggest the use of parenteral rather than oral drug therapy in debilitated or malnourished infants. On the basis of these data, there appears to be sufficient evidence to recommend oral administration of nonabsorbable antibiotics in the treatment of severely or moderately ill newborns with EPEC gastroenteritis. The drug most frequently used for initial therapy is neomycin sulfate in a dosage of 100 mg/kg/day administered orally every 8 hours in three divided doses.<sup>245</sup> In communities in which neomycin-resistant EPEC has been prevalent, treatment with colistin sulfate or polymyxin B in a dosage of 15 to 20 mg/kg/day orally and divided into three equal doses may be appropriate. However, it is rarely necessary to use this approach.

Treatment should be continued only until stool cultures become negative for EPEC.<sup>245</sup> Because of the unavoidable delay before cultures can be reported, most infants receive

therapy for 3 to 5 days. If fluorescent antibody testing of rectal swab specimens is available, therapy can be discontinued as soon as EPEC no longer is identified in smears; this takes no more than 48 hours in more than 90% of cases.<sup>245</sup> After diarrhea and vomiting have stopped and the infant tolerates formula feedings, shows a steady weight gain, and appears clinically well, discharge with outpatient follow-up is indicated. Bacteriologic relapses do not require therapy unless they are associated with illness or high epidemiologic risks to other young infants in the household. Because the infecting organisms in these recurrences generally continue to show *in vitro* susceptibility to the original drug, it should be reinstated pending bacteriologic results.<sup>245</sup>

When clinical judgment suggests that a neonate may be suffering from bacterial sepsis and EPEC diarrheal disease, parenteral antimicrobial therapy is indicated after appropriate cultures have been obtained. The routine use of systemic therapy in severe cases of EPEC enteritis is not appropriate on the basis of current clinical experience.

Antimicrobial susceptibility patterns of EPEC are an important determinant of the success of therapy in infections with these organisms.<sup>233,246,247</sup> These patterns are unpredictable, depending on the ecologic pressures exerted by local antibiotic usage<sup>246,247</sup> and on the incidence of transmissible resistance factors in the enteric flora of the particular population served by an institution.<sup>373-378</sup> For these reasons, variations in susceptibility patterns are apparent in different nurseries<sup>246,376</sup> and even from time to time within the same institution.<sup>247,248,250</sup> Sudden changes in clinical response may even occur during the course of a single epidemic as drug-susceptible strains of EPEC are replaced by strains with multidrug resistance.<sup>233,291,375</sup> Because differences can exist in the susceptibilities of different EPEC serogroups to various antimicrobial agents, regional susceptibility patterns should be reported on the basis of OB group or serotype rather than for EPEC as a whole.<sup>250</sup> Knowledge of the resistance pattern in one's area may help in the initial choice of antimicrobial therapy.

### Prevention

The prevention of hospital outbreaks of EPEC gastroenteritis is best accomplished by careful attention to infection control policies for a nursery. All infants hospitalized with diarrhea should have a bacteriologic evaluation. If the laboratory is equipped and staffed to perform fluorescent antibody testing, infants transferred from another institution to a newborn, premature, or intensive care nursery and all infants with gastroenteritis on admission during an outbreak of EPEC diarrhea or in a highly endemic area can be held in an observation area for 1 or 2 hours until the results of the fluorescent antibody test or PCR are received. Because of the difficulty in diagnosing EPEC infection, reference laboratories, such as those at the Centers for Disease Control and Prevention (CDC), should be notified when an outbreak is suspected. Infants suspected to be excreting EPEC, even if healthy in appearance, then can be separated from others and given oral therapy until the test results are negative. Some experts have suggested that when the rapid results obtainable with fluorescent antibody procedures are not available, all infants admitted with diarrhea in a setting where EPEC is common may be treated as if they were excreting EPEC or some other enteric pathogen until contrary

proof is obtained.<sup>372</sup> Stool cultures should be obtained at admission, and contact precautions should be enforced among all who come into contact with the infant. Additional epidemiologic studies are needed to establish the advantages of careful isolation and nursing techniques, particularly in smaller community hospitals in which the number of infants in a “gastroenteritis ward” may be small. The use of prophylactic antibiotics has been shown to be of no value and can select for increased resistance.<sup>377-379</sup>

Unfortunately, it can be difficult to keep a nursery continuously free of EPEC. Specific procedures have been suggested for handling a suspected outbreak of bacterial enteritis in a newborn nursery or infant care unit.<sup>235,355,380</sup> Evidence indicating that a significant proportion of *E. coli* enteritis may be caused by nontypeable strains has required some modification of these earlier recommendations. The following infection control measures may be appropriate:

1. The unit is closed, when possible, to all new admissions.
2. Cultures for enteric pathogens are obtained from nursing personnel assigned to the unit at the time of the outbreak.
3. Stool specimens obtained from all infants in the nursery can be screened by the fluorescent antibody or another technique and cultured. Identification of a classic enteropathogenic serotype provides a useful epidemiologic marker; however, failure to isolate one of these strains does not eliminate the possibility of illness caused by a nontypeable EPEC.
4. Antimicrobial therapy with oral neomycin or colistin can be considered for all infants with a positive fluorescent antibody test or culture result. The initial drug of choice depends on local patterns of susceptibility. Depending on the results of susceptibility tests, subsequent therapy may require modification.
5. If an identifiable EPEC strain is isolated, second and third stool specimens from all infants in the unit are reexamined by the fluorescent antibody technique or culture at 48-hour intervals. If this is not practical, exposed infants should be carefully followed.
6. Early discharge for healthy, mature, uninfected infants is advocated.
7. An epidemiologic investigation should be performed to seek the factor or factors responsible for the outbreak. A surveillance system may be established for all those in contact with the nursery, including physicians and other health care personnel, housekeeping personnel, and postpartum mothers with evidence of enteric disease. A telephone, mail, or home survey may be conducted on all infants who were residing in the involved unit during the 2 weeks before the outbreak.
8. When all patients and contacts are discharged and control of the outbreak is achieved, a thorough terminal disinfection of the involved nursery is mandatory.

Above all, personnel and parents should pay scrupulous attention to hand hygiene when handling infants.<sup>381</sup>

### Enterohemorrhagic *Escherichia coli*

Since a multistate outbreak of enterohemorrhagic colitis was associated with *E. coli* O157:H7,<sup>382</sup> Shiga toxin-producing *E. coli* (STEC) have been recognized as emerging gastrointestinal pathogens in most of the industrialized world. A

particularly virulent subset of STEC, EHEC, causes frequent and severe outbreaks of gastrointestinal disease<sup>98,383</sup>; the most virulent EHEC belong to serotype O157:H7. EHEC has a bovine reservoir and is transmitted by undercooked meat, unpasteurized milk, and contaminated vegetables such as lettuce, alfalfa sprouts, and radish sprouts (as occurred in more than 9000 schoolchildren in Japan).<sup>384,387</sup> It also spreads directly from person to person.<sup>387,388</sup> The clinical syndrome is that of bloody, noninflammatory (sometimes voluminous) diarrhea that is distinct from febrile dysentery with fecal leukocytes seen in shigellosis or EIEC infections.<sup>98</sup> Most cases of EHEC infections have been recognized in outbreaks of bloody diarrhea or HUS in daycare centers, schools, nursing homes, and communities.<sup>388-390</sup> Although EHEC infections often involve infants and young children, the frequency of this infection in neonates remains unclear; animal studies suggest that receptors for the Shiga toxin may be developmentally regulated and that susceptibility to disease may be age related.<sup>391</sup>

The capacity of EHEC to cause disease is related to the phage-encoded capacity of the organism to produce a Vero cell cytotoxin, subsequently shown to be one of the Shiga toxins.<sup>392-394</sup> Shiga toxin 1 is neutralized by antiserum against Shiga toxin, whereas Shiga toxin 2, although biologically similar, is not neutralized by anti-Shiga toxin.<sup>395,396</sup> Like Shiga toxin made by *Shigella dysenteriae*, both *E. coli* Shiga toxins act by inhibiting protein synthesis by cleaving an adenosine residue from position 4324 in the 28S ribosomal RNA (rRNA) to prevent elongation factor-1-dependent aminoacyl transfer RNA (tRNA) from binding to the 60S rRNA.<sup>392,393</sup> The virulence of EHEC also may be determined in part by a 60-MDa plasmid that encodes for a fimbrial adhesin in O157 and O26.<sup>397,398</sup> This phenotype is mediated by the LEE pathogenicity island, which is highly homologous to the island present in EPEC strains.<sup>328</sup>

EHEC and other STEC infections should be suspected in neonates who have bloody diarrhea or who may have been exposed in the course of an outbreak among older individuals. Because most cases are caused by ingestion of contaminated food, neonates have a degree of epidemiologic protection from the illness. Diagnosis of STEC diarrhea is made by isolation and identification of the pathogen in the feces. *E. coli* O157:H7 does not ferment sorbitol, and this biochemical trait is commonly used in the detection of this serotype.<sup>98,399</sup> Because some nonpathogenic *E. coli* share this characteristic, confirmation of the serotype by slide agglutination is required. These techniques can be performed in most clinical laboratories. However, detection of non-O157 serotypes is problematic and relies on detection of the Shiga toxin; available methods include Shiga toxin ELISA, latex agglutination, and molecular methods.<sup>98,399</sup> These should be performed by a reference laboratory.

HUS in infants is not necessarily caused by STEC infection. Even in older patients, however, the stool is typically negative for STEC at the time the that HUS develops.<sup>400,401</sup> Serum and fecal detection of cytotoxin has been performed in such patients, but no diagnostic modality is definitive once HUS has supervened.<sup>400,401</sup>

Antimicrobial therapy should not be administered to patients who may have STEC infection, although their role in inducing HUS remains controversial.<sup>402,403</sup> Management of the diarrhea and possible sequelae is supportive, with

proper emphasis on fluid and electrolyte replacement. Aggressive rehydration is helpful in minimizing the frequency of serious sequelae.

### Enteroaggregative *Escherichia coli*

The Hep-2 adherence assay is useful for the detection of EPEC, which exhibit a classic LA pattern.<sup>119</sup> Two other adherence patterns can be discerned in this assay: aggregative (AA) and diffuse (DA). These two patterns have been suggested to define additional pathotypes of diarrheogenic *E. coli*.<sup>98</sup> Strains exhibiting the AA pattern (i.e., EAEC) are common pathogens of infants.<sup>125</sup>

EAEC cause diarrhea by colonization of the intestinal mucosa and elaboration of enterotoxins and cytotoxins.<sup>125,404</sup> Many strains can be shown to elicit secretion of inflammatory cytokines in vitro, which may contribute to growth retardation associated with prolonged otherwise asymptomatic colonization.<sup>103</sup> Several virulence factors in EAEC are under the control of the virulence gene activator AggR.<sup>404</sup> Presence of the AggR regulator or its effector genes has been proposed as a means of detecting truly virulent EAEC strains (called typical EAEC),<sup>404,405</sup> and an empirical gene probe long used for EAEC detection has been shown to correspond to one gene under AggR control.<sup>406,407</sup>

### Epidemiology and Transmission

The mode of transmission of EAEC has not been well established. In adult volunteer studies, the infectious dose is high (>10<sup>8</sup> colony-forming units [CFU]), suggesting that in adults at least, person-to-person transmission is unlikely.<sup>408,409</sup> Several outbreaks have been linked to consumption of contaminated food.<sup>410,411</sup> The largest of these outbreaks involved almost 2700 schoolchildren in Japan<sup>410</sup>; a contaminated school lunch was the implicated source of the outbreak. Some studies have demonstrated contamination of condiments or milk, which could represent vehicles of food-borne transmission.

Several nursery outbreaks of EAEC have been observed,<sup>412,413</sup> although in no case has the mechanism of transmission been established. The first reported nursery outbreak involved 19 infants in Nis, Serbia, in 1995. Because these infants did not ingest milk from a common source, it is presumed that horizontal transmission by environmental contamination or hands of health care personnel was possible. Most of the infants were full term and previously well, and they were housed in two separate nursery rooms.

The earliest epidemiologic studies of EAEC implicated this organism as a cause of endemic diarrhea in developing countries.<sup>414-416</sup> In this setting, EAEC as defined by the AA pattern of adherence to Hep-2 cells can be found in upward of 30% of the population at any one time.<sup>417</sup> Newer molecular diagnostic modalities have revised this figure downward, although the organism remains highly prevalent in many areas. Several studies from the Indian subcontinent implicated EAEC among the most frequent enteric pathogens.<sup>414,415,418</sup> Other sites reproducibly reporting high incidence rates include Mexico<sup>416</sup> and Brazil.<sup>417,419</sup> There is evidence that EAEC may be emerging in incidence. A study from São Paulo, Brazil, implicated EAEC as the prevalent *E. coli* pathotypes in infants<sup>419</sup>; EPEC had previously been shown to be the most common pathogen in this community. Many other sites

in developing countries of Africa,<sup>421</sup> Asia,<sup>405,422</sup> and South America<sup>420</sup> have described high endemic rates.

Several studies have suggested that EAEC is also a common cause of infant diarrhea in industrialized countries.<sup>423-425</sup> Using molecular diagnostic methods, a large prospective study in the United Kingdom implicated EAEC as the second most common enteric bacterial pathogen after *Campylobacter*.<sup>426</sup> A similar study from Switzerland found EAEC to be the most common bacterial enteropathogen.<sup>423</sup> Studies from the United States also have demonstrated a high rate of EAEC diarrhea in infants; using molecular diagnostic methods, EAEC was implicated in 11% and 8% of outpatient and inpatient diarrhea cohorts, respectively, compared with less than 2% of asymptomatic control infants ( $P < .05$ ).<sup>427</sup> Although epidemiologic studies have shown that EAEC can cause diarrhea in all age groups, several studies suggest that the infection is particularly common in infants younger than 12 months old.<sup>405,420</sup>

### Clinical Manifestations

Descriptions from outbreaks and volunteer studies suggest that EAEC diarrhea is watery in character with mucus but without blood or frank pus.<sup>408,409,412</sup> Patients typically are afebrile. Several epidemiologic studies have suggested that many infants may have bloody diarrhea,<sup>416</sup> but fecal leukocytes are uncommon.

The earliest reports of EAEC infection suggested that this pathogen may be particularly associated with persistent diarrhea (>14 days).<sup>414-416</sup> However, later studies suggest that persistent diarrhea may occur in only a subset of infected infants.<sup>410</sup> In the Serbian outbreak of 19 infected infants, the mean duration of diarrhea was 5.2 days<sup>412</sup>; diarrhea persisted more than 14 days in only three patients. Infants in this outbreak had frequent, green, odorless stools. In three cases, the stools had mucus, but none had visible blood. Eleven babies developed temperatures in excess of 38°C; only one had vomiting.

Despite a lack of clinical evidence suggesting inflammatory enteritis, several clinical studies have suggested that EAEC is associated with subclinical inflammation, including the shedding of fecal cytokines and lactoferrin.<sup>103,428</sup> Studies in Fortaleza, Brazil, suggest that children asymptotically excreting EAEC may exhibit growth shortfalls compared with uninfected peers.<sup>103</sup> A study from Germany reported an association between EAEC isolation and infant colic in infants without diarrhea.<sup>425</sup> This observation has not been repeated. EAEC should be considered in the differential diagnosis of persistent diarrhea and failure to thrive in infants.

### Diagnosis and Therapy

Diagnosis of EAEC requires identification of the organism in the patient's feces. The HEP-2 adherence assay can be used for this purpose<sup>119</sup>; some reports suggest that the adherence phenotype can be observed using formalin-fixed cells,<sup>429,430</sup> thereby obviating the need to cultivate eukaryotic cells for each assay. PCR and gene probe for typical EAEC are available.

Successful antibiotic therapy has been reported using fluoroquinolones in adult patients,<sup>431</sup> although preliminary studies suggest that azithromycin<sup>432</sup> or rifaximin<sup>433</sup> also may be effective. Therapy in infected infants should be guided by the results of susceptibility testing, as EAEC frequently is antibiotic resistant.<sup>421</sup>

## Other *Escherichia coli* Pathotypes

Additional *E. coli* pathotypes have been described, including diffusely adherent *E. coli* (DAEC),<sup>434</sup> and cytotdetaching *E. coli*.<sup>435</sup> DAEC has been specifically associated with diarrhea outside of infancy, as infants may have some degree of inherent resistance to infection.<sup>436</sup> Cytodetaching *E. coli* represent organisms that secrete the *E. coli* hemolysin.<sup>437</sup> It is not clear whether these latter organisms are true enteric pathogens.

## SALMONELLA

### Nature of the Organism

*Salmonella* classification tends to be confusing. Although taxonomists classify *Salmonella* narrowly as a single species, with *Salmonella typhi*, *Salmonella choleraesuis*, and *Salmonella enteritidis* technically being serovars or subspecies, for clinical purposes, these subspecies conventionally are referred to as *species*. For example, clinical laboratories tend to use the shorthand *S. typhimurium* rather than the more formal designation *Salmonella enterica* serovar *typhimurium*. Biochemical traits are used routinely by hospital laboratories to differentiate *S. typhi*, *S. choleraesuis*, and *S. enteritidis* from each other. *S. typhi* is unlike other salmonellae in that it does not produce gas from glucose.<sup>438</sup> Because there are several thousand serotypes included in the species *S. enteritidis*, serotyping of *S. enteritidis* is usually performed by state health departments rather than by hospital laboratories. The most common serogroups and representative serotypes are listed in Table 20-3. Infection of humans with the other serogroups (e.g., C<sub>3</sub>, D<sub>2</sub>, E<sub>2</sub>, E<sub>3</sub>, F, G, H, I) is uncommon.

There are differences in invasiveness of *Salmonella* strains related to serotype. *S. typhi*, *S. choleraesuis*, *Salmonella heidelberg*,<sup>439,440</sup> and *Salmonella dublin*<sup>441</sup> are particularly invasive, with bacteremia and extraintestinal focal infections occurring frequently. *Salmonella* species possess genes closely related to those for the *Shigella* invasion plasmid antigens; these genes are probably essential to intestinal infection.<sup>442,443</sup> Virulence plasmids, which increase invasiveness in some serotypes, have been recognized, although the precise mechanisms of virulence remain to be elucidated; resistance to complement-mediated bacteriolysis by inhibition of insertion of the terminal C5b-9 membrane attack complex into the outer membrane may be important.<sup>444,445</sup> Laboratory studies have demonstrated dramatic strain-related difference in the ability of *S. typhimurium* to evoke fluid secretion, to invade intestinal mucosa, and to disseminate beyond the gut.<sup>446</sup> Production of an enterotoxin immunologically related to cholera toxin by about two thirds of *Salmonella* strains may be related to the watery diarrhea often seen.<sup>447</sup> The significance of protein synthesis-inhibiting cytotoxins<sup>448</sup> remains to be proved, although such toxins can damage gut epithelium, which could facilitate invasion. The cytotoxins produced by *Salmonella* are not immunologically related to Shiga toxin made by *Shigella dysenteriae* type 1<sup>449</sup> or *E. coli* O157:H7.

Salmonellae have the ability to penetrate epithelial cells and reach the submucosa, where they are ingested by phagocytes.<sup>450</sup> In phagocytes, salmonellae are resistant to killing, in

Table 20-3 Common Serotypes and Serogroups of *Salmonella*

Serogroups	Serotypes
A	Paratyphi A
B	Agona Derby Heidelberg Paratyphi B ( <i>schottmuelleri</i> ) Saint-paul Typhimurium
C <sub>1</sub>	Choleraesuis Eimsbuettel Infantis Montevideo Oranienburg Paratyphi C ( <i>hirschfeldii</i> ) Thompson
C <sub>2</sub>	Blockley Hadar Muenchen Newport
C <sub>3</sub>	Kentucky
D <sub>1</sub>	Dublin Enteritidis Javiana Panama Typhi
D <sub>2</sub>	Maarsen
E <sub>1</sub>	Anatum
E <sub>2</sub>	London Newington
E <sub>3</sub>	Illinois
E <sub>4</sub>	Krefeld Senftenberg

part because of the properties of their lipopolysaccharides.<sup>451,452</sup> Persistence of the organism within phagolysosomes of phagocytic cells may occur with any species of *Salmonella*. It is not completely clear how the organisms have adapted to survive in the harsh intracellular environment, but their survival has major clinical significance. It accounts for relapses after therapy. It explains the inadequacy of some antimicrobial agents that do not penetrate phagolysosomes. It perhaps is the reason for prolonged febrile courses that occur even in the face of appropriate therapy. Although humoral immunity and cell-mediated immunity are stimulated during *Salmonella* infections, it is believed that cell-mediated immunity plays a greater role in eradication of the bacteria.<sup>453</sup> T cell activation of macrophages appears to be important in killing intracellular *Salmonella*.<sup>454</sup> Defective interferon- $\gamma$  production by monocytes of newborns in response to *S. typhimurium* lipopolysaccharide may explain in part the unusual susceptibility of infants to *Salmonella* infection.<sup>455</sup> Studies in mice suggest that helper T cell ( $T_H1$ ) responses in Peyer's patches and mesenteric lymph nodes may be central to protection of the intestinal mucosa.<sup>456</sup> Humans who lack the IL-12 receptor and therefore have impaired  $T_H1$  responses and interferon- $\gamma$  production are at increased risk for *Salmonella* infection.<sup>457</sup>

In typhoid fever, presence of an envelope antigen, Vi, is known to enhance virulence. Patients who develop classic enteric fever have positive stool cultures in the first few days after ingestion of the organism and again late in the course after a period of bacteremia. This course reflects early

colonization of the gut, penetration of gut epithelium with infection of mesenteric lymph nodes, and reseeded of the gut during a subsequent bacteremic phase.<sup>458</sup> Studies of *S. typhimurium* in monkeys suggest similar initial steps in pathogenesis (e.g., colonization of gut, penetration of gut epithelium, infection of mesenteric lymph nodes) but failure of the organism to cause a detectable level of bacteremia.<sup>459</sup>

Although both *Salmonella* and *Shigella* invade intestinal mucosa, the resultant pathologic changes are different. *Shigella* multiplies within and kills enterocytes with production of ulcerations and a brisk inflammatory response, whereas *Salmonella* passes through the mucosa and multiplies within the lamina propria, where the organisms are ingested by phagocytes; consequently, ulcer formation is less striking,<sup>446</sup> although villus tip cells are sometimes sloughed. Acute crypt abscesses can be seen in the stomach and small intestine, but the most dramatic changes occur in the colon, where acute diffuse inflammation with mucosal edema and crypt abscesses are the most consistent findings.<sup>460,461</sup> With *S. typhi* there also is hyperplasia of Peyer's patches in the ileum, with ulceration of overlying tissues.

## Epidemiology and Transmission

*Salmonella* strains, with the exception of *S. typhi*, are well adapted to a variety of animal hosts; human infection often can be traced to infected meat, contaminated milk, or contact with a specific animal. Half of commercial poultry samples are contaminated with *Salmonella*.<sup>462</sup> Definition of the serotype causing infection can sometimes suggest the likely source. For example, *S. dublin* is closely associated with cattle; human cases occur with a higher-than-predicted frequency in people who drink raw milk.<sup>441</sup> For *S. typhimurium*, which is the most common serotype and accounts for more than one third of all reported human cases, a single source has not been established, although there is an association with cattle. Despite the 1975 ban by the U.S. Food and Drug Administration (FDA) on interstate commercial distribution of small turtles, these animals continue to be associated with infection, as illustrated by a series of cases in Puerto Rico.<sup>463</sup> Various pet reptiles are an important source of a variety of unusual *Salmonella* serotypes such as *Salmonella marina*, *Salmonella chameleon*, *Salmonella arizonae*, *Salmonella java*, *Salmonella stanley*, *Salmonella poona*, *Salmonella jangwain*, *Salmonella tilene*, *Salmonella pomona*, *Salmonella miami*, *Salmonella manhattan*, *Salmonella litchfield*, *Salmonella rubislaw*, and *Salmonella wassenaar*.<sup>464-466</sup> *Salmonella* organisms are hardy and capable of prolonged survival; organisms have been documented to survive in flour for nearly a year.<sup>467</sup> *Salmonella tennessee* has been shown to remain viable for many hours on non-nutritive surfaces (i.e., glass, 48 hours; stainless steel, 68 hours; enameled surface, 114 hours; rubber mattress, 119 hours; linen, 192 hours; and rubber tabletop, 192 hours).<sup>468</sup>

Infection with *Salmonella* is, like most enteric infections, more common in young children than in adults. The frequency of infection is far greater in the first 4 years of life; roughly equal numbers of cases are reported during each decade beyond 4 years of age. Although the peak incidence occurs in the second through sixth months of life, infection in the neonate is relatively common. Researchers at the CDC have

estimated the incidence of *Salmonella* infection in the first month of life at nearly 75 cases per 100,000 infants.<sup>469</sup>

Adult volunteer studies suggest that large numbers of *Salmonella* ( $10^5$  to  $10^9$ ) need to be ingested to cause disease.<sup>470</sup> However, it is likely that lower doses cause illness in infants. The occurrence of nursery outbreaks<sup>468,471-496</sup> and intrafamilial spread<sup>497</sup> suggests that organisms are easily spread from person to person; this pattern is typical of low-inoculum diseases transmitted by the fecal-oral route. The neonate with *Salmonella* infection infrequently acquires the organism from his or her mother during delivery. Although the index case in an outbreak can often be traced to a mother,<sup>474-477,495</sup> subsequent cases result from contaminated objects in the nursery environment<sup>498,499</sup> serving as a reservoir coming in contact with hands of attending personnel.<sup>468,483</sup> The mother of an index case may be symptomatic<sup>479,480,500,501</sup> or asymptomatic with preclinical infection,<sup>484</sup> convalescent infection,<sup>477,481,502</sup> or chronic carriage.<sup>503</sup> The risk of the newborn becoming infected once *Salmonella* is introduced into a nursery has been reported to be as high as 20% to 27%,<sup>487,493</sup> but the frequency of infection may be lower because isolated cases without a subsequent epidemic are unlikely to be reported.

Gastric acidity is an important barrier to *Salmonella* infection. Patients with anatomic or functional achlorhydria are at increased risk of developing salmonellosis.<sup>504,505</sup> The hypochlorhydria<sup>25</sup> and rapid gastric emptying typical of early life<sup>28</sup> may in part explain the susceptibility of infants to *Salmonella*. Premature and low-birth-weight infants appear to be at higher risk of acquiring *Salmonella* infection than term neonates.<sup>483,485</sup> Whether this reflects increased exposure because of prolonged hospital stays or increased susceptibility on the basis of intestinal or immune function is unclear. Contaminated food or water is often the source of *Salmonella* infection in older patients; the limited diet of the infant makes contaminated food a less likely source of infection. Although human milk,<sup>506-508</sup> raw milk,<sup>509</sup> powdered milk,<sup>510-512</sup> formula,<sup>493</sup> and cereal<sup>513</sup> have been implicated in transmission to infants, more often fomites, such as delivery room resuscitators,<sup>471</sup> rectal thermometers,<sup>486,514</sup> oropharyngeal suction devices,<sup>515-517</sup> water baths for heating formula,<sup>517</sup> soap dispensers,<sup>518</sup> scales,<sup>468,472,519</sup> "clean" medicine tables,<sup>468</sup> air-conditioning filters,<sup>468</sup> mattresses, radiant warmers,<sup>498</sup> and dust,<sup>472</sup> serve as reservoirs. One unusual outbreak involving 394 premature and 122 term infants was traced to faulty plumbing, which caused massive contamination of environment and personnel.<sup>493</sup> After *Salmonella* enters a nursery, it is difficult to eradicate. Epidemics lasting 6 to 7 weeks,<sup>486,491</sup> 17 weeks,<sup>468</sup> 6 months,<sup>485,490</sup> 1 year,<sup>480</sup> and 27 to 30 months<sup>487,493</sup> have been reported. Spread to nearby pediatric wards has occurred.<sup>488,494</sup>

The incubation period in nursery outbreaks has varied widely in several studies where careful attention has been paid to this variable. In one outbreak of *Salmonella oranienburg* involving 35 newborns, 97% of cases occurred within 4 days of birth.<sup>487</sup> In an outbreak of *S. typhimurium*, each of the ill infants presented within 6 days of birth.<sup>477</sup> These incubation periods are similar to those reported for *Salmonella newport* in older children and adults, 95% of whom have been reported to be ill within 8 days of exposure.<sup>520,521</sup> Conversely, one outbreak of *Salmonella nienstedten* involving newborns was characterized by incubation periods of 7 to 18 days.<sup>488</sup>

The usual incubation period associated with fecal-oral nursery transmission is not found with congenital typhoid. During pregnancy, typhoid fever is associated with bacteremic infection of the fetus. The congenitally infected infants are symptomatic at birth. They are usually born during the second to fourth week of untreated maternal illness.<sup>522</sup> Usually, the mother is a carrier; fecal-oral transmission of *S. typhi* can occur with delayed illness in the newborn.<sup>523</sup>

## Clinical Manifestations

Several major clinical syndromes occur with nontyphoidal *Salmonella* infection in young infants. Colonization without illness may be the most common outcome of ingestion of *Salmonella* by the neonate. Such colonization usually is detected when an outbreak is under investigation. Most infected infants who become ill have abrupt onset of loose, green, mucus-containing stools, or they have bloody diarrhea; an elevated temperature is also a common finding in *Salmonella* gastroenteritis in the first months of life.<sup>440</sup> Grossly bloody stools are found in the minority of patients, although grossly bloody stools can occur in the first 24 hours of life. Hematochezia is more typically associated with non-infectious causes (e.g., swallowed maternal blood, intestinal ischemia, hemorrhagic diseases, anorectal fissures) at this early age.<sup>524</sup> There appear to be major differences in presentation related to the serotype of *S. enteritidis* causing infection. For example, in one epidemic of *S. oranienburg*<sup>487</sup> involving 46 newborns, 76% had grossly bloody stools, 11% were febrile, 26% had mucus in their stools, and only 11% were healthy. In a series of *S. newport* infections involving 11 premature infants,<sup>474</sup> 90% of infants with gastroenteritis had blood in their stools, 10% had fever, 10% had mucus in their stools, and 9% were asymptomatic. In an outbreak of *S. typhimurium*<sup>477</sup> involving 11 ill and 5 healthy infants, none had bloody stools; all of the symptomatic infants were febrile and usually had loose, green stools. Of 26 infants infected by *Salmonella virchow*, 42% were asymptomatic; the rest had mild diarrhea.<sup>482</sup> Seals and colleagues<sup>488</sup> described 12 infants with *S. nienstedten*, all of whom had watery diarrhea and low-grade fever; none had bloody stools. In a large outbreak in Zimbabwe of *S. heidelberg* infection reported by Bannerman,<sup>485</sup> 38% of 100 infants were asymptomatic, 42% had diarrhea, 16% had fever, 15% had pneumonia, and 2% developed meningitis. An outbreak of *Salmonella worthington* was characterized primarily by diarrhea, fever, and jaundice, although 3 of 18 infants developed meningitis and 17% died.<sup>515</sup> In dramatic contrast to these series, none of 27 infants with positive stool cultures for *S. tennessee* had an illness in a nursery found to be contaminated with that organism.<sup>469</sup> A few infants with *Salmonella* gastroenteritis have developed necrotizing enterocolitis,<sup>492,525</sup> but it is not clear whether *Salmonella* was the cause.

Although gastroenteritis is usually self-limited, chronic diarrhea has sometimes been attributed to *Salmonella*.<sup>503,526</sup> Whether chronic diarrhea is caused by *Salmonella* is uncertain. Although some infants develop carbohydrate intolerance after a bout of *Salmonella* enteritis<sup>527,528</sup> and *Salmonella* is typically listed as one of the causes of postinfectious protracted diarrhea,<sup>529</sup> it is difficult to be sure that the relationship is causal. The prolonged excretion of *Salmonella* after a bout of gastroenteritis may sometimes cause non-

specific chronic diarrhea to be erroneously attributed to *Salmonella*.

Major extraintestinal complications of *Salmonella* infection may develop in the neonate who becomes bacteremic. Extraintestinal spread may develop in infants who initially present with diarrhea and in some who have no gastrointestinal tract signs. Bacteremia appears to be more common in the neonate than in the older child.<sup>530</sup> A study of more than 800 children with *Salmonella* infection showed that extraintestinal infection occurred significantly more often (8.7% versus 3.6%) in the first 3 months of life.<sup>531</sup> Several retrospective studies suggest that infants in the first month of life may have a risk of bacteremia as high as 30% to 50%.<sup>440</sup> One retrospective study<sup>439</sup> suggests that the risk is not increased in infancy and estimates that the risk of bacteremia in childhood *Salmonella* gastroenteritis is between 8.5% and 15.6%. Prospective studies of infants in the first year of life suggest that the risk of bacteremia is 1.8% to 6.0%.<sup>532,533</sup> Although selection biases in these studies limit the reliability of these estimates, the risk is substantial. The *Salmonella* species isolated from infants include some serotypes that appear to be more invasive in the first 2 months of life than in older children or healthy adults (*S. newport*, *S. agona*, *S. blockley*, *S. derby*, *S. enteritidis*, *S. heidelberg*, *S. infantis*, *S. javiana*, *S. saint-paul*, and *S. typhimurium*) and serotypes that are aggressive in every age group (*S. choleraesuis* and *S. dublin*). Other serotypes appear more likely to cause bacteremia in adults (*S. typhi*, *S. paratyphi A*, and *S. paratyphi B*).<sup>530</sup>

Virtually any *Salmonella* serotype can cause bacteremic disease in neonates. A few infants with *Salmonella* gastroenteritis have died with *E. coli* or *Pseudomonas aeruginosa* sepsis,<sup>494</sup> but the role of *Salmonella* in these cases is unclear. Unlike the situation in older children in whom bacteremic salmonellosis often is associated with underlying medical conditions, bacteremia may occur in infants who have no immunocompromising conditions.<sup>534</sup> *Salmonella* bacteremia is often not suspected clinically because the syndrome is not usually distinctive.<sup>439,440</sup> Even afebrile, well-appearing children with *Salmonella* gastroenteritis have been documented to have bacteremia that persists for several days.<sup>535</sup> Although infants with bacteremia may have spontaneous resolution without therapy,<sup>536</sup> a sufficient number develop complications to warrant empirical antimicrobial therapy when bacteremia is suspected. The frequency of complications is highest in the first month of life. Meningitis is the most feared complication of bacteremic *Salmonella* disease. Between 50% and 75% of all cases of nontyphoidal *Salmonella* meningitis occur in the first 4 months of life.<sup>537</sup> The serotypes associated with neonatal meningitis (*S. typhimurium*, *S. heidelberg*, *S. enteritidis*, *S. saint-paul*, *S. newport*, and *S. panama*)<sup>497</sup> are serotypes frequently associated with bacteremia. Meningitis has a high mortality rate, in part because of the high relapse rates. Relapse has been reported in up to 64% of cases.<sup>538</sup> In some studies, more than 90% of patients with meningitis have died,<sup>539</sup> although more typically, 30% to 60% of infants die.<sup>540,541</sup> The survivors suffer the expected complications of gram-negative neonatal meningitis, including hydrocephalus, seizures, ventriculitis, abscess formation, subdural empyema, and permanent neurologic impairment. Neurologic sequelae have included retardation, hemiparesis, epilepsy, visual impairment, and athetosis.<sup>537</sup>

In large nursery outbreaks, it is common to find infants whose course is complicated by pneumonia,<sup>485</sup> osteomyelitis,<sup>542,543</sup> or septic arthritis.<sup>483,485</sup> Other rare complications of salmonellosis include pericarditis,<sup>544</sup> pyelitis,<sup>545</sup> peritonitis,<sup>477</sup> otitis media,<sup>477</sup> mastitis,<sup>546</sup> cholecystitis,<sup>547</sup> endophthalmitis,<sup>548</sup> cutaneous abscesses,<sup>492</sup> and infected cephalohematoma.<sup>542</sup> Other focal infections seen in older children and adults, such as endocarditis and infected aortic aneurysms, rarely or never have been reported in neonates.<sup>537,549</sup> Although the mortality rate in two reviews of nursery outbreaks was 3.7% to 7.0%,<sup>495,496</sup> in some series, it reached 18%.<sup>485</sup>

Enteric fever, most often related to *S. typhi* but also occurring with *S. paratyphi* A, *S. paratyphi* B, *S. paratyphi* C, and other *Salmonella* species, is reported much less commonly in infants than in older patients. Infected infants develop typical findings of neonatal sepsis and meningitis. Current data suggest that mortality is about 30%.<sup>550</sup> In utero infection with *S. typhi* has been described. Typhoid fever<sup>518,551</sup> and nontyphoidal *Salmonella* infections<sup>552</sup> during pregnancy put women at risk of aborting the fetus. Premature labor usually occurs during the second to the fourth week of maternal typhoid if the woman is untreated.<sup>522</sup> In a survey of typhoid fever in pregnancy during the preantibiotic era, 24 of 60 women with well-documented cases delivered prematurely, with resultant fetal death; the rest delivered at term, although only 17 infants survived.<sup>553</sup> The outlook for carrying the pregnancy to term and delivering a healthy infant appears to have improved dramatically during the antibiotic era. However, one of seven women with typhoid in a series still delivered a dead fetus with extensive liver necrosis.<sup>554</sup> In the preantibiotic era, about 14% of pregnant women with typhoid fever died.<sup>555</sup> With appropriate antimicrobial therapy, pregnancy does not appear to put the woman at increased risk of death. Despite these well-described cases, typhoid fever is rare early in life.

Of 1500 cases of typhoid fever that Osler and McCrae<sup>556</sup> reported, only 2 were in the first year of life. In areas where typhoid fever is still endemic, systematic search for infants with enteric fever has failed to find many cases. The few infections with *S. typhi* documented in children in the first year of life often present as a brief nondescript "viral syndrome" or as pneumonitis.<sup>557,558</sup> Fever, diarrhea, cough, vomiting, rash, and splenomegaly may occur; the fever may be high, and the duration of illness may be many weeks.<sup>522</sup>

## Diagnosis

The current practice of early discharge of newborn infants, although potentially decreasing the risk of exposure, can make recognition of a nursery outbreak difficult. Diagnosis of neonatal salmonellosis should trigger an investigation for other cases. Other than diarrhea, signs of neonatal *Salmonella* infection are similar to the nonspecific findings seen in most neonatal infections. Lethargy, poor feeding, pallor, jaundice, apnea, respiratory distress, weight loss, and fever are common. Enlarged liver and spleen are common in those neonates with positive blood cultures. Laboratory studies are required to establish the diagnosis because the clinical picture is not distinct. The fecal leukocyte examination reveals polymorphonuclear leukocytes in 36% to 82%<sup>559,559</sup> of persons with *Salmonella* infection, but it has not been

evaluated in neonates. Obviously, the presence of fecal leukocytes is consistent with colitis of any cause and therefore is a nonspecific finding. Routine stool cultures usually detect *Salmonella* if two or three different enteric media (i.e., MacConkey's, eosin-methylene blue, *Salmonella-Shigella*, Tergitol 7, xylose-lysine-deoxycholate, brilliant green, or bismuth sulfite agar) are used. Stool, rather than rectal swab material, is preferable for culture, particularly if the aim of culture is to detect carriers.<sup>560</sup> On the infrequent occasions when proctoscopy is performed, mucosal edema, hyperemia, friability, and hemorrhages may be seen.<sup>461</sup> Infants who are bacteremic often do not appear sufficiently toxic to raise the suspicion of bacteremia.<sup>561</sup> Blood cultures should be obtained as a routine part of evaluation of neonates with suspected or documented *Salmonella* infection. Ill neonates with *Salmonella* infection should have a cerebrospinal fluid examination performed. Bone marrow cultures also may be indicated when enteric fever is suspected. There are no consistent abnormalities in the white blood cell count. Serologic studies are not helpful in establishing the diagnosis, although antibodies to somatic<sup>562,563</sup> and flagellar antigens<sup>487</sup> develop in many infected newborns.

If an outbreak of salmonellosis is suspected, further characterization of the organism is imperative.<sup>464</sup> Determination of somatic and flagellar antigens to characterize the specific serotype may be critical to investigation of an outbreak. When the serotype found during investigation of an outbreak is a common one (e.g., *S. typhimurium*), antimicrobial resistance testing<sup>475,565</sup> and use of molecular techniques such as plasmid characterization<sup>565</sup> can be helpful in determining whether a single-strain, common-source outbreak is in progress.

## Therapy

As in all enteric infections, attention to fluid and electrolyte abnormalities is the first issue that must be addressed by the physician. Specific measures to eradicate *Salmonella* intestinal infection have met with little success. Multiple studies show that antibiotic treatment of *Salmonella* gastroenteritis prolongs the excretion of *Salmonella*.<sup>566-573</sup> Almost one half of the infected children in the first 5 years of life continue to excrete *Salmonella* 12 weeks after the onset of infection; more than 5% have positive cultures at 1 year.<sup>574</sup> No benefit of therapy has been shown in comparisons of ampicillin or neomycin versus placebo,<sup>570</sup> chloramphenicol versus no antibiotic treatment,<sup>569</sup> neomycin versus placebo,<sup>571</sup> ampicillin or trimethoprim-sulfamethoxazole versus no antibiotic,<sup>568</sup> and ampicillin or amoxicillin versus placebo.<sup>572</sup> In contrast to these studies, data suggest that there may be a role for quinolone antibiotics in adults and children,<sup>573,575</sup> but these drugs are not approved for use in neonates, and resistance has been encountered.<sup>576</sup> Because these studies have few data as to the risk-benefit ratio of therapy in the neonate, it is uncertain whether they should influence treatment decisions in neonates. Studies that have included a small number of neonates suggest little benefit from antimicrobial therapy.<sup>477,487,568,577,578</sup> However, because bacteremia is common in neonates, antimicrobial therapy for infants younger than 3 months who have *Salmonella* gastroenteritis often is recommended,<sup>532,533,561</sup> especially if the infant appears toxic. Premature infants and those who have other

significant debilitating conditions also should probably be treated. The duration of therapy is debatable but should probably be no more than 3 to 5 days if the infant is not seriously ill and if blood cultures are sterile. If toxicity, clinical deterioration, or documented bacteremia complicates gastroenteritis, prolonged treatment is indicated. Even with antimicrobial therapy, some infants develop complications. The relatively low risk of extraintestinal dissemination must be balanced against the well-documented risk of prolonging the carrier state. For infants who develop chronic diarrhea and malnutrition, hyperalimentation may be required; the role of antimicrobial agents in this setting is unclear. The infant with typhoid fever should be treated with an antimicrobial agent; relapses sometimes occur after therapy.

Colonized healthy infants discovered by stool cultures during evaluation of an outbreak ought to be isolated but probably should not receive antimicrobial therapy. Such infants should be discharged from the nursery as early as possible and followed carefully as outpatients.

Antimicrobial treatment of neonates who have documented extraintestinal dissemination must be prolonged. Bacteremia without localization is generally treated with at least a 10-day course of therapy. Therapy for *Salmonella* meningitis must be given for at least 4 weeks to lessen the risk of relapse. About three fourths of patients who have relapses have been treated for three weeks or less.<sup>537</sup> Similar to meningitis, treatment for osteomyelitis must be prolonged to be adequate. Although cures have been reported with 3 weeks of therapy, 4 to 6 weeks of therapy is recommended.

In vitro susceptibility data for *Salmonella* isolates must be interpreted with caution. The aminoglycosides show good in vitro activity but poor clinical efficacy, perhaps because of the low pH of the phagolysosome. Aminoglycosides have poor activity in an acid environment. The stability of some drugs in this acid environment also may explain in vitro and in vivo disparities. The intracellular localization and survival of *Salmonella* within phagocytic cells also presumably explains the relapses encountered with virtually every regimen. Resistance to antibiotics has long been a problem with *Salmonella* infection.<sup>566,579,580</sup> There has been a steady increase in resistance to *Salmonella* in the United States over the last 20 years.<sup>581</sup> With the emergence of *typhimurium* type DT 104, resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline has increased from 0.6% in 1979 and 1980 to 34% in 1996.<sup>582</sup> Resistance plasmids have been selected and transmitted, partly because therapy has been given for mild illness that should not have been treated<sup>566</sup> and partly because of use of antibiotics in animal feeds. Resistance to chloramphenicol and ampicillin has made trimethoprim-sulfamethoxazole increasingly important for the treatment of *Salmonella* infection in those patients who require therapy. However, with increasing resistance to all three of these agents in Asia,<sup>583</sup> the Middle East,<sup>584</sup> Africa,<sup>585</sup> Europe,<sup>586,587</sup> Argentina,<sup>580</sup> and North America,<sup>579,588,589</sup> the third-generation cephalosporins and quinolones represent drugs of choice for invasive salmonellosis. The quinolones currently are not approved for persons younger than 18 years. Cefotaxime, ceftriaxone, and cefoperazone represent acceptable alternative drugs for typhoidal and nontyphoidal salmonellosis when resistance is encountered.<sup>590,591</sup> Because the second-generation cephalosporins, such as cefuroxime, are less active in vitro than the third-generation cephalosporins

and are not consistently clinically effective, they should not be used.<sup>590,592</sup> Data suggest that cefoperazone may sterilize blood and cause patients with typhoid fever to become afebrile more rapidly than with chloramphenicol,<sup>593</sup> perhaps because cefoperazone is excreted into bile in high concentrations.<sup>594</sup> The third-generation cephalosporins may have higher cure and lower relapse rates than ampicillin or chloramphenicol in children with *Salmonella* meningitis.<sup>595</sup> The doses of ampicillin, chloramphenicol, or cefotaxime used in infants with gastroenteritis pending results of blood cultures are the same as those used in treatment of sepsis. Because of the risk of gray baby syndrome, chloramphenicol should not be used in neonates unless other effective agents are not available. Trimethoprim-sulfamethoxazole, although useful in older children and adults, is not used in neonates because of the risk of kernicterus. Nosocomial infection with strains of *Salmonella* resistant to multiple antibiotics, including third-generation cephalosporins, has emerged as a problem in South America.<sup>580</sup>

Nonantibiotic interventions are important in the control of *Salmonella* infections. Limited data suggest that intravenous immune globulin (IGIV) (500 mg/kg on days 1, 2, 3, and 8 of therapy) along with antibiotic therapy may decrease the risk of bacteremia and death in preterm infants with *Salmonella* gastroenteritis.<sup>596</sup>

## Prevention

Early recognition and intervention in nursery outbreaks of *Salmonella* are crucial to control. When a neonate develops salmonellosis, a search for other infants who have been in the same nursery should be undertaken. When two or more cases are recognized, environmental cultures, cultures of all infants, cohorting and contact isolation of infected infants, rigorous enforcement of hand hygiene, early discharge of infected infants, and thorough cleaning of all possible fomites in the nursery and delivery rooms are important elements of control. If cases continue to occur, the nursery should be closed to further admissions. Cultures of nursery personnel are likely to be helpful in the unusual situation of an *S. typhi* outbreak in which a chronic carrier may be among the caretakers. Culture of health care personnel during outbreaks of salmonellosis caused by other *Salmonella* species is debatable, although often recommended. Data suggest that nurses infected with *Salmonella* rarely infect patients in the hospital setting.<sup>597</sup> The fact that nursing personnel are sometimes found to be colonized during nursery outbreaks<sup>468,474,487,489,490</sup> may be a result rather than a cause of those epidemics.

The potential role of vaccines in control of neonatal disease is minimal. For the vast number of non-*S. typhi* serotypes, there is no prospect for an immunization strategy. Multiple doses of the commercially available oral live attenuated vaccine (Ty21a; *Vivotif*, Berna), has been shown in Chilean schoolchildren to reduce typhoid fever cases by more than 70%.<sup>598,599</sup> However, the vaccine is not recommended for persons younger than 6 years, in part because immunogenicity of Ty21a is age dependent; children younger than 24 months fail to respond with development of immunity.<sup>600</sup> Vi capsular polysaccharide vaccine is available for children older than 2 years and is effective in a single dose. Whether some degree of protection of infants could

**Table 20-4 Shigella Serogroups**

Serogroups	Species	No. of Serotypes
A	<i>S. dysenteriae</i>	13
B	<i>S. flexneri</i>	15 (including subtypes)
C	<i>S. boydii</i>	18
D	<i>S. sonnei</i>	1

occur if stool carriage were reduced or could be transferred to infants by the milk of vaccinated mothers' remains to be studied. Data suggest that breast-feeding may decrease the risk of other *Salmonella* infections.<sup>601</sup>

## SHIGELLA

### Nature of the Organism

On the basis of DNA relatedness, shigellae and *E. coli* organisms belong to the same species.<sup>602</sup> However, for historical reasons and because of their medical significance, shigellae have been maintained as separate species. Shigellae are gram-negative bacilli that are unlike typical *E. coli* in that they do not metabolize lactose or do so slowly, are non-motile, and generally produce no gas during carbohydrate use. They are classically divided into four species (serogroups) on the basis of metabolic and antigenic characteristics (Table 20-4). The mannitol nonfermenters usually are classified as *S. dysenteriae*. Although the lipopolysaccharide antigens of the 13 recognized members of this group are not related to each other antigenically, these serotypes are grouped together as serogroup A. Serogroup D (*Shigella sonnei*) are ornithine decarboxylase positive and slow lactose fermenters. All *S. sonnei* share the same lipopolysaccharide (O antigen). Those shigellae that ferment mannitol (unlike *S. dysenteriae*) but do not decarboxylate ornithine or ferment lactose (*S. sonnei*) belong to serogroups B and C. Of these, the strains that have lipopolysaccharide antigens immunologically related to each other are grouped together as serogroup B (*Shigella flexneri*), whereas those whose O antigens are not related to each other or to other shigellae are included in serogroup C (*Shigella boydii*). There are six major serotypes of *S. flexneri* and 13 subserotypes (1a, 1b, 2a, 2b, 3a, 3b, 4a, 4b, 5a, 5b, 6, X and Y variant). There are 19 antigenically distinct serotypes of *S. boydii*. For *S. dysenteriae* and *S. boydii* serogroup confirmation, pools of polyvalent antisera are used.

The virulence of shigellae has been studied extensively since their recognition as major pathogens at the beginning of the 20th century. The major determinants of virulence are encoded by a 120- to 140-MDa plasmid.<sup>603,604</sup> This plasmid, which is found in all virulent shigellae, encodes the synthesis of proteins that are required for invasion of mammalian cells and for the vigorous inflammatory response that is characteristic of the disease.<sup>605,606</sup> Shigellae that have lost this plasmid, have deletions of genetic material from the region involved in synthesis of these proteins, or have the plasmid inserted into the chromosome lose the ability to invade eukaryotic cells and become avirulent<sup>607</sup>; maintenance of the plasmid can be detected in the clinical microbiology lab by

ability to bind Congo red. The ability to invade cells is the basic pathogenic property shared by all shigellae<sup>608,609</sup> and by the *Shigella*-like invasive *E. coli*, which also possesses the *Shigella* virulence plasmid.<sup>205,605,606,610-611</sup> In the laboratory, *Shigella* invasiveness is studied in tissue culture (HeLa cell invasion), in animal intestine, or in rabbit or guinea pig eye, where instillation of the organism causes keratoconjunctivitis (Sereny test).<sup>128</sup> Animal model studies have shown that bacteria penetrate and kill colonic mucosal cells and then elicit a brisk inflammatory response.

In addition to the virulence plasmid, several chromosomal loci enhance virulence.<sup>612,613</sup> This has been best studied in *S. flexneri* in which multiple virulence-enhancing regions of the chromosome have been defined.<sup>604,612-614</sup> The specific gene products of some of the chromosomal loci are not known; one chromosomal virulence segment encodes for synthesis of the O repeat units of lipopolysaccharide. Intact lipopolysaccharide is necessary but not sufficient to cause virulence.<sup>612,615</sup> At least two cell-damaging cytotoxins that also are chromosomally encoded are produced by shigellae. One of these toxins (Shiga toxin) is made in large quantities by *S. dysenteriae* serotype 1 (the Shiga bacillus) and is made infrequently by other shigellae.<sup>616</sup> Shiga toxin is a major virulence factor in *S. dysenteriae*, enhancing virulence at the colonic mucosa and also giving rise to sequelae similar to those caused by STEC (discussed earlier). This toxin kills cells by interfering with peptide elongation during protein synthesis.<sup>617-619</sup> Additional toxins may also be secreted by shigellae, although their roles in virulence are not established.<sup>620</sup>

### Epidemiology

Although much of the epidemiology of shigellosis is predictable based on its infectious dose, certain elements are unexplained. Shigellae, like other organisms transmitted by the fecal-oral route, are commonly spread by food and water, but the low infecting inoculum allows person-to-person spread. Because of this low inoculum, *Shigella* is one of the few enteric pathogens that can infect swimmers.<sup>621</sup> The dose required to cause illness in adult volunteers is as low as 10 organisms for *S. dysenteriae* serotype 1,<sup>622</sup> about 200 organisms for *S. flexneri*,<sup>623</sup> and 500 organisms for *S. sonnei*.<sup>624</sup> Person-to-person transmission of infection probably explains the continuing occurrence of *Shigella* in the developed world. Enteropathogens that require large inocula and hence are best spread by food or drinking water are less common in industrialized societies because of sewage disposal facilities, water treatment, and food-handling practices. In the United States, daycare centers currently serve as a major focus for acquisition of shigellosis.<sup>625</sup> Numerous outbreaks of shigellosis related to crowding, poor sanitation, and the low dose required for diseases have occurred in this setting.

Given the ease of transmission, it is not surprising that the peak incidence of disease is in the first 4 years of life. It is, however, paradoxical that symptomatic infection is uncommon in the first year of life.<sup>626-629</sup> The best data on the age-related incidence of shigellosis come from Mata's<sup>625</sup> prospective studies of Guatemalan infants. In these studies, stool cultures were performed weekly on a group of children followed from birth to 3 years old. The rate of infection was more than 60-fold lower in the first 6 months of life than

**Figure 20-1** Age-related incidence of *Shigella* infection. (Data from Mata LG: *The Children of Santa Maria Cauque: A Prospective Field Study of Health and Growth*. Cambridge, Mass, MIT Press, 1978.)

between 2 and 3 years (Fig. 20-1).<sup>626</sup> The same age-related incidence has been described in the United States<sup>629</sup> and in a rural Egyptian village.<sup>628</sup> This anomaly has been explained by the salutary effects of breast-feeding.<sup>630-632</sup> However, it is likely that breast-feeding alone does not explain the resistance of infants to shigellosis.

A review of three large case series<sup>633-635</sup> suggests that about 1.6% (35 of 2225) of shigellosis cases occur in infants in the neonatal period. The largest series of neonatal shigellosis<sup>632</sup> suggests that the course, complications, and etiologic serogroups are different in neonates than in older children. Although newborns are routinely contaminated by maternal feces, neonatal shigellosis is rare.

Other aspects of the epidemiology of shigellosis elude simple explanation. The seasonality (summer-fall peak in the United States, rainy season peak in the tropics) is not well explained. The geographic variation in species causing infection likewise is not well understood. In the United States, most *Shigella* infections are caused by *S. sonnei* or, less commonly, *S. flexneri*. In most of the developing world, the relative importance of these two species is reversed, and other *Shigella* serotypes, especially *S. dysenteriae* serotype 1, are identified more frequently. As hygiene improves, the proportion of *S. sonnei* increases and that of *S. flexneri*

decreases.<sup>636</sup> Data from Bangladesh suggest that *S. dysenteriae* is less common in neonates, but *S. sonnei* and *S. boydii* are more common.<sup>632</sup>

### Clinical Manifestations

There appear to be some important differences in the relative frequencies of various complications of *Shigella* infection related to age. Some of these differences and estimates are based on data that are undoubtedly compromised by reporting biases. *S. dysenteriae* serotype 1 characteristically causes a more severe illness than other shigellae with more complications, including pseudomembranous colitis, hemolysis, and HUS. However, illnesses caused by various *Shigella* serotypes usually are indistinguishable from each other and conventionally are discussed together.

The incubation period of shigellosis is related to the number of organisms ingested, but in general, it is between 12 and 48 hours. Volunteer studies have shown that after ingestion, illness may be delayed for a week or more. Neonatal shigellosis seems to have a similar incubation period. More than one half of the neonatal cases occur within 3 days of birth, consistent with fecal-oral transmission during parturition. Mothers of infected neonates are sometimes carriers, although more typically they are symptomatic during the perinatal period. Intrauterine infection is rare. In the older child, the initial signs are usually *high fever*, abdominal pain, vomiting, toxicity, and large-volume watery stools; diarrhea may be bloody or may become bloody. Painful defecation and severe, crampy abdominal pain associated with frequent passage of small-volume stools with gross blood and mucus are characteristic findings in older children or adults who develop severe colitis. Many children, however, never develop bloody diarrhea. Adult volunteer studies have demonstrated that variations in presentation and course are not related to the dose ingested because some patients develop colitis with dysentery but others develop only watery diarrhea after ingestion of the same inoculum.<sup>623</sup> The neonate with shigellosis may have a mild diarrheal syndrome or a severe colitis.<sup>633,637-645</sup> Fever in neonates is usually low grade (<102° F) if the course is uncomplicated. The neonate has less bloody diarrhea, more dehydration, more bacteremia, and a greater likelihood of death than the older child.<sup>632</sup> Physical examination of the neonate may show signs of toxicity and dehydration, although fever, abdominal tenderness, and rectal findings are less striking than in the older child.<sup>634</sup>

Complications of shigellosis are common.<sup>646</sup> Although the illness is self-limited in the normal host, resolution may be delayed for a week or more. In neonates and malnourished children, chronic diarrhea may follow a bout of shigellosis.<sup>637,645</sup> Between 10% and 35% of hospitalized children with *Shigella* have convulsions before or during the course of diarrhea.<sup>646-648</sup> Usually, the seizures are brief, generalized, and associated with high fever. Seizures are uncommon in the first 6 months of life, although neonates have been described with seizures.<sup>639,649</sup> The cerebrospinal fluid generally reveals normal values in these children, but a few have mild cerebrospinal fluid pleocytosis. The neurologic outcome generally is good even with focal or prolonged seizures, but fatalities do occasionally occur, often associated with toxic encephalopathy.<sup>650</sup> Although the seizures had been postulated to

result from the neurotoxicity of Shiga toxin, this explanation was proved to be incorrect because most shigellae make little or no Shiga toxin and the strains isolated from children with neurologic symptoms do not produce Shiga toxin.<sup>616,651</sup> Hemolysis with or without development of uremia is a complication primarily of *S. dysenteriae* serotype 1 infection.<sup>652</sup>

Sepsis during the course of shigellosis may be caused by the *Shigella* itself or by other gut flora that gain access to the bloodstream through damaged mucosa.<sup>632,653,654</sup> The risk of sepsis is higher in the first year of life, particularly in neonates,<sup>632,637-639,649,656</sup> in malnourished children, and in those with *S. dysenteriae* serotype 1 infection.<sup>654</sup> Sepsis occurs in up to 12% of neonates with shigellosis.<sup>631,646,653,655</sup> Given the infrequency of neonatal shigellosis, it is striking that 9% of reported cases of *Shigella* sepsis have involved infants in the first month of life.<sup>657</sup> One of the infants with bacteremia<sup>658</sup> reportedly had no discernible illness. Disseminated intravascular coagulation may develop in those patients whose course is complicated by sepsis. Meningitis has been described in a septic neonate. Colonic perforation has occurred in neonates,<sup>630,659</sup> older children,<sup>660</sup> and adults.<sup>661</sup> Although this complication of toxic megacolon is rare, it appears to be more common in neonates than in older individuals. Bronchopneumonia may complicate the course of shigellosis, but shigellae are rarely isolated from lungs or tracheal secretions.<sup>662</sup> The syndrome of sudden death in the setting of extreme toxicity with hyperpyrexia and convulsions but without dehydration or sepsis (i.e., Ekiri syndrome)<sup>663-665</sup> is rare in neonates. In the nonbacteremic child, other extraintestinal foci of infection, including vagina<sup>666,667</sup> and eye,<sup>668</sup> rarely occur. Reiter's syndrome, which rarely complicates the illness in children, has not been reported in neonates.

Although infection is less common in infants than in toddlers, case fatality rates are highest in infants.<sup>669,670</sup> The mortality rate in newborns appears to be about twice that of older children.<sup>632</sup> In industrialized societies, less than 1% of children with shigellosis die, whereas in developing countries, up to 30% die. These differences in mortality rates are related to nutrition,<sup>633</sup> availability of medical care, antibiotic resistance of many shigellae, the frequency of sepsis, and the higher frequency of *S. dysenteriae* serotype 1 infection in the less-developed world.<sup>654</sup>

## Diagnosis

Although the diagnosis of shigellosis can be suspected on clinical grounds, other enteropathogens can cause illnesses that are impossible to distinguish clinically. Shigellosis in the neonate is rare. The neonate with watery diarrhea is more likely to be infected with *E. coli*, *Salmonella* or rotavirus than *Shigella*. Infants presenting with bloody diarrhea may have necrotizing enterocolitis or infection with *Salmonella*, EIEC, *Yersinia enterocolitica*, *C. jejuni*, or *Entamoeba histolytica*. Before cultures establish a diagnosis, clinical and laboratory data may aid in making a presumptive diagnosis. Abdominal radiographs demonstrating pneumatosis intestinalis suggest the diagnosis of necrotizing enterocolitis. A history of several weeks of illness not associated with fever and with few fecal leukocytes suggests *E. histolytica* rather than *Shigella* infection.<sup>671</sup>

The definitive diagnosis of shigellosis depends on isolation of the organism from stool. Unfortunately, culture may be

insensitive.<sup>672</sup> In volunteer studies, daily stool cultures failed to detect shigellae in about 20% of symptomatic subjects.<sup>623</sup> Optimal recovery is achieved by immediate inoculation of stool (as opposed to rectal swabs) onto culture media. Use of transport media in general decreases the yield of cultures positive for *Shigella*<sup>673</sup> when compared with immediate inoculation.

Examination of stool for leukocytes as an indication of colitis is useful in support of the clinical suspicion of shigellosis. The white blood cell count and differential count also are used as supporting evidence for the diagnosis. Leukemoid reactions (white blood cells > 50,000/mm<sup>3</sup>) occur in almost 15% of children with *S. dysenteriae* serotype 1 but in less than 2% of children with other shigellae.<sup>651</sup> Leukemoid reactions are more frequent in infants than in older children.<sup>652</sup> Even when the total white blood cell count is not dramatically elevated, there may be a striking left shift. Almost 30% of children with shigellosis have greater than 25% bands on the differential cell count.<sup>674-676</sup> Few reports address the white blood cell count in newborns, but those that do suggest that normal or low rather than elevated counts are more common. Although serum and fecal antibodies develop to lipopolysaccharides and the virulence plasmid-associated polypeptides,<sup>677</sup> serologic studies are not useful in the diagnosis of shigellosis. PCR can identify *Shigella* and EIEC in feces.<sup>678</sup> Colonoscopy typically shows inflammatory changes that are most severe in the distal segments of colon.<sup>679</sup>

## Therapy

Because dehydration is particularly common in neonatal shigellosis, attention to correction of fluid and electrolyte disturbances is always the first concern when the illness is suspected. Although debate continues over the indications for antimicrobial therapy in the patient with shigellosis, the benefits of therapy generally appear to outweigh the risks. The chief disadvantages of antimicrobial therapy include cost, drug toxicity, and emergence of antibiotic-resistant shigellae. Because of the self-limited nature of shigellosis, it has been argued that less severe illness should not be treated. However, children can feel quite ill during the typical bout of shigellosis, and appropriate antimicrobial therapy shortens the duration of illness and eliminates shigellae from stool, decreasing secondary spread. Complications are probably decreased by antibiotics. Given the high mortality rates of neonatal shigellosis, therapy should not be withheld.

The empirical choice of an antimicrobial agent is dictated by susceptibility data for strains circulating in the community at the time the patient's infection occurs. Multiresistant shigellae complicate the choice of empirical therapy because availability of susceptibility data for the patient's isolate. Plasmid-encoded resistance (R factors) for multiple antibiotics has been observed frequently in *S. dysenteriae* serotype 1 outbreaks<sup>682</sup> and with other shigellae.<sup>683-685</sup> Antimicrobial resistance patterns fluctuate from year to year in a given locale.<sup>686</sup> However, despite the guesswork involved, early preemptive therapy is indicated when an illness is strongly suggestive of shigellosis. In vitro susceptibility does not always adequately predict therapeutic responses. Cefaclor,<sup>687</sup> furazolidone,<sup>688</sup> cephalixin,<sup>689</sup> amoxicillin,<sup>690</sup> kanamycin,<sup>691</sup> and cefamandole<sup>692</sup> all are relatively ineffective agents.

The optimal duration of therapy is debatable. Studies in children older than 2 years and in adults suggest that single-dose regimens may be as effective in relieving symptoms as courses given for 5 days. The single-dose regimens generally are not as effective in eliminating shigellae from the feces as are the longer courses. A third-generation cephalosporin, such as ceftriaxone, may be the best empirical choice. Optimal doses for newborns with shigellosis have not been established. Trimethoprim at a dose of 10 mg/kg/day (maximum, 160 mg/day) and sulfamethoxazole at a dose of 50 mg/kg/day (maximum, 800 mg/day) in two divided doses for a total of 5 days are recommended for the older child if the organism is susceptible.<sup>693-695</sup> If the condition of the infant does not permit orally administration, the drug usually is divided into three doses given intravenously over 1 hour.<sup>696</sup> Ampicillin at a dose of 100 mg/kg/day in four divided doses taken orally for 5 days may be used if the strain is susceptible.<sup>676</sup>

For the rare newborn who acquires shigellosis, appropriate therapy often is delayed until susceptibility data are available. This occurs because shigellosis is so rare in newborns that it is almost never the presumptive diagnosis of the child with watery or bloody diarrhea. Although a sulfonamide is as efficacious as ampicillin when the infecting strain is susceptible,<sup>675</sup> sulfonamides are avoided in neonates because of concern about the potential risk of kernicterus. The risk of empirical ampicillin therapy is that shigellae are frequently resistant to the drug; 50% of shigellae currently circulating in the United States are ampicillin resistant.<sup>696,697</sup> For the neonate infected with ampicillin-resistant *Shigella*, there are few data on which to base a recommendation. Ceftriaxone is generally active against shigellae, but in the neonate, this drug can displace bilirubin-binding sites and elicit clinically significant cholestasis. Data on children and adults suggest that clinical improvement occurs with ceftriaxone.<sup>698,699</sup> Quinolones, such as ciprofloxacin and ofloxacin, have been shown to be effective agents for treating shigellosis<sup>700,701</sup> in adults, but they are not approved for use in children younger than 18 years. Other drugs sometimes used to treat diarrhea pose special risks to the infant with shigellosis. The antimotility agents, in addition to their intoxication risk, may pose a special danger in dysentery. In adults, diphenoxylate hydrochloride with atropine has been shown to prolong fever and excretion of the organism.<sup>702</sup>

The response to appropriate antibiotic therapy is generally gratifying. Improvement is often obvious in less than 24 hours. Complete resolution of diarrhea may not occur until a week or more after the start of treatment. In those who have severe colitis or those infected by *S. dysenteriae* serotype 1, the response to treatment is somewhat delayed.

## Prevention

For most of the developing world, the best strategy for prevention of shigellosis during infancy is prolonged breast-feeding. Specific antibodies in milk appear to prevent symptomatic shigellosis<sup>66,68</sup>; nonspecific modification of gut flora and the lack of bacterial contamination of human milk also may be important. Breast-feeding, even when other foods are consumed, decreases the risk of shigellosis; children who continue to consume human milk into the third year of life are still partially protected from illness.<sup>703</sup> In the United

States, the best means of preventing infection in the infant is good hand hygiene when an older sibling or parent develops diarrhea. Even in unsanitary environments, secondary spread of shigellae can be dramatically decreased by hand hygiene after defecation and before meals.<sup>704</sup> Spread of shigellae in the hospital nursery can presumably be prevented by the use of contact isolation for infants with diarrhea and attention to thorough hand hygiene. Although nursery personnel have acquired shigellosis from infected newborns,<sup>685</sup> further transmission to other infants in the nursery, although described,<sup>705</sup> is rare. In contrast to *Salmonella*, large outbreaks of nosocomial shigellosis in neonates are rare.

Unfortunately, good hygiene is a particularly difficult problem in daycare centers. The gathering of susceptible children, breakdown in hand hygiene, failure to use different personnel for food preparation and diaper changing, and difficulty controlling the behavior of toddlers all contribute to daycare-focused outbreaks of shigellosis.

Immunization strategies have been studied since the turn of the 20th century, but no satisfactory immunization has been developed. Even if immunizations are improved, a role in managing neonates seems unlikely.

## CAMPYLOBACTER

### Nature of the Organism

*Campylobacter* was first recognized in an aborted sheep fetus in the early 1900s<sup>706</sup> and was named *Vibrio fetus* by Smith and Taylor in 1919.<sup>707</sup> This organism subsequently was identified as a major venereally transmitted cause of abortion and sterility and as a cause of scours in cattle, sheep, and goats.<sup>708,709</sup> It was not until 1947, when it was isolated from the blood culture of a pregnant woman who subsequently aborted at 6 months' gestation, that the significance of *Campylobacter* as a relatively rare cause of bacteremia and perinatal infections in humans was appreciated.<sup>710-712</sup> During the 1970s, *Campylobacter* was recognized to be an opportunistic pathogen in debilitated patients.<sup>713,714</sup> In 1963, *V. fetus* and related organisms were separated from the vibrios (such as *V. cholerae* and *V. parahaemolyticus*) and placed in a new genus, *Campylobacter* (Greek word for "curved rod").<sup>715</sup> Since 1973, several *Campylobacter* species have been recognized as a common cause of enteritis<sup>716-732</sup> and, in some cases, extraintestinal infections.

The genus *Campylobacter* contains 15 species, most of which are recognized as animal and human pathogens. The most commonly considered causes of human disease are *Campylobacter fetus*, *Campylobacter jejuni*, *Campylobacter coli*, *Campylobacter lari*, and *Campylobacter upsaliensis* (Table 20-5),<sup>730-732</sup> although *Campylobacter mucosalis* has been isolated from stool of children with diarrhea.<sup>733</sup> DNA hybridization studies have shown that these species are distinct, sharing less than 35% DNA homology under stringent hybridization conditions.<sup>734,735</sup> *Helicobacter pylori* was originally named *Campylobacter pylori*, but because of differences in DNA, it was reclassified and is no longer considered in the *Campylobacter* genus.

Strains of *C. fetus* are divided into two subspecies: *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis*. The first subspecies causes sporadic abortion in cattle and sheep<sup>736,737</sup>; in

Table 20-5 *Campylobacter* Species That Infect Humans

Current Nomenclature	Previous Nomenclature	Usual Disease Produced
<i>C. fetus</i>	<i>Vibrio fetus</i> <i>V. fetus</i> var. <i>intestinalis</i> <i>C. fetus</i> subsp. <i>intestinalis</i>	Bacteremia, meningitis, perinatal infection, intravascular infection
<i>C. jejuni</i>	<i>Vibrio jejuni</i>	Diarrhea
<i>C. coli</i>	<i>C. fetus</i> subsp. <i>jejuni</i>	Diarrhea
<i>C. lari</i>	Grouped with <i>C. jejuni</i> , nalidixic acid-resistant, thermophilic <i>Campylobacter</i> , <i>C. laridis</i> I	Diarrhea, bacteremia
<i>C. upsaliensis</i>	None	Diarrhea, bacteremia
<i>C. hyointestinalis</i>	None	Diarrhea, bacteremia
<i>C. concisus</i>	None	Diarrhea

the human fetus and newborn, it causes perinatal and neonatal infections that result in abortion, premature delivery, bacteremia, and meningitis.<sup>710-712,736-748</sup> Outside the newborn period, *Campylobacter* is a relatively infrequent cause of bacteremia, usually infecting those with impaired host defenses, including the elderly or the debilitated; less frequently, it causes intravascular infection.<sup>713-715,749,750</sup>

By far the most common syndrome caused by a *Campylobacter* species is enteritis. *C. jejuni* and *C. coli* cause gastroenteritis and generally are referred to collectively as *C. jejuni*, although DNA hybridization studies show them to be different. In the laboratory, *C. jejuni* can be differentiated from *C. coli* because it is capable of hydrolyzing hippurate, whereas *C. coli* is not. Most isolates that are associated with diarrhea (61% to 100%) are identified as *C. jejuni*,<sup>751-754</sup> and in some cases, individuals have been shown to be simultaneously infected with *C. jejuni* and *C. coli*.<sup>752</sup>

Because of the fastidious nature of *C. jejuni*, which is difficult to isolate from fecal flora, its widespread occurrence was not recognized until 1973.<sup>716-732</sup> Previously called *related vibrios* by King,<sup>749</sup> this organism had been associated with bloody diarrhea and colitis in infants and adults only when it had been associated with a recognized bacteremia.<sup>755-757</sup> In the late 1970s, development of selective fecal culture methods for *C. jejuni* enabled its recognition worldwide as one of the most common causes of enteritis in persons of all ages. It is an uncommon infection in neonates who generally develop gastroenteritis when infected.<sup>718,758-881</sup> Bacteremia with *C. jejuni* enteritis also is uncommon.<sup>718,759,764,769,772-778</sup> Maternal symptoms considered to be related to *C. jejuni* infection generally are mild and include fever (75%) and diarrhea (30%). In contrast to the serious disease in newborns that is caused by *C. fetus*, neonatal infections with *C. jejuni* usually result in a mild illness,<sup>758,760,762,763,765-768,771,778</sup> although meningitis occurs in rare instances.<sup>761,769</sup> Third trimester infection related to *C. fetus* or *C. jejuni* may result in abortion or stillbirth.

### Pathogenesis

*C. fetus* does not produce recognized enterotoxins or cytotoxins and does not appear to be locally invasive by the Sereny test.<sup>714,731</sup> Instead, these infections may be associated with penetration of the organism through a relatively intact intestinal mucosa to the reticuloendothelial system and bloodstream.<sup>714</sup> Whether this reflects a capacity to resist

serum factors or to multiply intracellularly remains to be determined.

*C. jejuni* is capable of producing illness by several mechanisms. These organisms have been shown to produce an LT enterotoxin and a cytotoxin.<sup>779-782</sup> This enterotoxin is known to be a heat-labile protein with a molecular mass of 60 to 70 MDa.<sup>779,782</sup> It shares functional and immunologic properties with cholera toxin and *E. coli* LT. *C. jejuni* and *C. coli* also elaborate a cytotoxin that is toxic for a number of mammalian cells.<sup>783-785</sup> The toxin is heat labile, trypsin sensitive, and not neutralized by immune sera to Shiga toxin or the cytotoxin of *Clostridium difficile*. The role of these toxins as virulence factors in diarrheal disease remains unproved.<sup>779,784</sup>

Several animal models have been tested for use in the study of this pathogen.<sup>786</sup> Potential models for the study of *C. jejuni* enteritis include dogs, which may acquire symptomatic infection<sup>787</sup>; 3- to 8-day old chicks<sup>788-790</sup>; chicken embryo cells, which are readily invaded by *C. jejuni*<sup>725</sup>; rhesus monkeys<sup>791</sup>; and rabbits by means of the removable intestinal tie adult rabbit technique. An established small mammal model that mimics human disease in the absence of previous treatment or surgical procedure has not been successful in adult mice.<sup>792</sup> An infant mouse model<sup>793,794</sup> and a hamster model<sup>795</sup> of diarrhea appear promising. *C. jejuni* is negative in the Sereny test for invasiveness,<sup>796</sup> and most investigators report no fluid accumulation in ligated rabbit ileal loops.

### Pathology

The pathologic findings of *C. fetus* infection in the perinatal period include placental necrosis<sup>711</sup> and, in the neonate, widespread endothelial proliferation, intravascular fibrin deposition, perivascular inflammation, and hemorrhagic necrosis in the brain.<sup>797</sup> The tendency for intravascular location and hepatosplenomegaly in adults infected with *C. fetus* has been shown.<sup>714</sup>

The pathologic findings in infants and children infected with *C. fetus* can include an acute inflammatory process in the colon or rectum, as evidenced by the tendency for patients to have bloody diarrhea with numerous fecal leukocytes.<sup>798</sup> There also can be crypt abscess formation and an ulcerative colitis or pseudomembranous colitis-like appearance<sup>799,800</sup> or a hemorrhagic jejunitis or ileitis.<sup>717,725,801,802</sup> Mesenteric lymphadenitis, ileocolitis and acute appendicitis also have been described.

## Epidemiology

Infection with *Campylobacter* species occurs after ingestion of contaminated food, including unpasteurized milk, poultry, and contaminated water.<sup>726,803-812</sup> Many farm animals and pets, such as chickens,<sup>813</sup> dogs,<sup>814,815</sup> and cats (especially young animals), are potential sources. The intrafamilial spread of infection in households,<sup>717,816</sup> the occurrence of outbreaks in nurseries,<sup>769,770,817</sup> and the apparent laboratory acquisition of *C. jejuni*<sup>818</sup> all suggest that *C. jejuni* infection may occur after person-to-person transmission of the organism. Outbreaks of *C. jejuni* in the child daycare setting are not common. Volunteer studies<sup>819</sup> have shown a variable range in the infecting dose, with many volunteers developing no illness. The report of illness after ingestion of  $10^6$  organisms in a glass of milk<sup>728</sup> and production of illness in a single volunteer by 500 organisms<sup>819</sup> substantiate the variation in individual susceptibility. The potential for low-inoculum disease has significant implications for the importance of strict enteric precautions when infected persons are hospitalized, particularly in maternity and nursery areas. When diarrhea in neonates caused by *C. jejuni* has been reported,<sup>758-771</sup> maternal-infant transmission during labor has generally been documented.<sup>758-763,765-768,770,771</sup> The Lior serotyping system, restriction length polymorphism, and pulse-field gel electrophoresis<sup>820</sup> have been used to confirm the identity of the infant and maternal isolates. Most mothers gave no history of diarrhea during pregnancy.<sup>762,763,765,766</sup> Outbreaks have occurred in neonatal intensive care units because of person-to-person spread.<sup>820</sup>

The frequency of asymptomatic carriage of *C. jejuni* ranges from 0% to 1.3%<sup>716,717</sup> to as high as 13% to 85%.<sup>716,717,732,821-823</sup> In a cohort study in Mexico, 66% of all infections related to *C. jejuni* were asymptomatic.<sup>732</sup> Infected children, if untreated, can be expected to excrete the organisms for 3 or 4 weeks; however, more than 80% are culture negative after 5 weeks.<sup>721,722</sup> Asymptomatic excretors pose a significant risk in the neonatal period, in which acquisition from an infected mother can be clinically important.<sup>718,760,762,766</sup> *C. jejuni* has increasingly been recognized as a cause of watery and inflammatory diarrhea in temperate and tropical climates throughout the world. It has been isolated from 2% to 11% of all fecal cultures from patients with diarrheal illnesses in various parts of the world.<sup>716-724,728,824-829</sup> There is a tendency for *C. jejuni* enteritis to occur in the summer in countries with temperate climates.<sup>825</sup>

The reservoir of *Campylobacter* is the gastrointestinal tract of domestic and wild birds and animals. It infects sheep, cattle, goats, antelope, swine, chickens, domestic turkeys, and pet dogs. *C. fetus* often is carried asymptotically in the intestinal or biliary tracts of sheep and cattle. During the course of a bacteremic illness in pregnant animals, *C. fetus* organisms, which have a high affinity for placental tissue, invade the uterus and multiply in the immunologically immature fetus. The infected fetuses generally are aborted. Whether this organism is acquired by humans from animals or is carried asymptotically for long periods in humans, who may then transmit the organism through sexual contact as appears to occur in animals, is unclear. It is believed that this subspecies rarely is found in the human intestine and that it is not a cause of human enteritis.<sup>725</sup> *C. fetus* infections predominantly occur in older men with a history of farm or

animal exposure and in pregnant women in their third trimester.<sup>710,711,716,717</sup> Symptomatically or asymptotically infected women may have recurrent abortions or premature deliveries and are the source of organisms associated with life-threatening perinatal infections of the fetus or newborn infant.<sup>710,739-748,830</sup> In several instances of neonatal sepsis and meningitis, *C. fetus* was isolated from culture of maternal cervix or vagina.<sup>712,747,795</sup> A nosocomial nursery outbreak has been associated with carriage in some healthy infants.<sup>831</sup> Other outbreaks have been associated with meningitis<sup>832,833</sup> Cervical cultures have remained positive in women who have had recurrent abortions and whose husbands have antibody titer elevations.<sup>738</sup>

The most commonly incriminated reservoir of *C. jejuni* is poultry.<sup>808,812,834,835</sup> Most chickens in several different geographic locations had a large number (mean,  $4 \times 10^6$ /g) of *C. jejuni* in the lower intestinal tract or feces. This occurred in some instances despite the use of tetracycline, to which the *Campylobacter* was susceptible in vitro, in the chicken feed.<sup>828</sup> The internal cavities of chickens remain positive for *Campylobacter* even after they have been cleaned, packaged, and frozen.<sup>834</sup> However, unlike *Salmonella*, *C. jejuni* organisms that survive usually do not multiply to high concentrations.<sup>725</sup> Domestic puppies or kittens with *C. jejuni* diarrhea also can provide a source for spread, especially to infants or small children.<sup>717,755,812,836-838</sup>

*C. jejuni* enteritis also has been associated in a number of outbreaks with consumption of unpasteurized milk.<sup>725,809-811,839-841</sup> In retrospect, the first reported human cases of *C. jejuni* enteritis were probably in a milk-borne outbreak reported in 1946.<sup>842</sup> Because *Campylobacter* infections of the udder are not seen, milk is probably contaminated from fecal shedding of the organism. These organisms are killed by adequate heating.

Fecally contaminated water is a potential vehicle for *C. jejuni* infections.<sup>843</sup> Several phenotypic and genotypic methods have been used for distinguishing *C. jejuni* strains from animals and humans involved in epidemics.<sup>844</sup> *C. jejuni* is associated with traveler's diarrhea among those traveling from England or the United States.<sup>720</sup>

## Clinical Manifestations

Clinical manifestations of infection caused by *Campylobacter* depend on the species involved (see Table 20-5). Human infections with *C. fetus* are rare and generally are limited to bacteremia in patients with predisposing conditions<sup>749,750</sup> or to bacteremia or uterine infections with prolonged fever and pneumonitis that lasts for several weeks in women during the third trimester of pregnancy. Unless appropriately treated, symptoms usually resolve only after abortion or delivery of an infected infant.<sup>710,712,739-748,750</sup> These infected neonates, who are often premature, develop signs suggesting sepsis, including fever, cough, respiratory distress, vomiting, diarrhea, cyanosis, convulsions, and jaundice. The condition typically progresses to meningitis, which may be rapidly fatal or may result in serious neurologic sequelae.<sup>712</sup> Additional systemic manifestations include pericarditis, pneumonia, peritonitis, salpingitis, septic arthritis, and abscesses.<sup>823</sup>

*C. jejuni* infection typically involves the gastrointestinal tract, producing watery diarrhea or a dysentery-like illness with fever and abdominal pain and stools that contain blood

and mucus.<sup>715,732,800</sup> Older infants and children generally are affected, but neonates with diarrhea have been reported. Infection in neonates generally is not clinically apparent or is mild. Stools can contain blood, mucus, and pus<sup>712,721,762,763</sup>; fever often is absent.<sup>721,762</sup> The illness usually responds to appropriate antimicrobial therapy,<sup>760,762,816</sup> which shortens the period of fecal shedding.<sup>845</sup> Extraintestinal infections related to *C. jejuni* other than bacteremia are rare but include cholecystitis,<sup>846</sup> urinary tract infection,<sup>847</sup> and meningitis.<sup>761</sup> Bacteremia is a complication of gastrointestinal infection,<sup>848</sup> especially in malnourished children.<sup>849</sup> Meningitis that appears to occur secondary to intestinal infection also has been reported in premature infants who have had intraventricular needle aspirations for neonatal hydrocephalus.<sup>712</sup> Complications in older children and adults that have been associated with *C. jejuni* enteritis include Reiter's syndrome,<sup>850</sup> Guillain-Barré syndrome,<sup>851,852</sup> and reactive arthritis.<sup>853,854</sup> Persistent *C. jejuni* infections have been described in patients infected with human immunodeficiency virus.<sup>855</sup> Extraintestinal manifestations generally occur in patients who are immunosuppressed or at the extremes of age.<sup>714</sup> *Campylobacter lari* has caused chronic diarrhea and bacteremia in a neonate.<sup>856</sup>

## Diagnosis

Most important in the diagnosis of *Campylobacter* infection is a high index of suspicion based on clinical grounds. *C. fetus* and *C. jejuni* are fastidious and may be overlooked on routine fecal cultures. Isolation of *Campylobacter* from blood or other sterile body sites does not represent the same problem as isolation from stool. Growth occurs with standard blood culture media, but it may be slow. In the case of *C. fetus* infecting the bloodstream or central nervous system, blood culture flasks should be blindly subcultured and held for at least 7 days or the organism may not be detected because of slow or inapparent growth.<sup>742</sup> The diagnosis of *C. fetus* infection should be considered when there is an unexplained febrile illness in the third trimester of pregnancy or in the event of recurrent abortion, prematurity, or neonatal sepsis with or without meningitis. A high index of suspicion and prompt, appropriate antimicrobial therapy may prevent the potentially serious neonatal complications that may follow maternal *C. fetus* infection.

*Campylobacter* is distinguished from the *Vibrio* organisms by its characteristics of carbohydrate nonfermentation and by its different nucleotide base composition.<sup>715,733-735,738</sup> *Campylobacter* is 0.2 to 0.5 μm wide and 0.5 to 8.0 μm long. It is a fastidious, microaerophilic, curved, motile gram-negative bacillus that has a single polar flagellum and is oxidase and catalase positive, except for *C. upsaliensis*, which is generally catalase negative or weakly positive. *C. jejuni* and *C. fetus* are separated by growth temperature (*C. fetus* grows best at 25°C but can be cultured at 37°C; *C. jejuni* grows best at 42°C) and by nalidixic acid and cephalosporin susceptibilities, because *C. jejuni* is susceptible to nalidixic acid and resistant to cephalosporins. *C. jejuni* grows best in a microaerobic environment of 5% oxygen and 10% carbon dioxide at 42°C. It grows on a variety of media, including *Brucella* and Mueller-Hinton agars, but optimal isolation requires the addition of selective and nutritional supplements. Growth at 42°C in the presence of cephalosporins is used to culture selectively for *C. jejuni* from fecal specimens. In a study of six

media, charcoal-based selective media and a modified charcoal cefoperazone deoxycholate agar were the most selective for identification of *Campylobacter* species. Extending the incubation time from 48 to 72 hours led to an increase in the isolation rate regardless of the medium used.<sup>857</sup> Its typical darting motility may provide a clue to identification, even in fresh fecal specimens, when viewed by phase-contrast microscopy.<sup>721,858</sup>

When the organism has been cultured, it is presumptively identified by motility and by its curved, sometimes sea gull-like appearance on carbolfuchsin stain. Polymorphonuclear leukocytes are usually found in stools when bloody diarrhea occurs and indicate the occurrence of colitis.<sup>762,798</sup> To avoid potentially serious *C. jejuni* infection in the newborn infant, careful histories of any diarrheal illnesses in the family should be obtained, and pregnant women with any enteric illness should have cultures for this and other enteric pathogens. Detection of *C. jejuni* and *C. coli* by PCR has been reported<sup>859</sup> and in the future may be useful for the rapid and reliable identification of this organism.

The differential diagnosis of *C. fetus* infections include the numerous agents that cause neonatal sepsis or meningitis, especially gram-negative bacilli. Diagnostic considerations for inflammatory or bloody enteritis include necrotizing enterocolitis, allergic proctitis, and *Salmonella*; rarely *Shigella*, and other infectious agents occur. Agglutination, complement fixation, bactericidal, immunofluorescence, and ELISA tests have been used for serologic diagnosis of *C. jejuni* infection and to study the immune response, but these assays are of limited value in establishing the diagnosis during an acute infection.<sup>731</sup>

## Therapy

The prognosis is grave in newborn infants with sepsis or meningitis caused by *C. fetus*. In infants with *C. jejuni* gastroenteritis, limited data suggest that appropriate, early antimicrobial therapy results in improvement and rapid clearance of the organism from stool.<sup>845</sup> *Campylobacter* species are often resistant to β-lactams, including ampicillin and cephalosporins.<sup>860,861</sup> Most strains are susceptible to erythromycin, gentamicin, tetracycline, chloramphenicol, and the newer quinolones, although resistance to these agents has been reported.<sup>862,863</sup> It appears that a parenteral aminoglycoside is the drug of choice for *C. fetus* infections, pending in vitro susceptibility studies. In the case of central nervous system involvement, cefotaxime and chloramphenicol are potential alternative drugs. Depending on in vitro susceptibilities, which vary somewhat with locale, erythromycin is the drug of choice for treating *C. jejuni* enteritis.<sup>717,721,722</sup> If erythromycin therapy is initiated within the first 4 days of illness, a reduction in excretion of the organism and resolution of symptoms occur.<sup>845</sup> Although data regarding treatment of asymptomatic or convalescent carriers are not available, it seems appropriate to treat colonized pregnant women in the third trimester of pregnancy when there is a risk of perinatal or neonatal infection. The failure of prophylactic parenteral gentamicin in a premature infant has been documented, followed by successful resolution of symptoms and fecal shedding with erythromycin. Because there appears to be an increased risk of toxicity with erythromycin estolate during pregnancy and infancy,<sup>864</sup> other

forms of erythromycin should probably be used in these settings. Azithromycin appears to be effective if the organism is susceptible.<sup>865</sup> Strains that are erythromycin resistant often are resistant to azithromycin.<sup>866</sup> *Campylobacter* tends to have higher minimal inhibitory concentrations for clarithromycin than for azithromycin.<sup>867</sup> Furazolidone has been used in children and ciprofloxacin in nonpregnant patients older than 17 years.

### Prevention

Contact precautions should be employed during any acute diarrheal illness and until the diarrhea has subsided. Hand hygiene after handling raw poultry and washing cutting boards and utensils with soap and water after contact with raw poultry may decrease risk of infection. Pasteurization of milk and chlorination of water are critically important. Infected food handlers and hospital employees who are asymptomatic pose no known hazard for disease transmission if proper personal hygiene measures are maintained. Ingestion of human milk that contains anti-*C. jejuni* antibodies has been shown to protect infants from diarrhea due to *C. jejuni*.<sup>63,868</sup>

## CLOSTRIDIUM DIFFICILE

### Nature of the Organism and Pathophysiology

*C. difficile* is a spore-forming, gram-positive, anaerobic bacillus that produces two toxins. In the presence of antibiotic pressure, *C. difficile* colonic overgrowth and toxin production occur. The virulence properties of *C. difficile* are related to production of an enterotoxin that causes fluid secretion (toxin A) and a cytotoxin detectable by its cytopathic effects in tissue culture (toxin B).<sup>869,870</sup> Both toxin genes have been cloned and sequenced, revealing that they encode proteins with estimated molecular masses of 308 kDa for toxin A and 270 kDa for toxin B.<sup>871</sup>

A wide variety of antibacterial, antifungal, antituberculosis, and antineoplastic agents have been associated with *C. difficile* colitis, although penicillin, clindamycin, and cephalosporins are associated most frequently. Rarely, no precipitating drug has been given.<sup>872-876</sup> *C. difficile* and its toxins can be demonstrated in up to one third of patients with antibiotic-associated diarrhea and in about 98% of patients with pseudomembranous colitis.<sup>877</sup>

### Epidemiology

*C. difficile* can be isolated from soil and frequently exists in the hospital environment. Spores of *C. difficile* are acquired from the environment or by fecal-oral transmission from colonized individuals or from items in the environment such as thermometers and feeding tubes.<sup>878-883</sup> *C. difficile* has been demonstrated to persist on a contaminated floor for 5 months.<sup>879</sup> Nosocomial spread is related to organisms on the hands of personnel<sup>879,880,884</sup> and to contaminated surfaces, which may serve as reservoirs.<sup>885,886</sup> Although all groups are susceptible to infection, newborn infants represent a special problem. Less than 5% of healthy children older than 2 years<sup>887</sup> and healthy adults carry *C. difficile*,<sup>877</sup> but more than

50% of neonates can be demonstrated to have *C. difficile* and its cytotoxin in their stools, usually in the absence of clinical findings.<sup>880,886,888-890</sup> Infants in neonatal intensive care units have high rates of colonization, in part because of frequent use of antimicrobial agents in these units.<sup>889-890</sup> Clustering of infected infants suggests that much of the colonization of newborn infants represents nosocomial spread<sup>886</sup> rather than acquisition of maternal flora. The number of *C. difficile* organisms present in stools of well infants is similar to that found in older patients with pseudomembranous colitis.<sup>890</sup> The high frequency of colonization has led to justified skepticism about the pathogenic potential of this organism in the very young.<sup>891</sup> Although some episodes of diarrhea in early infancy may be caused by *C. difficile*,<sup>892</sup> the diagnostic criteria used in older children and adults are inadequate to establish a definite diagnosis in this age group.

### Clinical Manifestations

The usual manifestations of *C. difficile* disease in older children and adults include watery diarrhea, abdominal pain and tenderness, nausea, vomiting, and low-grade fever. Grossly bloody diarrhea is unusual, although occult fecal blood is common. Leukocytosis is present during severe illness. Diarrhea usually begins 4 to 9 days into a course of antimicrobial therapy but may be delayed until several weeks after completion of the therapeutic course. Usually, the illness is mild and self-limited if the offending drug is discontinued. Severe colitis with pseudomembranes is less common now than in previous years because the risk of diarrhea developing during antimicrobial therapy is recognized and the antimicrobial agent typically is stopped.

It is unclear whether this organism causes disease in newborns. One study from a newborn intensive care unit suggests that toxin A in stools is associated with an increased frequency of abnormal stools.<sup>893</sup>

### Diagnosis

Endoscopic findings of pseudomembranes and hyperemic, friable rectal mucosa suggest the diagnosis of pseudomembranous colitis. Pseudomembranes are not always present in *C. difficile* colitis; mild cases are often described as non-specific colitis. Several noninvasive techniques are used to establish the diagnosis, including enzyme immunoassay (EIA) for toxin detection and PCR.<sup>893-896</sup> Isolation of *C. difficile* from stool does not distinguish between toxigenic and nontoxigenic isolates. If *C. difficile* is isolated, testing for toxin by cell culture or EIA should be performed to confirm the presence of a toxigenic strain. There are multiple commercially available EIAs that detect either toxin A or both toxins A and B.<sup>893-895</sup> These assays are sensitive and easy to perform. Other assays are available for epidemiologic investigation of outbreaks of disease due to *C. difficile*.<sup>896</sup>

In older children and adults, the diagnosis is confirmed by culture of *C. difficile* and demonstration of toxin in feces. In neonates, these data are inadequate to prove that an illness is related to *C. difficile*. When the clinical picture is consistent, the stool studies are positive for *C. difficile* and no other cause for illness is found, a diagnosis of "possible" *C. difficile* is made. A favorable response to eradication of *C. difficile* is supportive evidence that the diagnosis is correct.<sup>872</sup>

Because of the uncertainty implicit in the ambiguity of neonatal diagnostic criteria, other diagnoses must be considered.

### Therapy

When the decision is made that a neonate's illness might be related to *C. difficile*, the initial approach should include fluid and electrolyte therapy and discontinuation of the offending antimicrobial agent. If the illness persists or worsens or if the patient has severe diarrhea, specific therapy with metronidazole<sup>886,897</sup> should be instituted. Metronidazole is considered to be the treatment of choice for most patients with *C. difficile* colitis.<sup>898</sup> Rarely is there a need to consider orally administered vancomycin or bacitracin in neonates.<sup>899,900</sup>

After initiation of therapy, signs of illness generally resolve within several days, titers decrease, and fecal toxins disappear eventually. Recurrence of colitis after discontinuation of metronidazole or vancomycin has been documented in 10% to 20% of adults.<sup>901</sup> Relapses are treated with a second course of metronidazole or vancomycin. Drugs that decrease intestinal motility should not be administered.

Neutralizing antibody against *C. difficile* cytotoxin has been demonstrated in human colostrum.<sup>902</sup> Secretory component of sIgA binds to toxin A to inhibit its binding to receptors.<sup>903</sup> Data show that there are nonantibody factors present in milk that interfere with the action of toxin B in addition to secretory IgA directed at toxin A.<sup>904</sup> Breast-feeding appears to decrease the frequency of colonization by *C. difficile*.<sup>905</sup>

### Prevention

In addition to standard precautions, contact precautions are recommended for the duration of illness. Meticulous hand hygiene techniques, proper handling of contaminated waste and fomites, and limiting the use of antimicrobial agents are the best available methods for control of *C. difficile* infection.

## VIBRIO CHOLERAЕ

### Nature of the Organism

*V. cholerae* is a gram-negative, curved bacillus with a polar flagellum. Of the many serotypes, only enterotoxin-producing organisms of serotype O1 and O139 cause epidemics. *V. cholerae* O1 is divided into two serotypes, Inaba and Ogawa, and two biotypes, classic and E1 Tor; the latter is the predominant biotype. Nontoxicogenic O1 strains and non-O1 strains of *V. cholerae* can cause diarrhea and sepsis but do not cause outbreaks.<sup>906-908</sup>

### Pathogenesis

*V. cholerae* O group 1 is the classic example of an enteropathogen whose virulence is caused by enterotoxin production. Cholera toxin is an 84-MDa protein whose five B subunits cause toxin binding to the enterocyte membrane ganglioside GM<sub>1</sub> and whose A subunit causes adenosine diphosphate ribosylation of a guanosine triphosphate-binding regulatory subunit of adenylate cyclase.<sup>105,908</sup> The elevated cAMP levels

that result from stimulation of enterocytes by cholera toxin cause secretion of salt and water with concomitant inhibition of absorption. Two other toxins are also encoded within the virulence cassette that encodes cholera toxin. These toxins, zona occludens toxin (zot) and accessory cholera toxin (ace), are consistently found in illness-causing strains of O1 and O139 but not usually in *V. cholerae* organisms that are less virulent.

### Epidemiology

Since 1960, *V. cholerae* O1, biotype El Tor, has spread from India and Southeast Asia to Africa, the Middle East, southern Europe, and the southern, western, and central Pacific islands (Oceania). In late January of 1991, toxigenic *V. cholerae* O1, serotype Inaba, biotype El Tor, appeared in several coastal cities of Peru.<sup>907,908</sup> It rapidly spread to most countries in South and North America. In reported cases, travel from the United States to Latin America or Asia and ingestion of contaminated food transported from Latin America or Asia have been incriminated. *V. cholerae* O139 (Bengal) arose on the Indian subcontinent as a new cause of epidemic cholera in 1993.<sup>910-915</sup> It rapidly spread through Asia and continues to periodically reemerge as a cause of epidemic cholera. In the United States, an endemic focus of a unique strain of toxigenic *V. cholerae* O1 exists on the Gulf Coast of Louisiana and Texas.<sup>906,916</sup> This strain is different from the one associated with the epidemic in South America. Most cases of disease associated with the strain endemic to the U.S. Gulf Coast have resulted from the consumption of raw or undercooked shellfish. Humans are the only documented natural host, but free-living *V. cholerae* organisms can exist in the aquatic environment. The usual reported vehicles of transmission have included contaminated water or ice; contaminated food, particularly raw or undercooked shellfish; moist grains held at ambient temperature; and raw or partially dried fish. The usual mode of infection is ingestion of contaminated food or water. Boiling water or treating it with chlorine or iodine and adequate cooking of food kill the organism.<sup>907</sup> Asymptomatic infection of family contacts is common but direct person-to-person transmission of disease has not been documented. Persons with low gastric acidity are at increased risk for cholera infection.

### Clinical Manifestations

Cholera acquired during pregnancy, particularly in the third trimester, is associated with a high incidence of fetal death.<sup>917</sup> Miscarriage can be attributed to a fetal acidosis and hypoxemia resulting from the marked metabolic and circulatory changes that this disease induces in the mother. It is not surprising that the likelihood of delivering a stillborn child is closely correlated with the severity of the maternal illness. The inability to culture *V. cholerae* from stillborn infants of infected mothers, together with the usual absence of bacteremia in cholera, suggests that transplacental fetal infection is not a cause of intrauterine death.

Neonatal cholera is a rare disease. This generalization also applies to the new O139 strains, although mild<sup>918</sup> and severe forms of illness have rarely been described in newborns.<sup>919</sup> Among 242 neonates admitted to a cholera research hospital in Dacca, Bangladesh, there were 25 infants ill with cholera.<sup>920</sup>

Even infants born to mothers with active diarrheal disease may escape infection, despite evidence that rice-water stools, almost certain to be ingested during the birth process, may contain as many as  $10^9$  organisms/mL.<sup>920</sup> The reason for this apparently low attack rate among newborns is not certain; however, it probably can be attributed in large part to the protection conferred by breast-feeding.<sup>921</sup> Human milk contains antibodies<sup>62</sup> and receptor-like glycoprotein that inhibit adherence of *V. cholerae*<sup>64</sup> and gangliosides that bind cholera toxin.<sup>65</sup> The role of transplacentally acquired vibriocidal maternal antibodies has not been determined.<sup>922</sup> Because *V. cholerae* causes neither bacteremia nor intestinal invasion, protection against illness is more likely to be a function of mucosal rather than serum antibodies.<sup>923,924</sup> Additional factors that may reduce the incidence of neonatal cholera include the large inoculum required for infection<sup>925</sup> and the limited exposure of the newborn to the contaminated food and water.<sup>229</sup>

## Diagnosis

Clinicians should request that appropriate cultures be performed for stool specimens from persons suspected of having cholera. The specimen is plated on thiosulfate citrate bile salts sucrose agar directly or after enrichment in alkaline peptone water. Isolates of *V. cholerae* should be confirmed at a state health department and then sent to the CDC for testing for production of cholera toxin. A fourfold rise in vibriocidal antibody titers between acute and convalescent serum samples or a fourfold decline in titers between early and late (>2 months) convalescent serum specimens can confirm the diagnosis. Probes have been developed to test for cholera toxin.<sup>926,927</sup>

## Therapy and Prevention

The most important modality of therapy is administration of oral or parenteral rehydration therapy to correct dehydration and electrolyte imbalance and maintain hydration.<sup>907</sup> Antimicrobial therapy can eradicate vibrios, reduce the duration of diarrhea, and reduce requirements for fluid replacement. One cholera vaccine, which is administered parenterally, is licensed in the United States but is of very limited value. Several experimental oral vaccines are being tested.<sup>928-930</sup>

## YERSINIA ENTEROCOLITICA

### Nature of the Organism, Epidemiology, and Pathogenesis

*Y. enterocolitica* is a major cause of enteritis in much of the industrialized world.<sup>931,932</sup> Enteritis due to this organism primarily occurs in infants and young children, and infections in the United States are reported to be more common in the North than in the South.<sup>933-938</sup> Animals, especially swine, have been shown to serve as the reservoir for *Y. enterocolitica*. A history of recent exposure to chitterlings (i.e., pig intestine) is common. Transmission has also occurred after ingestion of contaminated milk and infusion of contaminated blood products.<sup>939,940</sup>

Virulence of *Y. enterocolitica* is related primarily to a virulence plasmid, which is closely related to the virulence plasmids of *Yersinia pseudotuberculosis* and *Yersinia pestis*.<sup>941,942</sup> An ST enterotoxin, which is closely related to the ST of ETEC,<sup>943</sup> may also be important.

## Clinical Manifestations

Infection with *Y. enterocolitica* is recognized as one of the causes of bacterial gastroenteritis in young children, but knowledge of neonatal infection with this organism is fragmentary. Even in large series, isolation of *Yersinia* from newborns is rare.<sup>931,932,944</sup>

The youngest infants whose clinical course has been described in detail were 11 days to several months old at the onset of their illness.<sup>932,944-952</sup> There were no features of the gastroenteritis to distinguish it from that caused by other invasive enteric pathogens such as *Shigella* or *Salmonella*. Infants presented with watery diarrhea or with stools containing mucus with streaks of blood. Sepsis was common in these infants particularly in the first 3 months of life when 28% of enteritis was complicated by sepsis.<sup>948,949,953,954</sup> Fever is not a consistent finding in children with bacteremia, and meningitis is rare. In older children, fever and right lower quadrant pain mimicking appendicitis are often found.<sup>940</sup>

## Diagnosis

*Y. enterocolitica* can be recovered from throat swabs, mesenteric lymph nodes, peritoneal fluid, blood, and stool. Because laboratory identification of organisms from stool requires special techniques, laboratory personnel should be notified when *Yersinia* is suspected. Because avirulent environmental isolates occur, biotyping and serotyping are useful in assessing the clinical relevance of isolates. PCR has been used to detect pathogenic strains.<sup>955,956</sup>

## Therapy

The effect of antimicrobial therapy on the outcome of gastrointestinal infection is uncertain. It has been recommended that antibiotics be reserved for sepsis or prolonged and severe gastroenteritis<sup>931</sup>; however, there are no prospective studies comparing the efficacy of various antimicrobial agents with each other or with supportive therapy alone. Most strains of *Y. enterocolitica* are susceptible to trimethoprim-sulfamethoxazole, the aminoglycosides, piperacillin, imipenem, third-generation cephalosporins, amoxicillin-clavulanate potassium, and chloramphenicol, and resistant to amoxicillin, ampicillin, carbenicillin, ticarcillin, and macrolides.<sup>957-959</sup> Therapy in individual cases should be guided by in vitro susceptibility testing, although cefotaxime has been successfully used in bacteremic infants.<sup>954</sup>

## AEROMONAS HYDROPHILA

### Nature of the Organism, Epidemiology, and Pathogenesis

*Aeromonas hydrophila* is widely distributed in animals and the environment. Although wound infection, pneumonia,

and sepsis (especially in immunocompromised hosts) represent typical *Aeromonas* infections, gastroenteritis increasingly is being recognized. The organism is a gram-negative, oxidase-positive, facultatively anaerobic bacillus belonging to the family Vibrionaceae. Like other members of this family, it produces an enterotoxin<sup>960</sup> that causes fluid secretion in rabbit ileal loops.<sup>961</sup> Some strains cause fluid accumulation in the suckling mouse model,<sup>962</sup> whereas other strains are invasive<sup>963</sup> or cytotoxic.<sup>964</sup> The enterotoxin is not immunologically related to cholera toxin or the heat LT of *E. coli*.<sup>965</sup>

Although volunteer studies and studies with monkeys have failed to provide supportive evidence for enteropathogenicity,<sup>966,967</sup> there is good reason to believe that *A. hydrophila* does cause diarrhea in children. The earliest description of *Aeromonas* causing diarrhea was an outbreak that occurred in a neonatal unit.<sup>968</sup> Although several studies have failed to show an association with diarrhea,<sup>969-974</sup> most studies have found more *Aeromonas* isolates among children with gastroenteritis than among controls.<sup>974-976</sup> Part of the controversy may be caused by strain differences; some strains possess virulence traits related to production of gastroenteritis, whereas others do not.<sup>970,977</sup>

The diarrhea described in children is a disease of summer, primarily affecting children in the first 2 years of life. In one study, 7 (13%) of 55 cases of *Aeromonas* detected during a 20-month period occurred in infants younger than 1 month.

### Clinical Manifestations

Typically, watery diarrhea with no fever has been described; although there are descriptions of watery diarrhea with fever.<sup>978</sup> However, in 22%, a dysentery-like illness occurred. Dysentery-like illness has been described in the neonate.<sup>979</sup> In one third of children, diarrhea has been reported to last for more than 2 weeks.<sup>970</sup> There may be species-related differences in clinical features of *Aeromonas*-associated gastroenteritis in children.<sup>980</sup> Organisms that were formerly classified as *A. hydrophila* are now sometimes labeled as *Aeromonas sobria* or *Aeromonas caviae*.<sup>981,982</sup> Fever and abdominal pain appear to be particularly common with *A. sobria*. One series of *A. hydrophila* isolates from newborns in Dallas showed more blood cultures than stool cultures positive for *Aeromonas*.<sup>983</sup>

### Diagnosis and Therapy

Diagnosis of enteric infection associated with *Aeromonas* often is not made because this organism is not routinely sought in stool cultures. When the organism is suspected, the laboratory should be notified so that oxidase testing can be performed. The organism is usually susceptible to aztreonam, imipenem, meropenem, third-generation cephalosporins, trimethoprim-sulfamethoxazole, and chloramphenicol.<sup>984-986</sup>

### PLESIOMONAS SHIGELLOIDES

*Plesiomonas shigelloides* is a gram-negative, facultative anaerobic bacillus that, like *Aeromonas*, is a member of the Vibrionaceae family. It is widely disseminated in the

environment; outbreaks of disease are usually related to ingestion of contaminated water or seafood.<sup>987</sup> Although it has been associated with outbreaks of diarrheal disease<sup>988</sup> and has been found more commonly in ill than well controls, the role of *P. shigelloides* in diarrheal disease has remained controversial.<sup>989</sup> If it is a true enteropathogen, the mechanism by which it causes disease is unclear.<sup>990,991</sup> The role of this organism in neonatal diarrhea has not been extensively investigated. Infections of neonates have been reported,<sup>992-995</sup> but most cases of enteric disease currently reported in the United States are in adults.<sup>987</sup> Typical illness consists of watery diarrhea and cramps; sometimes, fever, bloody stools, and emesis occur and last for 3 to 42 days.

Diagnosis is not usually made by clinical microbiology laboratory testing because, as with *Aeromonas*, coliforms can be confused with *P. shigelloides* unless an oxidase test is performed.<sup>996</sup> The true frequency of infection is unknown. The organism has antibiotic susceptibilities similar to those of *Aeromonas*.<sup>997,998</sup>

### OTHER BACTERIAL AGENTS AND FUNGI

Proving that an organism causes diarrhea is difficult, particularly when it may be present in large numbers in stools of healthy persons. Bacteria that have been associated with acute gastroenteritis may be considered causative when the following criteria are met:

1. A single specific strain of the organism should be found as the predominant organism in most affected infants by different investigators in outbreaks of enteric disease in different communities.
2. This strain should be isolated in a significantly lower percentage and in smaller numbers from stool specimens of healthy infants.
3. Available methods must be used to exclude other recognized enteropathogens, including viruses and parasites, enterotoxigenic agents, and fastidious organisms such as *Campylobacter*.
4. Demonstration of effective specific antimicrobial therapy and specific antibody responses and, ultimately, production of experimental disease in volunteers are helpful in establishing the identity of a microorganism as a pathogen.

Optimally, the putative pathogen should have virulence traits that can be demonstrated in model systems. Most bacteria that have been suggested as occasional causes of gastroenteritis in neonates fail to fulfill one or more of these criteria. Their role in the cause of diarrheal disease is questionable. This is particularly true of microorganisms described in early reports in which the possibility of infection with more recently recognized agents could not be excluded. Much of the clinical, bacteriologic, and epidemiologic data collected earlier linking unusual enteropathogens to infantile diarrhea must be reevaluated in light of current knowledge and methodology.

Several reports of acute gastroenteritis believed to have been caused by *Klebsiella* suggest that, rather than playing an etiologic role, these organisms had probably proliferated within an already inflamed bowel.<sup>999-1001</sup> The recovery of *Klebsiella-Enterobacter* in pure culture from diarrheal stools has led several investigators to suggest that these bacteria

may occasionally play a causative role in infantile gastroenteritis and enterocolitis.<sup>1002-1007</sup> Ingestion of infant formula contaminated with *Enterobacter sakazakii* has been associated with development of bloody diarrhea and sepsis.<sup>1008</sup> However, *Klebsiella* species also may be isolated in pure culture from stools of newborns with no enteric symptoms.<sup>1009-1011</sup> In one study, certain capsular types of *Klebsiella* were more often isolated from infants with diarrheal disease than from normal infants.<sup>1002</sup> Later work has shown that *Klebsiella pneumoniae*, *Enterobacter cloacae*, and *Citrobacter* species are capable of producing enterotoxins.<sup>139,166,167,175,193,1008,1012,1013</sup> Reports of isolation of *Citrobacter* species, such as those of *Klebsiella* species, describe associations with enteric illnesses in up to 7% of cases.<sup>1014-1016</sup> There is inadequate evidence to define the roles of *Klebsiella*, *Enterobacter*, and *Citrobacter* species as etiologic agents of enteric illnesses.

*Listeria monocytogenes*, one of the classic causes of neonatal sepsis and meningitis (see Chapter 14), has been linked to outbreaks of febrile diarrheal disease in immunocompetent adults and children.<sup>1017-1021</sup> Seventy-two percent of ill individuals have had fever.<sup>1022</sup> Outbreaks have been related to ingestion of contaminated foods. *Listeria* has rarely been described as a cause of neonatal gastroenteritis.<sup>1023-1026</sup>

Infection with enterotoxin-producing *Bacteroides fragilis* has been associated with mild watery diarrhea.<sup>1027</sup> These infections have a peak incidence in 2- to 3-year-old infants.<sup>1028</sup> These toxin-producing organisms cannot be detected in routine hospital laboratories.

A variety of organisms has been isolated from infant stools during episodes of diarrhea. Most of these reports have failed to associate illness with specific organisms in a way that has stood the test of time. For example, *P. aeruginosa*<sup>1029-1034</sup> and *Proteus*<sup>1017,1035-1041</sup> have been associated with diarrhea, but there are few convincing data suggesting that either is a true enteropathogen. These organisms generally are recovered as frequently from healthy infants as from infants with diarrheal disease, suggesting that their presence in stool cultures is significant.<sup>273,1042-1046</sup> An association between *Providencia* and neonatal enteritis has been substantiated largely by anecdotal reports of nursery outbreaks.<sup>215,271,1016,1047</sup> These bacteria are rarely isolated from infants with sporadic or community-acquired diarrheal disease.<sup>1042-1044,1048-1050</sup>

*Candida albicans* usually is acquired during passage through the birth canal and is considered a normal, although minor, component of the fecal flora of the neonate (see Chapter 33).<sup>1051</sup> Intestinal overgrowth of these organisms frequently accompanies infantile gastroenteritis,<sup>211,233,1051,1054</sup> particularly after antimicrobial therapy.<sup>233,247,1052-1055</sup> The upper small gut may become colonized with *Candida* in malnourished children with diarrhea<sup>1056</sup>; whether the presence of the organism is cause or effect is unclear. Stool cultures obtained from infants with diarrheal disease are therefore inconclusive, and although *Candida* enteritis has been reported in adults,<sup>1057</sup> the importance of this organism as a primary cause of neonatal gastroenteritis has been difficult to prove. Clinical descriptions of nursery epidemics of candidal enteritis are poorly documented, generally preceding the recognition of EPEC and rotaviruses as a cause of neonatal diarrhea. Even well studied cases of intestinal involvement add little in the way of substantive proof because secondary invasion of *Candida* has been shown to be a complication of coliform enteritis.<sup>211,233,247</sup>

Although diarrhea has sometimes been described as a finding in neonatal disseminated candidiasis, more typically, gastrointestinal tract involvement with disseminated *Candida* is associated with abdominal distention and bloody stools mimicking necrotizing enterocolitis.<sup>247,1056-1061</sup> Typically, affected infants are premature and have courses complicated by antibiotic administration, intravascular catheter use, and surgical procedures during the first several weeks of life. A trial of oral anticandidal therapy may be helpful in neonates suffering from diarrhea in the presence of oral or cutaneous candidiasis. If the therapy is appropriate, a response should be forthcoming within 2 to 5 days.

Diarrhea sometimes occurs as a manifestation of systemic infection. Patients with staphylococcal toxic shock syndrome, for example, often have diarrhea. Loose stools sometimes occur in sepsis, but it is unclear whether the diarrhea is a cause or an effect. The organisms isolated from blood cultures in a group of Bangladeshi infants and children with diarrhea included *Staphylococcus aureus*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *P. aeruginosa*, and various gram-negative enteric bacilli.<sup>1062</sup> It is unknown whether the bacteriology of sepsis associated with diarrhea is similar in the well-nourished infants seen in industrialized countries.

## PARASITES

Acute diarrhea associated with intestinal parasites is infrequent during the neonatal period. In areas with high endemicity, infection of the newborn is likely to be associated with inadequate maternal and delivery care, insufficient environmental sanitation, and poor personal hygiene standards. The occurrence of symptomatic intestinal parasitic infection during the first month of life requires acquisition of the parasite during the first days or weeks; the incubation period for *E. histolytica* and *G. lamblia* is 1 to 4 weeks, and for *Cryptosporidium parvum*, it is 7 to 14 days. The newborn can be infected during delivery by contact with maternal feces,<sup>1063</sup> in the hospital through contact with the mother or personnel, or in the household through contact with infected individuals in close contact with the child. Contaminated water can be an important source of infection for *G. lamblia* and *C. parvum*.

### *Entamoeba histolytica*

Organisms formerly identified as *E. histolytica* have been reclassified into two species that are morphologically identical but genetically distinct: *E. histolytica* and *E. dispar*. The former can cause acute nonbloody and bloody diarrhea, necrotizing enterocolitis, ameboma, and liver abscess, and the latter is a noninvasive parasite that does not cause disease. Early acquisition of disease tends to be more severe in young infants; rarely, amebic liver abscess and rapidly fatal colitis have been reported in infants.<sup>1064-1070</sup> For example, a 19-day-old child from India who presented with 10 to 12 episodes of watery and mucous diarrhea, lethargy, jaundice, and mildly elevated liver enzymes has been described; the child recovered completely after 10 days of intravenous omidazole.<sup>1064</sup> However, asymptomatic colonization of neonates with various species of ameba is common in areas of high endemicity.<sup>1071</sup>

Diagnosis can be established by stool examination for cysts and trophozoites and by serologic studies.<sup>1072</sup> Through the use of PCR, isoenzyme analysis, and antigen detection assays, *E. histolytica* and *E. dispar* can be differentiated.<sup>1073,1074</sup> Serum antibody assays may be helpful in establishing the diagnosis of amebic dysentery and extraintestinal amebiasis with liver involvement. The efficacy of treatment with metronidazole for colitis or liver abscess has not been established for the newborn period, although this therapy has been used with success.<sup>1065</sup> Patients with colitis or liver abscess caused by *E. histolytica* are treated also with iodoquinol, as are asymptomatic carriers.

### ***Giardia lamblia***

*G. lamblia* is a binucleate, flagellated protozoan parasite with trophozoite and cyst stages. It is spread by the fecal-oral route through ingestion of cysts. Child-care center outbreaks reflecting person-to-person spread have demonstrated high infectivity.<sup>1075-1078</sup> Foodborne transmission and waterborne transmission also occur. Infection is often asymptomatic or mildly symptomatic; cases of severe symptomatic infection during the immediate newborn period have not been reported. Symptoms in giardiasis are related to the age of the patient, with diarrhea, vomiting, anorexia, and failure to thrive typical in the youngest children. Seroprevalence studies have demonstrated evidence of past or current infection in 40% of Peruvian children by the age of 6 months.<sup>1081</sup> In a study of lactating Bangladeshi mothers and their infants, 82% of women and 42% of infants excreted *Giardia* once during the study; in some infants, this occurred before they were 3 months old.<sup>1082</sup> Of these infected infants, 86% had diarrhea, suggesting that the early exposure to the parasite resulted in disease. In a prospective study of diarrhea conducted in Mexico, infants frequently were infected with *Giardia* from birth to 2 months, with a crude incidence rate of first *Giardia* infection of 1.4 infections per child-year in this age group.<sup>6</sup> The symptom status of these children was not reported but this study strongly suggests that *G. lamblia* may be more common than currently recognized among newborns living in developing areas.

The diagnosis of giardiasis can be made on the basis of demonstration of antigen by EIA or by microscopy of feces, duodenal fluid or, less frequently, duodenal biopsy.<sup>1079,1080</sup> Breast-feeding is believed to protect against symptomatic giardiasis.<sup>6,69,1083</sup> This protection may be mediated by cellular and humoral immunity<sup>67,1084,1085</sup> and nonspecifically by the anti-giardial effects of unsaturated fatty acids.<sup>1086</sup> *Giardia* infections causing severe diarrhea may respond to metronidazole or furazolidone.<sup>1080</sup>

### ***Cryptosporidium***

*C. parvum* is a coccidian protozoon related to *Toxoplasma gondii*, *Isospora belli*, and *Plasmodium* species.<sup>1087,1088</sup> The life cycle involves ingestion of thick-walled oocysts; release of sporozoites, which penetrate intestinal epithelium; and development of merozoites. There is asexual and sexual reproduction, with the latter resulting in formation of new oocysts that can be passed in stools.

*Cryptosporidium* species are ubiquitous. Infection often occurs in persons traveling to endemic areas.<sup>1089</sup> Because *Cryptosporidium* infects a wide variety of animal species,

there is often a history of animal contact among infected individuals.<sup>1090</sup> Person-to-person spread, particularly in household contacts<sup>1091-1094</sup> and daycare centers,<sup>1095,1096</sup> is well documented and suggests that the organism is highly infectious. Waterborne outbreaks of cryptosporidiosis occur and can be of massive proportions.<sup>1097</sup>

The clinical manifestations of illness in immunocompetent persons resemble those of *Giardia* infection but are somewhat shorter in duration<sup>1098</sup>; asymptomatic carriage is rare. Symptoms and signs include watery diarrhea, abdominal pain, myalgia, fever, and weight loss.<sup>1089,1090,1095,1096,1098,1099</sup> Infection in the first month of life has been described.<sup>1100,1101</sup> Because symptoms resolve before excretion of oocysts ceases, a newborn whose mother has been ill with cryptosporidiosis in the month before delivery might be at risk even if the mother is asymptomatic at the time of the child's birth.<sup>1102</sup> With the increasing frequency of human immunodeficiency virus infection, it is likely that women with symptomatic cryptosporidiosis occasionally will deliver an infant who will become infected. Infants infected early in life may develop chronic diarrhea and malnutrition.<sup>1103</sup>

The diagnosis of cryptosporidiosis is most typically made by examination of fecal smears using the Giemsa stain, Ziehl-Neelsen stain, auramine-rhodamine stain, Sheather's sugar flotation, an immunofluorescence procedure, a modified concentration-sugar flotation method, or an EIA.<sup>1104,1105</sup> Nitazoxanide is effective therapy of immunocompetent adults and children ill with cryptosporidiosis.<sup>1106</sup> Because illness is usually self-limited in the normal host, attention to fluid, electrolyte, and nutritional status usually suffices. Enteric isolation of hospitalized infants with this illness is appropriate because of the high infectivity. Several studies suggest that the risk of infection early in life may be decreased by breast-feeding.<sup>1101,1107</sup>

## **VIRUSES**

### **Enteric Viruses**

Viruses that infect the intestinal mucosa and cause primarily gastroenteritis are referred to as *enteric viruses*; they should not be confused with enteroviruses, members of Picornaviridae family that are associated primarily with systemic illnesses. Enteric viruses include rotaviruses, enteric adenoviruses, human caliciviruses, and astroviruses. Other viruses such as coronaviruses, Breda viruses, pestiviruses, parvoviruses, toroviruses, and picobirnaviruses have been sporadically associated with acute diarrhea but are currently considered of uncertain relevance. Extensive reviews on the role of enteric viruses in childhood diarrhea can be found elsewhere.<sup>1108-1111</sup>

All four enteric viruses could conceivably infect the newborn, but the extent of exposure and clinical manifestations are largely unknown for astrovirus, enteric adenovirus, and human caliciviruses. Rotavirus is the most extensively studied enteric virus. Neonatal rotavirus infections have similar virologic and clinical characteristics to infection in older children, although some differences exist.

### **Rotavirus**

Rotavirus is a 75-nm, nonenveloped virus composed of three concentric protein shells: a segmented genome (11

segments), an RNA-dependent polymerase, and enzymes required for messenger RNA synthesis are located within the inner core. Each segment codes for at least one viral protein (VP). The VP can be part of the structure of the virus, or it may be a nonstructural protein (NSP) required for replication, viral assembly, budding, determination of host range, or viral pathogenesis.<sup>1110</sup>

Six distinct rotavirus groups (A through F) have been identified serologically based on common group antigens,<sup>1112,1113</sup> of which three (A, B, and C) have been identified in humans.<sup>1108</sup> Because group A rotaviruses represent more than 95% of isolated strains in humans worldwide, further discussion focuses on this group. Group A rotaviruses are subclassified into serotypes based on neutralization epitopes located on the outer capsid. Both rotavirus surface proteins, VP4 and VP7, can induce production of neutralizing antibodies.<sup>1114,1115</sup> At least 10 VP7 types (G serotypes: G1 to G6, G8 to G10, and G12) and nine VP4 types (P serotypes: P1A, P1B, P2A, P3, P3B, P4, P5, P8, and P12) have been detected among human rotaviruses.<sup>1116-1123</sup> By sequencing the VP4-coding gene, eight genomic P types (genotypes) have been identified that correspond to one or more of the described P antigenic types (genotype 8 to antigenic type P1A, 4 to P1B, 6 to P2A, 9 to P3, 13 to P3B, 10 to P4, 3 to P5, and 11 to P8).<sup>1110</sup> Combining G antigenic with P antigenic and genetic typing, a specific rotavirus strain can be identified: P antigenic type (P genetic type), G type. As an example, the human neonatal M37 strain is described as P2A[6], G1.

Four combined GP types: P1A[8], G1; P1B[4], G2; P1A[8], G3; and P1A[8], G4 account for more than 95% of the organisms isolated from children, and of these, P1A[8], G1 represents the single most common type.<sup>1118-1123</sup> Isolation of less common types appears to be more frequent among neonates with nosocomial rotavirus infections.<sup>1123-1130</sup> Some of these strains seem to be associated with occurrence of asymptomatic infections, although the existence of naturally acquired asymptomatic strains is controversial. Strains P2A[6], G9; P2A[6], G4; P2A[6], G2; and P2A[6], G8 have been reported<sup>1128-1131</sup> from newborn nurseries, some of which seem to be endemic to the newborn units with high rates of asymptomatic infection,<sup>1129-1131</sup> and less commonly, outbreaks of symptomatic infection.<sup>1128</sup> These findings suggest that specific conditions of the newborn environment (e.g., child, nursery, personnel) may increase the possibility of reassortments between human strains; such strains may persist in these settings possibly through constant transmission involving asymptomatic newborns, adults, and contaminated surfaces.

### Pathogenesis

Rotavirus primarily infects mature enterocytes located in the mid and upper villous epithelium.<sup>1132-1136</sup> Lactase, which is present only on the brush border of the differentiated epithelial cells at these sites, may act as a combined receptor and uncoating enzyme for the virus, permitting transfer of the particles into the cell.<sup>1137</sup> Perhaps for this reason, infection is limited to the mature columnar enterocytes; crypt cells and crypt-derived cuboidal cells, which lack a brush border, appear to be resistant to rotaviral infection.<sup>1137,1138</sup> This concept also may explain why rotavirus infection is less common in infants younger than 32 weeks' gestational age than in more mature infants<sup>1139</sup>; between 26 and 34 weeks'

gestational age, lactase activity is approximately 30% of that found in term infants.<sup>1140</sup>

The upper small intestine is most commonly involved, although lesions may extend to the distal ileum and rarely to the colon.<sup>1141,1142</sup> Interaction between intestinal cell and rotavirus structural and nonstructural proteins occurs, resulting in death of infected villous enterocytes.<sup>1143</sup> Once infected, the villous enterocyte is sloughed, resulting in an altered mucosal architecture that becomes stunted and flattened. The gross appearance of the bowel is usually normal; however, under the dissecting microscope, scattered focal lesions of the mucosal surface are apparent in most cases. Light microscopy also shows patchy changes in villous morphology, compatible with a process of infection, inflammation, and accelerated mucosal renewal. The villi take on a shortened and blunt appearance as tall columnar cells are shed and replaced by less mature cuboidal enterocytes.<sup>1133,1135,1144</sup> Ischemia may also play a role in the loss and stunting of villi<sup>1145</sup> and activation of the enteric nervous system; active secretion of fluid and electrolytes may be another pathogenic mechanism.<sup>1146</sup> During the recovery phase, the enteroblastic cells mature and reconstruct the villous structure. Because of the loss of mature enterocytes on the tips of the villi, the surface area of the intestine is reduced. Diarrhea that occurs may be a result of this decrease in surface area, disruption in epithelial integrity, transient disaccharidase deficiency, or altered counter-current mechanisms and net secretion of water and electrolytes.<sup>1133,1140,1142,1146,1147,1148</sup> NSP4 has been found to induce age-dependent diarrhea in CD1 mice by triggering calcium-dependent chloride and water secretion.<sup>1149</sup> The potential role of this "viral enterotoxin" in human disease is not yet clear.<sup>1150,1151</sup>

### Infection and Immunity

Infants with asymptomatic rotavirus infections in the nursery are less likely than uninfected nursery mates to experience severe rotavirus infection later in life<sup>1152-1153</sup>; this finding suggested protective immunity and supported vaccine development. Most studies have indicated that serum and intestinal antirotavirus antibody levels are correlated with protection against infection<sup>1153-1161</sup> although this correlation has not been universal.<sup>1162-1163</sup> Breast-feeding protects against rotavirus disease during the first year of life,<sup>57</sup> probably including newborns.<sup>1146</sup> The high prevalence of antirotaviral antibodies in colostrum and human milk has been demonstrated by numerous investigators in widely diverse geographic areas.<sup>8</sup> Maternal rotavirus infection or immunization is accompanied by the appearance of specific antibodies in milk, probably through stimulation of the enteromammary immune system.<sup>1164-1169</sup> Between 90% and 100% of women examined in London, Bangladesh, Guatemala, Costa Rica, and the United States had antirotaviral IgA antibodies in their milk for up to 2 years of lactation.<sup>8,1164-1170</sup> Rotavirus-specific IgG antibodies have been found during the first few postpartum days in about one third of human milk samples assayed,<sup>1164,1167</sup> whereas IgM antibodies were detectable in about one half.<sup>1167</sup>

Glycoproteins in human milk have been shown to prevent rotavirus infection *in vitro* and in an animal model.<sup>1170</sup> The concentration of one milk glycoprotein, lactadherin, was found to be significantly higher in human milk ingested by

infants who developed asymptomatic rotavirus infection than in milk ingested by infants who developed symptomatic infection.<sup>45</sup>

### Epidemiology

Rotaviruses probably infect neonates more commonly than previously recognized, although most infections seem to be asymptomatic or mildly symptomatic.<sup>1128-1130,1131,1172-1187</sup> In a prospective study, the prevalence of rotavirus infection among neonatal intensive care unit patients was 18.4%. Rotavirus has a mean incubation period of 2 days, with a range of 1 to 3 days in children and in experimentally infected adults. Fecal excretion of virus often begins a day or so before illness and maximal excretion usually occurs during the third and fourth days, and generally diminishes by the end of the first week, although low concentrations of virus have been detected in neonates for up to 8 weeks.<sup>1140,1186-1189</sup>

Rotavirus infections are markedly seasonal (autumn and winter) in many areas of the world, although in some countries seasonality is less striking; the reason for this is unclear.<sup>1190-1195</sup> In nurseries in which persisting endemic infection has permitted long-term surveillance of large numbers of neonates, rotavirus excretion can follow the seasonal pattern of the community but can also show no seasonal fluctuation.<sup>1196-1198</sup> It is not clear how units in which infection remains endemic for months or years differ from those with a low incidence of rotavirus. Some nurseries are free of rotavirus infection<sup>1198-1200</sup> or minimally affected<sup>45,1201</sup> whereas others have rotavirus diarrheal disease throughout the year or in outbreaks that involve 10% to 40% of neonates.<sup>1128,1139,1179,1202-1203</sup>

Low birth weight does not seem to be an important factor in determining the attack rate among infants at risk but may be important in mortality.<sup>1204</sup> Infants in premature or special-care nurseries, despite their prolonged stays and the increased handling necessary for their care, do not demonstrate a higher susceptibility to infection; data regarding shedding of the virus are inconsistent.<sup>45,1200</sup>

After infection is introduced into a nursery, rotavirus probably will spread steadily and remain endemic until the nursery is closed to new admissions or nursing practices permit interruption of the cycle.<sup>1205</sup> Exactly how the virus is introduced and transmitted is uncertain, although limited observations and experience with other types of enteric disease in maternity units suggest several possibilities. The early appearance of virus in stools of some neonates indicates that infection probably was acquired at delivery. Virus particles can be detected on the first<sup>45,1186</sup> or second<sup>1198</sup> day of life in a significant number of infected infants. By day 3 or 4, most infected infants who will shed virus, with or without signs of illness, are doing so.<sup>1174,1186,1198</sup> The large numbers of virus particles excreted<sup>1174,1198</sup> suggest a fairly large and early oral inoculum. It is unlikely that contamination from any source other than maternal feces could provide an inoculum large enough to cause infection by the second day.

Transfer of particles from infant to infant on the hands of nursing and medical staff is probably the most important means of viral spread. With  $10^8$  to  $10^{11}$  viral particles usually present in 1 g of stool, the hands of personnel easily could become contaminated after infection is introduced into a nursery. There are numerous reports of nosocomial and daycare center rotavirus gastroenteritis outbreaks that attest

to the ease with which this agent spreads through a hospital or institutional setting.<sup>1108</sup> Admission of a symptomatic child usually is the initiating event, although transfer of a neonate with inapparent infection from one ward to another also has been incriminated. The most important factors influencing the incidence of rotavirus diarrhea in a nursery are the proximity to other newborns and the frequency of handling.<sup>1187</sup> During a 4-month study, infants cared for by nursing staff and kept in communal nurseries experienced three epidemics of diarrhea with attack rates between 20% and 50%. During the same period, only 2% of infants rooming in with their mothers became ill, even though they had frequent contact with adult relatives and siblings.

There is no clear evidence of airborne or droplet infection originating in the upper respiratory tract or spread by aerosolization of diarrheal fluid while diapers are changed. Indirect evidence of airborne transmission includes the high infection rate in closed settings, the isolation of the virus from respiratory secretions,<sup>1206</sup> and the experimental observation of transmission by aerosol droplets in mice.<sup>1207</sup> However, the respiratory isolation achieved by placing an infant in a closed incubator is not fully protective.<sup>1187</sup> No evidence indicates that transplacental or ascending intra-uterine infection occurs. Transmission of virus through contaminated fomites, formula, or food is possible but has not been documented in newborns. Rotavirus particles have not been found in human milk or colostrum.<sup>1166,1170</sup>

### Clinical Manifestations

Exposure of a newborn to rotavirus can result in asymptomatic infection or cause mild or severe gastroenteritis.<sup>1129,1130,1173,1179,1196,1197,1201,1208</sup> Outbreaks with high attack rates as measured by rotavirus excretion have been described but the extent of symptomatic infection varies.<sup>1175,1177,1186,1198,1203</sup> Severe rotavirus infection is seldom reported during the newborn period<sup>1203</sup> but the extent of underreporting of severe disease, especially in the less developed areas of the world, has not been evaluated.

It has been hypothesized that asymptomatic infections during the newborn period are the result of naturally attenuated strains circulating in this environment. RNA electrophoretic patterns of rotaviruses found in certain nurseries have shown uniform patterns<sup>1180,1182,1184,1208</sup>, and it has been suggested that these strains may be attenuated. The presence of unusual antigenic types such as the P2A[6] type within nurseries also suggests "less virulent strains." At least 10 rotavirus strains were documented to co-circulate in a tertiary care center during a 2-month period<sup>1209</sup> and in a different setting the same rotavirus strains by electropherotype produced asymptomatic infection in neonates and symptomatic infection in older infants.<sup>1183</sup> Newborns within a nursery exposed to a given rotavirus strain can develop symptomatic or asymptomatic infection.<sup>1130,1210,1211</sup> Because newborns routinely have frequent relatively loose stools, it is possible that mild diarrhea episodes caused by rotavirus are being wrongly labeled as asymptomatic episodes.

No clinical feature is pathognomonic of rotaviral gastroenteritis. Early signs of illness, such as lethargy, irritability, vomiting, and poor feeding, usually are followed in a few hours by the passage of watery yellow or green stools free of blood but sometimes containing mucus.<sup>1187,1212-1214</sup> Diarrhea usually decreases by the second day of illness and is much

improved by the third or fourth day. Occasionally, intestinal fluid loss and poor weight gain may continue for 1 or 2 weeks, particularly in low-birth-weight infants.<sup>1175</sup> Although reducing substances frequently are present in early fecal samples<sup>1139,175,1176,1187</sup> this finding is not necessarily abnormal in neonates, particularly those who are breast-fed.<sup>1215</sup> Nevertheless, infants with prolonged diarrhea should be investigated for monosaccharide or disaccharide malabsorption or intolerance to cow's milk protein or both.<sup>1216</sup> In a prospective study,<sup>1185</sup> 49% of newborns with gastrointestinal symptoms in a neonatal intensive care unit had rotavirus detected in their stools. Frequent stooling (present in 60%), bloody mucoid stool (42%), and watery stools (24%) were risk factors for a rotavirus infection. Bloody mucoid stools, intestinal dilatation, and abdominal distention were significantly more common in preterm infants, but severe outcomes such as necrotizing enterocolitis and death did not differ among infected term and preterm infants.

Longitudinal studies in newborn nurseries and investigations of outbreaks among neonates rarely describe a severe adverse outcome or death.<sup>1139,1168,1187</sup> Because these infants are under constant observation, early detection of excessive fluid losses and the availability of immediate medical care are probably major factors in determining outcome. Rotavirus gastroenteritis causes almost 400,000 deaths of infants every year,<sup>1217</sup> concentrated largely in the poorest regions of the world. It is likely that in places where hospital-based care is uncommon, rotavirus causes neonatal deaths secondary to dehydration.

Group A rotavirus has been associated with a wide array of diseases in infants and children; Reye syndromes, encephalitis-aseptic meningitis, sudden infant death syndrome, inflammatory bowel disease, and Kawasaki syndrome have been described but not systematically studied.<sup>1108</sup> Case reports and small case series have associated neonatal rotavirus infection with necrotizing enterocolitis.<sup>1218,1219</sup> Rotavirus infection may play a role in a small proportion of cases of necrotizing enterocolitis, although it probably represents one of many potential triggering factors. A significant association between neonatal rotavirus infection and bradycardia-apnea episodes was detected in one prospective study.<sup>1220</sup> The possible association between natural rotavirus infection and intussusception<sup>1221-1223</sup> gained support after the association was made between the human-simian reassortant vaccine and intussusception in infants older than 2 months (attributable risk  $\approx$  1:10,000).<sup>1224</sup> Intussusception is extremely uncommon in the newborn; it is highly unlikely that rotavirus triggers this disease in neonates.

### Diagnosis

There are many methods used for detection of rotavirus in stool specimens, including electron microscopy, immune electron microscopy, ELISA, latex agglutination, gel electrophoresis, culture of the virus, and reverse transcriptase-polymerase chain reaction. ELISA and latex agglutination currently are the most widely used diagnostic techniques for detection of rotavirus in clinical samples. Many commercial kits are available that differ in specificity and sensitivity.<sup>1225-1229</sup> In general, latex agglutination assays are more rapid than ELISAs but are less sensitive. The sensitivity and specificity of the commercially available ELISAs surpass 90%. Checking of the ELISA by another method such as gel electrophoresis

or PCR amplification may be desirable if there is concern about false-positive results.

Fecal material for detection of rotavirus infection should be obtained during the acute phase of illness. Whole-stool samples are preferred, although suspensions of rectal swab specimens have been adequate for detection of rotavirus by ELISA.<sup>1230,1231</sup> Rotavirus are relatively resistant to environmental temperatures, even tropical temperatures,<sup>1232</sup> although 4°C is desirable for short-term storage and -70°C for prolonged storage.<sup>1108</sup> Excretion of viral particles may precede signs of illness by several days<sup>1190</sup>; maximal excretion by older infants and children usually occurs 3 to 4 days after onset of symptoms.<sup>1233</sup> Neonates can shed virus for 1 to 2 weeks after onset of symptoms.

### Therapy and Prevention

The primary goal of therapy is restoration and maintenance of fluid and electrolyte balance. Despite the documented defect in carbohydrate digestion with rotavirus diarrhea, rehydration often can be accomplished with glucose-electrolyte or sucrose-electrolyte solutions given orally.<sup>199,1234-1236</sup> Intravenous fluids may be needed in neonates who are severely dehydrated, who have ileus, or who refuse to feed. Persistent or recurrent diarrhea after introduction of milk-based formulas or human milk warrants investigation for secondary carbohydrate or milk protein intolerance.<sup>1139,1217</sup> Disaccharidase levels and xylose absorption return to normal within a few days<sup>1144</sup> to weeks after infection.<sup>1133</sup>

Intractable diarrhea related to severe morphologic and enzymatic changes of the bowel mucosa is possible although rare in the newborn; it may require an elemental diet or parenteral nutrition. Efficacy of anti-rotavirus antibodies (e.g., hyperimmune colostrum, antibody-supplemented formula, human serum immunoglobulin) and of probiotics has been postulated,<sup>1238-1241</sup> although not convincingly shown<sup>1242</sup>; the widespread clinical use of these measures seems remote. One study suggests that use of lactobacillus during the diarrheal episode may decrease the duration of rotavirus-associated hospital stays, especially when used early in the course of the disease, although more studies are needed before recommending widespread use.<sup>1241</sup>

Hand hygiene before and after contact with each infant remains the single most important means of preventing the spread of infection. Because rotavirus is often excreted several days before illness is recognized, isolation of an infant with diarrhea may be too late to prevent cross-infection unless all nursing personnel and medical staff have adhered to this fundamental precaution. Infants who develop gastroenteritis should be moved out of the nursery area if adequate facilities are available and the infant's condition permits transfer. The use of an incubator is of value in reducing transmission of disease only by serving as a reminder that proper hand-hygiene and glove techniques are required, but is of little value as a physical barrier to the spread of virus.<sup>1187</sup> Encouraging rooming-in of infants with their mothers has been shown to be helpful in preventing or containing nursery epidemics.<sup>1243</sup> Temporary closure of the nursery may be required for clinically significant outbreaks that cannot be controlled with other measures.<sup>1128</sup>

### Vaccines

Development of rotavirus vaccines began in the early 1980s. Candidate vaccines included bovine and rhesus monkey

Table 20-6 Differential Diagnosis of Neonatal Diarrhea

Diagnosis	Reference(s)
<b>Anatomic Disorders</b>	
Microvillous inclusion disease	1245
Hirschsprung's disease	1246
Massive intestinal resection (short-bowel syndrome)	1247
Intestinal lymphangiectasis	1248
<b>Metabolic and Enzymatic Disorders</b>	
Congenital disaccharidase deficiency (lactase, sucrase-isomaltase deficiency)	1249, 1250
Congenital glucose-galactose malabsorption	1251, 1252
Secondary disaccharide, monosaccharide malabsorption	337, 528, 1252-1258
After gastrointestinal surgery	
After infection	
With milk-soy protein sensitivity	
Cystic fibrosis	1259
Syndrome of pancreatic insufficiency and bone marrow dysfunction (Shwachman's syndrome)	1260
Physiologic deficiency of pancreatic amylase	1261
Intestinal enterokinase deficiency	1262
Congenital bile acid deficiency syndrome	1263
Alpha/beta-lipoproteinemia	1264
Acrodermatitis enteropathica	1265, 1266
Congenital chloride diarrhea	1267, 1268
Primary hypomagnesemia	1269
Congenital adrenal hyperplasia	1270
Intestinal hormone hypersecretion	1271, 1272
Non-beta islet cell hyperplasia (Wolman's disease)	1273
Transcobalamin II deficiency	1274
Congenital iron storage	1275
Hartnup's disease	1276
Congenital Na <sup>+</sup> diarrhea	1277
<b>Inflammatory Disorders</b>	
Cow's milk protein intolerance	1278
Soy protein intolerance	1279, 1280
Regional enteritis	1281
Ulcerative colitis	1282, 1283
<b>Primary Immunodeficiency Disorders</b>	
Wiskott-Aldrich syndrome	1284
Thymic dysplasia	1284
Acquired immunodeficiency syndrome	1285
<b>Miscellaneous</b>	
Irritable colon of childhood (chronic nonspecific diarrhea)	1286
Phototherapy for hyperbilirubinemia	1287
Familial dysautonomia (Riley-Day syndrome)	1288
Familial enteropathy	1289, 1290
High sulfates in water	1291
Phenolphthalein poisoning/child abuse	1292

attenuated strains, human attenuated strains, and bovine-human and rhesus-human reassortant strains.<sup>1109</sup> In August 1998, the first licensed rotavirus vaccine, Rotashield, an oral formulation of a simian-human quadrivalent reassortant vaccine, was recommended for use in children when they were 2, 4, and 6 months old. After approximately 500,000 children were vaccinated with more than 1 million doses, a significantly increased risk of intussusception was observed among vaccinated children, with an overall odds ratio of 1.8.<sup>1244</sup> Use of this vaccine was terminated. Two new vaccine candidates are undergoing phase III clinical trials: a "penta-valent" bovine-human reassortant vaccine including G types G1-G4 and P type P1A[8] and a monovalent human attenuated P1A[8]G1 vaccine. The epidemiology of rotavirus infection will change significantly if one or both candidates become widely available in the future. The impact on neonatal infection will depend on the effect of herd immunity in decreasing circulation of rotavirus strains.

## DIFFERENTIAL DIAGNOSIS

Stools from breast-fed neonates are typically watery and yellow, green, or brown. The frequency of stooling can vary from one every other day to eight evacuations per day. In an active, healthy infant who is feeding well, has no vomiting, and has a soft abdomen, these varied patterns of stooling are not a cause for concern. Physicians need to consider the child's previous frequency and consistency of stools and establish a diagnosis of acute diarrhea on an individual basis. Close follow-up of weight increase in infants with non-formed stools can help confirm the clinical impression. A normal weight gain should direct medical action away from stool exams or treatment.

Diarrhea during the neonatal period is a clinical manifestation of a wide variety of disorders (Table 20-6). The most common initiating factor is a primary infection of the gastrointestinal tract that is mild to moderate in severity,

self-limited, and responsive to supportive measures. Acute diarrhea can also be an initial manifestation of a systemic infection, including bacterial and viral neonatal sepsis. Infants with moderate to severe diarrhea require close monitoring until the etiologic diagnosis and the clinical evolution are clarified. There are noninfectious diseases leading to chronic intractable diarrhea that may result in severe nutritional disturbances or even death unless the specific underlying condition is identified and treated appropriately. The differential diagnosis of a diarrheal illness requires a careful clinical examination to determine whether the child has a localized or a systemic process. Lethargy, abnormalities in body temperature, hypothermia or hyperthermia, decreased feeding, abdominal distention, vomiting, pallor, respiratory distress, apnea, cyanosis, hemodynamic instability, hypotension, hepatomegaly or splenomegaly, coagulation or bleeding disorders, petechiae, and exanthemas should lead to an intense laboratory investigation directed at systemic viral or bacterial infection. If the process is deemed a localized intestinal infection, initial evaluation can be focused on differentiating an inflammatory-invasive pathogen from those that cause a noninflammatory process. For this, stool examination for fecal leukocytes, red blood cells, and lactoferrin can be a helpful indicator of the former.

Inflammatory diarrhea can be caused by *Shigella*, *Salmonella*, *Campylobacter*, *V. parahaemolyticus*, *Y. enterocolitica*, EIEC, EAEC, *C. difficile*, necrotizing enterocolitis, antibiotic-associated colitis, and allergic colitis (i.e., milk or soy intolerance). Noninflammatory causes of diarrhea include ETEC, EPEC, rotaviruses, enteric adenoviruses, calicivirus, astrovirus, *G. lamblia* and *Cryptosporidium*. Although supportive fluid therapy is mandatory for all types of diarrhea, the brief examination for fecal leukocytes and red blood cells can direct the diagnostic and therapeutic approach. Pathogens such as *Shigella*, *Salmonella*, and EHEC can cause watery or bloody diarrhea, depending on the specific host-pathogen interaction and the pathogenic mechanisms involved. Some of the noninfectious diseases responsible for neonatal diarrhea are listed in Table 20-6.<sup>337,528,1245-1292</sup> The evaluation and management of persistent infantile diarrhea has been reviewed.<sup>1293</sup>

The first descriptions of the acquired immunodeficiency syndrome (AIDS) in infants and children were published in the early 1980s.<sup>1-4</sup> As of December 2002, 9300 AIDS cases in children younger than 13 years had been confirmed by the Centers for Disease Control and Prevention (CDC) in the United States.<sup>5</sup> However, this represents only a fraction of the 2.5 million children living with human immunodeficiency virus type 1 (HIV-1) infection worldwide.<sup>6</sup> Although HIV infection in children has been acquired in the past by the transfusion of contaminated blood or coagulation products, this route has been virtually eliminated in the United States. It is estimated that 1700 new perinatally acquired HIV infections occur every day in the world, with most occurring in developing countries. Sexual abuse has been associated with the acquisition of HIV infection by some children, and the use of contaminated needles and unprotected sexual intercourse account for most infections in teenagers.

In this chapter, the experience with HIV infection in children is reviewed, with the focus on the infection in neonates and infants. We have a sound knowledge of the clinical presentation of HIV infection in infants and children and have made major progress in preventing vertical transmission in industrialized countries. However, there is an urgent need for the development of simple and inexpensive interventions and a need to better understand the point at which transmission occurs and the role of potentially protective factors. Such knowledge will impact future recommendations for the treatment of pregnant women, the management of very young children, and the use of preventive measures, including immunization and other supportive care modalities before the onset of disease manifestations.

### EPIDEMIOLOGY

HIV infection is a pandemic with cases reported to the World Health Organization (WHO) from virtually every country. Through December 2003, an estimated 40 million people were infected, including 2.5 million children younger than 15 years.<sup>6</sup> The epidemic continues unabated in Africa and is expanding rapidly in Southeast Asia, India, and Latin America.<sup>7-10</sup> It has been estimated that in 2003 alone, 4.2 million adults and 700,000 children were newly infected with HIV-1, and 2.5 million adults and 500,000 children younger than 15 years have died of HIV-related complications.

In contrast, in the United States, HIV-infected children younger than 13 years account for only 1% of all AIDS cases.<sup>5</sup> However, in developing nations, children constitute more than 5% of the people living with HIV/AIDS, and 17% of AIDS-related deaths have been children younger than 15 years. The Joint United Nations Programme on HIV/AIDS (UNAIDS) estimates that more than 13 million children have been orphaned by the AIDS epidemic.

As of December 2002, of the 9300 cases of AIDS in children younger than 13 years that have been reported to the CDC in the United States, more than one half have already died of their disease.<sup>5</sup> Minority groups are disproportionately affected, with 59% of cases occurring among black, non-Hispanic children (who account for only 14% of the U.S. pediatric population) and 23% in Hispanics (17% of the U.S. pediatric population), compared with 17% among white, non-Hispanic children (64% of the U.S. pediatric population).

Almost 80% of the children with AIDS are younger than 5 years, reflecting the predominant mode of transmission from mother to child, which accounts for 93% of HIV infections in children.<sup>5</sup> About 43% of the women in the United States have acquired HIV infection through intra-

venous drug use, but a growing number (53%) have been infected through sexual contact.<sup>5</sup> The increasing number of infected women of childbearing age will continue to greatly influence the number of infected children in the United States and worldwide.

## TRANSMISSION

Data suggest that most children are infected during the immediate peripartum period. In the United States, the transmission rate without intervention is estimated to be 25% to 30%; in Europe, it is lower (13% to 20%); and a rate of 40% has been observed in Africa.<sup>11,12</sup> These differences in transmission rates are difficult to explain. However, it has been clear that maternal disease status, especially a high viral load or a CD4 count less than 200 cells/mm<sup>3</sup>, is highly correlated with the risk for vertical transmission.<sup>11,13-17</sup>

In 1994, the results of the AIDS Clinical Trials Group protocol 076 (PACTG 076) employing zidovudine during pregnancy were published, resulting in guidelines issued by the CDC.<sup>18-21</sup> This trial, which resulted in a 67% reduction in perinatal transmission, has become the gold standard in the United States and western Europe to which future strategies for the prevention of perinatal transmission are being compared. In developing countries, other simpler and less expensive strategies have been used.<sup>22-25</sup>

### Intrauterine Transmission

The female glandular epithelium can contain HIV between the columnar and squamous cells of the cervix, whereas swabs from the vagina yield fewer virus particles.<sup>26,27</sup> Sperm cells do not express CD4 receptors and are therefore unlikely to be directly infected with HIV, but the virus can be detected in seminal white cells and plasma.<sup>27</sup>

Virus has been detected in some aborted fetuses of 8 to 20 weeks' gestational age and in amniotic fluid.<sup>28-31</sup> Maternal decidual leukocytes, villous macrophages (Hofbauer cells), and endothelial cells stain positive for gp41 antigen and HIV nucleic acids.<sup>32</sup> The placenta can be infected through the CD4<sup>+</sup> trophoblasts or through the occasional occurrence of chorioamnionitis.<sup>33,34</sup> Notably, there is not a clear predictive value for the identification of HIV in the placenta and the infection of the fetus or newborn.<sup>35</sup> Moreover, there are important technical limitations to studies of fetal or placenta tissues, particularly because of the difficulty of excluding contamination with maternal blood.

Several factors that might correlate with a heightened risk for transmission have been assessed, including the maternal viral burden, specific viral phenotypes or genotypes, the disease stage of the mother, her immune response to HIV infection, placental disruption by coexistence of other infections, and fetal susceptibility (which may be influenced by genetic factors).<sup>14-17,36-41</sup> In the absence of prophylactic zidovudine treatment, HIV-positive mothers have a potentially higher risk for transmission if they have mastitis, positive p24 antigenemia, a high HIV RNA or DNA level, and a CD4 count of less than 400 cells/mm<sup>3</sup>.<sup>13,41,42</sup> A high rate of transmission was reported with advanced clinical stage of disease, with 100% transmission among 10 patients with CDC class IV (symptomatic) disease, compared with 13% in 56 patients

with CDC class II (asymptomatic) or CDC class III (lymphadenopathy as only symptom) disease.<sup>43</sup>

### Intrapartum Infection

The bimodal course of disease in HIV-infected children and the fact that at the time of birth virus can only be recovered from less than 25% of the infants who are subsequently shown to be infected suggest that a large proportion of perinatal infections occur late during pregnancy or during delivery.<sup>44</sup> An infant is considered to have been infected in utero if the HIV-1 genome can be detected by polymerase chain reaction (PCR) or be cultured from blood within 48 hours of birth. In contrast, a child is considered to have intrapartum infection if diagnostic assays such as culture, PCR, and serum p24 antigen are negative in blood samples obtained during the first week of life but became positive during the period from day 7 to day 90 and the infant had not been breast-fed.<sup>45</sup>

In a study by the French Collaborative Study Group, timing of transmission was estimated with a mathematical model.<sup>46</sup> Data for the 95 infected infants (those seropositive at 18 months and those who died of HIV disease before this age and who were exclusively bottle-fed) were used in the model, which indicated that one third of the infants were infected in utero less than 2 months before delivery (95th percentile). In the remaining 65% of cases (95% confidence interval [CI], 22%-92%), the date of infection was estimated as the day of birth. Viral markers became positive after an estimated median time period of 10 days (95% CI, 6%-14%), and the 95th percentile was estimated at 56 days.<sup>46</sup>

Discordance of infection has been described among the progeny of different pregnancies and even more intriguingly among twins.<sup>47-50</sup> In a large multinational study, data were collected on 100 sets of twins and one set of triplets born to HIV-seropositive mothers.<sup>49</sup> HIV-1 infection was more common in first-born than in second-born twins ( $P = .004$ ), with 50% of first-born twins delivered vaginally and 38% of first-born twins delivered by cesarean section being infected, compared with 19% of second-born twins delivered by either route. Because passage through or proximity to the birth canal appeared to be an important factor, prophylactic measures such as cleansing the birth canal before delivery were suggested to reduce the risk of intrapartum infection.<sup>51</sup> One study performed in Africa compared the HIV transmission rate of infants born to 3327 women whose infants were delivered in a conventional way with that of 3637 infants of women who were treated with manual cleansing of the birth canal with a cotton pad soaked in 0.25% chlorhexidine on admission for labor and every 4 hours until delivery.<sup>52</sup> Although the intervention had no significant impact on HIV transmission rates (27% in 505 intervention women compared with 28% in 477 control women), cleansing the birth canal with chlorhexidine reduced the hospitalization rates for early neonatal and maternal postpartum infectious problems.<sup>53</sup> In this and two other studies, the concentrations of chlorhexidine were relatively low (0.25% to 0.4%).<sup>54-56</sup> A study of the safety and tolerability of higher concentrations of chlorhexidine for use as peripartum maternal and infant washes demonstrated that a 1% solution was safe and well tolerated, whereas a 2% solution was associated with maternal vaginal and vulvar or perineal burning or itching.<sup>56</sup> Further

studies of the efficacy of the 1% chlorhexidine solution in preventing perinatal HIV transmission are possible.

Cesarean section, although likely to reduce the risk of transmission to a certain degree (in one study from 32% to 18%,  $P = .11$ ), does not prevent it altogether.<sup>37,49</sup> However, one meta-analysis of 15 prospective cohort studies demonstrated a 50% reduction of transmission with elective cesarean section compared with other modes of delivery and an 87% reduction of transmission with both elective cesarean section and receipt of antiretroviral therapy during the prenatal, intrapartum, and neonatal periods compared with other modes of delivery and the absence of therapy.<sup>57</sup> It has been demonstrated that prolonged rupture of membranes over 4 hours increases the risk of transmission considerably, regardless of the mode of delivery.<sup>58,59</sup>

### Postpartum Infection

Breast-feeding has been implicated as a postnatal route of maternal-infant transmission of HIV disease.<sup>60,61</sup> HIV-1 has been demonstrated by culture or PCR in up to 73% of breast milk specimens from HIV-1-seropositive women.<sup>62,63</sup> The prevalence of cell-free HIV-1 appears to be higher in mature milk (47%) than in colostrum (27%;  $P = .1$ ).<sup>64</sup> Guay and colleagues collected expressed breast milk specimens from 201 HIV-1-seropositive and 86 HIV-1-seronegative Ugandan women approximately 6 weeks after delivery. Forty-seven of the 201 HIV-1-infected women had HIV-1-infected children, 143 had children who seroconverted, and 11 had children of indeterminate status. Breast milk supernatants were available for p24 antigen testing from 188 of the HIV-1-infected women, and breast milk cell pellets were available and contained amplifiable DNA in 125 of them (20 transmitters, 104 non-transmitters, 1 indeterminate). HIV-1 DNA was detected by PCR in 72% (75 of 104) of nontransmitters and 80% (16 of 20) of the transmitters.<sup>65</sup> Other studies have also shown that most breast-fed infants appear to remain uninfected.<sup>62,66</sup> A study of breast-fed infants born to HIV-infected mothers was performed in Kinshasa, Democratic Republic of Congo (formerly Zaire).<sup>68</sup> Among 69 HIV-infected children (26% of the cohort), 23% (CI, 14%-35%) were estimated to have had intrauterine transmission, 65% (CI, 53%-76%) intrapartum or early postpartum transmission, and 12% (CI, 5%-22%) late postpartum transmission. The investigators estimated the risks for intrauterine, intrapartum or early postpartum, and late postpartum infection, respectively, to be 6% (16 of 261; CI, 4%-10%), 18% (45 of 245; CI, 14%-24%), and 4% (8 of 189, CI, 2%-8%).<sup>67</sup> Others have estimated that the maximum risk of breast-feeding transmission occurs in the first 6 months,<sup>68</sup> coinciding with a period of maximum benefits of breast-feeding. There is a 5% to 10% risk of transmission from breast-feeding through 6 months of age and an additional 5% to 10% risk from breast-feeding through 18 to 24 months of age.<sup>69</sup> Early weaning at 6 months of age has therefore been proposed as a way to maximize the benefits of breast-feeding while minimizing the risk of HIV infection.

The risk of transmission of HIV-1 by breast-feeding and subsequent associated mortality has been compared with the mortality resulting from bottle-feeding with potentially contaminated water, and it is yielding controversial results. One study demonstrated that the benefits of breast-feeding over bottle-feeding can substantially outweigh the risk of

HIV transmission unless the prevalence of HIV infection is high or the difference in mortality of breast-fed and bottle-fed infants is very low<sup>70</sup>; however, another study did not support this conclusion.<sup>71</sup> The American Academy of Pediatrics (AAP) has issued the following policy statement (abbreviated form)<sup>72</sup>:

*Transmission of human immunodeficiency virus type 1 (HIV-1) through breast-feeding has been conclusively demonstrated. The risk of such transmission has been quantified, the timing has been clarified, and certain risk factors for breast-feeding transmission have been identified. In areas where infant formula is accessible, affordable, safe, and sustainable, avoidance of breast-feeding has represented one of the main components of mother-to-child HIV-1 transmission prevention efforts for many years. In areas where affordable and safe alternatives to breast-feeding may not be available, interventions to prevent breast-feeding transmission are being investigated. Complete avoidance of breast-feeding by HIV-1-infected women has been recommended by the American Academy of Pediatrics and the Centers for Disease Control and Prevention and remains the only means by which prevention of breast-feeding transmission of HIV-1 can be absolutely ensured.*

Several large studies have shown a lack of transmission of HIV infection to household contacts through casual interactions.<sup>73-76</sup> The AAP does not place any special restrictions on daycare or school attendance of HIV-infected children but recommends observance of universal precaution measures for all handling of blood and body fluids, regardless of the infection status of the child.<sup>77,78</sup> The same guidelines apply to the handling of *all* newborns during or after birth. Gloves should be worn when handling body fluids, including amniotic fluid, and only bulb or wall suction devices should be used to avoid exposure of medical personnel.<sup>79</sup>

### MOLECULAR BIOLOGY

HIV-1 is an enveloped virus with a diameter of 80 to 120 nm and a cylindrical, electron-dense core. HIV-1 and its close relative HIV-2 are members of the Lentiviridae family of retroviruses, which have a complex genomic structure.<sup>80,81</sup> Like all retroviruses, HIV-1 contains the genes for *gag*, which encodes the core nucleocapsid polypeptides (gp24, p17, p9), *env* for the surface-coat proteins of the virus (gp120 and gp41), and *pol*, which codes for the viral reverse transcriptase and other enzymatic activities (i.e., integrase and protease). There are at least six regulatory genes: *vif*, *vpr*, *vpx*, *tat*, *rev*, *vpu*, and *nef*.<sup>82</sup> The retroviral core also contains two copies of the viral single-stranded RNA associated with enzymes such as the reverse transcriptase, RNase H, integrase, and protease.<sup>81</sup>

The life cycle of HIV-1 is characterized by several distinct stages.<sup>83</sup> The first step in the entry process of HIV into a cell is the interaction of the virion envelope glycoproteins (gp120 and gp41) with the CD4 molecule and a chemokine receptor.<sup>84-90</sup> Human cord blood mononuclear cells are preferentially infected by macrophage-tropic (M-tropic) strains of HIV-1 using the CC chemokine receptor CCR5.<sup>88,90,91</sup> T cell-tropic strains replicate in CD4<sup>+</sup> T cells and macrophages. They use the chemokine receptor CXCR4, a member of the CXC chemokine family.<sup>84,87,88,90</sup>

The HIV virions enter the cell and are rapidly uncoated. The viral reverse transcriptase transforms the single-stranded viral RNA into linear double-stranded DNA, whereas the less specific ribonuclease H degrades and removes the RNA template.<sup>92</sup> This viral DNA is circularized and transferred to the nucleus, where it is inserted by the viral integrase at random sites as a provirus.<sup>93,94</sup> It is also a common feature of all retroviruses to accumulate large amounts of unintegrated viral DNA that are fully competent templates for HIV-1 core and envelope antigen production.<sup>95</sup> The inactive provirus in the form of HIV-1 DNA has been found in 0.1% to 13.5% of peripheral blood mononuclear cells, compared with viral mRNA, which is found in 0.002% to 0.25% of these cells.<sup>96-98</sup> The latent provirus is activated by host cell responses to antigens, mitogens, cytokines such as tumor necrosis factor, and different gene products of other viruses.<sup>98-101</sup>

HIV gene expression follows by using host cell RNA polymerase II (among other factors), forming a ribonucleoprotein core containing *gag* and *pol* gene products. The 53-kDa precursor of the *gag* protein is cleaved by the HIV-1–derived protease into the p24, p17, p9, and p7 proteins.<sup>102-104</sup> The assembly of new virions consists of the formation of the critical viral enzymes, including reverse transcriptase, integrase, ribonuclease, and a protease, and the aggregation into a ribonucleoprotein core.<sup>80,81</sup> This core then moves to the cell surface and buds as mature virions through the plasma membrane.

Perinatal HIV infection is characterized by plasma RNA levels that rapidly reach very high levels.<sup>105-108</sup> In a study of 106 HIV-infected infants, the median plasma HIV RNA value at 1 month old was 318,000 copies/mL, and it was not uncommon to see viral levels that exceeded 10<sup>6</sup> copies/mL. In the absence of antiretroviral therapy, the levels decrease only gradually over the first 24 to 36 months of life.<sup>109</sup> As in adults, higher viral loads correlate with a more rapid disease progression.<sup>105,110-113</sup> This provides a strong argument for early and aggressive intervention with antiretroviral therapy.

A controversial issue is the proposed clearance of HIV infection in some perinatally infected infants.<sup>114-118</sup> It was postulated that children rarely could have a positive culture of peripheral blood mononuclear cells for HIV-1 and positivity of plasma by PCR assay but later become negative as assessed by culture and PCR and remain seronegative without ever having received antiretroviral therapy. However, analysis of 42 cases of suspected “transient infection” among 1562 exposed seroreverting infants and one mother did not document a phylogenetic linkage between the infant’s and the mother’s virus in 17 cases, did not detect any HIV-1 *env* sequences in 20 cases, or demonstrated that the specimens were mistakenly attributed to the child (6 cases).<sup>119</sup>

## IMMUNE PATHOGENESIS

Infection with HIV results in profound deficiencies in cell-mediated and humoral immunity caused by quantitative and qualitative defects, leading to a progressive dysfunction of the immune system with depletion of CD4<sup>+</sup> T cells. Flow cytometric analysis of lymphocyte subpopulations in healthy children has revealed age-related changes in the number of the different subgroups.<sup>120-122</sup> Comparison of lymphocyte subsets in HIV-infected versus noninfected children younger

than 2 years demonstrated no difference for absolute CD8 counts but clearly decreased levels of CD4 cells.<sup>123</sup> In the absence of early antiretroviral therapy, an abnormal CD4 count (<10th percentile for uninfected children) was found in 83%, and an abnormally low absolute CD4 count was observed in 67% of the infected children. As in adults, the relative risks of death or disease progression are inversely related to the CD4 cell count, which is closely related to the viral load.<sup>107,113,124</sup> A rapid increase in HIV RNA levels correlates with early disease progression and loss of CD4 cells in vertically infected infants.<sup>124</sup>

Other immune abnormalities include decreased lymphocyte proliferation in response to an antigen, polyclonal B cell activation resulting in hypergammaglobulinemia, and altered function of monocytes and neutrophils.<sup>125-128</sup> In the European Collaborative Study, hypergammaglobulinemia (IgG, IgM, and IgA) identified 77% of infected children at the age of 6 months with 97% specificity.<sup>129</sup> In a group of 47 HIV-infected children (17 asymptomatic and 30 symptomatic), Roilides and co-workers<sup>125</sup> found an abnormality of at least one IgG subclass in 83%, including some patients who had IgG2, IgG4, or combined IgG2-IgG4 deficiencies. There was no clear correlation of the incidence of bacterial infections with specific subclass deficiencies. A virus-specific cytotoxic T lymphocyte response can be demonstrated at a very early age, even in the fetus, and becomes more pronounced with longer duration of infection.<sup>130,131</sup>

## DIAGNOSIS

Diagnosis of HIV infection as part of routine prenatal care of pregnant women is very important, because preventive therapies are now widely available, even in developing countries. The CDC recommends voluntary HIV testing for all pregnant women and strongly encourages antiretroviral therapy for HIV-positive pregnant women.<sup>20,21</sup>

Prenatal diagnosis in the fetus is difficult because of the risk for bleeding and contamination of the sample with maternal blood or the possibility for accidental iatrogenic infection of the fetus. Amniotic fluid has been found to be positive for p24 antigen and HIV reverse transcriptase.<sup>28,31</sup> Chorionic villus sampling and percutaneous umbilical blood sampling are associated with a higher risk for the fetus, and noninvasive techniques such as fetal ultrasonography or the clinical assessment of the mother give unspecific and not very predictive information.

The diagnosis of HIV infection in an infant born to a seropositive mother used to pose a problem because of the passive transfer of maternal antibodies. However, measurement of viral RNA or DNA copy numbers and the culture technique have become standardized and are now widely available in industrialized countries.<sup>132</sup> The PCR assay should not be performed on cord blood, because there is a possibility of contamination with maternal blood. However, any positive test should be repeated for confirmation. It is assumed that children who have a positive HIV PCR result within the first 48 hours after birth were infected in utero, whereas those who are infected during the intrapartum period might become positive 2 to 6 weeks after birth. In a study using dried blood spot specimens, a technique yielding equivalent results to fresh blood specimens, only 19% (5 of 26) of infected children

had detectable HIV DNA compared with a sensitivity of 96% (25 of 26) at 1 month old.<sup>133</sup>

In adults and in children older than 18 months, serologic tests for specific antibodies are still important tools to establish the diagnosis of HIV infection, especially if PCR assays or culture methods are not available. HIV-specific antibody is usually detectable within 4 to 24 weeks after initial infection.<sup>134</sup> These antibodies are directed against the envelope proteins gp160, gp120, and gp41; the core proteins p24, p55, and p18; and the enzyme bands p31 and p65/51. The response to the envelope proteins usually persists throughout life, but the antibodies to core (gag) proteins may become lost in more symptomatic patients, and severely hypogammaglobulinemic children do not produce detectable antibodies.<sup>135</sup> Most commercially available enzyme immunoassay tests measure IgG antibodies to HIV. Virtually all children born to seropositive mothers therefore are positive for HIV antibodies at birth, even though only a few are infected. Up to 75% of uninfected children lose these passively transferred antibodies between 6 and 12 months of age, but persistence of maternal antibodies has been documented in 2% up to 18 months of age.<sup>129,136</sup> Tests for IgM antibodies have been problematic, probably because of interaction with abundant IgG and the short duration of IgM production.<sup>137</sup> The 1994 revised CDC guidelines for the diagnosis of HIV infection in infants and children are shown in Table 21-1.

Clinical and nonspecific laboratory parameters may also suggest HIV infection. The newborn HIV-infected child is usually asymptomatic but can become seriously ill within the first weeks to months of life. Table 21-2 provides a diagram outlining the initial evaluation and the necessary follow-up tests for an asymptomatic child born to an HIV-positive mother, as recommended by the AAP.<sup>79</sup> Opportunistic infections, hepatosplenomegaly, and lymphadenopathy are indicators for infection in the antibody-positive child younger than 18 months. Hypergammaglobulinemia is a nonspecific but early finding of HIV infection, and CD4 counts must be interpreted within the bounds of the age-dependent normal range.<sup>120-122,138</sup> Diagnosis is established if an AIDS-defining disease occurs (Table 21-3). In developing countries with limited diagnostic resources, the diagnosis often has to be based on clinical symptoms, and a modified provisional definition for pediatric cases of AIDS has been issued by the WHO.<sup>139</sup>

## CLINICAL MANIFESTATIONS AND PATHOLOGY

HIV infection in infants and children has a different presentation from that in adults, and the CDC classifies HIV infection in children younger than the age of 13 years based on clinical and immunologic parameters (see Table 21-3). Children found to be HIV infected are reported to the CDC only at the time of diagnosis, and tables that list the incidence of certain marker diseases (Table 21-4) are necessarily incomplete because a child may show other symptoms after the initial registration. Growth delay is an early and frequent finding of untreated perinatal HIV infection, and the linear growth is most severely affected in children with high viral loads.<sup>140</sup> Children are more likely than adults to have serious

**Table 21-1 Centers for Disease Control and Prevention Definition of Human Immunodeficiency Virus Infection in Children Younger than 13 Years of Age**

### HIV Infected

- A. A child <18 mo of age who is known to be HIV seropositive or born to an HIV-infected mother  
and  
Has positive results on two separate determinations (excluding cord blood) from one or more of the following HIV detection tests:
- HIV culture
  - HIV polymerase chain reaction
  - HIV antigen (p24)
- or
- Meets criteria for AIDS diagnosis based on the 1987 AIDS surveillance case definition
- B. A child >18 mo of age born to an HIV-infected mother or any child infected by blood, blood products, or other known modes of infection who
- Is HIV antibody positive by repeatedly reactive EIA and confirmatory test (e.g., Western blot or immunofluorescence assay)
- or
- Meets any of the criteria in A

### Perinatally Exposed (Prefix E)

A child who does not meet the criteria above and who:

- Is HIV seropositive by EIA and confirmatory test and is <18 mo of age

or

- Has unknown antibody status but was born to a mother known to be HIV infected

### Seroreverter (SR)

A child who is born to an HIV-infected mother and who:

- Has been documented as HIV-antibody negative (i.e., two or more negative EIA tests performed at 6-18 mo of age or one negative EIA test performed after 18 mo of age)

or

- Has had no laboratory evidence of infection

and

- Has not had an AIDS-defining condition

EIA, enzyme immunoassay.

Adapted from 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR Morb Mortal Wkly Rep* 431:1-10, 1994.

bacterial infections, and lymphocytic interstitial pneumonitis is almost entirely restricted to the pediatric age group. However, toxoplasmosis, cryptococcal infection, and the occurrence of cancer, especially Kaposi's sarcoma, are less common in HIV-infected children.

The initial symptoms may be subtle and sometimes difficult to distinguish from manifestations caused by drug use during pregnancy, from problems associated with prematurity, or from congenital infections other than HIV. Premature birth has been reported in 19%, with no difference between children born to drug-using mothers and children of mothers who were infected through other routes.<sup>129,141</sup> However, children of drug-addicted mothers had significantly lower birth weights and smaller head circumferences.

Common clinical features seen during the course of HIV infection are lymphadenopathy, fevers, malaise, loss

**Table 21–2 Evaluation Schedule for Asymptomatic Infants Born to Human Immunodeficiency Virus–Seropositive Mothers**

Test	Age								
	Birth	2 wk	4 wk	6 wk	2 mo	3 mo	4 mo	5 mo	6 mo
History <sup>a</sup> , physical examination (including weight, height, head circumference)	+	+	+	+ <sup>b</sup>	+	+	+	+	+
Developmental testing	(+)		+		+	+	+	+	+
Complete blood cell test and platelets	+		+	+	+	+	+		+
Serum chemistry (blood urea nitrogen, creatinine, liver function tests)	+			+		+	+		+
Serum immunoglobulins							+		+
Lymphocyte subsets <sup>c</sup>			+			+			+
HIV peripheral blood culture and/or polymerase chain reaction <sup>d</sup>	+		+				+		+
Urine for cytomegalovirus	+				+				
Chest radiograph, computed tomography or magnetic resonance imaging of head <sup>e</sup>									(+)
Electrocardiogram or echocardiogram <sup>e</sup>									(+)

<sup>a</sup>The frequency of "common" pediatric problems, such as diaper rash, mucocutaneous *Candida* infection, diarrhea, otitis, and so on should be carefully monitored.  
<sup>b</sup>Zidovudine to prevent perinatal transmission is discontinued at 6 wk of age; however, strongly consider initiation of other antiretroviral therapy in a child who is proved to be infected. Initiate prophylaxis for *Pneumocystis pneumonia* (PCP).  
<sup>c</sup>T cell profile should be repeated at 6 mo if infection status is unclear at 6 mo.  
<sup>d</sup>Repeat PCR or viral culture immediately if positive to confirm infection. If the initial test is negative, repeat test at 4 wk to 2 mo (earlier if clinical or laboratory parameters suggest infection).  
<sup>e</sup>Optional in the absence of clinical symptoms.

**Table 21–3 1994 Centers for Disease Control and Prevention Revised Classification System for Human Immunodeficiency Virus (HIV) Infection in Children Younger than 13 Years of Age**

Using this system children are classified according to three parameters: infection status, clinical status, and immunologic status. The categories are mutually exclusive. Once classified in a more severe category, a child is *not* reclassified in a less severe category even if the clinical or immunologic status improves.<sup>a</sup>

**Pediatric HIV Virus Classification**

Immune Categories	Clinical Categories			
	(N) No Symptoms	(A) Mild Symptoms	(B) <sup>b</sup> Moderate Symptoms	(C) <sup>b</sup> Severe Symptoms
(1) No suppression	N1	A1	B1	C1
(2) Moderate suppression	N2	A2	B2	C2
(3) Severe suppression	N3	A3	B3	C3

**Immunologic Categories Based on Age-Specific CD4<sup>+</sup> T Lymphocyte Counts and Percent of Total Lymphocytes**

The immunologic category classification is based on age-specific CD4<sup>+</sup> T lymphocyte count or percent of total lymphocytes and is designed to determine severity of immunosuppression attributable to HIV for age. If either CD4 count or percent results in classification into a different category, the child should be classified into the more severe category. A value should be confirmed before reclassified into a less severe category.

Immunologic Category	Age Groups		
	0-11 mo	1-5 yr	>6 yr
(1) No suppression	>1500 cells/μL (>25%)	>1000 cells/μL (>25%)	>500 cells/μL (>25%)
(2) Moderate suppression	750-1499 cells/μL (15-24%)	500-999 cells/μL (15-24%)	200-499 cells/μL (15-24%)
(3) Severe suppression	<750 cells/μL (<15%)	<500 cells/μL (<15%)	<200 cells/μL (<15%)

**Clinical Categories for Children with HIV Infection**

**Category N: Not Symptomatic**

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in Category A

**Category A: Mildly Symptomatic**

Children with two or more of the conditions listed below but none of the conditions listed in Categories B and C

- Lymphadenopathy (>0.5 cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis

**Table 21–3 1994 Centers for Disease Control and Prevention Revised Classification System for Human Immunodeficiency Virus (HIV) Infection in Children Younger than 13 Years of Age—continued**

**Clinical Categories for Children with HIV Infection (continued)**

- Parotitis
- Recurrent or persistent respiratory infection, sinusitis, or otitis media

**Category B: Moderately Symptomatic**

Children who have symptomatic conditions other than those listed for Category A or C that are attributed to HIV infection. Examples of conditions in clinical Category B included but are not limited to:

- Anemia (<8 g/dL), neutropenia (<1000/mm<sup>3</sup>), or thrombocytopenia (<100,000/mm<sup>3</sup>) persisting >30 d
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal thrush, persisting for >2 mo in children >6 mo of age
- Cardiomyopathy
- Cytomegalovirus infection, with onset before 1 mo of age
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus stomatitis, recurrent (more than two episodes within 1 yr)
- Herpes simplex virus bronchitis, pneumonitis, or esophagitis with onset before 1 mo of age
- Herpes zoster (shingles) involving at least two distinct episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Persistent fever (lasting >1 mo)
- Toxoplasmosis, onset before 1 mo of age
- Varicella, disseminated (complicated chickenpox)

**Category C: Severely Symptomatic**

Children who have any condition listed in the 1987 surveillance case definition for AIDS, with the exception of lymphoid interstitial pneumonia

- Serious bacterial infections, multiple or recurrent (i.e., any combination of at least two culture-confirmed infections within a 2-yr period, of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal body organ or body cavity, excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections)
- Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs)
- Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar nodes)
- Cryptosporidiosis or isosporidiosis with diarrhea persisting >1 mo
- Cytomegalovirus disease with onset of symptoms at age >1 mo (other than liver, spleen, or lymph nodes)
- Encephalopathy (at least one of the following progressive findings present for at least 2 mo in the absence of a concurrent illness other than HIV infection that could explain the findings): (a) failure to attain or loss of development milestones or loss of intellectual ability verified by standard developmental scale or neuropsychological tests; (b) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computed tomography or magnetic resonance imaging (serial imaging is required for children <2 yr of age); (c) acquired symmetrical motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance
- Herpes simplex virus infection causing a mucocutaneous ulcer that persists for >1 mo or bronchitis, pneumonitis, or esophagitis for any duration affecting a child >1 mo of age
- Histoplasmosis, disseminated (other than or in addition to lungs or cervical lymph nodes)
- Kaposi's sarcoma
- Lymphoma, primary, in brain
- Lymphoma, small, noncleaved cell (Burkitt's), or immunoblastic or large cell lymphoma of B cell or unknown immunologic phenotype
- *Mycobacterium tuberculosis*, disseminated or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated (other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Mycobacterium avium-intracellulare* complex or *Mycobacterium kansasii*, disseminated (other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Pneumocystis carinii* pneumonia
- Progressive multifocal leukoencephalopathy
- *Salmonella* (nontyphoid) septicemia, recurrent
- Toxoplasmosis of the brain with onset >1 mo of age
- Wasting syndrome in the absence of a concurrent illness other than HIV infection that could explain the following findings: (a) persistent weight loss >10% of baseline or (b) downward crossing of at least two of the following percentile on weight-for-height chart on two consecutive measurements >30 d apart plus (a) chronic diarrhea (i.e., at least two loose stools per day for >30 d) or (b) documented fever (for >30 d, intermittent or constant)

<sup>a</sup>Children whose HIV infection status is not confirmed are classified by using the grid with a letter E (for vertically exposed) placed before the appropriate classification code (e.g., EN2).

<sup>b</sup>Both category C and lymphoid interstitial pneumonitis in category B are reportable to state and local health departments as acquired immune deficiency syndrome.

From Centers for Disease Control and Prevention. Recommendations of the U.S. Public Health Service Task Force on the use of zidovudine to reduce perinatal transmission of human immunodeficiency virus. MMWR Morb Mortal Wkly Rep 43:1-20, 1994.

**Table 21-4 Acquired Immunodeficiency Syndrome Indicator Diseases Diagnosed in 8086 Children Younger than Age 13 Years Reported to the Centers for Disease Control and Prevention Through 1997**

Disease	No. of Children Diagnosed	Percent of Total <sup>a</sup>
<i>Pneumocystis carinii</i> pneumonia	2700	33
Lymphocytic interstitial pneumonitis	1942	24
Recurrent bacterial infections	1619	20
Wasting syndrome	1419	18
Encephalopathy	1322	16
<i>Candida</i> esophagitis	1266	16
Cytomegalovirus disease	658	8
<i>Mycobacterium avium</i> infection	639	8
Severe herpes simplex infection	370	5
Pulmonary candidiasis	307	4
Cryptosporidiosis	291	4
Cancer	162	2

<sup>a</sup>The sum of percentages is greater than 100 because some patients have more than one disease. From Centers for Disease Control and Prevention (CDC). U.S. HIV and AIDS cases reported through December 1997. HIV/AIDS Surveillance report: year-end edition. MMWR Morb Mortal Wkly Rep 9:1-44, 1997.

of energy, hepatosplenomegaly, respiratory tract infections, and recurrent and chronic otitis and sinusitis. Other commonly encountered characteristics are failure to thrive, sometimes associated with chronic diarrhea; failure to grow; the presence and persistence of mucocutaneous candidiasis; and many nonspecific cutaneous manifestations.

### Infectious Complications

Infections in the HIV-infected newborn or infant can be serious or life threatening. The difficulty in treating these infectious episodes, their chronicity, and their tendency to recur distinguish them from the normal infections of early infancy. It is therefore helpful to document each episode and to evaluate the course and frequency of their recurrences.

#### Bacterial Infections

Recurrent serious bacterial infections such as meningitis, sepsis, and pneumonia are so typical of HIV infection in children that they were included in the revised CDC definition of 1987.<sup>142,143</sup> In a study of 42 vertically infected children, a mean of 1.8 febrile visits per child-year of observation was reported.<sup>144</sup> Eleven of the 27 positive blood cultures grew *Streptococcus pneumoniae*, and 16 grew organisms that were considered central venous line related (coagulase-negative *Staphylococcus*, gram-negative enterics, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Candida* species). This increased incidence of pneumococcal infections has been confirmed by other studies.<sup>145,146</sup>

Infections in the HIV-infected newborn have the same pattern as that seen commonly in the neonatal period. A syndrome of very-late-onset group B streptococcal disease (at the age of 3.5 to 5 months of life) has been described in HIV-infected children.<sup>147</sup> Other rare infections such as congenital syphilis or neonatal gonococcal disease may become more frequent in the future as the incidence rises among pregnant women.<sup>148-150</sup> Congenital syphilis may be missed if serologic tests are not performed on the mother and her child at the time of delivery and repeated later if indicated.

Mycobacterial infections have assumed an increasingly important role in the pathology of the HIV-infected infant and child. Although the number of HIV-infected children with *Mycobacterium tuberculosis* infection is still small, organisms resistant to multiple antituberculosis drugs cultured from adults and children pose a threat not only to other immunocompromised patients but also to health care providers.<sup>151-155</sup> An important issue for the neonatologist is whether the mother is infected with *M. tuberculosis* and may transmit the disease to her child. The diagnosis of *M. tuberculosis* infection is complicated in the HIV-infected patient because of the frequent anergy leading to a negative Mantoux test result even in the presence of infection. To diagnose anergy, a control (e.g., for mumps, *Candida*, or tetanus) should always be placed simultaneously with the Mantoux test.<sup>154,156</sup> Treatment of *M. tuberculosis* infection in children is complicated by the lack of pediatric formulations but usually includes isoniazid, rifampin, and during the first 2 months, pyrazinamide.<sup>157</sup>

Infection with *Mycobacterium avium-intracellulare* complex occurs in almost 20% of HIV-infected children with advanced disease and presents as nonspecific symptoms such as night sweats, weight loss, and low-grade fevers.<sup>158,159</sup> Treatment usually consists of three or more drugs (e.g., clarithromycin; ethambutol; rifampin or amikacin, or both; ciprofloxacin; clofazimine) but commonly provides only temporary symptomatic relief and not eradication of the infection. Prophylaxis with clarithromycin or azithromycin should be initiated in infants younger than 1 year with a CD4 count less than 750 cells/mm<sup>3</sup>, in children 1 to 2 years old with a CD4 count less than 500 cells/mm<sup>3</sup>, and in children 2 to 6 years old with a CD4 count less than 75 cells/mm<sup>3</sup>. In children older than 6 years, the adult threshold of 50 cells/mm<sup>3</sup> can be used.<sup>160</sup>

#### Viral Infections

Viral infections are important causes for morbidity and mortality in HIV-infected children. Primary varicella can be unusually severe and can recur as zoster, often presenting with very few, atypical lesions. The virus may become resistant

to standard treatment with acyclovir.<sup>161-163</sup> Cytomegalovirus infection can result in esophagitis, hepatitis, enterocolitis, or retinitis.<sup>164-167</sup> Cytomegalovirus can become resistant to the treatment with ganciclovir, necessitating the use of foscarnet or even combination regimens.<sup>168,169</sup>

Other commonly encountered viruses in the HIV-infected infant and child are hepatitis A, B, and C, often associated with a more fulminant or chronic aggressive course than in the non-HIV-infected patient.<sup>170-172</sup> Hepatitis C infection has been shown to be more common in children born to HIV-infected mothers in some studies,<sup>172</sup> but others have found no association between maternal HIV status and perinatal hepatitis C transmission.<sup>173,174</sup>

Infection with the measles virus is associated with a high mortality in HIV-infected children and often presents without the typical rash and can result in a fatal giant cell pneumonia.<sup>175-178</sup> Infection with respiratory syncytial virus or adenovirus, alone or in combination, can also result in rapid and sometimes fatal respiratory compromise and in chronic or persistent viral shedding or infection.<sup>179-181</sup>

An interesting observation is the occurrence of a polyclonal lymphoproliferative syndrome, often associated with evidence of primary or reactivated Epstein-Barr virus infection. These patients develop impressive lymphadenopathy and sometimes have concurrent lymphocytic interstitial pneumonitis or parotitis.<sup>182</sup> The distinction between a self-limited, benign hyperproliferation and the development of a monoclonal lymphoid malignancy is crucial for determining treatment and prognosis.

### **Fungal and Protozoal Infections**

Oral candidiasis is common even in healthy, non-HIV-infected newborns and infants. However, infection beyond infancy, involvement of pharynx and esophagus, and persistence despite treatment with antifungal agents are more typical for the immunocompromised child. Disseminated candidiasis is, however, uncommon in the absence of predisposing factors such as central venous catheters or total parenteral nutrition.<sup>183</sup>

Infection with *Cryptococcus neoformans*, although common in adults with HIV infection, is less common in children.<sup>184,185</sup> Colonization with *Aspergillus* species and invasive disease has been described in adult patients with HIV infection, and we have observed at least one infant with perinatally acquired HIV infection and associated myelodysplastic syndrome who developed fatal pulmonary aspergillosis.<sup>186-188</sup> The incidence of other fungal infections varies with the prevalence of the organism in the specific geographic area. Disseminated histoplasmosis as the AIDS-defining illness has been described in a few infants.<sup>189-191</sup>

Early in the HIV epidemic, *Pneumocystis jirovecii* (formerly known as *Pneumocystis carinii*) pneumonia (PCP) was the AIDS indicator disease in almost 40% of the pediatric cases reported to the CDC.<sup>192</sup> However, this has changed dramatically since the introduction of guidelines for PCP prophylaxis in HIV-exposed infants and HIV-infected children and in 1997 accounted for only 25% of the AIDS cases.<sup>193,194</sup> The peak incidence of PCP in infancy occurs during the first 3 to 6 months of life, often as the first symptom of HIV infection. Presumably, this represents primary infection in these infants. At least one case of maternal-fetal transmission of PCP has also been documented.<sup>195</sup>

Most children with PCP present with an acute illness, hypoxemia, and without a typical radiographic picture.<sup>196,197</sup> The diagnosis is usually made by obtaining an induced sputum (which can be done by experienced therapists even in very young children) or by performing a bronchoalveolar lavage, and only rarely is an open lung biopsy necessary.<sup>198,199</sup> Treatment options are high-dose intravenous trimethoprim-sulfamethoxazole (TMP-SMX) or pentamidine as first-line drugs.<sup>200</sup> Early adjunctive treatment with corticosteroids has been beneficial in adults and children with moderate to severe PCP and is commonly recommended for patients with an initial arterial oxygen pressure of less than 70 mm Hg or an arterial-alveolar gradient of more than 35 mm Hg.<sup>201-204</sup>

Unfortunately, PCP has been associated with a mortality of 39% to 65% in infants despite improved diagnosis and treatment.<sup>205,206</sup> In 1991, the CDC issued guidelines for PCP prophylaxis in children, taking into account the age-dependent levels of normal CD4 cell numbers.<sup>207</sup> However, these recommendations were applicable only if a child was known to be HIV infected. A survey published in 1995 revealed basically no change between 1988 and 1992 in the incidence of PCP among infants born to HIV-infected mothers.<sup>208</sup> Two thirds of these infants had never received PCP prophylaxis, and 59% of those children were recognized as having been exposed to HIV infection within 30 days or less of PCP diagnosis. Among the infants known to be HIV infected who had a CD4 count performed within 1 month of PCP diagnosis, 18% had a CD4 count higher than 1500 cells/mm<sup>3</sup>, the recommended threshold for initiation of PCP prophylaxis.<sup>208</sup> At the same time, it was shown that primary prophylaxis during the first year of life was highly effective in the prevention of PCP.<sup>209</sup> These pivotal studies led to revised guidelines in 1995.<sup>193</sup> The major new recommendation was that all infants born to HIV-infected women should be started on PCP prophylaxis at 4 to 6 weeks of age, regardless of their CD4 counts. More details are presented in Table 21-5.

The recommended prophylactic regimen is TMP-SMX with 150 mg/m<sup>2</sup>/day of TMP and 750 mg/m<sup>2</sup>/day of SMX given orally in divided doses twice each day during 3 consecutive days per week. If TMP-SMX is not tolerated, alternative regimens are dapsone taken orally (2 mg/kg/day, not to exceed 100 mg) once daily or aerosolized pentamidine. However, breakthrough infections can occur with every regimen and appear to be most frequent with intravenous pentamidine and least common with TMP-SMX.<sup>210,211</sup>

Encephalitis caused by *Toxoplasma gondii* is common in adults with HIV infection but only rarely seen in children.<sup>109</sup> However, several case reports of *T. gondii* encephalitis in infants between 5 weeks and 18 months old have been published. Some of these infants probably acquired toxoplasmosis infection in utero.<sup>213,214</sup> Toxoplasmosis remains an important differential diagnosis in the patient with an intracerebral mass.

Protozoal infections of the gastrointestinal tract often represent difficult diagnostic and therapeutic problems and can be associated with an intractable diarrhea. Infection with cryptosporidia has a prevalence of 3.0% to 3.6% among children with diarrhea.<sup>215</sup> HIV-infected children are at risk for prolonged diarrheal disease with often severe wasting.

**Table 21-5 Recommendations for *Pneumocystis jiroveci* Pneumonia (PCP) Prophylaxis and CD4 Monitoring in HIV-Exposed Infants and HIV-Infected Children**

Age/HIV-Infection Status	PCP Prophylaxis	CD4 <sup>+</sup> Monitoring
Birth to 4-6 wk, HIV exposed or infected	No prophylaxis (because PCP is rare and due to concerns regarding kernicterus with TMP/SMX)	1 mo
4-6 wk to 4 mo, HIV exposed	Prophylaxis	3 mo
4-12 mo	Prophylaxis	6, 9, 12 mo
• HIV infected or indeterminate	No prophylaxis	None
• HIV infection reasonably excluded <sup>a</sup>		
1-5 yr, HIV infected	Prophylaxis if <ul style="list-style-type: none"> <li>• CD4<sup>+</sup> count is &lt; 500 cells/mm<sup>3</sup> or</li> <li>• CD4<sup>+</sup> percentage is &lt; 15%</li> </ul>	Every 3-4 mo (more frequently if indicated)
Older than 6 yr, HIV infected	Prophylaxis if <ul style="list-style-type: none"> <li>• CD4<sup>+</sup> count &lt; 200 cells/mm<sup>3</sup> or</li> <li>• CD4<sup>+</sup> percentage is &lt; 15%</li> </ul>	Every 3-4 yr

<sup>a</sup>Two or more negative HIV diagnostic tests (i.e., HIV culture or polymerase chain reaction), both performed at  $\geq 1$  mo of age and one of which was performed at  $\geq 4$  mo of age, or  $\geq 2$  negative HIV IgG antibody tests performed at  $\geq 6$  mo of age among children without clinical evidence of HIV disease.

HIV, human immunodeficiency virus; TMP/SMX, trimethoprim-sulfamethoxazole.

From Centers for Disease Control and Prevention. 1995 Revised guidelines for prophylaxis against *Pneumocystis carinii* pneumonia for children infected with or perinatally exposed to human immunodeficiency virus. MMWR Morb Mortal Wkly Rep 44:1-12, 1995.

## Malignancies

Several case reports of malignancies associated with HIV infection in infants and children have been published; however, cancer is the AIDS-defining illness in only 2% of children, compared with 14% of the adults.<sup>5,216</sup> The most common cancer in HIV-infected children is non-Hodgkin's lymphoma as a systemic disease or as a primary central nervous system tumor.<sup>217-219</sup> Kaposi's sarcoma has been described in a few children, including a 6-day-old infant, but remains relatively uncommon.<sup>220-222</sup> Leiomyomas and leiomyosarcomas, soft tissue tumors associated with Epstein-Barr virus infection in immunocompromised patients, are increasingly common.<sup>220,223,224</sup>

## Encephalopathy

Encephalopathy, often with early onset, was a frequent and typical manifestation of HIV infection in children before the introduction of antiretroviral therapy. Symptoms of encephalopathy in the newborn or young infant initially include delayed head control or delayed acquisition of a social smile and variable degrees of truncal hypotonia.<sup>225-227</sup> Subsequently, impairment of cognitive, behavioral, and motor functions becomes apparent. Typical findings included a loss of or failure to attain normal developmental milestones, weakness, intellectual deficits, or neurologic symptoms such as ataxia and pyramidal tract signs, including spasticity or rigidity.<sup>228</sup> Seizures are rare but have been described, and cerebrovascular disease resulting in strokes or the formation of giant aneurysms at the base of the brain has been reported.<sup>229,230</sup> The course can be static, wherein the child attains milestones, albeit at a slower rate than normal for age, or the development can reach a plateau and then the child ceases to acquire new milestones. The most severe form is manifested by a subacute-progressive course in which the child loses previously acquired capabilities.<sup>231,232</sup> The older child has impaired expressive language function, whereas

receptive language appears to be slightly less affected.<sup>233,234</sup> Physical examination can reveal hypotonia or spasticity, and microcephaly may be present. Radiologic examination can suggest cerebral atrophy, calcifications in the basal ganglia and periventricular frontal white matter, and decreased attenuation in the white matter (Fig. 21-1).<sup>235-239</sup>

HIV-1 can be found in brain monocytes, macrophages, and microglia, and limited expression of the regulatory gene *nef*, but not of structural gene products, has been demonstrated in astrocytes.<sup>240-243</sup> Analysis of cerebrospinal fluid revealed HIV RNA in 90% of samples, and more than 10,000 copies/mL were associated with severe neurodevelopmental delay.<sup>244,245</sup> It is likely that immune-mediated mechanisms or the secretion of toxic cytokines by infected cells contributes to the pathogenesis of central nervous system disease in AIDS patients.<sup>246</sup> The level of quinolinic acid, a neurotoxin that has been implicated in the development of HIV-related encephalopathy, is elevated in children with symptomatic central nervous system disease and decreased during treatment with zidovudine.<sup>247,248</sup>

Postmortem examination shows variable degrees of white matter abnormalities, calcific deposits in the wall of blood vessels of the basal ganglia and the frontal white matter, and subacute encephalitis. At least one report described an HIV-related meningoencephalitis in a newborn, supporting the assumption of an intrauterine infection.<sup>249</sup> Spinal cord disease, manifested by vacuolar myelopathy, has been described in children but is less common than in adults.<sup>250</sup>

Dramatic improvements in the degree of encephalopathy have been achieved by treating the children with zidovudine, especially when given as a continuous intravenous infusion (see later).<sup>251</sup> Therapy with corticosteroids has also been shown to be beneficial in some patients.<sup>252</sup>

## Ophthalmologic Pathology

The ophthalmologic complications associated with HIV infection can be particularly devastating. HIV-1 can infect

**Figure 21-1** Computed tomographic scans of the brains of two infants with HIV-associated encephalopathy. **A**, Cerebral atrophy with enlarged ventricles and widened sulci. **B**, Calcifications in basal ganglia and frontal white matter.

the retina and manifest as cotton-wool spots on examination, but it rarely leads to impaired vision.<sup>253,254</sup> However, several other pathogens, some of them acquired in utero, can affect the eye and affect visual acuity. Fortunately, the incidence of blindness remains low in pediatric AIDS, but the infections caused by herpesviruses and especially by cytomegaloviral retinitis can be difficult to control and require intensive intravenous treatment.<sup>164,166,167</sup> A few children have been described with congenital toxoplasmosis and associated chorioretinitis, and one of the extrapulmonary manifestations of *P. jirovecii* infection is involvement of the retina.<sup>255-257</sup> Early recognition and aggressive intervention are crucial to prevent progression of visual impairment, and routine ophthalmologic examinations should be part of the care of all HIV-infected children.

### Interstitial Lung Disease

Lymphocytic interstitial pneumonitis, or pulmonary lymphoid hyperplasia, is seen almost exclusively in the pediatric patient with HIV infection and is still included into the CDC definition of AIDS-defining diseases for children younger than 13 years old (see Table 21-3). The incidence of lymphocytic interstitial pneumonitis is difficult to assess but may affect as many as 50% of the HIV-infected children.<sup>258</sup> Clinically, there is a wide spectrum in the severity of this disease; a child may be asymptomatic with only radiologic changes, or he or she can become severely compromised with exercise intolerance or even with oxygen dependency and the need for high-dose corticosteroid therapy. Children with lymphocytic interstitial pneumonitis are at higher risk to develop frequent bacterial and viral infections.<sup>259</sup>

A diffuse, interstitial, often reticulonodular infiltrative process is typically observed on radiologic examination and is sometimes associated with hilar or mediastinal lymphadenopathy (Fig. 21-2).<sup>258</sup> On biopsy, peribronchiolar lymphoid aggregates or a diffuse lymphoid infiltration of the alveolar septa and peribronchiolar areas is seen.<sup>182</sup> Treatment of lymphocytic interstitial pneumonitis is only indicated in

**Figure 21-2** Chest radiograph of an 8-year-old girl with severe lymphocytic interstitial pneumonitis who is oxygen and steroid dependent.

the symptomatic child with hypoxia and consists of oral therapy with corticosteroids, to suppress the lymphocytic proliferation.<sup>258</sup> Lymphocytic interstitial pneumonitis has been associated in some studies with a better prognosis than other HIV-related manifestations such as encephalopathy or PCP, with a median survival of 72 months after diagnosis compared with 1 and 11 months, respectively.<sup>260</sup>

## Cardiovascular Complications

Cardiovascular abnormalities are seen in more than 50% of HIV-infected adults and have been described in children.<sup>261,262</sup> A progressive left ventricular dilatation and an increase in ventricular afterload were demonstrated in a group of 51 children with symptomatic HIV disease but with a normal initial echocardiogram.<sup>262</sup> Clinical manifestations include hepatosplenomegaly, tachypnea, and tachycardia, often with an S<sub>3</sub> gallop or another arrhythmia. Postmortem examination is remarkable for biventricular dilatation with grossly unremarkable valves and coronary arteries and, less frequently, a pericardial effusion. Cardiomyopathy is more commonly found in children with HIV-related encephalopathy (30%) than in those without this manifestation (2%).<sup>227</sup>

Microscopically, a hypertrophy of the myocardium with only rare foci of inflammatory lymphocytic infiltrates is usually present.<sup>263,264</sup> HIV RNA can be demonstrated in only a small number of cells, probably representing macrophages, monocytes, or endothelial cells, but the distribution does not correlate with the structural damage.<sup>265,266</sup>

Another poorly understood phenomenon is the formation of aneurysms of the cerebral and coronary arteries in association with HIV infection.<sup>230,267,268</sup> A child who developed large cerebral aneurysms, leading to hypothalamic dysfunction and neurologic impairment, has been described.<sup>269</sup>

## Pathology of the Gastrointestinal Tract

Dysfunction of the digestive tract is a frequent problem in children with AIDS. In an Italian study of 200 HIV-infected children, Galli and colleagues<sup>270</sup> observed a higher incidence of hepatitis and diarrhea with onset during the first year of life (occurring in 20% to 50% of cases) than at any later time. Commonly encountered pathogens that may cause severe diarrhea are *Cryptosporidium*, *M. avium-intracellulare* complex, *Microsporidium*, *Salmonella*, and *Shigella*.<sup>271</sup> HIV nucleic acids have been found in the feces of children with persistent diarrheal disease.<sup>272</sup> However, many HIV-infected children have a gastrointestinal dysfunction due to disaccharide intolerance, and their clinical status can be improved with careful attention to dietary intake.<sup>272</sup>

Progressive weight loss, anorexia, and sometimes pathogen-negative diarrhea characterize the wasting syndrome often seen in association with HIV disease.<sup>273-276</sup> The cause is not clear but probably represents a combination of a metabolic imbalance with hypermetabolism, disturbed nitrogen balance, and increased cytokine levels. No specific treatment is available, but individual patients may benefit from appetite stimulants, dietary supplements, or parenteral nutrition.<sup>277</sup>

Liver dysfunction resulting from an infection, including that from cytomegalovirus, Epstein-Barr virus, the hepatitis viruses, *M. avium-intracellulare* complex, or HIV-1, is a common feature and can evolve into a chronic hepatitis or cholangitis.<sup>278,279</sup> *Candida albicans* and the herpesviruses are often the cause of infections of the oral cavity and of esophagitis. Esophagitis in the HIV-infected child does not necessarily manifest as the typical symptoms or dysphagia but may be the cause of poor appetite and weight loss. Pancreatitis is a rare complication of HIV infection in children and may occur as the result of opportunistic infections such as cytomegalovirus or as a side effect or therapeutic agents.<sup>280,281</sup>

## Nephropathy

Renal disease in children with HIV infection presents most often as focal glomerulosclerosis or mesangial hyperplasia. In one study, 12 of 155 children between the ages of 7 months and 8 years were found to have proteinuria, and 5 of them developed severe renal failure within a year of diagnosis.<sup>282,283</sup> This nephrotic syndrome is often resistant to treatment with corticosteroids, but cyclosporins may induce a remission.<sup>284</sup> IgA nephritis has been observed in a few HIV-infected children and adults, clinically manifesting as recurrent gross hematuria.<sup>285,286</sup> However, an infection with cytomegalovirus or treatment with the protease inhibitor indinavir can also cause hematuria.<sup>167,287,288</sup>

## Pathology of Endocrine Organs

Failure to thrive or grow is commonly seen in children with HIV infection. In a study of 35 HIV-positive hemophiliacs, a decrease of more than 15 percentile points in height or weight for age was a predictive marker for children who become symptomatic for AIDS.<sup>289-291</sup> Whereas a few patients may have some dysregulation of thyroid function or a lack of growth hormone, often there is no definable endocrine cause recognizable.<sup>292,293</sup> The exception is the child with adrenal insufficiency, which may be caused by cytomegalovirus infection of the adrenal gland.<sup>294</sup> One child with severe salt craving is described who required therapy with fluoro-cortisol. In a study of 167 HIV-infected children, Hirschfeld and associates<sup>295</sup> found low levels of free thyroxine in 18% and increased thyrotropin or thyroid binding globulin levels in 30% of children.

## Involvement of Lymphoid Organs and Thymus

Thymic abnormalities have been found in 3 of 37 fetuses aborted between 20 and 27 weeks' gestation.<sup>296</sup> This may represent the initial injury to the lymphoid system. In children with AIDS, the thymus can show precocious involution, with marked depletion of lymphocytes and loss of corticomedullary differentiation, or a thymitis, characterized by the presence of lymphoid follicles with germinal centers or a diffuse lymphomononuclear infiltration.<sup>297</sup> An interesting phenomenon is the occurrence of multilocular thymic cysts, often detected as an incidental finding.<sup>297</sup> Lymphadenopathy is common among infected children and adults, and lymphoid organs function as reservoirs for HIV-1.<sup>298-301</sup>

## Hematologic Problems

Anemia is the most common hematologic disorder observed in HIV-infected children, with the incidence depending on the severity of HIV disease, the age group, and the use of antiretroviral therapy.<sup>302-304</sup> In a retrospective study of 75 HIV-infected children, 19.7% had anemia at age 6 months, 32.9% at 9 months, and 37.3% at 12 months.<sup>305</sup> Bone marrow aspirate or biopsy specimens may show lymphoid aggregates, some degree of dysplasia, or an ineffective erythropoiesis.<sup>306</sup> Pure red cell aplasia from acute or persistent B19 parvovirus infection has been described in some HIV-infected children and adults and should be considered when the red blood cell production rate is less than expected for the degree of anemia.<sup>307-309</sup>

A white blood cell count of less than 3000 cells/mm<sup>3</sup> has been observed in 26% to 38% of untreated pediatric patients, and neutropenia, defined as an absolute neutrophil count of less than 1500 cells/mm<sup>3</sup>, has been found in 43%.<sup>302-304</sup> This can result from HIV infection, infection with opportunistic pathogens such as *M. avium-intracellulare* complex or cytomegalovirus, or therapy with a myelotoxic drug, including zidovudine.

In the patient population at the National Cancer Institute, a platelet count of less than 50,000 cells/mm<sup>3</sup> was found in 19% of the children; thrombocytopenia has also been described in HIV-infected infants.<sup>310-312</sup> Treatment options are similar to those of noninfected children and include intravenous g-globulins, corticosteroids, and WinRho. However, improvement is often best achieved by optimizing the antiretroviral therapy and decreasing the circulating viral load.

Deficiency of the vitamin K-dependent factors II, VII, IX, and X is common in HIV-infected children and can result in a coagulopathy that is relatively easy to correct. Also commonly seen are autoimmune phenomena, such as lupus anticoagulants and antiphospholipid or anti-cardiolipid antibodies.<sup>313-315</sup> Disseminated intravascular coagulopathy has been described as a complication of fulminant infectious conditions, but there are no data to indicate that this complication occurs more frequently in HIV-infected individuals.

## Skin

Mucocutaneous disease is very common in pediatric HIV infection but often manifests in an unusual or atypical form.<sup>316,317</sup> The most common lesions with an infectious cause are oral thrush and diaper rash (*C. albicans*), chickenpox (acute or chronic), and recurrent shingles (varicella zoster virus), and molluscum contagiosum.<sup>318</sup> Bacterial infections and a highly contagious form of scabies have also been reported with some frequency. Severe seborrheic dermatitis or an unspecific intensely pruritic eczematous dermatitis can pose difficult and frustrating clinical problems, necessitating prolonged therapy. Because of the atypical presentations and wide variety of possible causes, it is often prudent to culture lesions for bacteria or for varicella zoster virus or even to perform a scraping or biopsy. Drug eruptions appear to be more common in HIV-infected patients and can develop into a toxic epidermal necrolysis.<sup>316</sup> However, most drug-related rashes resolve after stopping the causative agent.

## MORBIDITY, MORTALITY, AND PROGNOSIS

Thanks to more effective treatment of HIV infection and associated complications and to improved guidelines for the prophylaxis of opportunistic infections, major decreases in the morbidity and mortality rates of HIV-infected children and adults have occurred. However, infants who are not known to be HIV infected or do not have access to early intervention are still at high risk for early and severe morbidity and continue to have a high mortality rate.<sup>319-321</sup>

Although the course of HIV infection in children is in general more accelerated than in adults, distinct subgroups are noticeable. Perinatally acquired HIV infection follows a bimodal course, with about one third of the children becoming symptomatic within the first 2 years of life and the

remainder in the next several years. Only a minority of patients remains relatively asymptomatic until the age of 8 years or older. In a study of HIV-seropositive and HIV-seronegative women and their newborns in Nairobi, Kenya, no statistically significant difference was found between the groups regarding occurrence of congenital malformations, stillbirths, Apgar score, or gestational age. However, the mean birth weight of singleton neonates of HIV-positive mothers was significantly lower than that of controls.<sup>322</sup> Although not as pronounced, there was also a difference between the height and weight of birth of HIV-infected infants born in the United States compared with uninfected infants.<sup>323</sup> These studies of natural history of perinatal HIV infection were performed before the routine use of antiretroviral therapy in pregnant women and their infants.

In a European study of 392 HIV-infected children, Blanche and colleagues<sup>319</sup> found that 20% of children died or developed an AIDS-defining symptom (CDC category C; see Table 21-3) within the first year of life and 4.7% per year thereafter, reaching a cumulative incidence of 36% by 6 years of age. Two thirds of the children alive at 6 years of age had only minor symptoms, and one third had well preserved CD4 counts (<25%) despite prior clinical manifestations. Children with HIV infection acquired through a transfusion during the neonatal period tend to have a prolonged asymptomatic period.<sup>324</sup>

Both clinical and laboratory factors have been evaluated in regard to their prognostic value. Children born to mothers with low CD4 counts and high viral load tend to progress more rapidly to category C disease or death, emphasizing the importance of diagnosis and adequate treatment of HIV-infected pregnant women.<sup>42,113,325</sup> Early manifestation of clinical symptoms in the infant, especially opportunistic infections, encephalopathy, or hepatosplenomegaly, has repeatedly been associated with a poor prognosis.<sup>305,326,327</sup>

A high virus copy number in the blood has been shown to be a strong predictor for progression of HIV disease.<sup>107,328-330</sup> Infants with very high HIV RNA copy numbers shortly after birth are presumed to have been infected in utero and tend to have early onset of symptoms.<sup>329</sup> Dickover and associates,<sup>329</sup> when calculating HIV-infected infants followed for up to 8 years, found that a 1-log higher HIV-1 RNA copy number at birth increased the relative hazard of developing CDC class A or B symptoms by 40% ( $P = .004$ ), to develop AIDS by 60% ( $P = .01$ ), and the risk of death by 80% ( $P = .023$ ). The peak HIV-1 RNA copy number during the period of primary viremia was also predictive of progression to AIDS (relative hazard 9.9; 95% CI, 1.8%-541%;  $P = .008$ ) and death (relative hazard, 6.9; 95% CI, 1.1%-43.8%;  $P = .04$ ).<sup>329</sup>

## PREVENTION

An important goal in the care of HIV-infected people is the prevention of further infections and especially the transmission from mother to infant. Many countries have initiated large educational programs to halt the spread of the epidemic in the heterosexual community. However, the prevalence of HIV infection is so high in certain populations, especially in developing countries, that a change in behavior results in only a very slow decrease in the number of new infections. Identifying pregnant women who are HIV infected is

essential for the potential initiation of therapy and for the coordination of optimal prenatal care.<sup>330,331</sup>

The birth order and delivery route appear to play a role in the infection rate. In the absence of zidovudine treatment, HIV infection occurred in 35% of first-born twins and 15% of second-born twins who were delivered vaginally, compared with 16% of first-born and 8% of second-born twins delivered by cesarean section.<sup>50</sup> The European Collaborative Study of 1254 HIV-infected mothers and their children estimated that cesarean section resulted in a 50% reduction of the transmission rate.<sup>333</sup> However, there is a potential bias in the indication for cesarean section. Obstetricians may be less likely to perform a surgical procedure in a mother with advanced HIV infection; emergency cesarean section is more common in the case of larger infants (who are less likely to be infected), and monitoring during vaginal deliveries may itself increase the risk for transmission, especially if fetal scalp electrodes are being used.<sup>51</sup> A European randomized clinical trial of 414 women demonstrated decreased perinatal HIV transmission among infants born by cesarean section versus vaginal delivery (1.7% versus 10.6%).<sup>334,335</sup> It has also been demonstrated that prolonged rupture of membranes (>4 hours before delivery) increases the risk for perinatal transmission and should therefore be avoided.<sup>58,59</sup>

The success of the AIDS Clinical Trials Group 076 (PACTG 076) protocol has had a major impact on the prevention of perinatal transmission of HIV-1 and has resulted in guidelines issued by the CDC.<sup>18-21</sup> In that landmark study, pregnant HIV-infected women received oral zidovudine starting at 14 to 34 weeks' gestation and intravenous zidovudine during labor and delivery, whereas the infants were treated with 6 weeks of oral zidovudine post partum (Table 21-6). This resulted in a 67% reduction in the perinatal transmission rate, from 25% to 8.3% ( $P = .00006$ ).<sup>19</sup> It has also been demonstrated that a high maternal plasma

concentration of HIV-1 is a risk factor for transmission to the infant.<sup>13</sup> The identification of HIV-infected pregnant women and their prompt treatment has already led to a marked decrease in the number of newly HIV-infected children in industrialized countries.<sup>336,337</sup>

This treatment regimen is not feasible for developing countries, where 1600 new perinatal infections occur per day. Discussions regarding the ethics of clinical trials in developing countries, especially trials involving a placebo group, occurred early in the course of developing strategies appropriate for developing countries.<sup>338</sup> Ultimately, a number of randomized clinical trials conducted in some of these countries led to a good understanding of the benefits and obstacles in developing effective and sustainable perinatal prevention programs. An attempt to decrease the transmission rate by cleansing the birth canal with dilute chlorhexidine solutions has unfortunately not been successful, although higher concentrations of chlorhexidine have been found to be safe and tolerable and may be studied as potential interventions.<sup>52-56</sup> Results from a study performed in Thailand as a collaboration between the Thailand Ministry of Health and the CDC demonstrated a 50% reduction in perinatal HIV transmission in a non-breast-feeding population.<sup>22</sup> This trial enrolled non-breast-feeding women who were treated with zidovudine (300 mg twice daily) beginning at week 36 of gestation. During labor and delivery, the oral dose of zidovudine was increased to 300 mg every 3 hours; the newborns were not treated. The estimated efficacy of this therapy was 51% (decrease from 18.6% transmission rate in placebo group to 9.2% in treated group). Although this transmission rate is somewhat higher than the one reported with the PACTG 076 regimen, it indicates that a two-part regimen without the intravenous and postnatal component (a more feasible alternative for developing countries) merits further investigation. Other studies, particularly in a variety of African countries, have demonstrated substantial reductions in perinatal transmission, especially with a simple and inexpensive two-dose nevirapine regimen studied in Uganda. This trial (HIVNET 012) demonstrated a 47% reduction in transmission at 14 to 16 weeks of age and a 41% reduction by 18 months of age when the mother was given a single 200-mg nevirapine tablet at the onset of labor and when a single 2-mg/kg oral dose of nevirapine suspension was given to the neonate at 72 hours after birth or at discharge from the hospital.<sup>24,25</sup>

A major challenge in the prevention of perinatal HIV transmission is the management of breast-feeding transmission in settings where replacement feeding is not feasible. The risks of acquiring HIV infection through breast-feeding may be lower than the risk of death from diarrheal diseases and malnutrition in areas where replacement feeding is not available or unsafe. Decision models to determine the optimal choice of interventions to reduce breast-feeding transmission have been proposed.<sup>341</sup> For developing areas of the world, the WHO recommends exclusive breast-feeding through the first 6 months of life with early weaning in countries where replacement feeding is "acceptable, feasible, affordable, sustainable, and safe."<sup>342</sup>

Immunoglobulins of the IgG class are readily transported through the placenta, and passive immunization of the mother may protect the fetus, a model that has been extensively used in the prevention of neonatal hepatitis B infection. Passive

**Table 21-6 Pediatric AIDS Clinical Trials Group 076 Regimen**

Time of Zidovudine Administration	Regimen
Antepartum	100 mg zidovudine five times daily, initiated at 14-34 wk of gestation and continued throughout pregnancy
Intrapartum	During labor, intravenous administration of zidovudine in a 1-hr initial dose of 2 mg/kg, followed by continuous infusion of 1 mg/kg per hr until delivery
Postpartum	Oral zidovudine to the newborn (zidovudine syrup at 2 mg/kg per dose every 6 hr) for the first 6 wk of life, beginning at 8-12 hr after birth. If an infant cannot tolerate oral zidovudine, it can be given intravenously at a dosage of 1.5 mg/kg every 6 hr

From Centers for Disease Control and Prevention. Public Health Service task force recommendations for the use of antiretroviral drugs in pregnant women infected with HIV-1 for maternal health and for reducing perinatal HIV-1 transmission in the United States. *MMWR Morb Mortal Wkly Rep* 47:1-31, 1998.

immunization of the fetus in combination with antiretroviral therapy has been studied in a U.S. study called ACTG 185. Pilot studies evaluating the safety and toxicity of highly purified human immune globulin prepared from asymptomatic HIV-seropositive persons were conducted and demonstrated that HIV immune globulin (HIVIG) appeared to be safe and well tolerated.<sup>339,340</sup> However, the results of ACTG 185 demonstrated no decrease in the perinatal transmission rate because of the widespread concurrent use of antiretroviral therapy among pregnant HIV-infected women in the United States.<sup>343</sup>

## TREATMENT

### Supportive Care and General Management

Optimizing prenatal care, including nutrition, avoidance of drugs and other harmful substances, and recognition and treatment of concurrent infections, is crucial to prevent the premature delivery of children with low birth weight. The general care of the newborn and infant is not different for children born to seropositive mothers, but special attention should be given to the documentation of developmental milestones, frequency and course of infections, and nutritional status.

The AAP recommends routine immunizations with some modifications for all seropositive children, whether they are infected or not.<sup>79</sup> Similar to other newborns, children born to HIV-infected mothers should receive hepatitis B vaccinations, but if the mother is HBsAg positive, the child should also receive HBIG within 12 hours after birth. The current recommendation is that live virus vaccine (oral poliovirus) or live bacterial vaccines (bacillus Calmette-Guérin) should not be given to patients with HIV infection. The exception is MMR, because the risk for measles in immunocompromised children is much higher than the risk associated with the vaccination, although only children with mild to moderate immunosuppression should have the MMR vaccine.<sup>176</sup> However, varicella-zoster immunization is contraindicated in HIV-infected children and adults. A recommended prophylaxis regimen in HIV-infected infants is the administration of intravenous immunoglobulin (IGIV) or specific hyperimmune globulin within 72 to 96 hours after the exposure to varicella-zoster virus or measles.<sup>160,344</sup> Immunization with the conjugated pneumococcal vaccine series may be started at 2 months of age. Alternatively, children older than 2 years with HIV infection should be administered the 23-valent polysaccharide pneumococcal vaccine, and revaccination should be offered after 3 to 5 years in children younger than 10 years and after 5 years in older children.<sup>160</sup> However, prior immunization does not give complete protection from further infection, as has been described for pertussis occurring in previously immunized children.<sup>345</sup>

The monthly administration of IGIV has been studied in asymptomatic and symptomatic children with HIV infection. IGIV has been shown to prevent serious bacterial infections in patients with congenital immunodeficiencies. However, in a group of children who did not receive any antiretroviral treatment, only children with a CD4 count of 200 cells/mm<sup>3</sup> or more appeared to benefit from monthly IGIV administration.<sup>346</sup> A study evaluating children receiving antiretroviral

therapy did not find a statistically significant difference between children who received IGIV and children treated with placebo (albumin), as long as they were also receiving PCP prophylaxis with TMP-SMX. The current recommendation is to use prophylactic IGIV (400 mg/kg per dose every 28 days) in HIV-infected children with hypogammaglobulinemia, poor functional antibody performance (i.e., lack of antibody response after immunizations), or significant recurrent infections despite therapy with appropriate antibiotics.<sup>160</sup>

Prophylactic measurements for the prevention of PCP have been discussed previously. Prophylaxis for *M. tuberculosis* exposure follows the guidelines used for immunocompetent children, but all children born to HIV-infected mothers should have a purified protein derivative test placed at or before 9 to 12 months of age and should be retested every 2 to 3 years.<sup>160</sup> Prophylaxis with clarithromycin or azithromycin for *M. avium-intracellulare* complex infection should be offered to children younger than 12 months if their CD4 count is less than 750 cells/μL, children 1 to 2 years old with CD4 counts less than 500 cells/μL, children 2 to 6 years old with CD4 counts less than 75 μL, and children older than 6 years if the CD4 count is less than 50 cells/μL.<sup>160</sup>

The evaluation and therapy for an infectious complication in the HIV-infected child mandates a high level of suspicion for unusual presentations, an aggressive approach for the establishment of the diagnosis, and the use of intravenous antibiotics, at least during the initial days. Chronic and recurrent infections can compromise the nutritional status of the child and influence the neurodevelopmental state. However, these symptoms are also typical for progressive HIV infection and should be monitored carefully.

### Antiretroviral Therapy—General Guidelines

As our knowledge about the dynamics of viral replication and its implications for disease progression and prognosis has evolved, it has become clear that early and aggressive therapy offers the potential benefit of a prolonged asymptomatic time period. Panels of experts have developed guidelines for the use of antiretroviral agents in children, adolescents, and adults, including pregnant women, with HIV infection.<sup>21,347,348</sup> The indications for the initiation of antiretroviral therapy include clinical, immunologic, and virologic parameters (Table 21-7). Pediatric HIV experts agree that infected infants with clinical symptoms of HIV disease or with evidence of immune compromise should be treated, but there remains controversy regarding treatment of asymptomatic infants with normal immunologic status. Guidelines from The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children recommend initiation of therapy for infants younger than 12 months who have clinical or immunologic symptoms of HIV disease, regardless of HIV RNA level, and consideration of therapy for HIV-infected infants younger than 12 months who are asymptomatic and have normal immune parameters (see Table 21-7). Because of the high risk for rapid progression of HIV disease, many experts would treat all HIV-infected infants younger than 12 months, regardless of clinical, immunologic, or virologic parameters. Other experts would treat all infected infants younger than 6 months old and use clinical and immunologic parameters and assessment of adherence issues for decisions regarding initiation of therapy

**Table 21-7 Indications for the Initiation of Antiretroviral Therapy****Initiation of Therapy**

These recommendations are continuously updated by the Panel on Clinical Practices for Treatment of HIV Infection and reflect the opinions of the Panel. For information on a diversity of recommendations from other HIV experts and for the most up-to-date recommendations, the Panel summary statements can be viewed at <http://aidsinfo.nih.gov/guidelines/>.

**Infants < 12 Months Old**

- All HIV-infected infants < 12 months old, with clinical or immunologic symptoms of HIV disease, regardless of HIV RNA level, should be treated.
- Consideration of therapy should be made for those who are asymptomatic and have normal immune parameters

**Children > 12 Months Old**

- Therapy should be started for all children > 12 months old with AIDS (clinical category C [see Table 21-3]) or severe immune suppression (immune category 3)
- Therapy should be considered for children who have
  - Mild to moderate clinical symptoms (clinical categories A or B [see Table 21-3])
  - Moderate immunologic suppression (immune category 2)
  - And/or confirmed plasma HIV RNA levels  $\geq 100,000$  copies/mL

From Panel on Clinical Practices for Treatment of HIV Infection. Guidelines for the Use of Antiretroviral Agents in HIV-1 Infected Adolescents and Adults. <http://aidsinfo.nih.gov/guidelines/>, accessed January 2004.

in infants 6 to 12 months old. The Working Group recommends that treatment should be started for all children older than 12 months with AIDS (clinical category C) or severe immune suppression (immune category 3) and be considered for children who have mild to moderate clinical symptoms (clinical categories A or B), moderate immunologic suppression (immune category 2), or confirmed plasma HIV RNA levels higher than 100,000 copies/mL (see Table 21-7). Many experts would defer treatment in asymptomatic children older than 1 year with normal immune status in situations in which the risk for clinical disease progression is low (e.g., HIV RNA < 100,000 copies/mL) and when other factors (i.e., concern for adherence, safety, and persistence of antiretroviral response) favor postponing treatment. In such cases, the health care provider should closely monitor virologic, immunologic, and clinical status.

Monotherapy is no longer considered appropriate treatment for the HIV-infected child or adult. The only exception is the use of zidovudine monotherapy in infants of indeterminate HIV status during the first 6 weeks of life as part of the regimen to prevent perinatal transmission. As soon as a child is proved to be infected, therapy should be changed to a combination of agents.<sup>348</sup> Based on results from trials in adults, a recommended three-drug combination provides the best opportunity to preserve immune function and to prevent disease progression. This therapy should include a highly active protease inhibitor plus two dideoxynucleoside reverse transcriptase inhibitors (NRTIs) as the initial therapeutic regimen or two NRTIs and a non-nucleoside reverse transcriptase inhibitor (NNRTI).<sup>348</sup> As of January 2004, 20 antiretroviral drugs were approved for use in the United

States in HIV-infected adolescents and adults; of those, 12 have approved pediatric indications. Therapeutic drugs fall into four major classes based on mechanism of action: nucleoside analogues or nucleotide reverse transcriptase inhibitors (NRTIs, NtRTIs), NNRTIs, protease inhibitors, and fusion inhibitors. More detailed information about these agents can be obtained at the U.S. federal AIDS information website (<http://aidsinfo.nih.gov/guidelines>). The most pediatric experience with NRTIs is with zidovudine (ZDV), lamivudine (3TC), didanosine (ddI), and stavudine (d4T). All are available in a liquid formulation. Dual NRTI combinations are the backbone of highly active antiretroviral therapy (HAART) in adults and children. The combinations of NRTIs with the most data available include zidovudine and didanosine (ZDV/ddI), zidovudine and lamivudine (ZDV/3TC), and stavudine and lamivudine (d4T/3TC). Added to this dual NRTI backbone is an NNRTI or a protease inhibitor. The acceptable NNRTIs for pediatric use are nevirapine or efavirenz (approved for children > 3 years old); efavirenz is not available in a liquid formulation. Delavirdine is the other available NNRTI but is not approved for pediatric use. The one available NtNRTI, tenofovir, is approved only for adult use, and pediatric trials are underway. The protease inhibitors recommended for pediatric use are nelfinavir, ritonavir, and lopinavir plus ritonavir. These are available in powder or liquid formulations. Other protease inhibitors available for pediatric use are available in capsule formulation only and include indinavir, saquinavir, and amprenavir. However, no data are available for the long-term tolerance and efficacy of any of these combinations in children. Certain combinations are not recommended because of overlapping toxicities, including zalcitabine plus didanosine, zalcitabine plus stavudine, and zalcitabine plus lamivudine. The combination of stavudine and zidovudine is not recommended because of their antagonism.

The most commonly used antiretroviral agents in newborns and infants, the NRTIs zidovudine, didanosine, lamivudine, the NNRTI nevirapine, and the protease inhibitors nelfinavir and ritonavir, are briefly reviewed. More extensive reviews are available in specific textbooks or the current recommendations from the CDC and the federal guidelines website (<http://aidsinfo.nih.gov>).<sup>348,349</sup> Because the standards of care are still evolving, collaboration between the child's primary health care provider and an HIV treatment center is strongly suggested. Whenever possible, children should be enrolled in clinical trials; access and information can be obtained by calling 1-800-TRIALS-A (AIDS Clinical Trials Group [ACTG]), or 301-402-0696 (HIV & AIDS Malignancy Branch, National Cancer Institute).

**Zidovudine**

Only limited data are available regarding the appropriate dosing of antiretroviral drugs in the neonate. Zidovudine does cross the placenta and can be measured in amniotic fluid, cord blood, and fetal organs.<sup>350,351</sup> The total body clearance and terminal half-life of zidovudine is similar in nonpregnant women and in women during the third trimester of pregnancy, and the half-life in the neonate is about 10-fold longer than in the mother.<sup>352,353</sup> Elimination of the drug and its main metabolite is markedly prolonged during the first 24 to 36 hours of life, with a mean serum

half-life after maternal ingestion of  $14.4 \pm 7.5$  hours.<sup>350,354-356</sup> The total-body clearance of zidovudine increases rapidly within the first few weeks of life from 10.9 mL/min/kg in infants 14 days old or younger to 19.0 mL/min/kg in older infants ( $P < .0001$ ).<sup>357,358</sup> Oral bioavailability decreases from 89% in the younger group to 61% in infants older than 14 days.

Some studies have demonstrated that zidovudine is incorporated into the DNA of newborn mice and monkeys and into the nuclear DNA of cord blood samples drawn from children whose mothers were being treated with zidovudine.<sup>359,360</sup> Studies of the offspring of mice who had been treated with zidovudine during the last trimester of pregnancy revealed an increased risk for developing tumors of the liver, lung, and reproductive organs. However, a similar study performed by Burroughs Wellcome, the manufacturer of zidovudine, was not able to support these findings. A panel convened by the National Institutes of Health, although acknowledging the validity of the findings, recognized that the benefit of preventing transmission of HIV disease in most children outweighs the potential concerns about carcinogenicity.

Common side effects of zidovudine include bone marrow suppression, myopathy, and liver toxicity.<sup>357,361,362</sup> Severe, unusual toxicity includes lactic acidosis and severe hepatomegaly with steatosis.

The recommended dosage of zidovudine (in combination with other antiretroviral agents as discussed earlier<sup>348</sup>) is as follows:

Premature babies (under study): 1.5 mg/kg per dose given intravenously or 2 mg/kg given orally every 12 hours from birth to 2 weeks of age; then increase to 2 mg/kg per dose every 8 hours at 2 weeks (neonates  $\geq 30$  weeks gestational age) or at 4 weeks (neonates  $< 30$  weeks gestational age)

Neonatal dosage: 2 mg/kg per dose every 6 hours given orally or 1.5 mg/kg every 6 hours administered intravenously

Pediatric dosage: 160 mg/m<sup>2</sup> per dose every 8 hours given orally (range, 90 to 180 mg/m<sup>2</sup> every 6 to 8 hours); intermittent intravenous dosing at 120 mg/m<sup>2</sup> every 6 hours or continuous intravenous dosing at 20 mg/m<sup>2</sup>/hour

### Didanosine

Didanosine has a plasma half-life of about an hour but, in contrast to zidovudine, a lower oral absorption rate (19%  $\pm$  17%) that is further characterized by high interpatient variability and a low penetration rate into cerebrospinal fluid.<sup>363</sup> Some of the variation in bioavailability could be because didanosine is acid labile and has to be taken with an antacid. The amount of antacid necessary to neutralize gastric acidity may vary among patients. Pharmacokinetic data for neonates or young infants are limited because of these problems, but data from the macaque animal model indicate limited transplacental transport.<sup>364-366</sup>

Side effects of didanosine include dose-related peripheral neuropathy, diarrhea, abdominal pain, nausea, vomiting, pancreatitis, retinal depigmentation, and increased liver enzymes.<sup>281,367-369</sup> Cases of lactic acidosis and severe hepatomegaly with steatosis have been reported.

The recommended dosage of didanosine (in combination with other antiretroviral agents as discussed earlier<sup>348</sup>) is as follows:

Premature babies: no data available

Neonatal dosage (infants younger than 90 days old): 50 mg/m<sup>2</sup> per dose every 12 hours given orally

Pediatric dosage: 120 mg/m<sup>2</sup> per dose every 12 hours orally (range, from 90 to 150 mg/m<sup>2</sup> per dose every 8 to 12 hours)

### Lamivudine

Lamivudine has been approved for the use in combination with zidovudine. Lamivudine at doses between 0.5 to 20 mg/kg/day given to children in two daily doses was well tolerated.<sup>370,371</sup> Side effects include hyperactivity (2%), increase in liver function to more than 10 times normal (3%), neutropenia (3%), and reversible pancreatitis (8%). Other less common toxicities include peripheral neuropathy and lactic acidosis with severe hepatomegaly and steatosis. Lamivudine was rapidly absorbed after oral administration and 66%  $\pm$  25% of the oral dose was absorbed.

The recommended dosage of lamivudine (in combination with other antiretroviral agents as discussed earlier<sup>348</sup>) is as follows:

Premature babies: no data available

Neonatal dosage (infants  $< 30$  days old): 2 mg/kg per dose given twice daily orally

Pediatric dosage: 4 mg/kg per dose administered twice daily

### Nevirapine

Nevirapine is also a reverse transcriptase inhibitor but, unlike zidovudine, didanosine, and lamivudine, does not belong to the dideoxynucleoside family of drugs.<sup>372</sup> Nevirapine therapy results in a rapid and marked decrease in HIV-1 RNA concentrations in plasma, which makes it a useful agent for the prevention of vertical transmission.<sup>373</sup> However, a drawback of nevirapine is that resistance develops rapidly during monotherapy because of several possible mutations.<sup>346,374</sup> Nevirapine was well tolerated in pediatric trials.<sup>375,376</sup> At doses of more than 240 mg/m<sup>2</sup>/day, 5 of 10 children experienced a prolonged reduction in p24 antigenemia. Eight infants born to seven HIV-infected mothers were studied after the mothers received 200 mg of nevirapine during labor. The infants were treated with 2-mg/kg oral doses of nevirapine at a mean of 56.6 hours after birth.<sup>377</sup> No side effects were observed in mothers or children, and with a dose of nevirapine during labor and another 48 to 72 hours after birth, nevirapine levels of more than 100 ng/mL (10 times the IC<sub>50</sub>) were achieved throughout the first week of life.

The recommended dosage of nevirapine (in combination with other antiretroviral agents as discussed earlier<sup>348</sup>) is as follows:

Premature babies: no data available

Neonatal dosage (under study in PACTG 356): 5 mg/kg per dose given once daily for 14 days, followed by 120 mg/m<sup>2</sup> every 12 hours for 14 days, followed by 200 mg/m<sup>2</sup> per dose every 12 hours

Pediatric dosage: 120 to 200 mg/m<sup>2</sup> per dose every 12 hours. Note: Therapy should be initiated at 120 mg/m<sup>2</sup> per dose (maximum dose 200 mg every 12 hours) once

daily for 14 days to decrease the risk of cutaneous reactions.

### **Nelfinavir**

Nelfinavir, a protease inhibitor approved for the use in children and adults with HIV infection, was studied in an open-label, uncontrolled clinical trial of 38 children 2 to 13 years old.<sup>378</sup> Nelfinavir should be taken with food to optimize absorption of the drug. The most common adverse event is diarrhea of mild to moderate intensity. Less common toxicities include asthenia, abdominal pain, rash, exacerbation of chronic liver disease, and fat redistribution and lipid abnormalities. Nelfinavir, as with all protease inhibitors, is metabolized by the hepatic cytochrome P-450 enzyme system, which can lead to drug interactions with a variety of commonly used medications.<sup>379</sup>

The recommended dosage of nelfinavir (in combination with other antiretroviral agents as discussed see earlier<sup>348</sup>) is as follows:

Premature babies: no data available

Neonatal dosage (under study in PACTG 353): 40 mg/kg every 12 hours

Pediatric dosage (limited data): 20 to 30 mg/kg per dose three times daily

### **Ritonavir**

Ritonavir, another protease inhibitor approved for use in children, is extensively metabolized by the P-450 enzyme system, and drug interactions are very common.<sup>379</sup> In a phase I/II study performed by the National Cancer Institute, HIV-infected children between 6 months and 18 years old were eligible to enroll at four different dose levels of ritonavir oral solution (250, 300, 350, and 400 mg/m<sup>2</sup> given every 12 hours).<sup>380</sup> Ritonavir was administered alone for the first 12 weeks and then in combination with zidovudine or didanosine, or both. Dose-related nausea, diarrhea, and abdominal pain were the most common toxicities. Less common toxicities include circumoral paresthesias, increase in liver enzymes, fat redistribution, and lipid abnormalities. CD4 cell counts increased by a median of 79 cells/mm<sup>3</sup> after 4 weeks of monotherapy and were maintained throughout the study. Plasma HIV RNA levels decreased by 1 to 2 log<sub>10</sub> copies/mL within 4 to 8 weeks of ritonavir monotherapy, and this level was sustained in patients enrolled at the highest dose level of 400 mg/m<sup>2</sup> for the 24-week period.

The recommended dosage of ritonavir (in combination with other antiretroviral agents as discussed earlier<sup>348</sup>) is as follows:

Premature babies: no data available

Neonatal dosage: no data available but being studied under PACTG 354

Pediatric dosage (limited data): 400 mg/m<sup>2</sup> (range, 350 to 400 mg/m<sup>2</sup>) every 12 hours orally. To minimize nausea and vomiting, initiate therapy at 250 mg/m<sup>2</sup> every 12 hours and increase stepwise over 5 days to full dose.

## **FUTURE GOALS**

The past decade has brought major advances in the understanding, prevention, and treatment of HIV disease.

Application of the PACTG 076 protocol has led to a marked decrease in the perinatal transmission rate of HIV infection in industrialized countries. Better understanding of the interactions between viral load and immunologic status and their implications for prognosis has prompted earlier and more aggressive antiretroviral therapy. The advent of the protease inhibitors and the accelerated approval of antiretroviral drugs both children and adults have broadened the therapeutic armamentarium. However, many problems remain.

The most urgent need continues to be the prevention of further spread of HIV infection among adults and from a mother to her unborn child. Almost 2 decades after the description of the clinical syndrome of AIDS, we are still dealing with an ever-growing pandemic, affecting certain minorities, both sexes, and all age groups and social levels but targeting mainly the developing countries with already limited resources. The staggering demands put on public health systems and their financial resources could easily create tensions regarding the distribution of available funds. Before the widespread use of combination therapy and protease inhibitors, the estimated lifetime cost of hospital-based care for children with HIV infection was \$408,307.<sup>381</sup> Assuming that hospital-based care represents 83% of the total charges, the mean overall lifetime cost would be about \$500,000. The cost of current antiretroviral therapy is even higher and life expectancy longer, although this is partially offset by fewer hospitalizations. It has become very clear that major efforts are needed to make prevention and therapy for HIV infection feasible and affordable for developing nations, because they have the highest numbers of infected people with the fewest financial and organizational resources.

New and different antiretroviral agents are needed because of toxicities and emergence of resistance to provide more effective or even permanent inhibition of viral replication. We need to know the pharmacokinetic properties of drugs when given to the pregnant mother, the neonate, or the very young infant. Progress has been made in the early recognition and prophylaxis of opportunistic infections. However, as patients with HIV infection survive longer, problems with resistant organisms, multidrug allergies, altered organ function, and long-term side effects of medications emerge and complicate adequate therapy.

Advocacy for children and pregnant women, ensuring equal access to new drugs and providing sound data regarding dosing and potential toxicities, continues to be important. The U.S. Food and Drug Administration allows the approval of drugs for use in children based on efficacy data gathered in adults if the disease in children and adults is reasonably similar and if the pharmaceutical companies provide dosing (pharmacokinetic) and safety (toxicity) data from controlled trials performed in an adequate number of children. The treatment and care of HIV-infected children and adults has become increasingly complex, and close collaboration with physicians and centers specialized in their care is highly recommended.

The viruses that cause varicella, zoster, measles, and mumps may complicate the management of a mother, fetus, or newborn when maternal infection with one of these agents occurs during pregnancy or at term. In the United States, because most women of childbearing years are immune to measles and mumps and because there is little opportunity for exposure to these infections because the current population is highly immunized, these diseases posed more problems during pregnancy during the first half of the 20th century than they do now.

Because a licensed varicella vaccine is routinely used in the United States, the incidence of varicella among women of childbearing age can be predicted to decrease in the future. However, the varicella-zoster virus (VZV) still inflicts significant fetal damage as the cause of the congenital varicella syndrome, especially in locations where the vaccine is not being used routinely. Improved methods for control, including better diagnostic methods, antiviral therapy with acyclovir, passive immunization with varicella-zoster immune globulin (VZIG), and use of live-attenuated varicella vaccine, have decreased prenatal and postnatal morbidity from this virus. Understanding of this viral infection at the molecular level, including clarification of the cause of zoster by studies of viral DNA, RNA, and proteins in latency, and study of specific viral

glycoproteins and their importance in the immune response have advanced our knowledge and can be expected to lead to improved therapeutic measures.

**CHICKENPOX AND ZOSTER**

Chickenpox (i.e., varicella) is an acute, contagious disease that most commonly occurs in childhood. It is characterized by a generalized exanthem consisting of vesicles that develop in successive crops and that rapidly evolve to pustules, crusts, and scabs. Zoster (i.e., herpes zoster, shingles) occurs in persons who have previously had chickenpox. It is typified by a painful vesicular eruption usually restricted to one or more segmental dermatomes. An abundance of virologic, epidemiologic, and immunologic evidence has been amassed, indicating that these two illnesses are caused by the same etiologic agent,<sup>1</sup> which therefore was designated VZV. Chickenpox is a manifestation of primary infection with VZV. After the acute infection subsides, VZV, like other herpesviruses, persists in a latent form. For VZV, the site of latent infection is in the dorsal root and cranial nerve ganglia, where certain early viral genes and proteins are expressed in latency.<sup>2-4</sup> VZV may subsequently be reactivated with expression of all of its genes as immunity wanes. The reactivated infection assumes the segmental distribution of the nerve cells in which latent virus resided, giving rise to zoster. A description of the historical recognition of disease caused by VZV follows.

*Varicella* is a modernized Latin word used since at least 1764 and intended to connote a diminutive of the more serious variola (i.e., smallpox).<sup>5</sup> The etymology of chicken in chickenpox is less clear. It may also be a diminutive derived from the French *pois chiche*, or “chick pea,” a dwarf species of pea (*Cicer arietinum*).<sup>5</sup> Other workers doubt this Latin origin and conjecture that the word originated from the farmyard fowl, in which case it has a Teutonic ancestry in the Old English *cicen* and the Middle High German *kuchen*.<sup>6</sup> Herpes has been used to designate a malady since 1398 (“this euyll callyd Herpes”)<sup>7</sup> but derives from the Greek word meaning “to creep”; *zoster* is the Greek and Latin word meaning “girdle” or “belt.” Shingles, from the Latin *cingulus* (meaning “girdle”), was also used in the 14th century as *schingles* to describe “icchyge and scabs wett and drye.”<sup>7</sup>

**The Organism****Classification and Morphology**

The VZV (*Herpesvirus varicellae*) is a member of the herpesvirus family. In addition to a burgeoning number of animal herpesviruses, this group includes eight additional, closely related viruses that infect humans: herpes simplex viruses (HSV) types 1 and 2 (*Herpesvirus hominis*), cytomegalovirus

(CMV), Epstein-Barr virus (EBV), and human herpesviruses 6, 7, and 8. Only one antigenic type of VZV has been identified, but molecular studies have revealed some minor differences in VZV that have proved useful for epidemiologic studies.<sup>8</sup>

Common properties of the family include a DNA genome and enveloped virions exhibiting icosahedral symmetry with a diameter of 180 to 200 nm.<sup>1</sup> Nucleocapsids, which are assembled in the nucleus, have a diameter of about 100 nm and consist of a DNA core surrounded by 162 identical subunits, or capsomeres. Nucleocapsids acquire a temporary envelope at the nuclear membrane; they are further transported by means of the endoplasmic reticulum to the Golgi, where they receive a final envelope. In cell cultures, virions are packaged in vesicles identified as endosomes, which are acidic.<sup>9,10</sup> Virus particles are released from these structures at the cell surface by exocytosis. Extracellular virions are extremely pleomorphic compared with those of HSV. This pleomorphism, presumably reflecting injury to the envelope possibly caused by exposure to acid or enzymes in endosomes, is believed to account for the lability and lack of cell-free virus that characterizes VZV in tissue culture and in its spread through the body during varicella infection, and it distinguishes VZV from HSV.<sup>9-11</sup> In vivo, however, enveloped and well-formed VZV is released from skin cells, yielding highly infectious virions capable of airborne spread and with a great degree of communicability.

Molecular studies have elucidated some details concerning how latent VZV infection is established, maintained, and reactivated. Latent infection probably comes from virions present in skin during varicella. However, it is unlikely that complete viral replication occurs in the neuron during establishment of latency, because the neuron must survive, and replication would cause cell death. The replication process of VZV is begun during latent infection, but a block in the cascade of viral gene expression takes place. About six viral genes and their protein gene products are expressed in latently infected neurons. These proteins are confined to the cell cytoplasm. It appears that when these proteins are transduced into the nucleus by factors still to be determined, reactivation occurs, with production of all 70 VZV gene products and synthesis of infectious, enveloped virions in the nerve and skin.<sup>12,13</sup>

### Propagation

VZV grows readily in diploid human fibroblasts such as WI 38 cells, the most commonly used cell type for virus isolation. VZV also can be propagated in certain epithelial cells, such as human embryonic kidney, primary human amnion cells, primary human thyroid cells, and Vero (African green monkey kidney) cells. Like CMV, the cytopathic effect of VZV is focal in cell culture because of its cell-associated character, and cytopathic effects develop more slowly (3 to 7 days) than with HSV. Animal models for varicella (guinea pigs)<sup>14</sup> and for zoster (rats)<sup>15</sup> have been described. An in vitro model of latency and reactivation in guinea pig enteric neurons has also been developed and provides a setting in which to study factors that influence latency and reactivation.<sup>12</sup>

### Serologic Tests and Antigenic Properties of Varicella-Zoster Virus

Several serologic tests are available to measure antibodies to VZV. These tests include indirect immunofluorescence, often

called *fluorescent antibody to membrane antigen* (FAMA)<sup>16,17</sup>; latex agglutination (LA)<sup>18</sup>; enzyme-linked immunosorbent assay (ELISA)<sup>19-22</sup>; radioimmunoassay<sup>23</sup>; immune adherence hemagglutination<sup>24</sup>; neutralization<sup>19,25</sup>; and complement-enhanced neutralization.<sup>26</sup> All of these methods are more sensitive than the complement fixation assay.<sup>27</sup> Data gathered from these assays show that antibody to VZV develops within a few days after the onset of varicella, persists for many years, and is present before the onset of zoster.

Serologic cross-reactions between HSV and VZV have been described.<sup>28,29</sup> HSV and VZV share common antigens, and similar polypeptides and glycoproteins have been identified for both viruses, but cross-protection has not been observed.<sup>30-32</sup> Rare simultaneous infections with one or more human herpesviruses have been reported.<sup>33,34</sup> Elevations in heterologous antibody titers in apparent HSV or VZV infections may result from cross-reactions of the viruses but also may indicate simultaneous infection by both viruses.

VZV produces at least eight major glycoprotein antigens—B, C, E, H, I, K, L, and M—all of which are on the envelope of the virus and on the surface of infected cells. The glycoproteins and internal antigens, such as the capsid and tegument, stimulate production of neutralizing and other types of antibodies, as well as cellular immunity.<sup>35-37</sup> Antibodies elaborated in varicella and zoster are of the immunoglobulin G (IgG), IgA, and IgM classes.<sup>38,39</sup>

## Epidemiology and Transmission

Chickenpox ranks as one of the most communicable of human diseases. No extrahuman reservoir of VZV is known. Because the supply of susceptible persons, especially in the era before the urbanization of society, would be rapidly exhausted by so contagious a disease, virus latency may have adaptive evolutionary significance in perpetuating infection. In isolated communities, cases of zoster would be responsible for the reintroduction of VZV and its transmission as varicella to new generations of susceptible individuals.<sup>1,40</sup>

### Communicability by Droplets and Contact

Historically, transfer of VZV was believed to occur by way of respiratory droplets, and epidemiologic evidence suggests that transmission can occur before the onset of rash.<sup>41-43</sup> It is rare, however, to isolate VZV from the pharynx of infected patients. A study using polymerase chain reaction (PCR) methods demonstrated that VZV DNA is present in the nasopharynx of a high percentage of children during the early stages of clinical varicella,<sup>44</sup> but PCR does not necessarily indicate the presence of infectious virus. In contrast, the vesicular lesions in varicella and zoster are full of infectious VZV that can readily be cultured. Moreover, in a study of leukemic recipients of live-attenuated varicella vaccine, only those with skin lesions as a side effect of varicella vaccination spread vaccine-type virus to varicella-susceptible close contacts.<sup>45</sup> Similarly, the rare instances of transmission of vaccine virus from healthy vaccinees to other susceptibles occurred only when the vaccinee had a rash.<sup>46</sup> Cell-free VZV virions are known to be copiously produced in skin lesions and are the type of particle that could be aerosolized and involved in viral transmission. It appears that the major source of infectious VZV is the skin, although it is possible that transmission from the respiratory tract can occur.

Airborne spread of varicella has been documented,<sup>47,48</sup> but indirect transfer by fomites has not. VZV DNA has been detected in air samples for many hours in hospitals,<sup>49</sup> but the relation to infectivity of the virus is unclear. Varicella is most contagious at the time of onset of rash and for 1 to 2 days afterward,<sup>50</sup> but the period of infectivity probably encompasses 1 to 2 days before the rash is noticed until 5 days after onset of the rash.

### **Incubation Period**

The usual incubation period for chickenpox is 13 to 17 days, with a mean of 15 days. The extremes are 10 and 21 days, unless passive immunization has been given, in which case the incubation period may be prolonged.<sup>43,51</sup>

### **Relationship between Varicella and Zoster**

It is amply documented that exposure of susceptible persons to zoster may result in chickenpox. Vesicular fluid from patients with zoster produced chickenpox when inoculated into susceptible children.<sup>52,53</sup> Other studies have confirmed that a similar relationship exists under conditions of natural exposure.<sup>54</sup> Claims to the contrary notwithstanding,<sup>55,56</sup> it has not been documented that zoster is acquired from other patients with zoster or chickenpox. Instances that have been reported do not exclude the chance sporadic occurrence of zoster in persons who happen to have been exposed to chickenpox or zoster. It is difficult to reconcile this postulated mode of transmission with current concepts of the pathogenesis of zoster, particularly the strict segmental distribution of lesions and the demonstrated presence of VZV DNA, RNA, and certain viral proteins in ganglia during latency.<sup>2,4,13,57</sup> Studies have also determined that the VZV DNA from zoster isolates is identical to that which caused the primary infection, proving that zoster is caused by reactivation of latent VZV.<sup>58-60</sup>

### **Transplacental Transmission**

In pregnancy, VZV may be transmitted across the placenta, resulting in congenital or neonatal chickenpox.<sup>61</sup> The consequences of transplacental infection are discussed in a later section.

### **Incidence and Distribution of Chickenpox**

The distribution of chickenpox is worldwide. Because vaccination is routine for children in the United States, significant changes in the epidemiology of varicella have occurred, with evidence of personal and herd immunity.<sup>62</sup> Before the vaccine era in the United States, which began in 1995 with vaccine licensure, outbreaks of varicella occurred each year without major fluctuations between years.<sup>63</sup> Although the disease was seen in all months, more cases occurred in the winter and early spring. This seasonal variation was attributed primarily to the gathering of children in school but also may be related to changes in environmental temperature. With introduction of the vaccine, there is less varicella disease occurring in all age groups, and the seasonality of the disease is blurred.<sup>62</sup>

Chickenpox is more contagious than mumps but somewhat less so than measles.<sup>57,64</sup> After exposure within households, 61% of susceptible persons of all age groups (without a history of previous disease) developed chickenpox, compared with 76% for measles and 31% for mumps.<sup>51</sup> Compared with measles, chickenpox is about 80% as infectious in the household but only 35% to 65% as infectious in society. The

reason probably is that chickenpox requires relatively intimate contact for transmission, such as that occurring in the household, whereas in society, there are more casual contacts. Measles may infect efficiently even through casual contacts.<sup>64</sup>

An estimated 4 million cases of chickenpox used to occur yearly in the United States. Varicella remains a nonreportable disease, but this is expected to change as more and more vaccine is used and there are fewer and fewer cases of varicella annually. The disease affects both sexes equally and is most commonly seen in children of early school age. Increasing urbanization was associated with acquisition of the disease at younger ages. In Massachusetts between 1952 and 1961, 29% of children reported with chickenpox were younger than 4 years old, 62% were 5 to 9 years old, 7% were 10 to 14 years old, and less than 3% were older than 15 years.<sup>65</sup> Later data also indicated that varicella is primarily a disease of young children.<sup>66</sup> Between 70% and 80% of young American adults report a history of varicella.<sup>65,67</sup> This compares with histories in the same age group in the prevaccine era of 92% for measles, 45% for mumps, and 31% for rubella. Subclinical varicella is uncommon. Data from family studies indicate that only 8% of adults without a history of varicella develop clinical disease when exposed to their own infected children.<sup>68</sup> The relative importance of faulty memory or past subclinical infection in this secondary attack rate is uncertain.

With the use of sensitive assays for the measurement of antibodies to VZV, it appears that less than 25% of adults with no history of chickenpox are susceptible.<sup>69</sup> Based on a population of adults in which 90% are immune, this suggests a subclinical attack rate of varicella of roughly 7%.

### **Incidence of Chickenpox, Mumps, and Measles in Pregnancy**

Few studies have addressed the incidence of chickenpox, mumps, and measles during pregnancy. In these studies, two questions are posed. First, of all pregnancies, how many are complicated by measles, mumps, or chickenpox? Second, among all reported cases of those diseases, how many occur in pregnant women? In a prospective study of clinically recognized infections that occurred during 30,059 pregnancies between 1958 and 1964, the Collaborative Perinatal Research Study identified approximately 1600 women with presumed viral infections (excluding the common cold).<sup>70</sup> Serologic testing was used to confirm the diagnoses of measles, varicella, and mumps. Taking into account the many possible inaccuracies in such a study, the minimum frequency per 10,000 pregnancies of confirmed cases was 0.6 case for measles, 5 cases for varicella, and 10 cases for mumps.

In another study of maternal virus diseases in New York City between 1957 and 1964, Siegel and Fuerst<sup>71</sup> followed pregnant women for whom a clinical diagnosis of measles, mumps, chickenpox, or other viral infection had been made. Of the 826 virus-infected pregnant women who were identified, 417 were infected with rubella (50.5%), 150 with chickenpox (18.1%), 128 with mumps (15.5%), and 66 with measles (8.0%). Approximately 190,000 pregnancies per year were reported in this population. The calculated attack rates of varicella, mumps, and measles are shown in Table 22-1. The data in these studies are undoubtedly inaccurate because of incorrect clinical diagnoses, underreporting of mild or subclinical infections, and other factors. These figures reflect findings in the prevaccine era, and it seems likely that measles

**Table 22-1 Attack Rates of Various Viral Infections during Pregnancy in the Prevaccine Era<sup>a</sup>**

<sup>a</sup>Based on 3.5 million U.S. births yearly.

occurred less frequently during pregnancy than mumps or chickenpox in the prevaccine era. The probable explanation is that in unvaccinated populations the greater communicability of measles resulted in fewer females reaching childbearing age without already having been infected.

Today, measles and mumps are rare in the United States, and varicella is becoming less common. In highly immunized populations such as exist in the United States, an even lower incidence of infection during pregnancy is predicted for measles, mumps, and varicella. It is possible that the incidence of varicella in pregnant women in the United States is affected by the influx of varicella-susceptible immigrants from countries with tropical climates. A calculation in 1992 projected an incidence of seven cases of varicella per 10,000 pregnancies.<sup>72</sup> Even these crude data, however, indicate that varicella, mumps, and measles are unusual during pregnancy.

The relative rarity of the association of each of these diseases with pregnancy, as indicated by these studies, highlights the difficulties involved in obtaining data on their effect on the outcome of pregnancy compared with a disease with a higher incidence during pregnancy, such as was once true for rubella. Answers can come only from uniform national reporting policies involving many collaborating agencies.

### **Incidence and Distribution of Zoster**

In contrast to chickenpox, zoster is primarily a disease of adults, especially older adults or immunosuppressed patients. Hope-Simpson, describing patients of all ages in a general practice observed during a 16-year period, found an incidence of 3.4 cases per 1000 people per year.<sup>40</sup> Zoster occurs with approximately the same frequency each month, which is compatible with the concept that zoster results from reactivation of latent infection rather than exogenous reinfection with VZV. In the household or hospital, VZV-naïve persons exposed to zoster are not at increased risk of developing zoster but are likely to develop chickenpox in the absence of a previous history of varicella. Zoster "epidemics" have been claimed in special circumstances, such as in a hospitalized leukemic population,<sup>55</sup> but their documentation is not convincing.

Adults and children older than 2 years who have zoster usually give a history of a previous attack of varicella, whereas in younger infants a history of intrauterine exposure to VZV can often be elicited.<sup>40</sup> The latency period between primary infection and zoster is shorter if varicella occurs in prenatal rather than in postnatal life.<sup>73</sup> Chickenpox in the first year of life also increases the risk of childhood zoster, with a relative risk roughly between 3 and 21.<sup>74,75</sup> Possibly, this phenomenon

is caused by immaturity of the immune response to chickenpox in young infants, permitting early viral reactivation.<sup>76</sup>

After infancy, the incidence of zoster rises progressively with age. The attack rate in octogenarians was 14 times that of children in Hope-Simpson's series.<sup>40</sup> Second attacks of zoster are unusual; 8 were observed among 192 cases in the previously cited series.<sup>40</sup> Four of those attacks involved the same dermatome as the first attack, suggesting a tendency for reactivation of VZV from the same ganglion cells in which the virus was dormant. Some of these cases, however, might have been caused by reactivation of HSV; in one study, HSV was isolated from 13% of a series of 47 immunocompetent patients with clinically diagnosed zoster.<sup>77</sup> Zoster in adults and children occurs with increased frequency in patients with malignant hematopoietic neoplasms (especially Hodgkin's disease), after organ transplantation, and in individuals infected with human immunodeficiency virus (HIV).<sup>78-80</sup> Spinal trauma, irradiation, and corticosteroid therapy may also be precipitating factors. The distribution of lesions in chickenpox, which primarily affects the trunk, head, and neck, is reflected in a proportionately greater representation of these regions in the segmental lesions of zoster.<sup>40</sup>

### **Incidence of Zoster in Pregnancy**

Several reports describe the occurrence of zoster during pregnancy, but adequate statistics from which to calculate attack rates are not available. Brazin and associates<sup>81</sup> have projected an incidence of 6000 cases annually in pregnant women, which would mean that gestational zoster is more common than gestational chickenpox. Assuming that there are 3.5 million pregnant women yearly in the United States, this calculates to a rate of 20 cases per 10,000 pregnant women per year. Prospective studies of pregnant women in Sweden, however, have suggested that zoster is less common in pregnancy than varicella.<sup>82</sup> In any case, zoster, like varicella, appears to be a rarity in pregnancy. The severity or natural history of zoster does not appear to be worse in pregnant women than in the population at large. Implications of gestational zoster for the fetus are discussed in a subsequent section.

### **Nosocomial Chickenpox in the Nursery**

The precise risk of horizontal transmission in maternity wards or the newborn nursery after VZV has been introduced is unclear, but based on experience, it is very low. This is in part because maternal immunity plays a role in protection of the infant. About 70% of persons give a history of chickenpox by age 20 years, and still others are immune in the absence of a

positive history, so that most mothers and hospital personnel are not at risk. Many hospital workers require proof of immunity to varicella (or vaccination) for employment. It appears that only 5% to 10% of women born in the United States are susceptible to varicella and that more than 75% of those with no history of chickenpox are immune.<sup>69,83-86</sup> The percentage of susceptible persons among women raised in tropical climates is somewhat higher, probably because viral spread is impeded by high temperatures and the lack of urbanization.<sup>83,87-90</sup>

Because IgG antibodies to VZV cross the placenta,<sup>83,91</sup> the newborn infants of immune mothers should be at least partially protected. Using the sensitive FAMA assay to measure antibodies to VZV in a study of 67 infants, even among children 5 months old, 50% still had detectable VZV antibodies.<sup>83</sup> Even in premature and low-birth-weight infants, antibodies to VZV are likely to be detectable.<sup>92-94</sup> Nevertheless, perinatal chickenpox has been reported rarely in infants born to women with positive histories of chickenpox.<sup>95-99</sup> In Newman's study,<sup>98</sup> varicella developed in a mother and her baby after exposure to a student midwife with chickenpox. The mother had experienced varicella as a child and had a few remaining skin scars; apparently, she had developed a second attack as an adult. Readett and McGibbon<sup>99</sup> reported two cases of extrauterine infection in neonates whose mothers had histories of chickenpox. After delivery at home, each of these infants was exposed within 24 hours of birth to a sibling with chickenpox and subsequently developed skin lesions when 12 and 14 days old, respectively. Their mothers did not develop chickenpox in the perinatal period and were found to have serum-neutralizing antibodies to VZV. In the literature before 1975, VZV antibody titers were not often reported because sensitive tests for measuring these antibodies were not readily available. Since that time, infection of a few seropositive infants after postnatal exposure to VZV has been documented.<sup>95,96</sup> These infants had mothers with a history of varicella, and the VZV antibody in the infants' blood was transplacentally acquired. In one instance, mild varicella developed in a 2-week-old, 1040-g infant who was seropositive at exposure and was also passively immunized with VZIG 72 hours after the exposure.<sup>96</sup> In another study, five infants younger than 2 months old, all of whom were seropositive at exposure, developed varicella in a children's custodial institution.<sup>95</sup> Even when varicella develops in the presence of maternal antibodies, it appears to be modified. Although complete protection of every neonate against chickenpox is not guaranteed by immunity in the mother, protection is the exception rather than the rule.

Not unexpectedly, horizontal transmission of chickenpox in maternity wards and newborn nurseries is an uncommon event. In some reports, lack of transmission is difficult to explain. In 1965, Newman<sup>98</sup> reported two cases of varicella that occurred in mothers in the same prenatal ward 18 to 19 days after exposure to the index-infected infant and its mother. One mother developed chickenpox 7 days ante partum, and the other developed the disease 3 days post partum. Each mother was immediately isolated from the ward but not from her own infant; neither of the infants developed chickenpox. In all, 139 mothers, excluding the index case, were exposed, and 8 developed infection. Three of the 42 staff members also became infected. Remarkably, the index infant was the only neonate infected; all other

infants, including those born to the eight infected mothers, remained free of disease. Gershon and co-workers<sup>83</sup> described an outbreak in which a woman developed varicella post partum and exposed 10 mothers, their infants, 1 antepartum woman, and approximately 25 staff members during a brief period while she was waiting in the hospital corridor. Her infant developed varicella 10 days afterward. About 2 weeks later, three cases of varicella developed in the exposed persons: a hospital employee and a postpartum woman and her infant. Gustafson and colleagues<sup>96</sup> described another mini-outbreak that took place during a 2-month period in a neonatal intensive care unit in which a total of 29 infants were exposed. Two of these infants, whose mothers gave a history of previous varicella, developed chickenpox after exposure to two hospital employees who had been infected nosocomially.<sup>96</sup>

Other reports largely confirm the low rate of transmissibility of chickenpox in neonates. Freud<sup>100</sup> described an infant who had transplacentally acquired disease and developed lesions on the second day of life. None of the other 17 neonates in the nursery became infected, but the index infant had been isolated immediately, so exposure had been very brief.<sup>100</sup> When transferred to another ward, this same infant transmitted the disease to two older children, who were 4 and 7 years old. Odessky<sup>101</sup> reported three instances of congenital varicella: two infants were immediately isolated, but the third was not recognized as having chickenpox and exposed other neonates for 4 days. The number at risk is not stated, but no instances of transmission were observed. In the report of Harris,<sup>102</sup> a total of 35 infants were exposed to two infants with congenital chickenpox for periods of 18 and 10 hours before isolation. None subsequently became infected, possibly because all the mothers had positive histories of chickenpox. In an additional case described by Matseane and Abler,<sup>103</sup> an infant developed transplacentally acquired chickenpox at the age of 9 days and exposed 13 other neonates in the nursery for periods of 2 to 10 hours before isolation. Six mothers had a positive history of varicella, three did not, and four did not know. None of the exposed mothers or infants developed chickenpox. Lack of transmission despite hospital exposure to an adult with varicella in neonatal intensive care nurseries was also reported by Wang and associates (32 infants),<sup>94</sup> Lipton and Brunell (22 infants),<sup>104</sup> Patou and co-workers (15 infants),<sup>105</sup> Mendez and associates (16 infants),<sup>92</sup> and Gold and co-workers (29 infants).<sup>106</sup>

One experience in a neonatal intensive care unit in Mississippi is illustrative.<sup>107</sup> After the development of hemorrhagic varicella in a 25-week-gestation infant whose mother had varicella 2 weeks previously, 14 infants in the unit were exposed over a period of several days. None of the infants in isolettes became ill, but four who were in open warming units at exposure developed varicella 10 days later. All had received VZIG, and in each instance, the mother gave a history of varicella. The illnesses were mild with only a few papular skin lesions, but three of the four infants were positive for VZV on immunofluorescence testing of skin scrapings. Each child with varicella was treated with intravenous acyclovir. The incidence of disease was higher in infants with less than 29 weeks' gestation than in infants with longer gestational periods.

Of historical interest is an extensive epidemic lasting 5 months that was described by Apert in 1895.<sup>108</sup> Two infants in a newborn nursery developed chickenpox on January 7

Table 22-2 Nosocomial Chickenpox Infections in the Nursery

<sup>d</sup>Exposure 1-2 days before rash in index case.

and 8. They were immediately transferred with their mothers to another ward, where they were isolated, but a third infant (second generation of chickenpox) developed disease on January 24 and was likewise isolated with its mother. A fourth infant (third generation) developed varicella on February 7 but was not isolated until February 13 because the mother deliberately obscured the fact that the infant had lesions. Subsequently, a fifth infant (fourth generation) developed chickenpox on February 21. Because the number of infants exposed and the maternal histories of varicella are not stated, the attack rates are unclear. Although this was the last case of chickenpox in the newborn nursery, one of the infected neonates introduced the virus to another ward of 40 to 45 debilitated infants. Before the epidemic was over in May, nine generations of chickenpox separated with mathematical precision by 14 days had occurred. In all, 19 infants, 12 younger than 6 six months, were infected along with two mothers.

These experiences with nosocomial chickenpox in the newborn nursery are summarized in Table 22-2. In the 20th century, in reports in which the number of neonates exposed is explicitly stated, a total of 218 exposures resulted in only eight instances of transmission to infants. Most of the mothers had histories of varicella, although in many the history was unknown. Several factors undoubtedly contribute to the low rate of transmission of disease to neonates: passive immunity in most; relatively brief exposure compared with

that in the household setting, where 80% to 90% of susceptibles become clinically infected<sup>40,68</sup>; and relative lack of intimacy of contact in the nursery, particularly for infants in isolettes.

### Pathogenesis of Varicella and Zoster

In the usual case of chickenpox, the portal of entry and initial site of virus replication is probably the oropharynx, but attempts to demonstrate this directly have been surprisingly unrewarding. In five patients whose blood, throat secretions, and skin were cultured repeatedly during the prodromal period and after the appearance of cutaneous lesions, VZV was recovered from a throat swab in only one instance and from the blood in none. In contrast, vesicle fluid from these patients yielded VZV in all instances.<sup>109</sup> Attempts to isolate the virus from the blood of six additional patients were positive in only one instance: on the second day of rash in an immunosuppressed host. Other, more extensive searches for VZV in throat secretions of patients with varicella, even during the incubation period, proved essentially negative.<sup>110,111</sup> However, in one report, VZV was isolated from nasal swabs in 4 of 11 children on days 2 through 4 after onset of the rash. VZV could not be isolated during the incubation period or even during the first day of the rash. It was not clear whether the virus was multiplying in the nasal mucosa.<sup>112</sup>

VZV has been isolated from blood obtained from patients with varicella. Ozaki and colleagues<sup>113</sup> cultured blood from seven immunocompetent children; VZV was isolated a few days before the onset of rash or within 1 day after onset. Asano and co-workers<sup>114</sup> similarly isolated VZV from the blood of 7 of 12 otherwise healthy patients with early varicella. Those from whom virus could not be isolated had been studied after they had the rash for more than 4 days. Both investigators introduced an additional technical step into the blood culture process that might explain why they were successful in isolating VZV while many others before them had not been. The white blood cells were separated on Ficoll-Hypaque gradients and added to cell cultures. Although there was no evidence of viral growth in these cultures, they were blindly passaged onto new cell cultures. Evidence of growth of VZV was present in these second cultures after the blind passage within 2 to 5 days. Before these studies, VZV had been isolated only from blood obtained from immunocompromised patients with varicella or zoster.<sup>110,115,116</sup> The white blood cell infected with VZV is a mononuclear cell, but it is uncertain whether monocytes or lymphocytes, or both, are involved.<sup>113,114</sup> Experiments in the SCID-hu mouse model have shown that VZV is lymphotropic for human CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes and that human T cells release some infectious virus.<sup>117</sup>

Data from PCR studies of patients with varicella are of interest, although they have yielded various results. In the study of Koropchak and colleagues,<sup>118</sup> performed 24 hours after rash onset in 12 patients, 3.3% of oropharyngeal samples, 67% of mononuclear cells, and 75% of skin vesicles were positive for VZV DNA. In the study by Ozaki and co-workers<sup>119</sup> of pharyngeal secretions of chickenpox patients, 26% and 90% were positive during the incubation period and after clinical onset, respectively.

Virus is readily recovered from cutaneous lesions soon after the onset of chickenpox. Isolation of VZV was successful in 23 of 25 cases in which vesicle fluid was cultured within 3 days after the onset of the rash but was successful in only 1 of 7 specimens collected between 4 and 8 days after onset.<sup>109</sup> In contrast, the virus apparently persists longer in vesicles of zoster patients, in whom 7 of 10 specimens collected later than 3 days after onset were positive.<sup>104</sup> PCR is more sensitive than virus culture. In the study of Koropchak and co-workers,<sup>118</sup> for example, VZV was recovered from only 21% of skin lesions, but 75% were positive by PCR. Unlike smallpox, chickenpox is no longer communicable by the time the lesions have crusted and scabbed.

The pathogenesis of chickenpox appears to be as follows. Transmission is probably effected by airborne spread of virus from cutaneous vesicles and by respiratory droplets from patients with varicella or zoster. After an initial period of virus replication in the oropharynx in the susceptible individual, there is invasion of the local lymph nodes and then a primary viremia of low magnitude, delivering virus to the viscera.<sup>120</sup> After several more days of virus multiplication, a secondary viremia of greater magnitude occurs, resulting in widespread cutaneous dissemination of virus and rash. Cropping of the vesicles is thought to represent several viremic phases. In the body, the virus spreads by cell-to-cell contact; viremia also is cell associated. Enveloped, cell-free infectious VZV is, however, present in the vesicular skin vesicles. Crusting and scabbing of the vesicles and pustules

occur as host defense mechanisms, particularly as various forms of cell-mediated immunity become active. Latency is achieved from the cell-free VZV particles in the skin that are in proximity to sensory nerve endings.

The pathogenesis of zoster is different from that of varicella. Before development of zoster, latent VZV begins to reactivate and multiply in the sensory ganglion (or ganglia) because of unknown local factors.<sup>2</sup> The virus then travels down the axon to the skin supplied by that nerve. Development of a localized rash occurs if there is a deficiency in cell-mediated immunity to VZV.<sup>121-124</sup> This compromise in cell-mediated immunity may be obvious, as in patients who have had transplantation, therapy for malignant disease, or HIV infection,<sup>125</sup> or presumably, it may be transient, as in normal persons who develop zoster for no apparent reason. In immunosuppressed patients, a viremic phase with zoster has been documented occasionally,<sup>126,127</sup> and this probably happens after skin involvement has occurred, especially if there continues to be an inadequate immune response to VZV after the virus has reached the skin. The clinical manifestation of this viremia is disseminated zoster, in which vesicular lesions develop outside the original dermatome. A viremic phase in pregnant patients with disseminated zoster has not been documented, but it seems logical to assume that viremia would be a prerequisite for dissemination.

## Pathology

### Cutaneous Lesions

Histologic changes in the skin leading to the formation of vesicles are essentially identical for chickenpox, zoster, and HSV infection. The hallmark of each is the presence of multinucleated giant cells and intranuclear inclusions, changes that are not found in the vesicular lesions caused by vaccinia virus and coxsackieviruses. The lesion is primarily localized in the epidermis, where ballooning degeneration of cells in the deeper layers is accompanied by intercellular edema. As edema progresses, the cornified layers are separated from the more basal layers to form a delicate vesicle with a thin roof. An exudate consisting primarily of mononuclear cells is seen in the dermis, but the characteristic nuclear changes of epithelial cells are absent in this region.

The predominant cells in vesicular lesions are polymorphonuclear leukocytes. These cells may play a role in generating interferon in vesicular lesions, which may be important in recovery from the disease.<sup>128</sup> In vitro data also suggest that the polymorphonuclear leukocyte plays a role in host defense against VZV, possibly by mediating antibody-dependent cell-mediated cytotoxicity (ADCC).<sup>129-131</sup>

### Visceral Lesions in the Fetus and Placenta

Few reports describe the appearance of the placenta in cases of congenital chickenpox with or without survival. Garcia<sup>132</sup> observed grossly visible necrotic lesions of the placenta in a case of chickenpox occurring in the fourth month of pregnancy that resulted in spontaneous abortion. Microscopically, central areas of necrosis were surrounded by epithelioid cells and rare giant cells of the foreign body type, giving a granulomatous appearance. Peripherally, these lesions in the villi were accompanied by an exudate of necrotic material, nuclear fragments, and leukocytes filling the intervillous spaces. Some decidual cells had typical intranuclear inclusions.

**Table 22-3 Frequency of Gross and Microscopic Lesions in Seven Autopsied Cases of Fetal and Neonatal Chickenpox**

Organ	No. of Cases/No. Examined	Percent	References

Bone marrow	1		135
Placenta	1		132

<sup>a</sup>Not well documented; possibility of concomitant toxoplasmosis not definitely excluded.

Descriptions of the pathology of visceral lesions in fetal or neonatal chickenpox are necessarily restricted to autopsies in fatal cases.<sup>132-137</sup> Grossly, the lesions are small, punctate, white or yellow, and resemble miliary tuberculosis. Microscopically, their appearance resembles that of the lesions of the placenta: central necrotic areas, often resembling fibrinoid necrosis, surrounded by a few epithelioid cells and a scant infiltrate of mononuclear cells. Intranuclear inclusions are present. The skin, lungs, and liver are uniformly involved (Table 22-3). Slightly less frequently, the adrenals, gastrointestinal tract mucosa, and thymus are also involved. Less often, lesions appear in the kidneys, spleen, pancreas, and heart. Only one report describes necrotic foci in the brain.<sup>132</sup> In this case, the cortical, subependymal, and basilar structures of the cerebrum were totally destroyed and accompanied by extensive calcification. Although a search for *Toxoplasma* was negative, serologic data to rule out dual infection are lacking in the report. The gross and microscopic lesions of fatal perinatal chickenpox resemble those of disseminated HSV infection, including a preference for the liver and adrenal gland, but the provided data suggest that involvement of the brain is more common in neonatal HSV infection than it is in fatal neonatal chickenpox. A neonate with fatal hemorrhagic varicella with pneumonia and hepatitis is shown in Figure 22-1.

#### Visceral Lesions in the Mother

In fatal cases of chickenpox in pregnant women, maternal death is usually caused by pulmonary involvement. The pathologic course of chickenpox pneumonia in pregnant women is identical to that in nonpregnant women and in children.<sup>138,139</sup> The lungs are usually edematous and congested. Interstitial pneumonitis may follow a peribronchiolar distribution of disease. Edema, septal cell proliferation, and infiltration of the alveolar septa by mononuclear leukocytes occur. Intranuclear inclusions may be found in alveolar lining cells, macrophages, capillary endothelium, and tracheobronchial mucosa. Necrotic foci may be accompanied by hemorrhage, and hyaline membranes lining the alveoli are often prominent.

**Figure 22-1** Congenital hemorrhagic varicella complicated by pneumonia and hepatitis. The mother of this infant developed varicella a few days before delivery. Zoster immune globulin was not available at that time. *Inset* shows a section of liver with intranuclear inclusion bodies obtained at autopsy.

#### Zoster

The pathologic picture of cutaneous lesions in zoster is indistinguishable from that of chickenpox lesions. The dorsal

root ganglion of the affected dermatome exhibits a mononuclear inflammatory infiltrate. There may also be necrosis of ganglion cells and demyelination of the corresponding axon. There are no descriptions of these lesions in pregnant women or in neonates specifically.

## Clinical Manifestations

### Chickenpox Rash

After an incubation period of usually 13 to 17 days,<sup>40,65</sup> chickenpox is heralded by the approximately simultaneous occurrence of fever and rash. In adults, the exanthem is often preceded by a prodromal fever and constitutional symptoms lasting 2 or 3 days.<sup>6</sup> Occasionally, one or more isolated vesicles may precede a generalized exanthem by 1 or 2 days. The rash is characteristically centripetal, beginning on the face or scalp and spreading rapidly to the trunk, but with relative sparing of the extremities. The lesions begin as red macules but progress quickly to vesicles and crusts. Itching is the rule. There is a tendency for new lesions to occur in crops. Unlike smallpox, all stages of lesions—vesicles, pustules, and scabs—may occur simultaneously in the same anatomic region. New crops often continue to appear over a 2- to 5-day period. Lesions may be more numerous in skin folds or in the diaper area. The total number of vesicles varies from only two or three in very mild cases, especially in infants, to thousands of lesions that border on confluence, especially in adults.<sup>6</sup> In many cases, one or two mucosal lesions may occur in the mouth or, less commonly, on the vulva. Occasionally, the lesions may be bullous or hemorrhagic. Residual scarring is exceptional. Constitutional symptoms tend to be mild even in the presence of an extensive exanthem.

### Complications of Chickenpox

The most common complication is secondary bacterial infection, usually caused by streptococci or staphylococci. Skin infections may lead to severe sequelae such as toxic shock syndrome and necrotizing fasciitis.<sup>140-148</sup> Septicemia was observed in 0.5% of 2534 cases seen at the Willard Parker Hospital from 1929 to 1934.<sup>149</sup> Central nervous system complications, which are uncommon, include encephalitis, cerebellar ataxia, aseptic meningitis, and myelitis.<sup>150,151</sup> Glomerulonephritis,<sup>152,153</sup> myocarditis,<sup>154,155</sup> and arthritis<sup>156,157</sup> have also been reported.

### Chickenpox in Immunocompromised Children

It is widely appreciated that varicella may be severe and even fatal in children with an underlying malignancy, those with congenital deficits in cellular immunity, those receiving high doses of corticosteroids for any reason,<sup>158</sup> and children with underlying infection with HIV and the acquired immunodeficiency syndrome (AIDS).<sup>80,159</sup> Leukemic children have a mortality rate approaching 10% if untreated<sup>160</sup> and may develop what has been called *progressive varicella*. Instead of developing new vesicular lesions for several days, they continue to have fever and new lesions for as long as 2 weeks after the onset of illness. Frequently, their skin lesions become hemorrhagic, large, and umbilicated. Varicella pneumonia often ensues and is a major factor contributing to the death of a child. It is believed that this abnormal response to VZV represents a failure of the normal cell-mediated immunity

response to eliminate the virus.<sup>160</sup> The cell-mediated immunity response to VZV includes ADCC, natural killer cells, and cytotoxic T cells, including CD4 and CD8 cells.<sup>35,129-131,161-163</sup>

### Chickenpox Pneumonia

Primary varicella pneumonia is a dreaded complication of chickenpox and is responsible for most fatalities. It is most common in immunocompromised patients, in adults, and in most fatal cases of neonatal chickenpox,<sup>132-134,164</sup> but it is rarely seen in otherwise healthy children. It has been suggested that the incidence is about 15% in adults and that 90% of cases have occurred in persons older than 19 years.<sup>164,165</sup> The true incidence is difficult to determine because chest radiographs are not performed in most cases of chickenpox and extensive radiographic evidence of disease may be present when pulmonary symptoms are only minimal. In male military recruits with varicella, virtually all of whom had been hospitalized and had chest radiographs, radiographic evidence of pneumonia was found in 16.3% of 110 cases.<sup>166</sup>

Two reviews of chickenpox pneumonia in adults outline the major features.<sup>139,167</sup> The onset of pneumonia usually occurs in 2 to 4 days but sometimes occurs as long as 10 days after the appearance of the exanthem. Fever and cough are present in 87% to 100% of cases, and dyspnea occurs in 70% to 80%. Other symptoms and signs include cyanosis (42% to 55%), rales (55%), hemoptysis (35% to 38%), and chest pain (21%). Radiographic changes seem to correlate best with the severity of the rash rather than with the physical examination of the lungs. The radiograph typically reveals a diffuse nodular or miliary pattern, most pronounced in the perihilar regions. The radiographic appearance changes rapidly. The white blood cell count varies between 5000 and 20,000 cells/mm<sup>3</sup> and is of little help in differentiating viral from secondary bacterial pneumonia. Pneumonia is usually self-limiting, and recovery is temporally correlated with clearing of skin lesions. The fatality rate has been variously estimated at 10% to 30%, but it probably approximates the lower of these values if immunocompromised hosts are excluded.<sup>139,167</sup> Blood gas analyses and pulmonary function tests indicate a significant diffusion defect that may persist in some cases for months after clinical recovery.<sup>168</sup> The introduction of antiviral chemotherapy has greatly improved the outcome in this disease.

### Maternal Effects of Chickenpox

Reports from the middle of the 20th century suggested that when chickenpox occurred during pregnancy, it was a highly lethal disease. Deaths usually resulted from varicella pneumonia, in some cases accompanied by glomerulitis and renal failure or myocarditis, occurring after the fourth month of gestation.<sup>169,170</sup> Harris and Rhoades<sup>171</sup> reviewed the literature to 1963 and found a reported mortality of 41% for 17 pregnant women with chickenpox pneumonia compared with 11% for 236 nonpregnant adults with chickenpox pneumonia. Other reports, however, question whether varicella, especially in the absence of pneumonia, is more serious in pregnant women than in the adult population at large.<sup>136,172,173</sup> Because most cases of gestational varicella with an uncomplicated course are undoubtedly not reported, the denominator of the case-fatality ratio is unknown. In a prospective study of 150 cases of chickenpox in pregnancy in 1966, only one maternal death related to chickenpox pneumonia was

<sup>a</sup>The antiviral therapy era is considered to have begun after 1985.

<sup>b</sup>If specified.

<sup>c</sup>Numbers in parentheses give deaths at indicated gestational periods.

<sup>d</sup>Includes one patient with zoster whose gestational dates are not given.

<sup>e</sup>Includes review of the literature before 1963.

<sup>f</sup>Reports five new cases with a review of additional case reports in the literature.

<sup>g</sup>In a series of 28 pregnant women with varicella, 1 (3.6%) had pneumonia.

<sup>h</sup>In a series of 347 pregnant women with varicella, 18 (5.2%) had pneumonia.

recorded.<sup>174</sup> In a very large, collaborative, prospective study published in 2002, there were no fatalities in 347 consecutive pregnant women with varicella, although 18 (5.2%) had radiologic evidence of pneumonia.<sup>175,176</sup> Although the data did not reach statistical significance in this study, it seems striking that 16 (89%) of 18 of the reported cases of pneumonia occurred in women who developed varicella after the 16th week of pregnancy.

To a review of the literature on varicella pneumonia in pregnancy before 1964,<sup>171</sup> Table 22-4 adds data from subsequent case reports of gestational varicella, with and without pneumonia, and reports of perinatal varicella in which the outcome in the mother is described. Among 545 cases of chickenpox in pregnant women, there were 16 deaths (3%). All of the deaths occurred among the 75 women who had chickenpox pneumonia (21% fatality rate for pneumonia). One (<1%) of 166 women whose disease occurred during the first trimester died, as did 4 (2%) of 168 women with disease in the second trimester and 11 (5%) of 208 women who became ill in the third trimester. No deaths occurred among 8 women who were exposed to chickenpox in late pregnancy but did not develop an exanthem until the first few days post partum. In summary, it remains uncertain whether chickenpox pneumonia has a graver prognosis when it occurs during pregnancy. There is no definitive evidence that chickenpox in the absence of pneumonia is a more serious illness in pregnant women than in other adults; however, the risk of developing pneumonia may be increased after the 16th week of pregnancy. It seems likely that older mortality

information on varicella in pregnancy reflected the pre-antiviral therapy era and was biased by selective reporting of fatal cases.

Some patients with varicella during pregnancy who were treated with acyclovir have been reported.<sup>173,175,176,183,185-196</sup> These reports suggest that acyclovir has improved the outcome of this complication of varicella, although controlled studies have not been performed. Although a wide variety of dosages has been used, the standard dosage of 30 mg/kg/day given intravenously would seem appropriate for treatment of pregnant women with varicella pneumonia. Congenital abnormalities from administration of acyclovir to women during pregnancy have not been observed.<sup>197,198</sup>

Controlled studies of the value of corticosteroids in pregnant women with varicella pneumonia have not been performed. Several reports indicate that 2 of 6 pregnant women treated with corticosteroids died, whereas 8 of 17 pregnant women given supportive therapy without corticosteroids died.<sup>171,179-181,199</sup> It seems that administration of an antiviral drug is of greater importance than administration of corticosteroids. VZIG may be administered to seronegative women after close exposure to VZV to attempt to modify the infection; although not certain, this approach may prevent fetal infection.<sup>200,201</sup> In a study from 1994, among 97 women who developed varicella after receiving VZIG, there were no observed cases of the congenital varicella syndrome.<sup>201</sup> About two abnormal infants could be expected in a series of this magnitude, but the number of women followed is too low to achieve statistical significance.

**Table 22-5 Frequency of Low Birth Weight among Infants Born to Mothers with Selected Viral Infections during Pregnancy**

Disease	Virus-Infected Group			Control Group <sup>a</sup>

<sup>a</sup>Control group was matched for age, race, and parity of the mother and type of obstetric service.

<sup>b</sup>Low birth weight was defined as less than 2500 g.

Table modified from data of Siegel M, Fuerst HT. Low birth weight and maternal virus diseases: a prospective study of rubella, measles, mumps, chickenpox, and hepatitis. *JAMA* 197;88, 1966. Fetal deaths and multiple births were excluded from the analysis.

### Effects of Gestational Varicella on the Fetus

#### CHROMOSOMAL ABERRATIONS

VZV can induce chromosomal abnormalities *in vitro* and *in vivo*. When human diploid fibroblasts are infected with the virus, a high proportion of cells is observed in metaphase arrest, as if they were under the influence of colchicine.<sup>202</sup> Twenty-four hours after infection, the incidence of chromatid and chromosomal breaks ranges from 26% to 45%, compared with 2% for control cultures. In the acute phase of chickenpox, up to the fifth day of rash, peripheral blood leukocytes show a 17% to 28% incidence of chromosomal breaks, compared with 6% in controls, but 1 month after infection, these abnormalities have disappeared.<sup>203</sup> A single case report suggests the possibility that chromosomal damage may be more lasting when chickenpox is acquired *in utero*. A boy with bird-headed dwarfism, born to a mother who contracted chickenpox in the sixth month of pregnancy, had a 26% incidence of chromosomal breakage in peripheral blood leukocytes when he was examined at 2 years of age.<sup>204</sup> However, chromosomal analyses in four infants with the congenital varicella syndrome, whose mothers had chickenpox at the 8th, 14th, 16th, and 20th week of gestation, respectively, were reported as normal.<sup>205-208</sup> Information on chromosomal aberrations in infants who have no congenital anomalies and are the offspring of mothers with gestational varicella is unfortunately lacking. Further concern about the possibility of persistent chromosomal abnormalities after intrauterine exposure to VZV is suggested by a prospective survey of deaths among children born in England and Wales between 1950 and 1952 whose mothers had chickenpox in pregnancy. Two deaths, both from acute leukemia, were reported among the offspring of 270 women; the two children developed acute leukemia at the ages of 3 and 4 years after intrauterine exposure at 25 and 23 weeks' gestation, respectively.<sup>209</sup> In the absence of confirmation, it remains questionable whether exposure to chickenpox *in utero* is a risk factor for leukemia or other malignancies.

#### ABORTION AND PREMATURITY

Several studies have addressed the question of whether gestational chickenpox and other viral diseases result in an increased incidence of spontaneous abortion or prematurity. In a retrospective study in 1948, only four cases of chicken-

pox were identified among 26,353 pregnant women.<sup>210</sup> No stillbirths occurred among these four. Prospective studies have tended to confirm that maternal chickenpox during pregnancy is not associated with a significant excess of prematurity<sup>174</sup> or fetal death.<sup>178</sup> Among 826 virus-infected pregnant subjects observed in New York City from 1957 to 1964, 150 women with chickenpox were followed to term. After exclusion of fetal deaths and multiple births, 5 of 135 live-born infants were found to have birth weights of less than 2500 g. This incidence of prematurity was lower than that in the control group of non-virus-infected pregnant women (Table 22-5). Similarly, in the study of Paryani and Arvin,<sup>182</sup> premature delivery occurred in 2 (5%) of 42 pregnancies, with delivery at 31 and 35 weeks' gestation. In a prospective study involving 194 women with gestational varicella and 194 control women, the rate of spontaneous abortion was 3% and 7%, respectively, in the first 20 weeks.<sup>211</sup> In the large prospective series of Enders and associates<sup>201</sup> of 1330 women in England and Germany who developed varicella, 36 (3%) experienced spontaneous abortions after varicella in the first 16 weeks. However, in the prospective study of Pastuszak and co-workers<sup>212</sup> involving 106 women with varicella in the first 20 weeks of pregnancy, there were more premature births (14.3%) among women with varicella than among controls (5.6%;  $P = .05$ ). There is no question, however, that the congenital varicella syndrome is associated with low birth weight. Approximately one third of reported cases of the syndrome have been premature, had low birth weight, or were small for dates.

An accurate assessment of the incidence of fetal mortality after maternal chickenpox is difficult to obtain. Fetal wastage is probably unreported, in part because some spontaneous abortions occur before prenatal care is sought. In the prospective study of maternal viral diseases in New York City referred to earlier,<sup>178</sup> nine fetal deaths were observed among 144 instances of maternal chickenpox. Five fetal deaths occurred among 32 pregnancies in the first trimester, four among 60 second-trimester pregnancies, and none among 52 third-trimester pregnancies (Table 22-6). These do not represent significant increases in fetal wastage associated with chickenpox infection compared with control groups in which no maternal viral infection occurred. Only for mumps was there a significant excess of fetal deaths, and these occurred primarily in the first trimester. Only three of the nine fetal

deaths associated with maternal chickenpox occurred within 2 weeks of the onset of the mother's illness, and two of these were in the first trimester. Two additional deaths occurred 2 to 4 weeks after the onset of maternal chickenpox, two after 5 to 9 weeks, and two 10 or more weeks after the onset of maternal illness. The absence of a close temporal relationship between most fetal deaths and maternal disease provides further support for the concept that maternal chickenpox during pregnancy does not commonly result in fetal mortality.

Although the incidence of fetal death is not increased by maternal varicella, fetal deaths have been associated with maternal varicella. Deaths in utero may result from direct invasion of the fetus by VZV<sup>132,201,213-215</sup> or from the presumed toxic effects of high fever, anoxia, or metabolic changes caused by maternal disease.<sup>178</sup> The precise mechanisms of these toxic effects have not been elucidated. When maternal disease is unusually severe, particularly in cases of chickenpox pneumonia, fetal death may also result from premature onset of labor or death in utero caused by maternal death.<sup>136,171,179,180,185,214</sup>

#### CONGENITAL MALFORMATIONS

For many years, there was uncertainty about whether gestational varicella led to a symptomatic congenital infection. Intensive investigation during the past 30 years has led to the recognition that VZV can cause fetal malformations. Two types of investigations were carried out to determine whether chickenpox during pregnancy leads to a congenital syndrome. The first were retrospective analyses or case reports describing specific anomalies that occurred in the offspring of mothers who had gestational varicella. These reports were necessarily highly selective and did not define the incidence of such

anomalies. However, they consistently described a syndrome of skin scarring, eye and brain damage, and limb hypoplasia that might follow intrauterine varicella.

The second type of analysis consisted of prospective studies of pregnant women followed throughout pregnancy and afterward. The problem was to delineate the coincidence of two events, each of which is itself uncommon—gestational chickenpox and congenital malformations—to determine the magnitude of risk to the fetus. Siegel,<sup>71</sup> despite an 8-year observation period encompassing approximately 190,000 pregnancies annually in New York City, was able to identify only four malformations among infants born to 135 mothers who had chickenpox during pregnancy, compared with five malformations among 146 matched controls. The follow-up period was 5 years and included psychomotor and audiometric tests. Only 27 of the pregnancies complicated by chickenpox occurred during the first trimester, and of these, 2 (7.4%) were associated with congenital anomalies, compared with three anomalies (3.4%) among 87 pregnancies in the control population. The largest single prospective series is that of Enders and associates.<sup>201</sup> In a joint prospective study in Germany and the United Kingdom between 1980 and 1993, Enders and associates<sup>201</sup> followed 1373 women with varicella and 366 with zoster during pregnancy. Of the women with varicella, 1285 continued to term, and 9 had defects attributed to the congenital varicella syndrome.<sup>201</sup> The incidence was 2 (0.4%) of 472 for infections between 0 and 12 weeks and 7 (2%) of 351 for infections between 13 and 20 weeks. In a collaborative prospective study in the United States, 347 women with gestational varicella were reported, and adequate follow-up of their infants was available in 231.<sup>176</sup> In this cohort, there was one case (0.4%) of the congenital syndrome and two cases of fetal demise, including one case of hydrops. If these cases are included, the rate of congenital varicella was 1.3%. The mother of the one child with the syndrome had varicella at 24 weeks; the child had skin, eye, and central nervous system involvement.

That the congenital varicella syndrome is a reality is now widely appreciated. Only recently has it become possible to make a tissue diagnosis of the congenital varicella syndrome, because affected infants do not chronically shed virus as is seen in congenital infections with rubella virus and CMV.<sup>201,213,215-217</sup> It may be prevented in the future by widespread use of varicella vaccine, analogous to the situation for congenital rubella.

The constellation of developmental abnormalities described in individual case reports of infants born to mothers who had varicella in early pregnancy and in prospective series is sufficiently distinctive to indicate that VZV is a teratogen. In 1947, LaForet and Lynch<sup>218</sup> described an infant with multiple congenital anomalies after maternal chickenpox in early pregnancy. The infant had hypoplasia of the entire right lower extremity, talipes equinovarus, and absent deep tendon reflexes on the right. There were cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, right torticollis, insufficiency of the anal and vesical sphincters, and cicatricial cutaneous lesions of the left lower extremity. In 1974, Srabstein and co-workers<sup>219</sup> rekindled interest in the subject, reported another case, and reviewed the literature, concluding that although the virus could not be isolated from the infants, the congenital syndrome typically consisted of some combination of cicatricial skin lesions, ocular abnormalities, limb deformities,

**Figure 22-2** Fundus photograph of the right eye of a 13-month-old patient shows central gliosis with a surrounding ring of black pigment. The child's mother had varicella during the early fourth month of pregnancy. (Adapted from Charles N, Bennett TW, Margolis S. Ocular pathology of the congenital varicella syndrome. *Arch Ophthalmol* 95:2034, 1977.)

**Figure 22-3** This infant, whose mother had varicella during the 13th to 15th weeks of pregnancy, had bilateral microphthalmia with cataracts and an atrophic left leg. The infant died of bronchopneumonia at age 6.5 months. (From Srabstein JC, Morris N, Larke RPB, et al. Is there a congenital varicella syndrome? *J Pediatr* 84:239, 1974.)

mental retardation, and early death after maternal varicella in early pregnancy (Figs. 22-2 to 22-4). There have been numerous additional reports in the literature of the syndrome, encompassing more than 100 cases, indicating that there is a wide spectrum of manifestations (Table 22-7).<sup>71,73,182,201,205-286</sup>

Whereas at one time it was thought that the syndrome occurred after maternal VZV infection in the first trimester of pregnancy, current evaluation of the data indicates that cases also occur in the second trimester. Of 82 cases for which data are available, 32 (39%) occurred after maternal varicella that developed before the 13th week, 47 (59%) occurred between weeks 13 and 26, and 1 (1%)<sup>249</sup> occurred during the 28th week. The average gestation when maternal varicella occurred was 15 weeks. Five cases occurring after maternal zoster have been reported<sup>250,251,280,281</sup>; four occurred after maternal zoster in the first trimester, and one followed zoster in the second trimester.<sup>280</sup> Of 108 reported affected infants, 103 (95%) cases followed maternal varicella, and 5 (5%) followed maternal zoster (disseminated in one instance).

Scars of the skin, usually cicatricial lesions, are the most prominent stigmata, although a few patients have had no rash whatsoever.<sup>267,270,271,288</sup> Eye abnormalities (i.e., chorioretinitis, microphthalmia, Horner's syndrome, cataract, and nystagmus) and neurologic damage are almost as common; other features include a hypoplastic limb, prematurity, and early death. The features of the syndrome are summarized in Table 22-7.

Cutaneous scars were usually observed overlying a hypoplastic limb but also have been seen in the contralateral limb.<sup>218</sup> Characteristically, the skin scars are cicatricial, depressed, and pigmented and often have a zigzag configuration. Such scars are thought to be the result of zoster that occurred before birth. In some patients, large areas of scarred skin have required skin grafting.<sup>231,239</sup> In other patients, the rash was bullous<sup>238</sup> or consisted of multiple, scattered, depressed, white scars.<sup>242,246,259</sup> In one infant, healing zoster was present at the T11 dermatome at birth; there was also spinal cord atrophy at the same level and aganglionosis of the intestine.<sup>258</sup>

**Figure 22-4** A child, whose mother had varicella during the 16th week of pregnancy, had atrophy of the left orbit, with blindness that required cosmetic enucleation. Severe chorioretinitis occurred in the right eye. Except for blindness, the child developed normally. She died of pneumonia when approximately 4 years old. (Adapted from Frey HM, Bialkin G, Gershon A: Congenital varicella: case report of a serologically proved long-term survivor. *Pediatrics* 59:110, 1977.)

Ocular abnormalities include chorioretinitis, Horner's syndrome or anisocoria, microphthalmia, cataract, and nystagmus.\* Rarely, major abnormalities were confined to the eye. There was no apparent effect of timing of maternal varicella during gestation; the times of infection varied from 9 to 23 weeks in these infants. Figure 22-2 is a photograph showing retinal involvement in one of these patients.<sup>242,253</sup>

Neurologic involvement is about as common as skin and eye abnormalities in infants with this syndrome. Patients with cerebral cortical atrophy, diffuse brain involvement, or mental retardation (frequently accompanied by abnormal electroencephalograms and seizures or myoclonic jerks) have been described.<sup>218,219,226-228,261</sup> In a few patients, cerebrospinal fluid findings were normal<sup>73,219,228,255</sup>; in others, there were increased numbers of leukocytes or protein levels.<sup>218,225,227</sup> Bulbar palsy is suspected to result in dysphagia and bouts of aspiration pneumonia in some of these children.<sup>†</sup> Deep tendon reflexes were reported as normal in one infant<sup>227</sup> and diminished to absent in six,<sup>207,208,218,219,223,224</sup> and they were in some cases accompanied by sensory deficits.<sup>73,219,224,228,255</sup> Electromyography in some patients revealed a denervation pattern with loss of motor units.<sup>219,228,229,251,255</sup> Biopsy in one instance showed replacement of muscle bundles by fat.<sup>219</sup> At least five children with vocal cord paralysis have been reported.<sup>261,269,272,273,274</sup>

Abnormalities of the limbs can be extremely dramatic in presentation, and are seen in about half of affected infants. The most common limb abnormality, which first called

**Table 22-7** Reported Symptoms in Infants with the Congenital Varicella Syndrome, 1947-2002

Symptom	Estimated Incidence (%)

See references 71, 73, 182, 201, 205-286.

attention to this congenital syndrome, is hypoplasia of a limb, most commonly unilateral involvement of a leg or arm (see Table 22-7). Hypoplasia or absence of digits has also been observed.<sup>218,220,223,224,227-229</sup> Talipes equinovarus or a calcaneovalgus deformity has also occurred.\* This complex of abnormalities in the limbs, including the bony abnormalities, is probably attributable to a neuropathy caused by direct viral invasion of the ganglia and spinal cord.<sup>270</sup>

About one fourth of these infants died within the first 14 months of life. One child with the obvious syndrome was stillborn.<sup>215</sup> In one who died at 6 months, autopsy revealed a necrotizing encephalitis with various degrees of gliosis and inflammatory infiltrates. Focal calcification was observed in white and gray matter of the cerebrum, brain stem, and cerebellum. Atrophy of the anterior columns of the spinal cord and scarring in the ganglion corresponding to the distribution of the skin lesions and an atrophic limb were also present. No inclusion bodies were identified.<sup>219</sup> Among infants with a hypoplastic limb, 40% had evidence of mental retardation or died early. The presence of a hypoplastic limb on an ultrasound examination suggests a poor outcome.

About one third of affected infants were premature or had low birth weight for their gestational ages, and about 10% had various abnormalities of the gastrointestinal tract, including reflux, duodenal stenosis, jejunal dilatation, microcolon, atresia of the sigmoid colon, and sphincter malfunction.<sup>70,217,218,225,239,254,257,253,258,260</sup> A similar percentage had abnormalities of the urinary tract, often due to poor or absent bladder sphincter function.<sup>73,182,218,219,222,237,250,255,258</sup> Involvement of the cervical or lumbar spinal cord and the autonomic nervous system is thought to account for the observed hypoplasia or aplasia of limbs and digits, motor and

sensory defects, decrease or absence of deep tendon reflexes, Horner's syndrome, and gastrointestinal and urinary tract abnormalities.<sup>282</sup>

Figures 22-3 and 22-4 depict two children with stigmata of the congenital varicella syndrome. One has severe<sup>219</sup> and one has relatively mild involvement.<sup>242,253</sup>

**Zoster after the Congenital Varicella Syndrome.** Fifteen percent of children with the congenital varicella syndrome develop clinical zoster in infancy or early childhood, almost all in the first year of life.\* This is of particular interest because cell-mediated immunity to VZV in 2 of 10 of children with the syndrome has been reported to be absent as determined by lymphocyte transformation.<sup>182,206</sup> In Enders' series<sup>201</sup> of 1291 livebirths (without the congenital syndrome), of whom conservatively perhaps 25% were infected with VZV (the attack rate could be as high as 50%), the rate of zoster in childhood was 3%. It appears therefore that zoster is even more common in children with the congenital syndrome than in infants who were infected with VZV in utero but were asymptomatic at birth.

**Diagnosis of the Congenital Varicella Syndrome.** During the neonatal period or infancy, attempts to isolate VZV from the skin, cerebrospinal fluid, eye, and other tissues in infants with developmental defects were negative.<sup>73,205,219,227,235,236,241,242</sup> Although rubella virus and CMV are commonly isolated from young infants afflicted by these viruses, failure to isolate VZV in these cases is probably explained by the fact that the period of viral replication took place during early gestation and no replicating virus persisted by the time of birth. In children who developed zoster at an early age, it has been possible to isolate VZV from the rash.<sup>210,229,254</sup> In seven infants who died, autopsy results demonstrated apparent dissemination of VZV with varicella-like involvement of the lungs, liver, spleen, adrenals, or pancreas.<sup>206-208,212,228-231</sup>

Total IgM concentrations in the serum or cord blood of six infants were measured.<sup>205,219,228,240-242</sup> In three instances, the levels were clearly increased, with values of 48 to 100 mg/dL found when the infants were 1.5 to 6 weeks old. Specific VZV antibodies in the IgM fraction were not detected in seven cases in which they were sought,<sup>182,228,242,248,282</sup> but they were detectable in six other cases.<sup>201,206,207,232,240</sup> In one of these cases, VZV IgM was detected prenatally by obtaining blood by cordocentesis.<sup>282</sup> In most infants, a decline of antibodies in the serum was observed, a finding compatible with a fetal or a maternal origin. In 10 instances, however, persistence of or an increase in antibodies in the infant supported a presumption of intrauterine infection.<sup>73,205,221,226,243,241,242,253,255</sup>

It has been possible to document some reported cases of the congenital varicella syndrome but not all of them, because antibody titers may be inconclusive even in children with the apparent full-blown and rather distinctive constellation of abnormalities. Some children were diagnosed even before it was possible to measure antibody titers to VZV. The development of zoster at an early age can be interpreted as substantiating VZV infection in utero. Although many of the cases reported as the congenital varicella syndrome lack proof, it has been possible to show that some infants with characteristic stigmata were infected in utero with VZV,

although an active, chronic infection does not exist. Modern molecular methods such as PCR and in situ hybridization have been useful for proving the congenital syndrome in a few reported infants and will undoubtedly be used to prove future cases.<sup>201,213,215-217,261</sup> In the future, it is expected that these will become the methods of choice rather than antibody testing. It is also predicted that with widespread use of varicella vaccine, the incidence of this unusual cause of congenital disease will become rare.

#### MANAGEMENT OF PREGNANT WOMEN WITH VARICELLA-ZOSTER VIRUS INFECTION WITH REGARD TO FETAL MALFORMATIONS

In the decade of the 1990s, the incidence of fetal malformations after maternal VZV infection was clarified. Varicella is a significantly greater threat than zoster; 95% of reported cases of the congenital varicella syndrome have followed maternal chickenpox. In Enders' series<sup>201</sup> of 366 women with zoster in pregnancy, there were no cases of the congenital syndrome. This outcome is not unexpected, because zoster is probably less likely to be accompanied by a viremia than is varicella; many fetuses may escape VZV infection from maternal zoster. Because zoster is a secondary infection, residual maternal immunity to VZV may at least partially protect the fetus from damage, analogous to that seen when congenital CMV infection is caused by reactivation rather than to primary CMV infection.<sup>288</sup> As with CMV infection, however, it is possible, although rare, for fetal stigmata to follow secondary maternal infection.

The time at which maternal VZV infection occurs during gestation also influences whether the infant is likely to be severely damaged. Infection during the first and early second trimester appears to be the most critical. Most of the reported cases of the congenital syndrome have occurred when the onset of maternal infection was before the 20th week of pregnancy. Only six infants with some of the stigmata have been recorded as the result of maternal varicella after the 20th week.<sup>213,176,247-249,257</sup> When maternal varicella occurs after the 20th week, the infant may be infected, but usually the only evidence is a positive VZV antibody titer when the infant is older than 1 year and, in some cases, development of zoster at an early age.

Eleven prospective studies of the incidence of the congenital varicella syndrome have been published. Data from these studies are presented in Table 22-8. There are 14 cases of the congenital varicella syndrome in 858 (1.6%) women who developed varicella in the first 20 weeks of pregnancy. If the entire gestational period is considered, 2245 women who had varicella during pregnancy were delivered of live-born infants; the overall incidence of the congenital syndrome was 0.6%. These data indicate that the risk for development of the congenital varicella syndrome is mostly confined to the first 20 weeks of pregnancy, and even the risk after maternal varicella in the first 20 weeks of pregnancy is extremely low, on the order of 1% to 2%. Weeks 7 to 20 are the time of the greatest risk.<sup>201</sup> The tendency to develop overwhelming forms of VZV infection in the fetus indicates the increased ability of VZV to multiply in fetal tissues, which is similar to that of other viruses such as rubella virus and CMV.

Counseling of pregnant women who have acquired varicella during pregnancy can be very difficult. Because the congenital syndrome is rare, termination of pregnancy is not

routinely recommended, in contrast to recommendations for gestational rubella. When the syndrome does occur, however, it is likely to be severe. It would be helpful if prenatal diagnoses were available, but diagnostic attempts such as measurement of maternal antibody titers and amniocentesis have not proved useful. Although blood may be obtained by cordocentesis for antibody testing, even the presence of fetal VZV IgM does not mean that the infant has the congenital varicella syndrome but only that infection with VZV has taken place. Similarly, PCR may identify an infected fetus but not necessarily one with malformations.<sup>286,287</sup>

Ultrasound has been used successfully to identify the following fetal abnormalities after maternal varicella: hydrocephalus 12 weeks later<sup>206</sup>; clubfeet and hydrocephalus 13 weeks later<sup>235</sup>; a large, bullous skin lesion originally believed to be a meningocele 15 weeks later<sup>238</sup>; calcifications in the liver and other organs 9, 15, and 18 weeks later<sup>216,236,263</sup>; a hypoplastic limb and clubfoot 11 and 16 weeks later<sup>201,216</sup>; and a lacuna of the skull 25 weeks later.<sup>232</sup> Additional successes with ultrasound as a diagnostic tool to identify this syndrome prenatally have also been reported in cases with evidence of widespread infection.<sup>275-278</sup> Three published reports, however, indicate that ultrasound is not infallible. In two infants, ultrasound was normal 3 weeks after maternal varicella, but the fetus was later diagnosed as having the congenital varicella syndrome.<sup>207,235</sup> One infant was diagnosed with liver calcifications by ultrasonography at 27 weeks and a positive PCR for VZV; his mother had varicella at 12.5 weeks. At birth, no obvious anomalies were present, and the infant did well except for development of zoster at age 8 months.<sup>286</sup> Even defects detected by ultrasonography must be interpreted with some caution.

Because about 40% of reported patients with a hypoplastic limb also sustained brain damage or died in early infancy, the presence of a limb abnormality on ultrasound seems to suggest a poor overall prognosis for the fetus. Two women were reported to have terminated their pregnancies after the diagnosis of the congenital varicella syndrome was made based on abnormal limbs at ultrasound. At physical examination, the infants were found to be severely affected.<sup>201,286</sup>

Because abnormalities may not be detected by ultrasound immediately after maternal varicella, by the time any is noticed, it may be too late to consider interruption of pregnancy, depending on the time of onset of maternal varicella.

Although the congenital varicella syndrome varies in severity, most cases are severe. It would be helpful if maternal infection could be identified and appropriate management initiated as early as possible. It is not known whether administration of VZIG or acyclovir to a pregnant woman can prevent her fetus from developing the congenital varicella syndrome. In Enders' study,<sup>201</sup> there were no cases of the congenital syndrome in 97 women who were given VZIG on exposure; unfortunately, it is not known how many of these women were in the first 20 weeks of pregnancy.

### Perinatal Chickenpox

Perinatal chickenpox includes disease that is acquired postnatally by droplet infection and that is transplacentally transmitted or congenital. Chickenpox is considered to be transplacentally transmitted when it occurs within 10 days of birth.

#### POSTNATALLY ACQUIRED CHICKENPOX

Postnatally acquired chickenpox, which begins between 10 and 28 days after birth, is generally mild.<sup>289</sup> The experiences with nosocomial chickenpox infections in the newborn nursery that were described in a previous section further corroborate the benign nature of the disease and the fact that transmission to neonates in this environment is inefficient and rarely reaches epidemic proportions.

Deaths among neonates caused by postnatally acquired disease are rare, but some data indicate an appreciably higher incidence of complications or deaths in neonates than in older children.<sup>96,101-103,108,289,290</sup> Preblud and associates<sup>289</sup> found that of 92 reported deaths caused by varicella from 1968 to 1978 in children younger than 1 year, only 5 occurred in newborns (8 hours to 19 days old). Although mortality was increased by a factor of four for infants younger than 1 year compared with older children, there was a low calculated death rate for varicella throughout childhood (8 in 100,000 patients if younger than 1 year and 2 in 100,000 patients 1 to 14 years old).<sup>289</sup> One 15-day-old infant with severe disseminated chickenpox born to a woman who developed varicella 7 days after delivery has been described.<sup>290</sup> The child survived; acyclovir was administered for 10 days. The only other report in the English literature of severe postnatally acquired varicella in an infant younger than 1 month is that of Gustafson and colleagues.<sup>96</sup> The term infant with Turner's syndrome was exposed to varicella when 7 days old, developed more than 200 vesicles, and died of pneumonia; however, the role of VZV in the child's death was unclear because no autopsy was performed.

#### CONGENITAL CHICKENPOX: MATERNAL INFECTION NEAR TERM

Congenital chickenpox is not inevitable when maternal chickenpox occurs in the 21 days preceding parturition. In only 8 (24%) of 34 reported cases of maternal disease with onset during this period did chickenpox develop in the neonate within the first 10 days of life.<sup>98,136,172,174</sup> An identical attack rate of 24% for congenital varicella after the occurrence of maternal varicella within 17 days preceding delivery was arrived at by Meyers,<sup>291</sup> who reviewed many cases in the

literature and 14 examples reported to the Centers for Disease Control and Prevention in 1972 to 1973. However, attack rates on the order of 50% were reported in two studies on the efficacy of passive immunization to prevent severe neonatal varicella.<sup>292,293</sup> In Meyers' study,<sup>291</sup> there was no statistically significant relationship between day of onset of the rash in the mother and subsequent attack rates of congenital varicella. Seven of 22 neonates born to mothers whose rash appeared less than 5 days ante partum ultimately developed congenital chickenpox, whereas 4 of 24 infants born to mothers whose rash began 5 to 14 days ante partum had congenital disease.<sup>291</sup> These data indicate that the attack rate in congenital varicella (25% to 50%) is lower than that after household exposure to VZV (90%) and suggest that blood-borne transmission is less efficient than by the skin and respiratory routes.

The incubation period in congenital varicella, defined as the interval between the onset of rash in the mother and onset in the fetus or neonate, is usually 9 to 15 days.<sup>294</sup> This interval is slightly shorter than the normal postnatal incubation period, possibly because fetal tissues are more susceptible to VZV than more mature tissues. Rarely, presumably when fetal infection is caused by the primary maternal viremia, the exanthem appears in the mother and neonate within 3 days of each other<sup>101</sup> or even simultaneously.<sup>294</sup> The average incubation period in 36 cases reported in the literature was 11 days, with a maximum of 16 days. In only three instances was the incubation period less than 6 days.<sup>291</sup>

In contrast to postnatally acquired neonatal chickenpox, congenital chickenpox can be associated with significant mortality. Severe cases clinically resemble varicella in the immunocompromised host. A child who died of hemorrhagic varicella with pulmonary and liver involvement is shown in Figure 22-1. The spectrum of illness also includes extremely mild infections with only a handful of vesicles. Erlich and co-workers<sup>133</sup> first observed that infants born with the rash or who had an early onset of rash survived, whereas those who died had a relatively late onset of rash. It was hypothesized that for those neonates with early onset, maternal illness had occurred long enough before parturition to allow antibodies to be elaborated by the mother and to cross the placenta. Subsequent reports offer strong confirmation of these observations. There were no deaths among 22 infants with congenital chickenpox (reviewed by Meyers) whose onset of rash occurred between birth and 4 days of age. In contrast, 4 (21%) of 19 neonates in whom the rash began when they were 5 to 10 days old died (Table 22-9).<sup>291</sup> These four deaths occurred among 13 neonates (31%) whose mothers' exanthems developed within 4 days before birth, but no deaths were observed among 23 neonates with congenital chickenpox whose mothers developed a rash 5 or more days before birth.

Further support for the protective or modifying effect of maternal antibody has come from measurements of placental transfer of IgG to VZV.<sup>91</sup> When varicella occurred more than 1 week before delivery, complement-fixing antibody titers in maternal and cord blood were similar. In contrast, when infection occurred 3 to 5 days before delivery, maternal antibody was present at parturition, and antibodies to VZV in the neonate were absent or at least eightfold lower. These data suggest that a lag of several days occurs before IgG anti-

bodies to VZV cross the placenta and equilibrate with the fetal circulation. The development of mild congenital varicella in the presence of placentally transferred maternal antibody has also been demonstrated using the more sensitive FAMA test.<sup>61</sup> The neonate may be at risk for developing severe varicella because the immune system is immature, as has been demonstrated by Kohl with regard to host defense against HSV.<sup>295</sup>

### Zoster in Neonates and Older Children

The most characteristic feature of zoster is the localization of the rash. It is nearly always unilateral, does not cross the midline, and is typically limited to an area of skin served by one to three sensory ganglia. In children, prodromata of malaise, fever, headache, and nausea may be observed. Pain and paresthesias in the involved dermatome may precede the exanthem by 4 or 5 days. Involvement of the dermatomes of the head, neck, and trunk is more common than involvement of the extremities, a distribution that also reflects the density of lesions in chickenpox.<sup>40</sup> Erythematous papules give rise to grouped vesicles, which progress to pustules in 2 to 4 days. New crops of vesicles may keep appearing for a week. Pain may be associated with the exanthem and usually abates as the skin lesions scab; in elderly adults, severe and incapacitating neuralgia of the involved nerve may persist for months. Cutaneous dissemination of vesicles to sites distant from the involved dermatome is observed uncommonly and is more frequent in compromised hosts such as patients with lymphoma or immunologic deficiencies.

Zoster occurs as host defense mechanisms against VZV wane in a person who has previously experienced chickenpox. Because immunity is relatively durable, this hypothesis presumes that zoster will occur predominantly in the older population and will be rare in neonates. Among 192 patients with zoster in a general practice, the attack rate increased progressively with age.<sup>40</sup> Only six patients were younger than 10 years; the youngest was 2 years old. In two reported series describing zoster in a total of 22 children, only two cases occurred in children younger than 2 years old.<sup>172,296</sup> These reports confirm the rarity of zoster among infants. When zoster occurs in children who have not previously had chickenpox, there is often a history of intrauterine exposure to VZV. In these reports, the mothers contracted chickenpox

**Table 22-9 Deaths from Congenital Varicella in Relation to Date of Onset of Rash in Mother or Neonate**

Onset	Neonatal Deaths	Neonatal Cases	%

0-4	4	13	31

Data from Meyers JD. Congenital varicella in term infants: risk reconsidered. *J Infect Dis* 129:215, 1974, with permission from the University of Chicago.

during gestation but gave birth to normal infants who, without ever developing chickenpox despite frequent childhood exposure, developed typical zoster at a young age, many in the first few months of life.<sup>73,262,297-301</sup> In most of these infants, the course of zoster was benign. One child developed a second attack of zoster when 10 months old; the first occurred when the child was 4 months old.<sup>297</sup>

Although there are six reports of zoster during the neonatal period,<sup>302-307</sup> it is doubtful whether any of these cases diagnosed on clinical grounds is an authentic example of zoster. HSV may produce a vesicular exanthem in the newborn that appears to have a dermatomal distribution. Virus isolation (or demonstration of VZV antigen from skin lesions) is required before a diagnosis of zoster can be accepted. Serologic studies are not useful in differentiating these diseases.

## Diagnosis and Differential Diagnosis

### Chickenpox

In a neonate with a widespread, generalized vesicular exanthem and a history of recent maternal varicella or postnatal exposure, a diagnosis of chickenpox can usually be made with confidence on clinical grounds alone. Greater difficulty is encountered when lesions are few or when there is no history of exposure.

#### DIAGNOSTIC TECHNIQUES

If laboratory diagnosis is required, it is best accomplished by demonstration of VZV antigen or DNA in skin lesions or isolation of virus from vesicular fluid. VZV antigen may be demonstrated by using immunofluorescence, employing a monoclonal antibody to VZV that is conjugated to fluorescein and is commercially available.<sup>308-310</sup> For virus isolation, fluid should be promptly inoculated onto tissue cultures because VZV is rather labile. PCR has proved extremely sensitive and accurate for diagnosis of VZV infections, although it remains a research test in most locations.<sup>118,311-317</sup> In situ hybridization is also a useful diagnostic technique.<sup>217,318,319</sup>

VZV infections may be documented by demonstration of a fourfold or greater rise in VZV antibody titer by using a sensitive test such as FAMA or ELISA. The presence of specific IgM in one serum specimen suggests recent VZV infection.<sup>38,39,320</sup> Persistence of VZV antibody beyond the age of 8 months is highly suggestive of intrauterine varicella, providing there is no history of clinical varicella after birth.<sup>24</sup> Persistence of VZV antibody with no fall in titer over several months in a young infant (as long as all sera are tested simultaneously) is highly suggestive of intrauterine infection. A FAMA or LA antibody titer of 1:4 or greater beyond 8 months of life is suggestive of immunity to varicella, provided that the patient has not received  $\gamma$ -globulin or other blood products in the previous 3 to 4 months. Physicians should be aware that no serologic test is 100% accurate for identifying individuals immune to varicella, although these antibody tests are generally reliable.<sup>321</sup>

#### DIFFERENTIAL DIAGNOSIS

Several diseases may be considered in the differential diagnosis of varicella in the newborn: neonatal HSV, smallpox, disseminated vaccinia, contact dermatitis, hand-foot-and-mouth syndrome, impetigo, and other conditions.

In *neonatal HSV*, cutaneous lesions may be relatively sparse and may be absent altogether despite widespread visceral dissemination. Vesicles tend to occur in clusters rather than in the more even distribution seen in chickenpox. Fever, marked toxicity, and encephalitis are more common in neonates with HSV. Stained smears of vesicle fluid (i.e., Tzanck preparation) are of no help in differentiating HSV from varicella because both are characterized by multinucleated giant cells and intranuclear inclusion bodies. In cell cultures, HSV typically produces a widespread cytopathic effect in 24 to 48 hours, whereas the cytopathic effect caused by VZV is cell associated and focal and develops more slowly. Indirect immunofluorescence using monoclonal antibodies conjugated to fluorescein can be performed on smears of skin scrapings; if positive, the assay can identify VZV, HSV-1, and HSV-2 within several hours. Paired serum samples can be examined for rising antibody titers to HSV and VZV antigens. It is exceedingly rare for varicella to develop in a newborn in the absence of any (i.e., infant or mother) exposure to varicella or zoster. In contrast, most infants with neonatal HSV have no recognized exposure to the virus.

Although 95% of cases of perinatal HSV are transmitted during delivery, a syndrome similar to the congenital varicella syndrome, with limb and eye abnormalities, skin scarring, and zosteriform rashes, has been observed after the unusual occurrence of intrauterine transmission of HSV.<sup>322,323</sup> In an infant with stigmata of the congenital varicella syndrome whose mother has no history of varicella during pregnancy, congenital HSV should be considered. It may not be possible to make a definitive diagnosis immediately unless the infant develops a vesicular rash from which the causative virus can be identified. Determination of antibody titers to HSV and VZV at presentation and when they are 8 to 12 months old may be useful to establish a diagnosis.

*Smallpox* is traditionally part of the differential diagnosis of vesicular lesions in neonates. Although smallpox was eradicated, there is concern that the disease may reemerge because of bioterrorism. Classically, the vesicles of smallpox appear to be at the same stage of development instead of showing the pattern of crops over a period of several days. Centrifugal distribution the skin rash distribution is prominent. The best approach in a suspicious situation is to rule out the possibility of VZV or HSV infection as described previously, preferably by immunofluorescence testing. If the test results are negative, a search for smallpox may then be indicated, especially if the history of the patient warrants it. Accurate diagnosis may be achieved in a matter of hours by electron microscopy of the vesicle fluid or crusts; such microscopic examination reveals virus particles whose morphology is very different from that of viruses of the herpes family. Smallpox modified by exposure to vaccinia in the distant past and alastrim (i.e., variola minor) may be particularly difficult to distinguish from chickenpox. In suspicious cases, the local health department should be promptly involved.

*Disseminated vaccinia* is rare today because smallpox vaccine (i.e., vaccinia virus) is not routinely used, although a bioterrorism attack could change the scenario. Vaccinia can be considered in a neonate exposed postnatally to a person who has been recently vaccinated. The lesions resemble those of smallpox. Impression smears of vesicle fluid do not show intranuclear inclusions or giant cells. Laboratory diag-

nosis may be achieved by electron microscopy and immunofluorescence.

In some cases of *contact dermatitis*, papules and vesicles may appear after exposure to specific chemical irritants. Typically, they appear on exposed body surfaces and do not have the characteristic distribution of chickenpox or smallpox.

In patients with *hand-foot-and-mouth syndrome*, a vesicular exanthem usually caused by coxsackievirus A16 or A5 may be observed during the enterovirus season (i.e., summer or early autumn). Vesicles rarely exceed a dozen and typically occur on the distal extremities, especially the palms and soles. Vesicular lesions that ulcerate quickly may also be seen in the oropharynx. The causative virus is readily isolated from vesicle fluid or from feces.

*Impetigo* may occur in neonates. In bullous impetigo (i.e., pemphigus neonatorum), large blebs are present instead of the smaller vesicles of chickenpox. This disease, which is caused by *Staphylococcus aureus*, may be associated with high fever, toxicity, septicemia, and death.

*Alternative diagnoses* include syphilis, group B streptococcal infection, and incontinentia pigmenti, which may cause vesiculobullous lesions in the neonate.

### Zoster

Zoster usually is easily recognized by the typical dermatomal distribution of the vesicular lesions. In the differential diagnosis, the main entity to be distinguished in the neonatal period is HSV appearing in a linear pattern. Identification of VZV or HSV antigen by immunofluorescence or virus isolation is the only reliable means of differentiating these entities when the distribution of the exanthem is linear. Contact dermatitis should also be considered in the differential diagnosis of zosteriform lesions in the neonatal period.

## Therapy

### Treatment of the Mother

Acyclovir is the antiviral drug of choice for treatment of potentially severe or severe VZV infections.<sup>324,325</sup> Acyclovir itself has no antiviral action, but when it is phosphorylated by enzymes produced by cells infected with VZV, it is incorporated as a DNA chain terminator and it also inhibits viral DNA polymerase. Because these actions occur only in virus-infected cells, acyclovir is well tolerated and associated with little toxicity. The drug is available in topical, oral, and intravenous formulations.

The safety of acyclovir has been demonstrated in the past 30 years, and there is good reason to use this drug liberally in clinical situations for which it is indicated, even during pregnancy. Although most VZV infections in normal hosts are self-limited, there is a low but real fatality rate from varicella in adults. For this reason and because long-term toxicity of acyclovir in the fetus seems unlikely, acyclovir is recommended more often for use during pregnancy in women with varicella than previously. A registry of patients (and their offspring) who have received acyclovir during pregnancy has been established.<sup>197,198</sup> In general, pregnant women who develop varicella should be treated with orally administered acyclovir and observed carefully. Pregnant women who develop severe varicella while receiving oral therapy, especially those who develop pneumonia, should be

promptly treated with intravenous acyclovir.<sup>326</sup> Supportive respiratory therapy (e.g., nasal oxygen, tracheostomy, ventilatory assistance) should be used as needed. Controlled studies of corticosteroids for varicella pneumonia are not available; therefore, steroids are not recommended. Antibiotics should be given if there is evidence of bacterial superinfection.

Anecdotal reports on the apparently successful use of acyclovir in pregnant women with varicella have been published, although controlled studies have not been performed. The data suggest that most women who develop varicella in pregnancy ultimately survive without sequelae.<sup>175</sup> This is undoubtedly the result of increasing awareness of the potential seriousness of the illness on the part of medical providers and also the more liberal use of acyclovir today.

There is little information on the use of acyclovir for pregnant women with zoster. Presumably, because zoster would be expected to be self-limited in most women of childbearing age, there would be little need for antiviral therapy in this situation. However, especially in the setting of an extensive rash or severe pain, use of acyclovir, particularly as oral therapy, should be strongly considered. Alternatively, one of the newer drugs, such as famciclovir or valacyclovir, can be used to treat pregnant women who develop severe zoster. The dose of famciclovir is 500 mg taken orally three times daily; the dose of valacyclovir is 1 g taken orally three times daily. Both medications are administered for 7 days. There is no information on the use of famciclovir or valacyclovir in pregnancy. Although famciclovir and valacyclovir are both converted to acyclovir, and acyclovir is the active drug in the blood, there is more safety information on use of acyclovir in pregnancy and for that reason it is probably preferable.

Acyclovir has been most effective when it is administered within 1 day after the onset of varicella and 3 days after onset of zoster. The usual adult dose for intravenous acyclovir is 10 mg/kg, given three times per day. Orally administered acyclovir has been found to have a modest effect on the fever and rash of varicella in otherwise healthy populations. A multicenter, double-blind, placebo-controlled, collaborative study involving 815 similarly treated children, who were given 20 mg/kg of acyclovir orally four times per day, shortened the course of illness by about 1 day.<sup>327</sup> The benefit to secondary household cases was not increased beyond that of primary cases. Similar results emerged from a study involving adolescents with varicella.<sup>328</sup> The modest benefit conferred by oral acyclovir therapy is not surprising in view of the self-limited nature of chickenpox in children and the poor oral absorption of acyclovir. There is a similar small benefit for adults with varicella who were given oral acyclovir (800 mg taken five times each day for 5 days) within 24 hours of onset of rash.<sup>329,330</sup> In the double-blind, placebo-controlled study of Wallace and associates,<sup>330</sup> involving 76 military recruits, the duration of illness was shortened by about 1 day and the personnel were able to return to work 1 day sooner on average, if they received acyclovir. There is no information regarding treatment of pregnant women, and physicians are reluctant to extrapolate to them from studies involving mainly healthy young men. However, given the possibility that acyclovir will help and is unlikely to harm, the drug should be strongly considered for most adults today with early varicella, pregnant or not.

### **Treatment of the Newborn Infant**

Although there is little information on the use of acyclovir in newborns for varicella, it has been used to treat a great many infants with neonatal HSV infection. In a study in which 95 infants received acyclovir (30 mg/kg/day given intravenously), no short- or long-term toxicity was observed.<sup>325-327</sup> Neonates with HSV that is disseminated or involves the central nervous system should receive double this dose (60 mg/kg/day). Pharmacokinetic studies have indicated that dose adjustments for acyclovir may be necessary in premature infants and those with hepatic or renal dysfunction.<sup>331-333</sup> There are no data about the use of oral acyclovir for severe neonatal infections caused by VZV, and acyclovir is poorly absorbed when given by the gastrointestinal route. A dose of 1500 mg/m<sup>2</sup> of acyclovir, given intravenously in three divided daily doses, is recommended for infants with severe or rapidly progressing varicella. It is not recommended that infants with the congenital varicella syndrome receive treatment with acyclovir, except in the unusual setting of severe active zoster.

### **Prevention**

#### **Immunity to Varicella-Zoster Virus**

Immunity to VZV may be incomplete in some persons. It was recognized years ago that waning of immunity to VZV might predispose a person to zoster.<sup>40</sup> That immunity to varicella might wane on occasion and result in a second case of chickenpox has been recognized only fairly recently. Immunologic evidence consistent with asymptomatic reinfection with VZV, manifested by an increase in VZV-specific IgG or IgA or the production of IgM, as well as an increase in the cell-mediated immune response to VZV, has been documented in adults with a household exposure to varicella.<sup>334,335</sup> Symptomatic reactivation with subsequent boosting of immunity is also possible but is difficult to substantiate. Clinical reinfection with VZV has been observed in some persons despite a positive antibody titer at exposure.<sup>336-339</sup> However, most clinical reinfections are mild, which suggests that partial immunity to the virus may be present. Cellular immunity as well as antibodies may play a role in protection. In a study by Bogger-Goren and co-workers,<sup>340</sup> children with positive cellular immune responses were likely to be protected against varicella after household exposure even if they were seronegative; in contrast, children with negative responses became infected. Secretory IgA against VZV has also been demonstrated after chickenpox.<sup>341</sup> Although it has not yet been demonstrated, it is hypothesized that cellular immunity at the mucosal level may play an important role in protection against clinical varicella.

In addition to predisposing to reinfection with the virus, incomplete immunity to VZV is associated with development of zoster. In addition to clinical zoster, silent reactivation of latent VZV in those who have had previous varicella probably occurs; this may be detected immunologically by an increase in antibody titer or the transient appearance of specific IgM, although it is difficult to rule out the possibility of an exogenous exposure.<sup>39,342-344</sup> Sometimes, clinical manifestations of zoster such as pain may occur in the absence of a rash, so-called zoster sine herpete. Silent reactivation of VZV in bone marrow transplant patients has been demonstrated by PCR.<sup>345</sup>

Zoster results in patients who have latent VZV infection when specific cell-mediated immunity is depressed.<sup>121,122,124,346</sup> Defective antibody responses to VZV glycoproteins have not been associated with development of zoster in immunocompromised persons.<sup>347</sup> Similarly, the increased incidence of zoster in the elderly has been associated with loss of cell-mediated immunity to VZV,<sup>348,349</sup> whereas antibody to VZV does not wane with age but rather tends to increase.<sup>350</sup> Immunity to VZV may be seen as a complex interaction between humoral and cell-mediated immunity responses, with the possibility of partial as well as complete immunity to the virus.

It is possible to provide humoral immunity to persons at high risk for developing severe varicella by passive immunization with VZIG. Although used successfully to prevent severe varicella, passive immunization has not prevented zoster in those at high risk for it,<sup>351</sup> nor is it believed to be useful to treat patients with varicella or zoster.<sup>352</sup> Passive immunization should therefore not be employed to try to prevent development of varicella pneumonia in the pregnant woman with chickenpox or dissemination in an already infected infant. It is uncertain whether passive immunization of a woman with varicella can prevent infection of her fetus or development of the congenital varicella syndrome. It is possible to increase cell-mediated immunity to VZV by immunization, and whether this approach can prevent or modify zoster is being explored.<sup>353-355</sup> Results of a large, double-blind, controlled study in healthy vaccinees older than 60 years are expected to be available in 2005.

#### **Passive Immunization: Zoster Immunoglobulin and Varicella-Zoster Immune Globulin**

Controlled studies have indicated that pooled immunoglobulin attenuates but does not prevent chickenpox when administered to susceptible family contacts<sup>63</sup> and that zoster immune globulin (ZIG) prevents clinical chickenpox when given to susceptible healthy children within 72 hours of household exposure.<sup>356</sup> Additional uncontrolled studies of immunocompromised children, such as leukemics receiving maintenance chemotherapy, at high risk for developing severe or fatal varicella have indicated that ZIG administered within 3 to 5 days of a household exposure usually modifies varicella so that the infection is mild or subclinical.<sup>357-359</sup> ZIG that was prepared from plasma from donors with zoster has been supplanted by VZIG, which is prepared from normal donors with high antibody titers to VZV. The antibody content of the two preparations is similar,<sup>360</sup> as is the protective efficacy.<sup>361</sup> VZIG is licensed in the United States, and it is commercially available through the American Red Cross and local blood centers.<sup>200</sup> Passive immunization may prolong the incubation period of varicella.<sup>358</sup>

Passive immunization has also been studied for its possible efficacy in modifying severe congenital varicella that may occur in the infant of a woman who develops chickenpox close to term. Infants born to women with the onset of varicella more than 5 days before delivery can be expected to have mild infection,<sup>61,153,291,362,363</sup> and these infants do not require passive immunization. In contrast, infants born to women who develop varicella 5 days or less before delivery are at risk for developing disseminated or fatal varicella, and these infants can be expected to benefit from passive immunization. In an uncontrolled study by Hanngren and co-workers<sup>292</sup> of 41 neonates born to women who developed

**Figure 22-5** Diagrammatic representation of transmission of varicella-zoster virus (VZV) and VZV antibody to the fetus in maternal varicella near term. When the infant is born during the maternal incubation period (1), no varicella occurs unless the infant is exposed postnatally to the infection. When the infant is born 0 to 4 days after onset of maternal varicella (2), disseminated varicella may develop because the infection is not modified by maternal antibody. The onset of varicella occurs when the infant is 5 to 10 days old. Infants born 5 days or more after maternal varicella (3) receive maternal antibody, which leads to mild infection. This diagram is based on data for 50 newborn infants with varicella. (Adapted from Gershon A. Varicella in mother and infant: problems old and new. *In* Krugman S, Gershon A [eds]: *Infection of the Fetus and Newborn Infant*. New York, Alan R Liss, 1975, pp 79-95.)

varicella between 4 days before and 2 days after delivery, the illness appeared to be modified. These infants received 1 mL of ZIG. Although the attack rate was 51%, and the incubation period averaged 11 days, there were no fatalities instead of the expected mortality rate of about 30%, and 13 (62%) of 21 had fewer than 20 vesicles with no fever. Two (10%) had rather severe infections, and one was treated with interferon. In a similar study of VZIG by Preblud and colleagues,<sup>293</sup> a similar varicella attack rate of 45% was observed in 132 infants. In this study, a dose of 125 units (1.25 mL) of VZIG was administered. The illness also appeared to be modified, because of 53 infants with varicella, 74% had fewer than 50 vesicles, and only 10% had more than 100 vesicles. No antiviral therapy was given; there was one death in the group, but it was not clear that it was caused by varicella. The high attack rates of varicella in these studies in comparison with historical data have not been explained. In previous studies, infant attack rates of 24% in late<sup>291</sup> and overall<sup>182</sup> pregnancy have been reported. Successful passive immunization would, if anything, be expected to decrease the attack rate rather than increase it. Nevertheless, the mildness of the illness and absence of mortality in these two studies are suggestive if not proof positive of successful passive immunization of infants born to women with varicella at term. Since the introduction of ZIG and VZIG for use in appropriate neonates, fatalities from neonatal varicella have become rare.

It is recommended that VZIG be administered to infants whose mothers have the onset of varicella 5 days or less before delivery or in the first 48 hours after delivery.<sup>200,364</sup> A dose of 125 units (1.25 mL or one vial) should be administered intramuscularly as soon as possible after birth. Administration of VZIG to the mother before delivery of the infant is not recommended, because a larger dose would be required to passively immunize the infant, and no benefit to the mother will result. Early delivery of the infant of a mother with active varicella is also not recommended; the longer the infant remains in utero, the more likely there will be transplacental transfer of maternal antibody. A diagram of the relationship between maternal and infant varicella, development of maternal antibodies, and transplacental transfer of these antibodies is shown in Figure 22-5. Because women with zoster near term have high antibody titers to VZV, it is not necessary to administer VZIG to their infants.

A small number of infants have developed severe or fatal congenital varicella despite prompt administration of VZIG in adequate dosage.<sup>365-370</sup> The reason for the severity of these

cases is not fully understood, but they appear to be unusual or rare. Presumably, they were immunologically normal infants. Many of these children were reported from the United Kingdom, and the VZIG used there might have been less potent than that produced in the United States. The antibody titers of the two preparations have not been compared. It seems obvious, however, that passively immunized infants should be observed carefully for the rare instance in which antiviral therapy may also be required. Rapid evolution of large numbers of vesicles, hemorrhagic manifestations, and respiratory involvement are indications for the use of intravenous acyclovir. Some investigators have recommended prophylactic use of intravenously administered acyclovir in any infant who develops varicella despite passive immunization,<sup>366,367,371,372</sup> but this strategy has not been formally studied. Based on the studies cited previously, most passively immunized infants who develop clinical illness will have mild or moderate infections. Administration of acyclovir to all such infants who develop clinical illness would result in needless hospitalization of many infants and potential iatrogenic problems and would not be cost effective. Unless additional data become available, acyclovir should be given only to infants who manifest early signs of potentially severe varicella.

Although it is recommended that VZIG be administered to infants born to women who develop varicella in the first 2 days after delivery, few reports indicate that this timing of birth at onset of maternal varicella is associated with increased risk to the infant. One of the reported infants with fatal varicella despite passive immunization was born to a woman who developed chickenpox on the second postpartum day.<sup>368</sup> A child with severe varicella whose mother developed chickenpox 3 days after delivery has also been reported.<sup>373</sup> This child was treated with a leukocyte transfusion from her mother and thymic hormone and survived. In view of the absence of data indicating efficacy and the potential danger of graft-versus-host reaction after leukocyte transfusion in immunocompromised patients,<sup>374</sup> this therapy cannot be recommended.

To minimize the possibility of infection of the infant, mother and infant should be separated until the mother's chickenpox vesicles have dried, even if the infant has been passively immunized. Normally, this will be 5 to 7 days after the onset of maternal rash. If the infant develops clinical varicella, the mother may care for the infant.

Pregnant women who are closely exposed to persons with varicella or zoster and who have no history of varicella and are seronegative may be passively immunized with VZIG.<sup>200</sup> Although precise information regarding dosage is not available, a dose of 5 mL (625 units) is usually recommended for adults. The rationale for passive immunization of the mother is to protect her from developing severe chickenpox.

Because some low-birth-weight infants may have low or absent levels of transplacentally acquired maternal VZV antibody, it is recommended that infants of less than 28 weeks' gestation or who weighed less than 1000 g at birth be passively immunized with VZIG after close exposure.<sup>200,364</sup> There is no recognized age at which passive immunization is no longer recommended for these infants, but presumably it would not be necessary in an infant more than several weeks old. Administration of VZIG to term infants who are 2 to 7 days old at the time of exposure is not recommended, but it may be done optionally to decrease morbidity from varicella in this age group.<sup>375</sup> VZIG should not be used to try to control nosocomial varicella because it does not necessarily prevent varicella but rather modifies it.

#### **Guidelines for Preventive Measures and Isolation Procedures in the Nursery**

In contrast to transplacentally transmitted chickenpox, there is little evidence that postnatally acquired chickenpox (defined as disease beginning after the infant is 10 days old) is significantly more serious in infants than in older children (discussed in the preceding section). Nevertheless, despite the evidence cited previously indicating that nosocomial chickenpox among infants in the nursery is relatively uncommon, it is desirable to institute preventive measures to minimize the possibility of transmission of infection to other neonates, mothers, and hospital personnel. Any hospital patient isolated because of chickenpox or zoster should be in a separate room with the door closed, preferably in a room with air pressure negative compared with that in the corridor. Visitors and staff should be limited to persons immune to varicella. They should wear a new gown for each entry and wash their hands when leaving. Bedding and tissues soiled with respiratory excreta of the patient should be bagged and autoclaved. Special precautions for feces, urine, and needles or blood products are not required. Terminal disinfection of the room is likewise unnecessary.

Guidelines for isolation procedures and other measures are summarized in Table 22-10. If there are siblings or others at home with active VZV infections at the time mother and infant are ready for discharge from the hospital, one of the following alternatives is recommended:

1. The mother and neonate may be sent home after boarding the older siblings with immune relatives until they are no longer infectious, generally when no new vesicles have appeared for 72 hours and all lesions have progressed to the stage of crusts.
2. The mother can return home while the neonate remains in the nursery.
3. The neonate can be boarded with a surrogate mother until the siblings are no longer infectious.
4. VZIG may be given to the newborn.

If siblings at home develop chickenpox at the time of delivery or shortly after birth and the mother lacks a definite

history of previous chickenpox, the first or last alternative is recommended. Serologic determination of the mother's immune status to varicella is recommended. Women with detectable VZV antibodies may be discharged home. Those who are seronegative should be offered varicella vaccine. Theoretically, if a woman has a history of varicella, her newborn should be at least partially protected from varicella. It seems prudent, however, to use a conservative approach, such as outlined here, because the real risk of varicella to the newborn is unknown.

When a mother with a negative history is exposed to chickenpox or zoster 6 to 20 days ante partum, she may become infectious before the onset of exanthem, during hospitalization for labor and the puerperium, assuming an average stay of 72 hours. This calculation is based on a minimum incubation period (exposure until onset of rash) of 10 days and a period of communicability preceding the exanthem by 3 days. When maternal exposure occurs less than 6 days before the onset of labor, the mother is unlikely to become infectious until after she has returned home. In either case, if the mother is exposed to chickenpox during the 20-day period ante partum, it is advisable to send the mother and infant home at the earliest possible date.

No special management is necessary for other mothers and infants in the nursery or for physicians and nurses potentially exposed in the delivery room or the nursery if they have previously had chickenpox. In the absence of a positive history, immediate serologic testing to determine the immune status of exposed hospital personnel may be performed when diagnostic facilities are available. Exposed personnel with negative histories may continue to work in the nursery for a period of 8 days after exposure pending serologic results because they are not potentially infectious during this period. Personnel with positive VZV antibody titers in serum are probably immune. Nonimmune (seronegative) nursery and delivery personnel should be excluded from patient care activities between days 8 and 21 after exposure. Subsequently, they should be strongly encouraged to be immunized against varicella, and they may be given postexposure prophylaxis with varicella vaccine (discussed later).

The greatest risk of nosocomial chickenpox exists when a mother develops chickenpox lesions less than 5 days before delivery or in the immediate postpartum period. If the neonate is born with lesions (i.e., congenital chickenpox), the mother and her newborn should be isolated together and sent home as soon as they are clinically stable. Other exposed mothers and infants in the nursery may also be sent home at the earliest date possible. Restriction of patient care activities and serologic testing of exposed delivery and nursery personnel as described earlier should be instituted. Passive immunization of exposed infants is optional considering the usually benign course of postnatally acquired chickenpox.

When maternal chickenpox occurs within approximately 5 days of delivery or immediately post partum and no lesions are present in the neonate, the mother and the infant should be isolated separately. Transplacentally acquired chickenpox, beginning 7 to 15 days after disease appears in the mother, will ultimately develop in about one half of these neonates despite administration of VZIG. The remainder will be at risk for postnatally acquired chickenpox unless isolated from their mothers. If no lesions develop in the

Send home with mother if no lesions develop by the time mother is noninfectious.</li> <li><i>Other mothers and infants</i>: send home at earliest date. VZIG may be given optionally to exposed neonates</li> <li><i>Hospital personnel</i>: same as B-3.</li> </ol>
D. Onset of maternal chickenpox ante partum <sup>f</sup>			<ol style="list-style-type: none"> <li><i>Mother</i>: isolation unnecessary if no longer infectious.</li> <li><i>Infant</i>: isolate from other infants but not from mother.</li> <li><i>Other mothers and infants</i>: same as C-3 (if exposed).</li> <li><i>Hospital personnel</i>: same as B-3.</li> </ol>
E. Congenital chickenpox	No	Yes	<ol style="list-style-type: none"> <li><i>Infected infant and mother</i>: same as D-1 and D-2.</li> <li><i>Other mothers and infants</i>: same as C-3.</li> <li><i>Hospital personnel</i>: same as B-3.</li> </ol>

<sup>a</sup>Send serum to virus diagnostic laboratory for determination of antibodies to VZV by a sensitive technique such as FAMA, LA, or ELISA. Personnel may continue to work for 8 days after exposure pending serologic results because they are not potentially infectious during this period. Antibodies to VZV >1:4 probably are indicative of immunity.

<sup>b</sup>VZIG is available through the American Red Cross. The dose for a newborn is 1.25 mL (1 vial). The dose for a pregnant woman is conventionally 6.25 mL (5 vials).

<sup>c</sup>Considered noninfectious when no new vesicles have appeared for 72 hours and all lesions have crusted.

<sup>d</sup>If exposure occurred less than 6 days ante partum, mother would not be potentially infectious until at least 72 hours post partum.

ELISA, enzyme-linked immunosorbent assay; FAMA, fluorescent antibody to membrane antigen; LA, latex agglutination; VZIG, varicella-zoster immune globulin; VZV, varicella-zoster virus.

neonate by the time its mother is noninfectious, both may be sent home. Guidelines for exposed hospital personnel and patients are like those described previously.

In congenital chickenpox, lesions may be absent in the mother at the time of delivery but present in the neonate. This may occur after rare subclinical infection in the mother<sup>98</sup> or because the onset of the exanthem in the infant occurs after the lesions in the mother have already healed. In either circumstance, the mother is not at risk and may be isolated with her newborn infant.

### Active Immunization against Chickenpox

A live-attenuated varicella vaccine was developed in Japan by Takahashi and colleagues.<sup>376</sup> This vaccine was licensed in 1995 by the U.S. Food and Drug Administration for varicella-susceptible healthy children older than 1 year, adolescents, and adults. The vaccine is also licensed for routine use in a number of countries in Europe and in Asia, including Japan. The vaccine has proved to be safe and highly effective,<sup>46,377,378</sup> and it is recommended for routine use by the American Academy of Pediatrics<sup>364,379</sup> and the Centers for Disease

Control and Prevention.<sup>200</sup> The vaccine protects against varicella in about 85% of those vaccinated and decreases the incidence of zoster in immunocompromised patients and presumably in healthy vaccinees.<sup>122,377,378,380</sup>

The major adverse effect of vaccination is development of a very mild transient rash about 1 month (range, few days to 6 weeks) after immunization. The main concern about the rash is the possibility of spread of the vaccine-type virus to varicella-susceptible persons intimately exposed to a vaccinee with a rash. Contagion has not been reported in the absence of rash, and contact cases have uniformly been mild. There is no evidence of clinical reversion to wild-type VZV.<sup>45,158,377</sup> The vaccine-type virus spreads less efficiently than the wild-type virus, by a factor of about four, in children with leukemia who were immunized.<sup>45</sup> There is a much greater tendency to develop rash and also to transmit vaccine-type VZV from immunocompromised vaccinees than from healthy vaccinated individuals. A quantitative comparison is difficult to make, but in household contacts of leukemic vaccinees with rash, transmission occurred in about 25%.<sup>45</sup> In contrast, since the licensure of vaccine in the United States, about 40 million doses of vaccine have been distributed by the manufacturer, with only three reported instances of spread.<sup>46</sup> (There is one additional recorded instance of spread of varicella vaccine from a healthy vaccinee involving an experimental varicella vaccine.<sup>381</sup>) Unfortunately, one instance of spread occurred when a healthy child was immunized and his pregnant mother developed mild varicella, from which the vaccine-type virus was identified by PCR.<sup>382</sup> The mother terminated the pregnancy; the products of conception were negative for VZV by PCR. It is important to immunize susceptible women of childbearing age before they become pregnant. The risk of immunizing healthy toddlers is calculated to be lower than not immunizing them and risking their development of natural varicella that would expose a pregnant varicella-susceptible pregnant mother to the fully virulent virus.<sup>383</sup> Widespread use of vaccine in the United States may decrease or even eliminate the problems of congenital malformations and severe varicella in the neonatal period, as has occurred with rubella. Although varicella vaccine-type virus has not been shown to cause the congenital varicella syndrome, immunization during pregnancy is contraindicated. It is also recommended that immunized women refrain from becoming pregnant for at least 3 months after receipt of vaccine.<sup>200,364,379</sup> Individuals older than 13 years are recommended to receive two doses of vaccine 4 to 8 weeks apart. The reported seroconversion rate after two doses of vaccine in healthy adults is about 90%.<sup>158,377</sup> Ideally, women should have serologic testing for immunity after immunization, but a negative antibody titer after immunization does not necessarily indicate vaccine failure because commercially available ELISA antibody tests may fail to identify some individuals who have responded to the vaccine.<sup>384</sup>

The vaccine program in the United States has been highly successful, with a decrease in varicella incidence in the vaccinated and unvaccinated in regions where there is active reporting of varicella.<sup>46,385,386</sup> There is evidence of herd immunity with this vaccine.

The vaccine is under scrutiny for two reasons. One concern is the possibility of rare primary (no take) and secondary (waning immunity) immune failure. Studies involving outbreaks of varicella in children in daycare have suggested that

these phenomena can result in transmission and even lead to mini-epidemics. In one daycare study, protection against varicella was only 44% in vaccinees.<sup>387</sup> Considerable data have suggested that children younger than 15 months may respond slightly less effectively to vaccine than older children.<sup>387-390</sup> A two-dose schedule to obviate these unusual problems has been suggested, but the recommendations for vaccine use in the United States remain unchanged.<sup>391</sup>

The second issue surrounding varicella vaccine is whether its widespread use will lead to a significant increase in the incidence of zoster in the unvaccinated. It is thought that zoster is less common in those vaccinated than in those who have had natural infection.<sup>392</sup> This probably occurs because the vaccine virus is less likely to establish latent infection than the wild-type virus. After natural infection, however, reexposure to wild-type VZV can boost immunity to the virus, resulting in protection against zoster, presumably caused by control of reactivating virus before it results in illness.<sup>392</sup> The important question is how significant an increase in zoster is likely to occur in the vaccine era. Based mainly on epidemiologic evidence and computer modeling, some studies predict a serious increase in zoster with accompanying fatalities.<sup>393,394</sup> The incidence of zoster is roughly 2 cases per 1000 person-years of observation.<sup>395</sup> If this incidence doubles as a result of routine vaccination, it is unlikely to represent an epidemic of zoster. Moreover, zoster is rarely fatal even in immunocompromised patients, in contrast to varicella, which continues to cause fatalities and has a higher mortality rate than zoster.<sup>396-399</sup>

## MEASLES

Measles (i.e., rubeola) is a highly communicable childhood disease whose hallmarks are fever, coryza, conjunctivitis, cough, and a generalized maculopapular rash that usually appears 1 to 2 days after a specific enanthem (i.e., Koplik's spots). The word *measles* means "little spots" and is derived from the Dutch word for the disease, *maeselen*, a diminutive of *maese*, meaning "spot" or "stain."<sup>400</sup> Although measles was described in medieval times, it was not until the 17th century that Sydenham differentiated the disease from smallpox and scarlet fever.

### The Organism

#### *Classification and Morphology*

Measles virus is a paramyxovirus, but some of its properties, such as the lack of neuraminidase, are distinct from those of other members of this family. Like paramyxoviruses, measles virions have a diameter of 100 to 250 nm and consist of a helical ribonucleoprotein core surrounded by a lipid envelope.

In cell culture, virions replicate predominantly in the cytoplasm and are released from the cell surface by budding. The envelope of the virion is composed of at least two glycoproteins: E, which causes membrane fusion and is crucial for infectivity, and H, the hemagglutinin. A nonglycosylated matrix protein, M, also exists on the envelope. Antibodies to glycoprotein F inhibit viral infectivity.<sup>401</sup> Other internal structural proteins are the large protein (L), the phosphoprotein or polymerase (P), and the nucleocapsid protein (N). The cellular receptors for measles virus are the CD46 and

CD150 molecules expressed on human lymphocytes and many other human cell types.<sup>402,403</sup>

Measles virus has been fully sequenced. Genomic data indicate that the viruses that caused the resurgence of measles between 1989 and 1992 were not new strains, that most of the reported cases in 1994 and 1995 were the result of international importation of virus, and that aggressive control measures in 1992 resulted in control of the viruses circulating at that time.<sup>404</sup> The latest data support this contention and indicate that there is no endemic measles in the United States; the few circulating viruses identified are imported from other countries.<sup>403,405</sup>

### **Propagation of Measles Virus**

Primary cultures of human embryonic kidney and rhesus monkey kidney cells have proved to be superior to all others for the isolation of measles virus, although the agent has been adapted after several passages to a number of continuous cell lines.<sup>402</sup> Cytopathic effect on primary isolation is not generally detected before 5 to 10 days. Rapid identification may be accomplished by use of immunofluorescent staining using monoclonal antibodies.<sup>402</sup>

### **Antigenic Properties and Serologic Tests**

Measles virus isolates are antigenically homogeneous. Some cross-reactivity of soluble ribonucleoprotein antigens and hemagglutinins has been observed among measles and the related viruses of rinderpest and canine distemper but not with other paramyxoviruses. The hemagglutination inhibition (HI) test has essentially been replaced with more modern assays for antibodies.

ELISA is the most useful and sensitive method for measuring antibodies to measles virus.<sup>402,406</sup> A similar test that identifies specific IgM antibody and is useful diagnostically when only one serum specimen is available has also been developed.<sup>402,407,408</sup>

## **Transmission and Epidemiology**

### **Transmission by Droplets and Fomites**

Measles is the most communicable of the childhood exanthems.<sup>51,64</sup> The virus is spread chiefly by droplets expectorated by an infected subject in proximity to susceptible persons. Rarely, transmission may occur by means of articles soiled by respiratory secretions. There is some uncertainty concerning the precise portal of entry of the virus. Although the virus may gain access through the nose or the oropharynx, the work of Papp<sup>409</sup> suggests that the conjunctival mucosa is at least a possible portal of entry.

Measles occurs worldwide in temperate, tropical, and arctic climates. Before the introduction of live measles vaccines, urban areas of the United States typically experienced epidemics at intervals of 2 to 3 years. In interepidemic years, few cases of measles occur, probably because the supply of susceptible persons has been exhausted. Additional births add to this pool, permitting epidemic transmission when the pool is sufficiently large. In the United States, the disease had a peak incidence between March and May. Seasonal variation is attributed to the crowding of children indoors and in schools in the winter, resulting in increased transmission. Amplification of each cycle leads to a progressively larger number of cases of measles by the end of the

winter. Attack rates are highest among the lowest socioeconomic populations.

Patterns of disease vary strikingly with respect to age, incidence, and severity in different geographic regions. In urban areas of industrialized countries, measles infects predominantly children between the ages of 2 and 6 years, and the disease is relatively mild. In rural areas of the same countries, children are characteristically older when they contract the disease and may reach adulthood without becoming infected. For this reason, measles in pregnant women may be observed more often among women from rural or otherwise geographically isolated localities (see later discussion). A different pattern of disease is seen in less developed areas, such as equatorial Africa, where measles occurs predominantly in children younger than 2 years and has a high fatality rate.<sup>410</sup> Protein deficiency is associated with an increased incidence of complications, such as bronchopneumonia and death. Still another pattern of infection has been observed in extremely isolated regions of the world, where whole populations may never have experienced measles before its exogenous introduction. In a classic description of such an epidemic in the Faroe Islands in 1846, measles was observed to spread rapidly through an entire population, irrespective of age, with an attack rate of virtually 100%.<sup>411</sup> Mortality rates tend to be higher in populations having little experience with measles. An extreme example is the Fiji Islands epidemic of 1875, in which 20,000 people, or about one fourth of the population, are said to have died.<sup>411</sup>

The use of live-attenuated measles vaccine in the United States since 1963 has decreased the incidence of measles to less than 1% of its former incidence. Before 1963, there were about 400,000 reported cases of measles annually; a record low of 1497 cases was reported in 1983, but in the late 1980s and early 1990s, there was an increase in the incidence of measles that has since come under control.<sup>372</sup> From 1989 to 1991, there were more than 55,000 reported cases with more than 120 measles-associated deaths reported to the Centers for Disease Control and Prevention, but after 1991, the number of reported cases dropped significantly.<sup>412</sup> Measles occurring despite vaccination may be the result of primary vaccine failure, a "no take" for the vaccine, or secondary vaccine failure due to loss of immunity to measles after vaccination.<sup>413,414</sup> There is little evidence, however, that secondary immune failure (i.e., that protective immunity induced by measles wanes with time) is significant.<sup>413-416</sup> Since the requirement for two doses of measles vaccine in childhood was instituted in 1993, the number of annual cases of measles has fallen to an all-time low. In 1995, 309 cases were reported, and in 1996, 508 cases were reported to the Centers for Disease Control and Prevention.<sup>412</sup> Measles has become a rare disease in the United States; in 2001, only 116 cases were reported.<sup>403,405</sup>

### **Incidence of Measles in Pregnant Women**

Because measles is well controlled in the United States by immunization, it occurs even less frequently during pregnancy than chickenpox.

## **Pathogenesis**

By analogy with other viral infections whose pathogenesis has been better delineated, the initial multiplication of

measles virus is believed to occur in epithelial and lymphoid cells near the portal of entry. A transient viremia then delivers virus to the reticuloendothelial system, where further replication occurs. A second viremia, more severe and more sustained, disseminates virus to the skin, gut, respiratory tract, and other affected organs. In monkeys, this viremia may occur over a period as long as 1 week before the appearance of the prodrome or exanthem. Measles virus replicates in and probably destroys lymphocytes in the peripheral blood,<sup>417</sup> giving rise to a circulating lymphopenia. The symptoms of measles are probably attributable to inflammation accompanying necrosis of cells in which the virus is replicating. By the time the exanthem appears, 13 to 14 days after infection, measles virus is actively replicating in the skin, gut, and respiratory mucosa. Electron microscopy of biopsies of Koplik's spots and cutaneous lesions reveals syncytial giant cells whose nuclear and cytoplasmic inclusions contain aggregates of microtubules that are 15 to 20 nm in diameter and characteristic of paramyxovirus infection.<sup>418</sup> This finding and the observation that convalescent measles serum injected into the skin can prevent the local development of the exanthem<sup>419</sup> suggest that replication of virus *per se* is directly responsible for the lesions. Nevertheless, it is possible that an interaction between viral antigen and antibody is required. The latter hypothesis is supported by the observation that immunosuppressed children who develop giant cell pneumonia caused by measles virus do not develop a rash and do not elaborate antibodies.<sup>420,421</sup> Virus titers in the viscera have already diminished considerably by the time the exanthem appears, and serum antibodies are readily detectable within 24 hours. There is also experimental evidence that T lymphocytes are important in the development of some symptoms of measles such as the rash, as well as in recovery from the disease.<sup>422</sup>

#### **Incubation Period for Measles Acquired by Droplet Infection**

The usual interval between exposure to measles and onset of first symptoms (i.e., prodrome) is about 10 days; 12 to 14 days usually elapse before the onset of rash. However, considerable variation may be observed.<sup>383</sup> The incubation period in modified measles (see "Clinical Manifestations") may last as long as 17 to 21 days, because of the presence of low levels of measles antibodies.<sup>423</sup>

#### **Incubation Period for Hematogenously Acquired Measles**

It has been claimed that infantile measles may be acquired by transfusion of maternal blood presumably containing measles virus.<sup>424</sup> Two infants developed typical exanths and exanths 13 and 14 days after transfusion, and their mothers developed measles exanths 4 and 2 days, respectively, after blood donation. The infants had not been visited by their mothers for 4 days and 1 day, respectively, before transfusion. Hematogenous transmission may not have occurred, however, because the mothers may well have been shedding virus from the respiratory tract at the time they last handled their infants.

Intrauterine hematogenous transmission is well documented (discussed later). In these cases, the onset of disease in the infant may occur almost simultaneously with that in the mother or after a variable interval that is less than the

minimum time required for extrauterine infection by the respiratory route.

#### **Period of Communicability**

Measles is more communicable during the prodrome and catarrhal stage of infection than during the period of the exanthem. Dramatic corroboration of this observation was provided during an epidemic in Greenland in 1962.<sup>425</sup> Deliberate exposure of 400 susceptible persons to disease was achieved by having a patient on the first day of appearance of the exanthem cough twice in the face of each. Not a single transmission resulted. When the experiment was repeated with a patient during the pre-exanthematous period, measles was readily transmitted.

Patients with measles should be considered infectious from the onset of the prodrome (about 4 days before the appearance of the exanthem) until 3 days after the onset of the exanthem, although the risk of contagion abruptly diminishes 48 hours after the rash appears, concomitant with the appearance of circulating neutralizing antibodies. Measles virus is most readily recovered from respiratory secretions from 2 days before until 1 or 2 days after the onset of the rash.

#### **Pathology**

The replication of measles virus in epithelial cells of the mucous membranes and skin leads to the formation of intranuclear inclusions and syncytial giant cells with up to 100 nuclei per cell (i.e., Warthin-Finkeldey cells).<sup>426</sup> Focal hyaline necrosis of epithelial cells is accompanied by a sub-epithelial exudate containing predominantly mononuclear leukocytes. The pathology of cutaneous lesions and Koplik's spots is essentially similar.<sup>418</sup> It is likely that virus replicates simultaneously in the skin and mucous membranes, but Koplik's spots are detected earlier than the exanthem, probably because the epithelium that forms the roof of the lesions is thinner and more translucent in the mucous membranes.

Similar lesions containing the characteristic multinucleated giant cells may be widespread throughout the respiratory and gastrointestinal tracts. The pharynx, tonsils, bronchial epithelium, appendix, colon, and lymph nodes have been involved. Viral bronchitis occurs in most cases of measles. Necrotic columnar epithelial cells and giant cells are sloughed into the lumen of the bronchi and bronchioles. When this damage is extensive, the regenerating epithelium frequently undergoes squamous metaplasia and is accompanied by bronchial and peribronchial inflammation. Extension of the process into the alveolar septa results in interstitial pneumonitis. Secondary bacterial infection commonly supervenes, leading to a bronchopneumonia with purulent exudate.

Measles virus has been demonstrated, using immunofluorescence and immunoperoxidase methodology, in the placental syncytial trophoblastic cells and decidua, in a 25-week fetus of a woman who developed gestational measles. The fetus was spared. It is postulated that placental damage induced by the virus, leading to hypoxia, is responsible for fetal death during maternal measles.<sup>427</sup>

The pathologic signs of measles encephalitis are not readily distinguishable from those of other postinfectious

encephalitides, such as those caused by vaccinia, chickenpox, and rubella. The characteristic lesion is perivenous demyelination, often accompanied by mild perivascular infiltrates of mononuclear leukocytes, petechial hemorrhages, and microglial proliferation. Neuronal damage and meningeal inflammation are not prominent. Nuclear or cytoplasmic inclusions and giant cells are inconstant. Measles virus has been isolated only infrequently from the brain or spinal cord, and it remains unclear whether the pathologic changes in the brain are a direct result of measles virus or an allergic response to a virus-induced product or antigen-antibody complexes.<sup>428,429</sup> Because of the spectrum of pathology, including acute demyelinating encephalitis and acute hemorrhagic leukoencephalitis, it has been postulated that measles encephalitis is an autoimmune process. Myelin basic protein has been demonstrated in the cerebrospinal fluid of patients with measles encephalitis, and the pathologic process has been likened to experimental allergic encephalitis as produced in animal models.<sup>430</sup> One theory regarding pathogenesis is that measles virus has an epitope similar to that of the encephalitogenic sequence in central nervous system myelin (i.e., an instance of molecular mimicry leading to disease).<sup>431</sup> A second form of encephalitis is caused by continued replication of measles virus in the brains of immunocompromised patients.<sup>432</sup>

## Clinical Manifestations

### Prodrome and Rash

The prodrome typically begins 10 to 11 days after exposure, with fever and malaise, followed within 24 hours by coryza, sneezing, conjunctivitis, and cough. During the next 2 to 3 days, this catarrhal phase is accentuated, with markedly infected conjunctivae and photophobia. Toward the end of the prodrome, Koplik's spots appear. They are tiny (no larger than a pinhead), granular, slightly raised white lesions surrounded by a halo of erythema. Beginning with fewer than a dozen specks on the lateral buccal mucosa, Koplik's spots may multiply during a 24-hour period to affect virtually all the mucous membranes of the cheeks and may extend to the lips and eyelids. Hundreds of spots may be present. At this stage, the lesions may be said to resemble grains of salt on a wet background. Koplik's spots appear 1 to 2 days before the exanthem.

The rash, which appears 12 to 14 days after exposure, begins on the head and neck, especially behind the ears and on the forehead. At first, the lesions are red macules 1 to 2 mm in diameter, but during a period of 2 or 3 days, they enlarge and coalesce. By the second day, the exanthem has spread to the trunk and upper extremities. The lower extremities are involved by the third day. The lesions are most prominent in those regions where the exanthem appears first, namely, the face and upper trunk. By the third or fourth day, the exanthem begins to fade in the order of its appearance. A brown staining of the lesions often persists for 7 to 10 days and is followed by fine desquamation.

The clinical course of measles may be greatly altered by administration of immunoglobulin during the incubation period. In modified measles, the catarrhal phase may be completely suppressed and the exanthem limited to a few macules on the trunk.

### Complications and Mortality

The most frequent complications of measles involve the respiratory tract. Otitis media and mild croup are common in young children during the catarrhal phase, but bacterial pneumonia is the complication that results in death most frequently. If carefully sought, fine rales and radiologic evidence of bronchopneumonia can be found during the early exanthematous phase in most patients. Cough may persist beyond the peak of the exanthem in uncomplicated measles, but when the fever fails to decline or recurs as the rash is fading, a bacterial superinfection is usually present. The chest radiograph may show consolidation. A peripheral blood polymorphonuclear leukocytosis is present. When bacterial superinfection occurs, antimicrobial therapy is indicated and should be directed against the most likely etiologic agents: *Streptococcus pneumoniae*, *S. aureus*, and *Streptococcus pyogenes*. Smears and cultures of sputum should be obtained, but in young infants it may be necessary to treat bacterial superinfection without a specific etiologic diagnosis because of the difficulty in obtaining adequate sputum and the potential gravity of the illness (see "Therapy").

After otitis and pneumonia, encephalitis is the most frequent serious complication of measles. It is far less common than pneumonia. Encephalitis, including coma and gross cerebral dysfunction, is estimated to occur with a frequency of 1 per 1000 cases<sup>428</sup> but is probably more common if drowsiness, irritability, and transient electroencephalographic changes are accepted as evidence of encephalitis. This complication occurs in all age groups, including the neonatal period. A fatal outcome has been recorded in an infant, born in the hospital, who developed measles with encephalitis when 27 days old.<sup>429</sup> Measles encephalitis may occur at any stage of the illness but appears most commonly 3 to 7 days after the onset of the exanthem. The initial symptoms are drowsiness and irritability, followed by lethargy, convulsions, and coma. The cerebrospinal fluid changes are those of a mild aseptic meningitis. Mental obtundation may clear over a period of 1 to 4 days or may assume a more protracted course that is associated with a higher incidence of such sequelae as severe behavioral abnormalities and mental retardation. Death occurs in about 11% of cases.<sup>428</sup> Other complications of measles have been described. These include thrombocytopenic purpura, appendicitis, myocarditis, subacute sclerosing panencephalitis, and reactivation or exacerbation of previously acquired tuberculosis. In a study of 3220 U.S. Air Force recruits with measles, whose mean age was 19 years, between 1976 and 1979, bacterial superinfection and elevated serum transaminase levels were observed in 30%, otitis in 29%, sinusitis in 25%, bronchospasm in 17%, and pneumonia in 3%.<sup>433</sup>

The precise case-fatality ratio in measles is highly variable among different populations and at different periods in the history of the same population. Between 1920 and 1950 in Massachusetts, deaths caused by measles declined progressively during each successive 5-year period from 7.6 to 0.28 per 100,000 people, despite an approximately constant morbidity related to measles.<sup>411</sup> Because the decline preceded the widespread use of antibiotics, much of the change is attributed to improved social conditions, less crowding, improved nutrition, and medical care. In the United States since 1963 the case-fatality ratio has averaged about 0.1% based on reported cases, but it may be closer to 0.01% if estimated unreported

cases of measles are included in the calculation.<sup>434</sup> However, the risk is considerably greater in children younger than 1 year old. The age-specific death rates for measles in the United States reported in 1949 (per 100,000 people) were 7.8 when younger than 1 year, 2.8 at 1 to 4 years old, 1.3 at 5 to 9 years old, and 0.4 at 10 to 14 years old. That death rates are higher for infants is confirmed by data obtained during an epidemic in Greenland in 1951, in which the age-specific death rates (per 1000 people) were 26 for infants younger than 1 year and 15 for infants 1 to 2 years old; no deaths were recorded in children between 2 and 14 years old.<sup>435</sup> In cases for which adequate information was available, all deaths of children younger than 1 year old apparently were caused by pneumonia, which appeared during the prodrome or shortly after the onset of the exanthem.

Children with underlying infection with HIV have been reported to be at risk for developing severe measles, and fatalities have been reported, especially in children who have developed AIDS.<sup>436</sup> In Africa, it has also been observed that infants born to HIV-infected women have lower titers of measles antibodies in cord sera than infants from women not infected with HIV. The outcome has been that these infants are at greater risk for developing measles early in infancy.<sup>437</sup> One adolescent with HIV infection who had previously received measles vaccine developed fatal measles pneumonia after the second dose.<sup>438</sup> Because the infection was proved to be from the vaccine virus, measles vaccine is no longer recommended for HIV-infected children who have developed AIDS or evidence of severe immunosuppression.<sup>412</sup>

Immunocompromised children with underlying malignant diseases who have not been immunized are also at risk for developing severe and even fatal measles.<sup>439-441</sup>

### **Maternal Effects of Measles**

Is the pregnant woman with measles at greater risk of serious complications and death than other adults with this disease are? The answer is probably yes. Some of the published experiences leading to this conclusion are summarized in the following paragraphs.

In the early part of the 20th century, fatality rates for pregnant women with measles were reported to be approximately 15%, mostly caused by pneumonia in the puerperium.<sup>442,443</sup> In the 1951 Greenland epidemic, 4 deaths (4.9%) occurred among 83 women who had measles during pregnancy or the puerperium. In contrast, there were 19 deaths (1.7%) among 1099 nonpregnant women between the ages of 15 and 54.<sup>435</sup> This difference is probably significant ( $\chi^2 = 3.9, P = .05$ ). There was no significant difference in the frequency of pneumonia as a complication of measles among pregnant and nonpregnant women in the same age group, but heart failure was observed far more often in pregnant women with measles. Heart failure was observed in seven patients with gestational measles. Of these, three were in the second half of pregnancy, and four were puerperal. Although in some patients heart failure occurred during the prodrome, in most women, it occurred within 2 weeks after onset of the exanthem.

Additional experience in the United States and Australia since 1940 supports the concept that measles during pregnancy is only rarely catastrophic. Among 24 women with gestational measles in an outbreak in rural Oklahoma, no deaths occurred and serious morbidity was likewise not

increased.<sup>444</sup> In another epidemic, reported in 1950 from Australia, 18 cases of gestational measles were observed. In only one case—a woman in the third trimester with measles pneumonia—were complications reported.<sup>445</sup>

Between 1988 and 1992 in the United States, when there was a resurgence of measles, a number of pregnant women developed this infection. Thirteen such women who were hospitalized in Houston, Texas, were reported because 7 (54%) had respiratory complications that were the basis for their hospitalization. They required supplemental oxygen and monitoring in the intensive care unit, and 1 woman died.<sup>446</sup> These women appeared to have primary measles pneumonia rather than bacterial superinfection. Nine of these 13 women were treated with aerosolized ribavirin administered by facemask. Hepatitis, demonstrated by elevations of transaminases, also occurred frequently in these women, but this is a common finding in nonpregnant adults that seems to be of little clinical importance. During this same period, medical records from 58 pregnant women from Los Angeles with measles were reviewed. Thirty-five (60%) were hospitalized for measles, 15 (26%) developed pneumonia, and 2 (3%) died.<sup>447</sup> Although it is difficult to prove that measles is more severe in pregnant than nonpregnant women, it seems likely to be so.

### **Effects of Gestational Measles on the Fetus**

#### **CHROMOSOMAL ABERRATIONS**

The possibility that measles occurring in pregnancy may potentially damage the fetus is suggested by the observation that there is a high frequency of chromosomal breaks in leukocyte metaphase preparations between the second and fifth day of the exanthem.<sup>448</sup> Other reports, however, have not fully confirmed the preceding observations. Miller<sup>449</sup> found no chromosomal breaks in leukocytes of patients with measles who were examined 1 to 12 days after onset of the rash, but he attributed this discrepancy to methodologic differences involving more gentle treatment of the leukocytes. A report from Japan<sup>450</sup> also failed to show an increased frequency of chromosomal breaks per cell in patients with measles compared with those in normal subjects. However, a significant increase in chromosomal breaks was observed in patients with Down syndrome who had measles and it was inferred that their chromosomes were more sensitive to measles infection.<sup>450</sup>

These chromosomal abnormalities are transient and disappear during convalescence. No studies have examined whether intrauterine exposure of the fetus to measles results in more lasting chromosomal aberrations.

#### **ABORTION AND PREMATURITY**

The consensus of several reports dealing with the frequency of premature births is that this untoward event occurs more often in association with measles during pregnancy than in the pregnant population at large. In contrast to rubella, in which there is retarded intrauterine development, prematurity caused by measles is associated with normal intrauterine development but premature expulsion of the fetus. Although there is no statistically valid proof that gestational measles also causes a higher rate of abortion, it seems probable that measles is responsible for some instances of abortion.

Among the retrospective studies is that of Dyer,<sup>444</sup> who reported 24 cases of gestational measles from rural Oklahoma in 1938 and 1939. Uterine contractions, which typically occurred during the illness, were identified in 11 of the 24 women and caused premature delivery of the fetus in 9 (38%). In one woman in whom measles occurred at 18 weeks' gestation, the exanthem was followed by spontaneous abortion 7 days later. Two additional pregnancies were associated with premature births at 33 weeks' gestation. No abortions were associated with eight cases of measles occurring in the first trimester.

Adverse outcomes of gestational measles on the fetus involving 18 pregnant women with measles were reported in the epidemic in South Australia in 1950.<sup>445</sup> There were three spontaneous abortions (17%), which occurred in one of seven women who had measles in the first trimester, one of eight in the second trimester, and one of three in the third trimester. Abortions followed the onset of the exanthem by 2 to 3 weeks in the patients who became ill in the first and second trimesters. The patient with measles in the third trimester had severe measles pneumonia and expelled a macerated fetus 7 weeks later. One live premature birth was recorded in the third trimester.

In the 1951 Greenland epidemic, birth or abortion occurred in 26 of the 76 pregnant women while they had measles.<sup>435</sup> Thirteen were term pregnancies. Of the remainder, spontaneous abortion at 3 to 5 months' gestation occurred in seven women (9%). There were six instances of premature delivery (8%), and perinatal death ensued in three. A retrospective analysis of 51 women in Greenland who developed measles during the first 3 months of pregnancy between 1951 and 1962 also suggested a high fetal death rate. One half with measles in the first 2 months and one fifth with measles in the third month had spontaneous abortions.<sup>451</sup> Five infants born to women with measles during an outbreak in 1981 and 1982 in Israel have been reported.<sup>452</sup> All were born prematurely (range, 28 to 34 weeks) with a mean duration between maternal onset of illness and delivery of 3.5 days and a mean birth weight of 1496 g. None had any signs of measles at birth or in the neonatal period.

Controlled, prospective studies carried out in New York City during the period from 1957 to 1964 demonstrated a significant association between maternal measles and prematurity but not between maternal measles and abortion. Low birth weight (<2500 g) was identified in 10 (16.7%) of 60 infants born to measles-infected mothers, compared with 2 (3.3%) of 62 matched controls ( $\chi^2 = 6.2$ ,  $P < .025$ ) (see Table 22-5).<sup>178</sup> When fetal mortality was examined in relation to gestational age (see Table 22-6), it was found that 3 deaths (15.8%) occurred in 19 cases of measles in the first trimester, 1 (3.4%) in 29 in the second trimester, and 1 (5.9%) in 17 in the third trimester.<sup>178</sup> These figures were not significantly different from those for fetal deaths in control pregnancies not involving measles. Of the five fetal deaths that occurred in pregnant women with measles, two of the deaths occurred within 2 weeks of maternal disease.

The resurgence of measles from 1989 to 1991 resulted in measles in a number of pregnant women. In the experience of Atmar and associates,<sup>446</sup> there was an adverse fetal outcome in 4 (31%) of 13 pregnancies complicated by maternal measles. Two women gave birth in the 34th and 35th weeks,

and one spontaneously aborted at 16 weeks during measles. One additional woman and her fetus died at 20 weeks. In a report from Los Angeles of 58 women, the incidence of abortion was 5 (9%), and that of prematurity was 13 (22%).<sup>447</sup>

#### CONGENITAL DEFECTS

The teratogenic potential of gestational measles for the fetus has been neither proved nor refuted because of the rarity of the infection during pregnancy, particularly during the first trimester when the process of organogenesis is most active. It seems clear, however, that if measles causes congenital malformations, it does so far less frequently than does rubella. Unlike gestational chickenpox, no particular constellation of abnormalities has been found among the sporadic instances of congenital defects that have occurred because of measles in the mother during pregnancy.

Isolated instances of buphthalmos,<sup>453</sup> congenital heart disease,<sup>454</sup> cleft lip,<sup>210</sup> pyloric stenosis,<sup>454</sup> genu valgum,<sup>453</sup> cerebral leukodystrophy,<sup>451</sup> and cyclopia<sup>451</sup> have been reported in infants born to mothers with measles diagnosed during the organogenic period. In these and other cases, documentation that the maternal illness was measles and not rubella or other exanthems is often lacking.

No congenital malformations were observed among four infants born to mothers who had measles during the first 4 months of pregnancy in the Oklahoma outbreak.<sup>444</sup> Similarly, in the 1951 Greenland epidemic, there were no congenital malformations among the infants of 76 mothers with gestational measles, although the number of cases that occurred in the first trimester is unclear.<sup>435</sup> After the epidemic in South Australia,<sup>445</sup> two infants with congenital defects (one with Down syndrome and one with partial deafness) were recorded among those whose mothers had measles during the first trimester. No birth defects occurred in infants born to eight mothers with measles in the second trimester and three mothers who had been ill in the third trimester. Although one of the five infants born during the outbreak in 1981 and 1982 in Israel was severely malformed, this was not caused by maternal measles, which had begun only a few days before birth. Five additional reported Israeli infants had no congenital anomalies, but all their mothers had measles just before delivery.<sup>452</sup> In the Houston report of 13 pregnant women, the fetal gestational age at onset of maternal measles ranged from 16 to 35 weeks (mean, 27 weeks). Follow-up of eight of these infants, delivered a mean of 12 weeks later (range, 1 to 24 weeks), revealed that no infants had congenital malformations.<sup>446</sup> These analyses are incapable of establishing whether the incidence of congenital defects is increased as a result of gestational measles because they were uncontrolled. One controlled prospective study is inconclusive because only small numbers of pregnant women with measles could be studied. Among 60 children who were born to mothers who had gestational measles and were followed to the age of 5 years, only one congenital malformation was identified, compared with a virtually identical incidence of one defect among 62 controls.<sup>174</sup> The defect in the infected group was bilateral deafness in an infant weighing 1990 g born to a mother who had measles at 6 weeks' gestation. In summary, if there is any increased risk of malformations from gestational measles, this risk appears to be small if it exists at all.

### Perinatal Measles

As in chickenpox, perinatal measles includes transplacental infection and disease acquired postnatally by the respiratory route. Because the usual incubation period from infection to the first appearance of the exanthem is 13 to 14 days, measles exantheams acquired in the first 10 days of life may be considered transplacental in origin, whereas disease appearing at 14 days or later is probably acquired outside the uterus.

#### POSTNATALLY ACQUIRED MEASLES

Several reports describe cases of measles in which the onset of the exanthem occurred in infants 14 to 30 days old. The course of the disease in these cases was generally mild.<sup>444,455,456</sup> In one infant with notably mild illness and little fever, the illness began at the age of 14 days. This neonate had been suckled by the mother, in whom the prodrome of measles developed on the first postpartum day. Because circulating and presumably also secretory antibodies appear within 48 hours of the onset of the exanthem, it is possible that the neonate's illness was modified by measles-specific IgA antibodies present in the mother's milk.<sup>444,455,456</sup> A report from Japan in 1997 described seven cases of measles in infants during the first month of life. No case was believed to be severe, although there were three infants with pneumonia, two of whom had received immunoglobulin at exposure.<sup>457</sup> Measles acquired postnatally may also cause more severe illness; when a mother developed the disease 20 days post partum, her infant was quite sick with measles 10 days later, but complications such as pneumonia or otitis apparently did not develop.<sup>458</sup>

Outbreaks of nosocomial measles in the newborn nursery apparently have not been recorded in the 20th century, probably because of the low incidence of measles in the United States and other developed countries, nearly universal immunity in mothers in urban areas, and corresponding protection of the newborn by passive antibodies.

#### CONGENITAL MEASLES

Congenital measles includes cases in which the exanthem is present at birth and infections acquired in utero in which the rash appears during the first 10 days of life. In congenital measles, the incubation period, defined as the interval between onset of exanthem in the mother and in the infant, varies between 2 days<sup>444</sup> and 10 days<sup>459</sup> (mean, 6 days). A nearly simultaneous onset in mother and neonate implies that measles virus in the maternal bloodstream may sometimes cross the placenta in sufficient quantity to cause disease in the fetus without the need for many additional cycles of replication. However, the placenta may act as a barrier of limited effectiveness, as suggested by those instances in which disease does not appear in the fetus until 10 days after its appearance in the mother. Even more cogent is the fact that maternal measles immediately preceding parturition by no means invariably involves the fetus. Of 44 pregnancies in which a maternal rash was present at delivery, only in 13 (30%) was exanthematous measles reported in the neonate.<sup>443</sup> Later reports include 13 instances in which maternal rashes with onsets ranging from 7 days ante partum to 3 days post partum were associated with clinically apparent measles in the infant in only 3 (23%).<sup>444,452,458,460</sup> However, eight of these children received immunoglobulin (0.25 mL/kg) at birth,

**Table 22-11 Deaths in Neonates Whose Mothers Had Measles at Parturition**

Exanthem in Neonate	Neonatal Deaths <sup>a</sup>	Neonatal Cases	%
Present at birth	4	12	33
Appeared after birth	3	10	30
Did not appear	7 <sup>b</sup>	16	44

<sup>a</sup>Stillborns excluded.

<sup>b</sup>All of these were premature infants reported in a single series.<sup>435</sup>

**Table 22-12 Deaths from Congenital Measles in Relation to Date of Onset of Rash in Mothers**

Onset of Maternal Rash	Neonatal Deaths	Neonatal Cases	%
Ante partum	4	15	27
Post partum	3	11	27

including the three who developed measles.<sup>452,460</sup> During the Greenland epidemic of 1951, no examples of congenital measles were observed among infants born to 13 women who had measles at parturition.<sup>435</sup> It appears that most of these neonates do not experience subclinical measles without exanthem but simply are not infected. This conclusion is supported by the observation that infants whose mothers had measles late in the third trimester are fully susceptible to infection later in childhood.<sup>443</sup> During the Faroe Islands epidemic of 1846, many pregnant women had measles, but 36 years later, their infants were infected as adults in a new epidemic in 1882.<sup>458</sup>

As in congenital chickenpox, the spectrum of illness in congenital measles varies from a mild illness, in which the rash is transient and Koplik's spots may be absent, to rapidly fatal disease. The precise case-fatality ratio is uncertain because the course of measles in different populations has been so variable, even in older children and adults. Among 22 cases of congenital measles culled from the literature in which immunoglobulin prophylaxis was not given, there were seven deaths (Table 22-11).<sup>443,444,458,459</sup> Approximately the same case-fatality ratio (30% to 33%) was observed whether the rash was present at birth or appeared subsequently. Although the number of observations is small, it appears that for premature infants with congenital measles, the death rate is higher (5 of 9) than for infants with congenital measles delivered at term (2 of 10). The death rate has also been high among premature infants born to women who had measles at parturition even when the infant never developed clinically apparent measles (see Table 22-11).<sup>435,443</sup>

Insufficient data are available to evaluate whether transplacentally acquired antibodies to measles virus may diminish the case-fatality ratio in congenital measles when the mother's exanthem appears more than 48 hours ante partum. The death rate from congenital measles does not appear to differ appreciably whether the maternal rash appears ante partum or post partum (Table 22-12), but more precise information on the time of appearance of the maternal rash is needed to

answer this question definitively. Although firm data are not available, administration of immunoglobulin at birth may also decrease mortality.<sup>446,452,460</sup>

Most reports of death related to congenital measles do not specify the immediate cause, but pneumonia is among the leading complications.<sup>443,444,446,452,460,461</sup> Because nearly all reports of deaths preceded the antibiotic era, the current case-fatality ratio may be significantly lower than it was previously because of improved supportive care and appropriate antimicrobial therapy of bacterial superinfections.

## Diagnosis and Differential Diagnosis

The diagnosis of measles is easy when there is a history of recent exposure and the typical catarrhal phase is followed by Koplik's spots and a maculopapular exanthem in the characteristic distribution. Koplik's spots are pathognomonic. However, the diagnosis is more difficult during the prodrome (when the illness is maximally communicable) or when the illness and the exanthem are attenuated by passively acquired measles antibodies. Measles antibodies may be contained in transfused plasma or immunoglobulin, or they may cross the placenta to the neonate if the mother develops measles shortly before parturition. The atypical exanthem of measles in subjects who have been previously immunized with inactivated measles vaccine may potentially also cause diagnostic difficulties. When the diagnosis cannot be made confidently on clinical and epidemiologic grounds, laboratory confirmation is indicated so that appropriate measures can be taken to prevent the occurrence of nosocomial measles among susceptible persons. Aids to rapid diagnosis include examination of exfoliated cells from the pharynx, nasal and buccal mucosa, conjunctiva, or urinary tract by direct staining for epithelial giant cells<sup>462,463</sup> or identification of measles antigens by direct immunofluorescence.<sup>464-466</sup> PCR assays can diagnose acute measles.<sup>402</sup> These tests are positive in more than 90% of patients during the prodrome and the period of the early exanthem. At later stages of the illness, the diagnosis may be confirmed by detecting measles-specific IgM antibodies in serum or rising antibody titers in acute and convalescent sera.<sup>406,407,467</sup> Because serum antibodies appear within 48 hours of the exanthem, it is important that the acute-phase serum be collected at the onset of the rash or earlier.

Among the diseases and conditions to be considered in the differential diagnosis of measles are the following. None is likely to occur in the newborn.

1. *Drug eruptions and other allergies.* Maculopapular exanthems may be caused by a variety of drugs and chemicals in susceptible persons. A history of exposure is of paramount importance in distinguishing these causes from measles. An urticarial component may be seen in some instances of drug hypersensitivity but is not present in measles.

2. *Kawasaki disease.* This illness is often confused with measles and vice versa in children younger than 5 years. Classic signs include conjunctivitis, red cracked lips, strawberry tongue, morbilliform or scarlatiniform rash, induration of the hands and feet, and usually a solitary enlarged cervical lymph node. In confusing cases, viral diagnostic procedures may be necessary to rule measles in or out.

3. *Rubella.* The maculopapular exanthem of rubella is finer and more transient. It undergoes a more rapid evolution

and does not assume the blotchy configuration often seen in measles. The posterior cervical and postauricular lymphadenopathies of rubella are not present in measles, and conversely the prominent catarrhal symptoms in the prodrome of measles are not a feature of rubella.

4. *Scarlet fever.* The rash of scarlet fever is punctate and extremely fine rather than papular. It blanches on pressure and is accentuated in skin folds. The onset is typically abrupt without a prodrome. There is an accompanying sore throat, and the cheeks are flushed. Peripheral blood leukocytosis is usual, in contrast to the leukopenia of measles.

5. *Meningococemia.* When the early rash of meningococemia is maculopapular rather than petechial, it may be confused with measles. Unlike measles, it has no characteristic distribution.

6. *Roseola.* The exanthem of roseola, which usually appears when the patient's temperature drops to normal, typically appears on the trunk before it is evident on the head. It lasts only 1 or 2 days. Roseola, which is caused by human herpesvirus type 6, is seen most often in children younger than 3 years and is almost never seen in adults.

7. *Atypical measles.* This hypersensitivity disease is related to infection with measles virus in persons who received killed measles vaccine years ago. Killed measles vaccine was removed from the U.S. market in 1968. Extremely high measles HI antibody titers (e.g., 1:1 million) have been observed in patients with this disease.

8. *Other infections.* Rocky Mountain spotted fever, toxoplasmosis, enterovirus infections, parvovirus infection, and infectious mononucleosis may cause maculopapular exanthems resembling measles.

## Therapy

The treatment of uncomplicated measles is symptomatic. Immunoglobulin has no proven value in established disease. Antibiotics are not indicated for prophylaxis of bacterial superinfections (i.e., otitis and pneumonia). When these complications develop, antimicrobial therapy should be selected on the basis of Gram stain and culture of appropriate body fluids, such as sputum. If culture specimens cannot be obtained or if the illness is grave, broad-spectrum antibiotics may be selected on the basis of the most likely offending pathogens. The antibiotic regimen for pneumonia, most commonly caused by *S. pneumoniae* or *S. aureus*, should include a penicillinase-resistant penicillin; the drug of choice for otitis media, which is usually caused by *S. pneumoniae* or *Haemophilus influenzae*, is amoxicillin. Vitamin A (200,000 IU orally for 2 days) has been used to treat infants with measles and seems to decrease the severity of the infection.<sup>468-470</sup> The drug ribavirin has been used experimentally to treat severe measles in immunocompromised and other high-risk patients.<sup>471,472</sup>

## Prevention

### Passive Immunization

Passive immunization is recommended for the prevention of measles in exposed, susceptible pregnant women, neonates, and their contacts in the delivery room or newborn nursery (see "Nosocomial Measles in the Nursery"). Therapy with intramuscularly administered immunoglobulin should

be given as soon as possible after exposure. A dose of 0.25 mL/kg given within 72 hours of exposure is a reliable means of prevention of clinical measles, although immunoglobulin given later (up to 7 days after exposure) or in smaller doses (0.04 mL/kg) may also prevent or at least modify the infection. It is recommended that passive prophylaxis be followed in 5 months or more by administration of live measles vaccine in those old enough to receive it.<sup>364</sup>

### Active Immunization

The currently recommended live measles vaccines are derivatives of the Edmonston B strain that have been further attenuated. They produce a noncommunicable infection, which is mild or inapparent. Fever occurs in about 5% of susceptible recipients. A mild rash is observed in 10% to 20% of susceptible recipients 5 to 10 days after administration. The vaccines induce seroconversion in 95% and prevent clinical disease in more than 90% of exposed susceptible recipients. Live-attenuated measles vaccines are contraindicated in pregnant women.<sup>364</sup> In one small series, Edmonston B measles vaccine and  $\gamma$ -globulin were administered to seven pregnant women, 18 to 34 years old, who were in the second to eighth months of pregnancy. There were no serologic data. Three of the seven developed fever ( $>38.5^{\circ}\text{C}$ ) and rash. All were delivered of healthy infants at term.<sup>473</sup> Vaccination is likewise not usually recommended for infants younger than 12 months because the induction of immunity and the elaboration of antibodies may be suppressed by residual transplacentally acquired antibodies in the fetal circulation or other mechanisms. A single fatality in an HIV-infected young adult due to pneumonia after re-immunization has been reported.<sup>438</sup>

In exposed populations having little experience with measles or in populations in which the incidence of natural measles before the age of 1 year is high, live vaccines may be given when infants are 6 to 9 months old but should be followed by a second dose at 15 months to increase the seroconversion rate.<sup>364</sup> Data indicate that measles antibody titers are lower in women vaccinated as children than in women who have previously had natural measles and that the offspring of vaccinated women lose transplacentally acquired measles antibodies before they are 1 year old.<sup>474,475</sup> It is therefore predicted that routine vaccination against measles may be recommended at 12 rather than 15 months. Nevertheless, passive immunization should be given to protect young infants exposed during an epidemic.

Although the MMR vaccine had an excellent safety record in 2000, the question was raised about whether this vaccine might result in autism in previously healthy children.<sup>476</sup> After an extensive review by numerous experts, it was concluded that there was no relationship between MMR and development of autism.<sup>476-479</sup> Unfortunately, the public in the United Kingdom became so fearful of this possibility that use of measles vaccine has decreased significantly, leading to reported outbreaks.<sup>480</sup> Potentially this development could lead to an increase in measles in pregnant women in the United Kingdom and other countries where MMR coverage might fall off.

### Nosocomial Measles in the Nursery: Guidelines for Prevention

Most women of childbearing age in urban areas are immune to measles because of previous natural infection or vacci-

nation. Because it is amply documented that infants born to immune mothers are usually protected by transplacentally acquired antibodies, measles outbreaks in newborn nurseries are extraordinarily rare. Studies by Krugman and colleagues<sup>481</sup> indicated that before the introduction of live-attenuated measles vaccine, 94% of infants had passive HI antibodies when 1 month old, 47% had them at 4 months, and 26% had them at 6 months. The rarity of measles among mothers, newborns, and hospital staff in the newborn nursery makes it difficult to assess the precise risk once the virus has been introduced. Nonetheless, the fact that age-specific mortality rates related to measles are highest in the first year of life (see previous discussion) justifies instituting measures designed to prevent disease in those exposed and the spread of infection to neonates of uncertain immune status (Table 22-13).

Infants born to mothers with an unequivocal history of previous natural measles or vaccination with live-attenuated measles virus are assumed not to be at risk when exposed to measles in the neonatal period. If siblings at home have measles in a communicable stage, neonates born to immune mothers may be discharged from the hospital with no treatment. In the absence of a maternal history of measles or measles vaccine, the mother's serum should be tested for the presence of antibodies to measles. If the mother's serum contains detectable levels of measles antibodies by a reliable method, both mother and baby may be sent home. If specific antibodies are not detected in the mother's serum, the neonate and mother should not have contact with the older siblings until they are no longer infectious. The mother and neonate, as well as any nonimmune older siblings without disease, should receive immunoglobulin (0.25 mg/kg given intramuscularly) to prevent or modify subsequent measles infection that might have been incubating at the time of delivery.

If a mother without a history of previous measles or measles vaccination is exposed 6 to 15 days ante partum, she may be in the incubation period and capable of transmitting measles infection during the postpartum period before discharge from the hospital. In such a situation, it is optimal to test the mother for measles antibodies. If no antibodies are detected (or the test cannot be performed) and if she had been exposed less than 6 days ante partum, she could not transmit measles by the respiratory route until at least 72 hours post partum. By this time in most instances, the mother would have been discharged from the hospital and potential nosocomial transmission would not be a problem. In either event (exposure from 0 to 5 days or from 6 to 15 days ante partum), both the exposed susceptible mother and her neonate should receive immunoglobulin and be sent home as soon as possible unless siblings at home have measles in a communicable stage. If the mother's exposure occurred 6 to 15 days ante partum, prophylaxis with immunoglobulin should also be administered to the other mothers, neonates, and hospital personnel in the delivery room and nursery except those with a history of natural measles or vaccination with live-attenuated measles virus or who have detectable antibodies to measles virus. Globulin prophylaxis given within 72 hours of exposure prevents infection in nearly all instances, and in many cases it is effective for as long as 7 days.<sup>411,482</sup> Immunoglobulin given after this period but before the prodrome usually results in modified measles infection with diminished morbidity.<sup>411,482</sup> Those patients to

Table 22–13 Guidelines for Preventive Measures after Exposure to Measles in the Nursery or Maternity Ward

Type of Exposure or Disease	Measles Present (Prodrome or Rash) <sup>a</sup>		Disposition
	Mother	Neonate	
A. Siblings at home with measles <sup>a</sup> when neonate and mother are ready for discharge from hospital	No	No	<ol style="list-style-type: none"> <li>1. <i>Neonate</i>: protective isolation and immune globulin (IG) indicated unless mother had unequivocal history of previous measles or measles vaccination.<sup>b</sup></li> <li>2. <i>Mother</i>: with history of previous measles or measles vaccination, she may remain with neonate or return to older children. Without previous history she may remain with neonate until older siblings are no longer infectious, or she may receive IG prophylactically and return to older children.</li> </ol>
B. Mother without history of measles or measles vaccination exposed during period 6-15 days ante partum <sup>c</sup>	No	No	<ol style="list-style-type: none"> <li>1. <i>Exposed mother and infant</i>: administer IG to each and send home at earliest date unless there are siblings at home with communicable measles. Test mothers for susceptibility if possible. If susceptible, administer live measles vaccine 5 months after IG.</li> <li>2. <i>Other mothers and infants</i>: same unless clear history of previous measles or measles vaccination in the mother.</li> <li>3. <i>Hospital personnel</i>: unless clear history of previous measles or measles vaccination administer IG within 72 hours of exposure. Vaccinate 5 months or more later.</li> </ol>
C. Administer IG immediately. Send home when mother is no longer infectious. Alternatively, observe in isolation for 18 days for modified measles,<sup>e</sup> especially if IG administration was delayed more than 4 days.</li> <li>3. <i>Other mothers and infants</i>: same as C-2.</li> <li>4. <i>Hospital personnel</i>: same as B-3.</li> </ol>

<sup>a</sup>Catarrhal stage or less than 72 hours after onset of exanthem.

<sup>b</sup>Vaccination with live attenuated measles virus (see text).

<sup>c</sup>With exposure less than 6 days ante partum, mother would not be potentially infectious until at least 72 hours post partum.

<sup>d</sup>Considered infectious from onset of prodrome until 72 hours after onset of exanthem.

<sup>e</sup>Incubation period for modified measles may be prolonged beyond the usual 10 to 14 days.

whom immunoglobulin had to be given should later be vaccinated, after allowing an interval of at least 5 months so that residual measles antibody does not interfere with the immune response to the vaccine.<sup>411</sup>

If a mother develops measles immediately ante partum or post partum and her infant is born with congenital measles, the mother and infant should be isolated together until 72 hours after the appearance of the exanthem. Close observation of the neonate for signs of bronchopneumonia and other complications is warranted. Other susceptible mothers, neonates, and hospital personnel should receive immediate prophylaxis with immunoglobulin as outlined previously, followed by vaccination at a later date.

If a mother develops perinatal measles but her infant is born without signs of infection, each should be isolated separately. The infant may be incubating transplacentally acquired measles or may be at risk for postnatally acquired droplet infection. In either case, the infant should receive immunoglobulin. The mother may be discharged with her infant after the third day of exanthem. The neonate should be followed closely and observed for signs of modified measles, which may require up to 18 days' observation because

of the abnormally long incubation period of modified measles.<sup>411</sup>

The availability of virus diagnostic facilities varies, and the approach to potential nosocomial spread of measles therefore may differ from place to place. If serologic testing is expensive or unavailable, it may be simpler to administer immunoglobulin to all exposed persons who do not have an unequivocal history of previous measles or previous vaccination with live-attenuated measles virus vaccine. Serologic testing of those exposed who are thought to possibly be susceptible to measles, with administration of immunoglobulin to those exposed who are truly susceptible, would seem to be the ideal management for prevention of nosocomial measles.

Neonates or mothers isolated because of measles require a separate room with the door closed. Only immune visitors and staff should enter the room. Gown and hand-washing precautions must be observed, and containment of bedding and tissues soiled with respiratory excreta by double bagging and autoclaving is indicated. Because measles virus is excreted in the urine during the early exanthematous phase, it is also advisable to treat the urine as potentially infectious

and to disinfect bedpans. Terminal disinfection of the room is recommended.

## MUMPS

Mumps is an acute, generalized, communicable disease whose most distinctive feature is swelling of one or both parotid glands. Involvement of other salivary glands, the meninges, the pancreas, and the testes of postpubertal males is also common. The origin of the name is obscure but probably is related to the Old English verb *to mump*, meaning "to sulk," or to the Scottish verb meaning "to speak indistinctly."

### The Organism

#### *Properties and Propagation*

Mumps virus is a member of the paramyxovirus family and therefore has most of the morphologic and physicochemical properties described for measles. Five antigens have been described: two envelope glycoproteins, a hemagglutinin-neuraminidase (H-N), a hemolysis cell fusion (F) glycoprotein antigen, and a matrix envelope protein. There are two internal antigens: a nucleocapsid protein (NP) and an RNA polymerase protein (P).<sup>483</sup>

Mumps virus is readily isolated after inoculation of appropriate clinical specimens into a variety of host systems. Rapid identification may be accomplished by use of cells grown in shell vials and use of fluorescein-labeled monoclonal antibodies.<sup>484</sup>

The virus may be recovered during the first few days of illness from saliva, throat washings, and urine and from the cerebrospinal fluid of patients with mumps meningitis. Shedding of virus in the urine may persist longer, sometimes up to 2 weeks. Less commonly, the virus is present in blood, milk, and testicular tissue.<sup>483</sup>

A highly sensitive ELISA useful for diagnosing and determining susceptibility to mumps has been described. This assay has also been used to diagnose acute mumps in one serum specimen by the presence of specific IgM.<sup>483</sup> The diagnosis may also be established by demonstrating a rising antibody titer in paired acute and convalescent sera.

### Epidemiology and Transmission

#### *Period of Communicability*

Mumps occurs worldwide and is endemic in most urban areas where routine vaccination is not practiced. In the United States, before widespread vaccination against mumps, the incidence was highest in the winter, reaching a peak in March and April. Mumps was principally a disease of childhood, with most infections occurring between the ages of 5 and 15 years. Mumps in infancy is very uncommon (discussed later). In the prevaccine era, approximately one third of infections were subclinical. Epidemics tended to occur in confined populations such as those in boarding schools, the military, and other institutions. Since the introduction of mumps vaccine in 1967, the incidence of clinical mumps has declined dramatically in the United States and mumps remains an extremely uncommon disease.

### *Incubation Period*

The usual incubation period, measured between exposure to infection and onset of parotitis, is 14 to 18 days, with extremes between 7 and 23 days. However, because the contact may be shedding virus before the onset of clinical disease or may have subclinical infection and therefore be unrecognizable, the incubation period in individual cases is often uncertain.

### *Incidence of Mumps in Pregnancy*

The incidence of mumps in pregnancy is unknown. Because there is now little opportunity for exposure to mumps and many women are immune, the incidence is expected to be low. The incidence in prospective studies has been variously estimated as between 0.8 and 10 cases per 10,000 pregnancies.<sup>70,174</sup>

### Pathogenesis

Mumps is transmitted by droplet nuclei, saliva, and fomites. The precise pathogenesis of infection has not been established because, although experimentally infected monkeys may develop parotitis, no animal model closely resembles human disease. After entry into the host, the virus initially replicates in the epithelium of the upper respiratory tract. A viremia ensues, after which there is localization in glandular or central nervous system tissues. Parotitis is believed to occur as a result of viremia rather than the reverse, because in many instances, generalized disease precedes involvement of the parotid gland, which may not be involved at all.

### Pathology

Studies of the pathology of mumps are few because the disease is rarely fatal. The histologic changes that have been observed in the parotid gland and the testis are similar. The inflammatory exudate consists of perivascular and interstitial infiltrates of mononuclear cells accompanied by prominent edema. There is necrosis of acinar and duct epithelial cells in the salivary glands and of the germinal epithelium of the seminiferous tubules.

There are few reports of placental pathology in gestational mumps. Garcia and associates<sup>485</sup> described a 29-year-old Brazilian woman with a history of two bleeding episodes during pregnancy who developed mumps in her fifth month. A hysterotomy was subsequently performed, yielding a macerated 90-g fetus. Necrotizing villitis and accumulation of necrotic material, mononuclear cells, and nuclear fragments were found in the intervillous spaces of the placenta. Necrotizing granulomas and cytoplasmic inclusions consistent with mumps virus infection were also identified. Two additional women with mumps in the 10th week and second month of pregnancy underwent therapeutic abortions. Typical inclusion bodies were identified in both placentas and in the adrenal cortex of one fetus.<sup>485</sup> No serologic data were available on these three women, however, so that it is possible that their parotitis was caused by an agent other than mumps virus.

### Clinical Manifestations

The prodrome of mumps consists of fever, malaise, myalgia, and anorexia. Parotitis, when present, usually appears within

the next 24 hours but may be delayed for a week or even more. Swelling of the gland is accompanied by tenderness to palpation and obliteration of the space between the earlobe and the angle of the mandible. The swelling progresses for 2 to 3 days, then gradually subsides, and disappears in 1 week or less. The orifice of Stensen's duct is commonly red and swollen. In most cases, parotitis is bilateral, although the onset in each gland may be asynchronous by 1 or more days. The submaxillary glands are involved less often than the parotid and almost never by themselves. The sublingual glands are only rarely affected.

Orchitis is the most common manifestation other than parotitis in postpubertal males; it affects about 20% of this group of patients. Orchitis in infancy has been described but is not well documented.<sup>486</sup> Oophoritis is far less common. It is associated with lower abdominal pain, and the ovaries rarely may be palpable. Oophoritis does not lead to sterility.

Aseptic meningitis may occur in children and adults of either sex but is more common in males. Although pleocytosis of the cerebrospinal fluid may occur in up to 50% of cases of clinical mumps, signs of meningeal irritation occur in a smaller proportion of cases, variably estimated at 5% to 25%. The cerebrospinal fluid contains up to 1000 cells/mm<sup>3</sup>. Within the first 24 hours, polymorphonuclear leukocytes may predominate, but by the second day, most cells are lymphocytes. In the absence of parotitis, the syndrome of aseptic meningitis in mumps is indistinguishable clinically from that caused by enteroviruses and other viruses. The course is almost invariably self-limited. Rarely, cranial nerve palsies have led to permanent sequelae, of which deafness is the most common.

Mumps pancreatitis may cause abdominal pain. The incidence of this manifestation is unclear because reliable diagnostic criteria are difficult to obtain. An elevated serum amylase level may be present in parotitis or pancreatitis. The character of the abdominal pain is rarely sufficiently distinctive to permit unequivocal diagnosis. Other complications of mumps include mastitis, thyroiditis, myocarditis, nephritis, and arthritis.

The peripheral blood cell count in mumps is not characteristic. The white blood cell count may be elevated, normal, or depressed, and the differential count may reveal a mild lymphocytosis or a polymorphonuclear leukocytosis.

### **Maternal Effects of Mumps**

Unlike varicella and measles, when mumps occurs in pregnant women, the illness is generally benign and is not appreciably more severe than it is in other adult women.<sup>486-495</sup> In a 1957 "virgin soil" epidemic of mumps among the Inuit, 20 infections occurred in pregnant women. Of these, only 8 (40%) were clinically apparent, compared with an incidence of 57 clinically apparent cases (62%) among 92 nonpregnant women. Overt disease therefore does not appear to be more common during pregnancy.<sup>492</sup> Some complications such as mastitis and perhaps thyroiditis are more frequent in postpubertal women than in men but probably do not occur more commonly in pregnant women than in other adult women.<sup>492</sup> Mumps virus has been isolated on the third postpartum day from the milk of a woman who developed parotitis 2 days ante partum.<sup>496</sup> Her baby, who was not breast-fed, did not develop clinically apparent mumps. Aseptic meningitis, apparently without unduly high incidence or

severity, has also been reported in pregnant women.<sup>497</sup> In pregnant women, as well as in the population as a whole, deaths from mumps are exceedingly rare. One death has been reported in a woman who developed mumps complicated by glomerulonephritis at 8 months' gestation.<sup>497</sup>

### **Effects of Gestational Mumps on the Fetus**

#### **ABORTION**

An excessive number of abortions is associated with gestational mumps when the disease occurs during the first trimester. In prospective studies of fetal mortality in virus diseases, Siegel and associates<sup>178</sup> observed 9 fetal deaths (27%) among 33 first-trimester pregnancies complicated by mumps, compared with 131 (13%) of 1010 matched uninfected controls (see Table 22-6). This difference is significant ( $\chi^2 = 5.6$ ;  $P < .02$ ). Mumps-associated fetal deaths occurred in only 1 of 51 second-trimester pregnancies and none of 43 third-trimester pregnancies. Unlike fetal deaths associated with measles, those associated with mumps were closely related temporally to maternal infection: 6 of the 10 deaths occurred within 2 weeks after the onset of maternal mumps.<sup>178</sup>

Many other reports describe isolated cases of abortion associated with gestational mumps. Most cases occurred in the first 4 months of pregnancy.<sup>487,492,493,495,498-500</sup> In one instance, mumps virus was isolated from a 10-week fetus spontaneously aborted 4 days after the mother developed clinical mumps.<sup>500</sup>

#### **PREMATURITY**

In the only prospective study of low birth weight in relation to maternal mumps infection, no significant association was found.<sup>178</sup> Nine (7.7%) of 117 pregnant women with mumps gave birth to infants with birth weights of less than 2500 g, compared with 4 (3.3%) of 122 uninfected pregnant women in a control group (see Table 22-5).

#### **CONGENITAL MALFORMATIONS**

In experimentally infected animals, mumps virus may induce congenital malformations.<sup>501-503</sup> Definitive evidence of a teratogenic potential for mumps virus in humans, however, has not been shown. Many reports describe the occurrence of congenital malformations after gestational mumps, but no data are available in most of these studies regarding the incidence of anomalies in uninfected matched control pregnancies. Swan<sup>498</sup> reviewed the literature in 1951 and found 18 anomalies in the offspring of 93 pregnancies complicated by mumps. These included four malformations originating in the first trimester (i.e., cutaneous nevus, imperforate anus, spina bifida, and Down syndrome) and nine originating in the second trimester (i.e., four had Down syndrome and miscellaneous other malformations). Other reports have described malformation of the external ear,<sup>488</sup> intestinal atresia,<sup>495</sup> chorioretinitis and optic atrophy in the absence of evidence of congenital toxoplasmosis,<sup>504</sup> corneal cataracts,<sup>454</sup> and urogenital abnormalities.<sup>505</sup> One case of hydrocephalus caused by obstruction of the foramen of Monro in an infant whose mother had serologically proven mumps during the fifth month of pregnancy has been described.<sup>506</sup> A similar phenomenon has been seen after extrauterine mumps with encephalitis<sup>507</sup> and in an animal model.<sup>503</sup> In the only controlled, prospective study, the rate of congenital malfor-

mations in children whose mothers had mumps during pregnancy (2 of 117) was essentially identical to the rate of those in infants born to uninfected mothers (2 of 123).<sup>71</sup> Neither of the two affected infants, both of whom were mentally retarded, was born to any of the 24 pregnant women who had mumps in the first trimester. Similarly, no association between gestational mumps and fetal malformations was reported by British investigators, who evaluated the outcomes of 501 pregnancies complicated by maternal mumps and found no significant differences compared with a control series.<sup>508</sup>

#### ENDOCARDIAL FIBROELASTOSIS

A postulated association between gestational mumps infection and endocardial fibroelastosis in the offspring was at one time the subject of much debate.<sup>509</sup> An extensive review of evidence for and against an etiologic role for mumps virus in this condition was made by Finland in the 1970s that was inconclusive, and there was little more information in the literature for the next 30 years.<sup>510</sup> The issue remains unresolved. The rarity of mumps during pregnancy and the rarity of endocardial fibroelastosis as a possible sequel in the fetus make it unlikely that conclusive data will ever be obtained.

Molecular approaches, however, seem to have shed new light on the issue. Using PCR, mumps virus genome was detected in two of two fatal cases of fibroelastosis.<sup>511</sup> In another study of 29 fatal cases of this disease, fragments of the mumps genome were identified in 20 cases.<sup>512</sup> Adenovirus was identified in the remainder. It was hypothesized that endocardial fibroelastosis is the end result of myocarditis. As mumps has become rare because of vaccination, endocardial fibroelastosis has also become rare.<sup>512</sup> The possible role of intrauterine mumps was not addressed in these two modern studies and may be impossible to evaluate further given the rarity of mumps in developed countries today.

#### Perinatal Mumps

In contrast to congenital chickenpox and measles, congenital mumps or even postnatally acquired perinatal mumps has rarely been documented virologically or serologically. Although several cases of parotitis have been reported in women near delivery and their neonates and infants,<sup>492,513-516</sup> the significance of these reports is often uncertain, especially when clinically apparent mumps only is present in the mother. Other viral, bacterial, and noninfectious causes are difficult to exclude without laboratory evidence of mumps infection.

Among the possible explanations for the rarity of transplacental and postnatally acquired mumps in neonates are the rarity of mumps today, protection of the neonate by passive maternal antibodies, exclusion of mumps virus from the fetus by a hypothetical placental barrier, relative insusceptibility of fetal and neonatal tissues to infection by mumps virus, and occurrence of infections that are predominantly subclinical.

Passage of mumps virus across the human placenta has occasionally been reported. Live-attenuated mumps virus has been recovered from the placenta of pregnant women (but not from fetal tissues) who were vaccinated 10 days before undergoing saline-induced abortion.<sup>517</sup> Mumps virus was isolated from two infants whose mothers had mumps at

delivery. One infant had parotitis, and the other had pneumonia; presumably, transplacental transmission had occurred.<sup>515</sup> Mumps virus was also isolated from a fetus spontaneously aborted on the fourth day after the onset of maternal mumps.<sup>485</sup> However, transplacental passage of virus should not be assumed to occur invariably because in several instances passage could not be documented.<sup>485,518,519</sup>

A differentiation between lack of susceptibility and subclinical infection as explanations for failure of the neonate to develop parotitis or other manifestations of mumps can be made only by adequate serologic investigations and viral isolation attempts. Unfortunately, these data are not available. Several investigators have observed that clinically apparent mumps with parotitis<sup>520,521</sup> or orchitis<sup>486</sup> during the first year of life tends to be a very mild disease and that age-specific attack rates for manifest disease related to mumps increase progressively until the age of 5 years.<sup>522</sup> Antibodies to mumps virus are known to cross the placenta and to persist for several months.<sup>523</sup>

#### Diagnosis and Differential Diagnosis

The diagnosis of mumps is easy when there is acute, bilateral, painful parotitis with a history of recent exposure. More difficulty is encountered when the disease is unilateral or when the manifestations are confined to organs other than the parotid gland. In these cases, laboratory confirmation by virus isolation or demonstration of a rising antibody titer may be performed.

Among neonates, few conditions need be considered in the differential diagnosis. Clinical parotitis in this age group is rare. Suppurative parotitis of the newborn, usually caused by *S. aureus*, is most often unilateral.<sup>524</sup> Pus can be expressed from the parotid duct, and there is a polymorphonuclear leukocytosis of the peripheral blood. Other diagnostic considerations in the neonate include infection with parainfluenza viruses and coxsackieviruses, drug-induced parotitis, and facial cellulitis.

In addition to these conditions in the neonate, the differential diagnosis in pregnant women includes anterior cervical lymphadenitis, idiopathic recurrent parotitis, salivary gland calculus with obstruction, sarcoidosis with uveoparotid fever, and salivary gland tumors.

Other entities should be considered when the manifestations appear in organs other than the parotid. Testicular torsion in infancy may produce a painful scrotal mass resembling mumps orchitis.<sup>486</sup> Aseptic meningitis related to mumps typically occurs in the winter and early spring, and enterovirus aseptic meningitis is most common in the summer and early autumn. Other viruses may also cause aseptic meningitis that is clinically indistinguishable from mumps.

#### Therapy

Treatment of parotitis is symptomatic. Analgesics and application of heat or cold to the parotid area may be helpful. Mumps immune globulin has no proven value in the prevention or treatment of mumps. Mastitis may be managed by the application of ice packs and breast binders. Testicular pain may be minimized by the local application of cold and gentle support for the scrotum. In some instances, severe

cases of orchitis have appeared to respond to the systemic administration of corticosteroids.

## Prevention

### Active Immunization

Live-attenuated mumps virus vaccine induces antibodies that protect against infection in more than 95% of recipients. The subcutaneously administered vaccine may be given to children older than 1 year, but its use in infants younger than this is not recommended because of possible interference by passive maternal antibodies. Usually, it is administered simultaneously with measles and rubella vaccines when children are 15 months old. The vaccine is recommended for older children and adolescents, particularly adolescent males who have not had mumps; it is not recommended for pregnant women, for patients receiving corticosteroids, or for other immunocompromised hosts.

### Passive Immunization

Passive immunization for mumps is ineffective and unavailable.

### Prevention of Nosocomial Mumps in the Newborn Nursery

In contrast to chickenpox and measles, mumps does not appear to be a potentially serious hazard in the newborn nursery. No outbreaks of nosocomial mumps have been described in this setting, and transmission of mumps in a hospital setting is highly unusual.<sup>525</sup> Most mothers are immune, and even neonates born to nonimmune mothers rarely develop clinically apparent mumps. Prudence dictates that mothers who develop parotitis or other manifestations of mumps in the period immediately ante partum or post partum should be isolated from other mothers and neonates. The case is less strong for isolating the puerperal mother with mumps from her own newborn. In the hospital setting, isolation of patients with mumps from the time of onset of parotitis has proved to be ineffective in preventing the spread of disease.<sup>526</sup> Infected subjects shed mumps virus in respiratory secretions for several days before the onset of parotitis or other manifestations recognizable as mumps.

At one time, exposed hospital personnel, particularly postpubertal males, and mothers with a negative history of mumps could be given mumps immunoglobulin, although the prophylactic effectiveness of this product was never established. This preparation is no longer available. Live-attenuated mumps virus vaccine has not been evaluated for protection after exposure but may theoretically modify or prevent disease by inducing neutralizing antibodies before the onset of illness because of the long incubation period of mumps. It should be considered for exposed susceptible hospital personnel and puerperal mothers. Some hospitals have the facilities to test for susceptibility to mumps by measurement of antibody titers, whereas others do not. Testing for susceptibility could eliminate some use of vaccine for the previously described situation.

Isolation procedures for mumps include the use of a single room for the patient with the door closed at all times except to enter. Immune personnel caring for the patient should exercise gown and hand-washing precautions. Isolation is continued until parotid swelling has subsided. Terminal disinfection of the room is desirable.

Cytomegaloviruses (CMVs) comprise a group of agents in the herpesvirus family known for their ubiquitous distribution in humans and in numerous other mammals. In vivo and in vitro infections with CMVs are highly species specific and result in a characteristic cytopathology of greatly enlarged (cytomegalic) cells containing intranuclear and cytoplasmic inclusions.<sup>1</sup> The strikingly large, inclusion-bearing cells with a typical owl's-eye appearance were first reported by Ribbert<sup>2</sup> in 1904 from the kidneys of a stillborn infant with congenital syphilis. Subsequently, Jesionek and Kiolemenoglou<sup>3</sup> reported similar findings for another stillborn infant with congenital syphilis. In 1907, Lowenstein<sup>4</sup> described inclusions in 4 of 30 parotid glands obtained from children 2 months to 2 years old. Goodpasture and Talbot<sup>5</sup> observed the similarity of these cells to the inclusion-bearing cells (giant cells) found in cutaneous lesions caused by varicella virus, and they postulated that cytomegaly was the result of a similar agent. The observation of a similar cytopathic effect after infection with herpes simplex virus led Lipschutz<sup>6</sup> and then others to suggest that these characteristic cellular changes were a specific reaction of the host to infection with a virus. The observation by Cole and Kuttner<sup>7</sup> that inclusion-bearing salivary glands from older guinea pigs were infectious for younger animals after being passed through a Berkefeld N filter in a highly species-specific manner led to the denomination of these agents as *salivary gland viruses*. The cellular changes observed in tissue sections from patients with a fatal infection led to the use of the term *cytomegalic inclusion disease* (CID) years before the causative agent was identified.

In 1954, Smith<sup>8</sup> succeeded in propagating murine CMV in explant cultures of mouse embryonic fibroblasts. Use of similar techniques led to the independent isolation of human CMV (unless otherwise noted, CMV refers to human cytomegalovirus) shortly thereafter by Smith,<sup>9</sup> Rowe and co-workers,<sup>10</sup> and Weller and associates.<sup>11</sup> Smith<sup>9</sup> isolated the agent from two infants with CID. Rowe and associates<sup>10</sup> isolated three strains of CMV from adenoidal tissue of children undergoing adenoidectomy. The term *AD169*, used to designate a common laboratory-adapted strain of CMV, comes from these studies. Weller and associates<sup>11</sup> isolated the virus from the urine and liver of living infants with generalized CID. The term *cytomegalovirus* was proposed in 1960 by Weller and colleagues<sup>12</sup> to replace the names CID and salivary gland virus, which were misleading because the virus usually involved other organs and because the name *salivary gland virus* had been used to designate unrelated agents obtained from bats.

The propagation of CMV in vitro led to the rapid development of serologic methods such as neutralization and complement fixation. Using such antibody assays and viral isolation, several investigators quickly established that CMV was a significant pathogen in humans. This ancient virus, like other members of the herpesvirus family, infects almost

all humans at some time during their lives.<sup>13,14</sup> Evidence of infection has been found in all populations tested. The age at acquisition of infection differs in various geographic groups and socioeconomic settings, which results in major differences in prevalence among groups. The natural history of human CMV infection is very complex. After a primary infection, viral excretion, occasionally from several sites, persists for weeks, months, or even years before the virus becomes latent. Episodes of recurrent infection with renewed viral shedding are common, even years after the primary infection. These episodes of recurrent infection are caused by reactivation of latent viruses or reinfections with an antigenically diverse strain of CMV. In immunocompetent hosts, CMV infections are generally subclinical. However, when infection occurs during pregnancy without consequences for the mother, it can have serious repercussions for the fetus. Even though most immunocompromised hosts tolerate CMV infections relatively well, in some instances, such as acquired immunodeficiency syndrome (AIDS) and bone marrow transplantation, CMV can cause disease of diverse severity, and the infection can be life threatening. Because of a long-standing and close host-parasite relationship, many—probably thousands—genetically different strains of CMV have evolved and circulate in the general population.<sup>15</sup>

## THE VIRUS

CMV (human herpesvirus 5) is the largest and structurally most complex member of the family of human herpesviruses. It has been classified as a betaherpesvirus based on several biochemical criteria such as the genome size, guanosine and cytosine content, slow replicative cycle, and restricted *in vivo* and *in vitro* tropism. Other members of this subfamily of viruses include other mammalian CMVs and the agents associated with the exanthem roseola, human herpesviruses 6 and 7.<sup>16-18</sup> Early estimates of its size based on electron microscopic studies indicated that the CMV particle was approximately 200 nm in diameter, a finding consistent with its measurement by more contemporary techniques.<sup>19,20</sup> Intracellular and extracellular particles are heterogeneous in size, which is probably a reflection of the variability of envelope glycoprotein content. The virus genome consists of more than 250 kilobase pairs of linear double-stranded DNA, making CMV almost 50% larger than the alphaherpesviruses, herpes simplex virus and varicella-zoster virus.<sup>21</sup> In contrast to other betaherpesviruses, including other CMVs, CMV contains terminal and internal repeated nucleotide sequences that enable the genome to exist in four isomeric forms, similar to herpes simplex virus and other alphaherpesviruses.<sup>22</sup> The biologic advantages that favor four isomeric forms of the genome of this virus have not been determined but clearly depend on replication of the genome in a permissive cell.<sup>23</sup>

The nucleotide sequence of several clinical isolates of CMV has been determined, and from the analysis of these strains, it is estimated that CMVs could encode more than 250 open reading frames (ORFs). Individual viral genes and ORFs are designated by their location in the unique long (UL) region, unique short (US) region, or the internal or terminal repeat regions (IRS, IRL, TRS, TRL) of the prototypic genome of CMV.<sup>22</sup> In addition to the massive size of the genome, other post-transcriptional modifications can

increase the complexity of the coding sequence of CMV. A limited number of CMV genes represent spliced transcripts, primarily those encoding immediate-early gene products. In some cases, multiple proteins can arise from a single gene by use of internal translational initiation sites. Although in most cases experimental verification of virus-specific proteins arising from predicted ORFs has not been accomplished, it is nevertheless obvious from this analysis that the proteomes of the virus and of the virus-infected cell are exceedingly complex. Consistent with this observation has been the complexity of the proteome of the virion revealed by mass spectrometry.<sup>24</sup> Organization of the CMV genome is similar to that of other herpesviruses in that conserved gene blocks that encode replicative and virion structural proteins can be found in similar locations. This organization of the genome has allowed assignment of positional homologues between members for different subfamilies of herpesviruses, an approach that has been instrumental in the identification of genomic coding sequences of CMV proteins. Outside of these conserved gene blocks are genes or gene families that are specific for individual betaherpesvirus. These genes are thought to impart specific *in vivo* tropism and the species-restricted growth of these viruses.

The CMV virion consists of three identifiable regions: the capsid containing the double-stranded DNA viral genome, the tegument, and the envelope. The CMV capsid consists of six proteins that have functional and structural homologues in other herpesviruses. These proteins and their counterparts found in herpes simplex virus are listed in Table 23-1.

The capsid of CMV has been studied by high-resolution cryoelectron microscopy, and its structure is almost identical to that of herpes simplex virus, with the exception that it has slightly different internal dimensions because it must incorporate a genome that is about 60% larger than herpes simplex virus. The capsid consists of 162 capsomere subunits consisting of 150 hexons and 12 pentons arranged in icosahedral symmetry.<sup>19</sup> The subunits of the capsid are thought to be partially assembled in the cytoplasm of the infected cell, followed by self-assembly using products of the UL80a

**Table 23-1 Cytomegalovirus Proteins and Their Homologues in Herpes Simplex Virus**

Protein	Herpes Simplex Virus	Cytomegalovirus
Major capsid protein	Vp5 (UL119)	MCP (UL86) <sup>a</sup>
Small capsid protein	Vp26 (UL35)	SCP (UL48-49) <sup>a</sup>
Minor capsid protein	Vp23(UL18)	MnCP (UL85) <sup>a</sup>
Minor capsid protein	Vp19c (UL38)	MnCP-bp (UL46) <sup>a</sup>
Assembly protein	Vp22a(UL26.5)	Assembly protein (UL80.5)
Assembly protein precursor	Vp21(UL26)	Assemblin precursor <sup>COOH</sup> (UL80a)
Assembly protein precursor	Vp24(UL26)	Assemblin (UL80a) <sup>a</sup>
Portal protein	UL6	UL104

<sup>a</sup>Indicates capsid proteins that have been demonstrated in infectious virions.  
Data from Gibson W. Structure and assembly of the virion. *Intervirolgy* 39:389-400, 1996.

ORF.<sup>25</sup> Proteins encoded by this ORF serve as a scaffold for the assembly of the individual capsomeres.<sup>25</sup> After the shell is assembled, newly replicated concatemeric viral DNA enters the capsid shell through a portal generated by the portal protein and the action of a virus-encoded protein complex called the *terminase complex*, generating the intranuclear capsid.<sup>26,27</sup>

Several steps in the assembly of the viral DNA-containing capsid are unique to CMV, including the cleavage of unit length DNA and the formation of the capsid portal. At least one of these steps in virus replication have been demonstrated to be the target of antiviral drugs.<sup>28</sup> Capsids containing infectious DNA leave the nucleus by poorly understood pathways and are enveloped in the cytoplasm.

The tegument of CMV is the most complex and heterogeneous structure in the virion. An undetermined number of viral proteins and viral RNAs can be found in the tegument of infectious particles.<sup>29</sup> Although it is generally argued that the tegument has no identifiable structure and is usually described as an amorphous layer between the envelope and

the capsid, some studies have argued that at least the innermost region of the tegument assumes the structure of the underlying icosahedral capsid.<sup>19</sup> Proteins within the tegument are characteristically phosphorylated and in many cases serve regulatory functions for virus replication. Some tegument proteins appear to have a primary role in maintenance of the structural integrity of the virion. Tegument proteins have a variety of functions in the infected cell, including direct stimulation of cell cycle progression from G<sub>0</sub> to G<sub>1</sub> by degradation of the retinoblastoma (Rb) protein and blocking progression at the G<sub>1</sub>-S junction of the cell cycle.<sup>30-33</sup> Other tegument proteins enhance transcription from the immediate-early genes and accelerate the replication of viral DNA.<sup>34</sup> Some tegument proteins are thought to modify cellular structures such as the infected cell nucleus to facilitate nuclear egress of capsids containing viral DNA (Table 23-2).<sup>35</sup>

These examples illustrate the functional complexity of CMV tegument proteins and suggest that it will be difficult in some cases to assign a unique function to an individual protein in the replicative cycle of CMV. The tegument contains the most immunogenic proteins of the virions, including the immunodominant targets of T lymphocyte responses and antibody responses.<sup>36-40</sup> In the case of one of the most abundant tegument proteins, pp65 (UL83 ORF), studies have shown that approximately 2% to 5% of peripheral blood CD8<sup>+</sup> lymphocytes from CMV-infected hosts are specific for this single protein.<sup>40</sup> It remains unclear why the normal host has devoted such a large percentage of peripheral CD8<sup>+</sup> lymphocyte reactivity to a single CMV antigen.

The envelope of CMV rivals the tegument in terms of the number of unidentified proteins and the limited amount of information on the function of many envelope proteins. Sequence analysis of the CMV genome indicates that more than 50 ORFs exhibit predicted amino acid motifs found in glycoproteins.<sup>21,41</sup>

The number of glycoproteins in the envelope of CMV is unknown, but eight glycoproteins have been defined experimentally (Table 23-3). Results of studies have suggested that the gM/gN complex represents the most abundant proteins in the virion envelope, with gB and the gH/gL/gO complex being the second and third most abundant group of glycoproteins in the envelope, respectively. There appears to be a redundancy in function for several of these glycoproteins (see Table 23-3); however, it also is likely that these redundancies are a function of in vitro assays and that each of these proposed functions is essential for virus infectivity in vivo. The envelope glycoproteins induce a readily detectable

antibody response in the infected hosts and neutralizing antibodies directed against gB, gH, and the gM/gN complex can be demonstrated in human CMV immune serum.<sup>42-49</sup> Moreover, considerable amounts of data from human and animal studies have indicated that antiviral antibodies directed at proteins of the envelope are a major component of the host protective response to this virus. These and other findings further demonstrate that envelope glycoproteins play a key role in the early steps of viral infection.

### Cytomegalovirus Replication

Virus replication begins when CMV attaches to the cell surface. The initial engagement of virion glycoproteins with cell surface proteoglycans is followed by more specific receptor interactions.<sup>50-52</sup> Suggested cellular receptors for CMV include the epidermal growth factor receptor and integrins.<sup>53</sup> Regardless of the specific receptor used by CMV, several studies have shown that CMV attachment and likely fusion with the host cell membrane result in a cascade of cellular responses mediated by signaling pathways.<sup>54-57</sup> Signaling pathways can be activated by the attachment of ultraviolet light-inactivated, noninfectious virus and by a single envelope glycoprotein, indicating that the process of binding and fusion with the cell membrane is sufficient to induce these cellular responses.<sup>52,55-57</sup> After infection with CMV, more than 1400 cellular genes are induced or repressed, suggesting that infection with this virus elicits myriad host cell responses.<sup>56</sup> Included in these early responses are activation of transcription factors such as nuclear factor-kappa B (NF- $\kappa$ B), increases in levels of second messengers such as phosphoinositide-3 (PI3) kinase, inhibition of cellular innate responses that block virus infection (e.g., RNA-activated protein kinase [PKR]), and progression to apoptosis of the infected cell.<sup>22,55,56,58-60</sup> CMV infection prepares the host cell for virus replication and inhibits host cell responses that can block virus infection.

After attachment and penetration, the DNA-containing viral capsid is rapidly transported to the nucleus, probably using the microtubular network of the cell. Once in the nucleus, the immediate-early genes of the virus are expressed in the absence of any *de novo* viral protein synthesis, suggesting that host or virion proteins are responsible for their induction. The replication cycle is divided into three classes according to time of synthesis after infection: immediate early, early, and late. The immediate-early genes are the first set of viral genes to become active within infected cells, usually within the first 4 hours after infection, and the most abundantly expressed products of these genes are the immediate-early 1 (IE1) and 2 (IE2) proteins. Both gene products arise from the same region of the genome and share some amino acid sequences. IE1 is a 72-kDa phosphoprotein (pp72) that is readily detectable throughout infection in permissive cells and is the target of antibody assays for detection of CMV-infected cells.<sup>61-63</sup> IE2 is a promiscuous *trans*-activating protein that probably is responsible for activating many of the early and late genes of CMV and some cellular genes.<sup>22</sup> IE1, IE2, and additional immediate-early genes encode inhibitors of cellular apoptotic responses.<sup>64,65</sup>

The remaining replication program of CMV is similar to that initially described for bacteriophages and for herpes simplex virus. It involves the coordinated and sequential

temporal expression of viral genes and the coordinated inhibition of viral gene expression. This allows regulated expression of the viral genome. The next set of viral genes, the early or  $\beta$  genes, primarily encode viral proteins that are required for replication of viral DNA or alteration of cellular responses such as progression through the cell cycle or cellular apoptotic responses.<sup>22</sup> These include the viral DNA polymerase, alkaline exonuclease, ribonucleotide reductase, and other replicative enzymes. Some virion structural proteins are also made during this interval. The final set of viral genes, the late or  $\gamma$  genes, are expressed approximately 24 hours after infection. These genes encode virion structural proteins and are required for the assembly of an infectious particle. The entire replicative cycle is estimated to take between 36 and 48 hours in permissive cells. Abortive infections in nonpermissive cells have also been characterized, and viral gene expression usually is limited to the immediate-early genes and possibly to a limited number of early genes.

After viral DNA replication in the nucleus of infected cells, concatemeric DNA is cleaved during packaging into the procapsid by mechanisms that closely resemble the pathway of bacteriophage assembly. Studies<sup>66,67</sup> of the assembly of alphaherpesviruses have provided a better understanding of the mechanisms and pathways of viral capsid assembly and DNA packaging. The viral capsid leaves the nucleus by undetermined mechanisms and enters the cytoplasm as a partially tegumented, subviral particle. Assembly of the mature particle takes place in the cytoplasm of the infected cell in a specialized compartment that has been called the *assembly compartment*.<sup>68</sup> It is believed that this is a modified secretory compartment close to the *trans*-Golgi.<sup>68,69</sup> Virion structural proteins are transported to this compartment, and presumably through a series of protein interactions, the virus is assembled and enveloped. The latter step is of considerable complexity because of the large number of virion glycoproteins that constitute the envelope of infectious virion. Virus is presumably released by cell lysis in cells such as fibroblasts and by poorly defined exocytic pathways in certain other cell types.<sup>69,70</sup>

Latency is a common theme of herpesviruses, particularly of the betaherpesviruses. The concept of CMV latency is somewhat controversial in that viral persistence in the host is more likely associated with chronic, low-level productive infection and intermittent excretion. However, latent CMV infection has been demonstrated in macrophages obtained from infected nonimmunocompromised donors and in vitro models of infection with CMV.<sup>71-74</sup> The mechanisms that favor the establishment of latent infections are not known, but the viral genome is thought to be maintained as closed circular viral DNA that persists as an episome in latently infected cells, not by integration into the host DNA.<sup>75</sup> More definitive information is available on the signals that induce reactivation from latent infection. They include proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and possibly interferon- $\gamma$  (IFN- $\gamma$ ).<sup>73,74,76</sup> It has been argued that latently infected cells of the monocytic lineage can become activated and replicate CMV after exposure to these cytokines in vivo, such as in the setting of rejection of an allograft. This mechanism may explain aspects of the pathogenesis of CMV infection in uninfected allograft recipients transplanted with an organ from a CMV-infected donor.<sup>77,78</sup>

## Cytomegalovirus Cellular Tropism

CMV can be detected in a wide variety of cell types *in vivo*.<sup>77,79-84</sup> Studies using tissue from autopsies or biopsies have demonstrated virus in almost every cell type, including epithelial cells, endothelial cells, smooth muscle cells, neuronal cells and supporting cells in the central nervous system (CNS), retinal epithelium, dermal fibroblasts, and cells of the monocyte-macrophage lineage. There appears to be a very limited restriction of the host cellular tropism *in vivo*. Routine virus isolation and propagation *in vitro* requires that the host cell be permissive for CMV replication. Primary cells derived from a variety of organs such as primary astrocytes, primary endothelial cells, primary smooth muscle cells, primary macrophages, and primary fibroblasts are permissive for CMV replication *in vitro*. However, the yield of infectious virus from these various cell types is highly variable, ranging from very low (macrophages) to high (fibroblasts). Primary human fibroblasts are the most commonly employed cells for the recovery and propagation of CMV and if adequately maintained can yield up to  $10^6$  to  $10^7$  infectious particles per milliliter of supernatant from cultures infected with laboratory strains of CMV. In contrast, recent clinical isolates often yield a fraction of this amount of virus, and almost all of the progeny virions are cell associated. The explanation for the differences in replication phenotype is unknown. Clinical isolates often exhibit an extended tropism and infect primary endothelial cells, macrophages, and primary smooth muscle cells, whereas commonly used laboratory strains of CMV do not infect these cell types. Although not fully understood, studies have provided clues about possible mechanisms that lead to extended cellular tropisms of some recent clinical viral isolates. It has been argued that these clinical isolates contain a number of genes that facilitate their *in vivo* replication and spread. These genes are not required for *in vitro* replication in fibroblasts and perhaps even inhibit replication, particularly the production of extracellular virus.<sup>85</sup> They are selected against, and over time, viral mutants with deletions of genomic material can be isolated from these cultures. Loss of these viral genes restricts host cell tropism for cells such as

endothelial cells and macrophages. The *in vivo* phenotype of these viral genes and their importance to *in vivo* replication and spread are not understood, but they are assumed to be essential because they are conserved in recent virus isolates.

## EPIDEMIOLOGY

### Overview

Human CMV is highly species specific, and humans are believed to be its only reservoir.<sup>1</sup> CMV infection is endemic and has no seasonal variation.<sup>14</sup> Seroepidemiologic surveys have found CMV infection in every human population that has been tested.<sup>13,14</sup> The prevalence of antibody to CMV increases with age, but according to geographic and ethnic and socioeconomic backgrounds, the patterns of acquisition of infection vary widely among populations (Fig. 23-1).<sup>15</sup>

In general, the prevalence of CMV infection is higher in developing countries and among the lower socioeconomic strata of the more developed nations. These differences are particularly striking during childhood. For instance, in sub-Saharan Africa, South America, and South Pacific, the rate of seropositivity was 95% to 100% among preschool children studied, whereas surveys in Great Britain and in certain populations in the United States have generally found that less than 20% of children of similar ages are seropositive.

The level of immunity among women of childbearing age, which is an important factor in determining the incidence and significance of congenital and perinatal CMV infections, varies widely among different populations. Several reports indicate that seropositivity rates in young women in the United States and Western Europe range from less than 50% to 85%.<sup>13,14</sup> In contrast, in sub-Saharan Africa, Central and South America, India, and the far East, the rate of seropositivity is greater than 90% by the end of the second decade of life. More important, from the point of view of congenital infection, prospective studies of pregnant women in the United States indicate that the rate of CMV acquisition for childbearing-aged women of middle to higher socioeconomic background is approximately 2% per year, whereas

it is 6% per year among women of lower socioeconomic background.<sup>86</sup>

The modes of transmission from person to person are incompletely understood. Several features of CMV infection make it difficult to study the modes of acquisition. In most individuals, CMV infections are subclinical, including those acquired in utero and during the perinatal period. Infected persons continue to expose other susceptible people to CMV. Virus excretion persists for years after congenital, perinatal, and early postnatal infections. Prolonged viral shedding, which lasts more than 6 months in most individuals, is also a feature of primary infection in older children and adults. Because recurrent infections are fairly common, intermittent excretion of virus can be anticipated in a significant proportion of seropositive adults. Regardless of whether CMV is maintained as a latent infection with periodic reactivation or as a chronic, persistent infection yielding low titers of infectivity, the virus readily spreads within a population.

A large reservoir of CMV exists in the population at all times. Transmission occurs by direct or indirect person-to-person contact. Sources of virus include urine, oropharyngeal secretions, cervical and vaginal secretions, semen, milk, tears, blood products, and organ allografts.<sup>87-91</sup>

CMV is not very contagious because the spread of infection appears to require close or intimate contact with infected secretions. The prevalence of CMV infection is higher for populations of low socioeconomic status, presumably reflecting factors that account for increased exposure to CMV, such as crowding, sexual practices, and increased exposure to infants and toddlers. Sexual contact contributes to the spread of CMV. Higher rates of seropositivity have been observed among males and females with multiple sex partners and histories of sexually transmitted diseases.<sup>92-95</sup>

## Breast-feeding

CMV is commonly excreted in milk collected post partum from seropositive women.<sup>87,96</sup> The rates of excretion range from 13% to 32% by isolation of virus in tissue cultures to an excess of 70% when tested by polymerase chain reaction (PCR) methods. Peak excretion occurs between 2 weeks and 2 months post partum. The risk of transmission of CMV infection to the infants is 39% to 59%. The risk of transmission by lactating mothers correlates with viral loads of  $7 \times 10^3$  genome equivalents/mL. CMV can be detected in different components of breast milk. There is consensus that milk whey is the material of choice to detect the virus during lactation. Fractions of milk containing milk cells are less likely to show the virus by culture or PCR methods. This may explain why rates of viral isolation are lower in colostrum than in mature milk. Most infected infants begin to excrete CMV between 22 days and 3 months after birth.

Conservatively, it is estimated that almost 40% of all infants nursed for at least 1 month by CMV-seropositive mothers become infected postnatally. Most of these infants become chronic excretors of CMV in urine and saliva, creating a large pool of infected infants. Because in most populations of the world the seroprevalence of CMV infection in women of childbearing age is high (80% to 100%) and most women breast-feed their infants for more than 1 month, the rate of transmission of CMV is quite high (Table 23-4).

Trends in infant feeding practices have undergone major changes in the industrialized world. In the United States, breast-feeding in the hospital setting declined progressively during the 20th century to reach a nadir in the early 1970s, when exclusive breast-feeding was reported by 19% of white and 9% of black mothers.

### Young Children as a Source of Cytomegalovirus

Certain child-rearing practices influence the spread of CMV among children. In 1971, Weller<sup>7</sup> suggested that the high rate of seropositivity among Swedish children probably was caused by the frequent use of daycare centers. Swedish children had a rate of infection that was three to four times higher than that observed in London or in Rochester, New York. As shown in Table 23-5, high rates of CMV infection among children attending daycare centers were later confirmed in Sweden and have been reported in several studies in the United States.<sup>97-101</sup>

The studies, which included a control group of children, confirmed that the rate of CMV infection was substantially higher among those in daycare than in those who stayed at home.<sup>97,98</sup> In the study of Pass and co-workers<sup>97</sup> of a group of 70 children of middle- to upper-income background whose ages ranged from 3 to 65 months, the rate of CMV excretion in urine and saliva was 51%. The lowest rate of excretion (9%) occurred in infants younger than 1 year, and the highest rate (88%) was among toddlers in their second year of life. Twelve infants whose mothers were seronegative excreted CMV, which indicated that their infection was not congenitally or perinatally acquired. These findings have been corroborated by other investigators.

Similar results were reported by Adler and colleagues,<sup>100</sup> who found that more than 50% of initially seronegative children acquired daycare-associated strains of CMV as determined by restriction fragment length polymorphism analysis of viral DNA. The findings of Adler, which have been confirmed by others, demonstrate that CMV is very efficiently transmitted from child to child in the daycare setting and that it is not unusual to find excretion rates as high as 20% to 40% in young toddlers.<sup>99,102</sup> In many instances, these rates of infection are substantially higher than the seroprevalence rates for the parents of the children and young adults in the cities where the studies were done.<sup>103</sup> There is compelling evidence that the high rate of CMV infection among children in group daycare is caused by horizontal transmission from child to child. The route of transmission that appears most likely is the transfer of virus that occurs through saliva on hands and toys.<sup>104,105</sup> CMV can retain infectivity for hours on plastic surfaces and has been isolated from randomly selected toys and surfaces in a daycare center. No data have indicated CMV transmission through respiratory droplets.

These observations in daycare centers indicate that transmission of CMV between young children is very efficient. Once infected, these children excrete CMV in large quantities and for extended periods. With the changes in child-rearing practices occurring in the United States and the resurgence of breast-feeding, significant changes in the epidemiology of CMV can be expected within the next few decades.<sup>103</sup>

An important issue is whether children excreting CMV can become a source of infection for serosusceptible childcare personnel and parents, particularly women who may become pregnant. This type of transmission has been confirmed by restriction endonuclease mapping of CMV DNA.<sup>106,107</sup> Seroepidemiologic studies suggest that parents often acquire CMV from their children who became infected outside the family. For instance, Yeager<sup>108</sup> reported that 7 (47%) of 15 seronegative mothers of premature infants who acquired CMV in a nursery seroconverted within 1 year. Dworsky and colleagues<sup>109</sup> reported that the rate of seroconversion for women with at least one child living at home was 5.5%, significantly higher than the 2.3% rate for women from the same clinic who were pregnant for the first time or the rates for susceptible nursery nurses and for physicians in training. Taber and associates showed a significant association between seroconversion among children and seroconversion among susceptible parents and showed that, in most cases, the infection in a child preceded seroconversion in the parents.<sup>466</sup> There is also compelling evidence linking the acquisition of CMV by children in daycare with subsequent infection in their mothers and caregivers.<sup>102,106,110-113</sup> Several studies have demonstrated that CMV-seronegative parents have a significant risk of acquiring CMV infection if their infants and children attend daycare. The highest risk of seroconversion is approximately 20% to 45% for parents with a child shedding CMV at 18 months old. On average, parents acquire infection within 4.2 months (range, 3 to 7 months) after their children become infected. As determined by restriction fragment length polymorphism analysis of viral DNA, many of the strains isolated from the children, their parents, and their caretakers are epidemiologically related. For caretakers working with young children in daycare centers, the annual rate of seroconversion is approximately 10%, which is significantly higher than the 2% annual rate occurring in hospital employees matched for age, race, and marital status. These observations provide compelling evidence that serosusceptible parents and women who work with children in daycare centers have an occupational risk of

**Table 23-6 Rate of Congenital Cytomegalovirus Infection in Relation to Rate of Maternal Immunity in Various Locations**

acquiring CMV. It is reasonable to expect that as many as 50% of susceptible children between the ages of 1 and 3 years who attend daycare will acquire CMV from their playmates and become an important source of infection for susceptible parents and caregivers. Of particular concern is the risk to seronegative women who become pregnant.

### Maternal Infection and Vertical Transmission

Because maternal CMV infection is the origin of congenital infections and of most perinatal infections, it is important to review the relevant issues that pertain to vertical transmission. As used here, *vertical transmission* implies transmission from mother to infant.

### Congenital Infection

Congenital infection is assumed to be the result of transplacental transmission. In the United States, congenital CMV infection occurs in 0.2% to 2.2% (average, 1%) of all newborns. However, as shown in Table 23-6, the incidence of congenital infection is quite variable among different populations.

The natural history of CMV during pregnancy is particularly complex and has not been fully explained. Infections such as rubella and toxoplasmosis cannot serve as models. With these infections, in utero transmission occurs only as a result of a primary infection acquired during pregnancy, whereas the in utero transmission of CMV can occur as a consequence of primary and recurrent infections (i.e., reinfection or reactivation).<sup>114,115</sup> Congenital infection resulting from recurrent CMV infection is common, especially in highly immune populations. The initial clue was provided by three independent reports of congenital CMV infections that occurred in consecutive pregnancies.<sup>116-118</sup> In all three instances, the first infant was severely affected or died and the second born in each case was subclinically infected. More convincing evidence came from a prospective study of women known to be seroimmune before conception.<sup>115</sup> As shown in Table 23-7, the rate of congenital CMV infection was 1.9% among 541 infants born to these seropositive women. The 10 congenitally infected infants were not

**Table 23-7 Incidence of Congenital Cytomegalovirus Infection in a Low-Income Population**

Parameter	Total	No. Infected (%)
Incidence in general infant population	1412	31 (2.2)
Incidence with recurrent maternal infection		
Previously seropositive	457	8 (1.8)
Prior cytomegalovirus excretion	58	1 (1.7)
Prior intrauterine transmission	26	1 (3.8)
Total	541	10 (1.9)

Data from Stagno S, Pass RF, Dworsky ME, et al. Maternal cytomegalovirus infection and perinatal transmission. Clin Obstet Gynecol 25:567, 1982.

infected as a result of primary maternal CMV infection because all mothers were known to have been infected with CMV 1 year to several years before the onset of pregnancy. Shortly after our studies were published, Schopfer and associates<sup>114</sup> found that in an Ivory Coast population in which virtually all inhabitants are infected in childhood, the prevalence of congenital CMV infection was 1.4%.

This remarkable phenomenon of intrauterine transmission that occurs in the presence of substantial immunity has been attributed to reactivation of endogenous virus in some cases and to reinfection with different strains of CMV in other instances. In support of reactivation is our observation that the viruses isolated from each of three pairs of congenitally infected siblings were identical when examined by restriction endonuclease analysis.<sup>119</sup> In two of these three pairs, the first-born infant was severely affected, whereas the second-born sibling was subclinically infected, which suggested that virulence of infection was not related to strain and that maternal immunity in some way attenuated the fetal infection.

Another study<sup>120</sup> indicates that women who are CMV seropositive can become reinfected with a different strain of CMV, leading to intrauterine transmission and symptomatic

congenital infection. This study assessed maternal humoral immunity to strain-specific epitopes of CMV glycoprotein H. Serum specimens from women with preconceptional immunity were obtained during the previous and the current pregnancy. Of the 16 mothers with congenitally infected infants, 10 had acquired new antibody specificities against glycoprotein H, compared with only 4 of the 30 mothers of uninfected infants. The women participating in this study were from a group that is predominantly characterized by low socioeconomic rank, young age, unmarried status, high seroprevalence of CMV, and a strong background of sexually transmitted diseases, including high rates of CMV excretion. Whether the observations of this study can be extrapolated to other populations remains to be defined.

Intrauterine transmission in immune women accounts for the direct relationship between the incidence of congenital CMV infection and the rate of seropositivity shown in Table 23-6. It is extremely difficult to define by virologic or serologic markers which patient may undergo a reactivation of CMV, and it is almost impossible to define the time of intrauterine transmission with such reactivations or reinfections during pregnancy. The sites from which CMV reactivates to produce congenital infection are unknown and probably are inaccessible to sampling during pregnancy. Although CMV excretion is a relatively common event during and after pregnancy, the simple isolation of virus during pregnancy is a poor indicator of the risk of intrauterine infection.

Virus can be shed at variable rates from single or multiple sites after primary or recurrent infections in women whether pregnant or not. Sites of excretion include the genital tract, cervix, urinary tract, pharynx, and breast. In pregnant women, virus is excreted most commonly, in decreasing order, from the cervix, urinary tract, and the throat. In the immediate postpartum period, the frequency of viral shedding into breast milk can reach 40% of seropositive women. The rates of cervical and urinary tract shedding in nonpregnant women are comparable to those found in pregnant cohorts of similar demographic and socioeconomic characteristics. In general, rates of cervical shedding range from 5.2% for nonpregnant women drawn from private practice or family planning clinics to 24.5% among women attending a sexually transmitted disease clinic.<sup>92-95</sup>

Pregnancy per se has no discernible effect on the overall prevalence of viral shedding. However, the prevalence of excretion is lower (2.6%) in the first trimester than near term (7.6%).<sup>119</sup> This rate is comparable to the prevalence of genital excretion in nonpregnant women.

The rates of CMV excretion in the genital and urinary tracts of women are inversely related to age after puberty. In one study, the rate of genital CMV excretion fell from 15% in girls between 11 and 14 years old to undetectable levels in women 31 years old or older.<sup>119</sup> From a peak of 8% for the younger group, urinary excretion fell to zero among women 26 years old or older. No CMV excretion occurred from either site in postmenopausal women.

The transient depression of cellular immune responses to CMV antigens during the second and third trimesters is another peculiar aspect of the relationship between CMV and the pregnant human host.<sup>121</sup> In one study, there was no generalized depression of cellular immunity because numbers of T lymphocytes, T cell proliferative responses to other mitogens, and serum antibody titers remained

unchanged. None of these mothers shed virus during the period of depressed cellular immune response, nor did they transmit the infection to their infants. It has been shown that antibody responses to glycoprotein B are significantly higher at the time of delivery in women with primary CMV infection who transmitted the infection in utero compared with those who did not, suggesting that the amount of antiviral antibody is not reflective of protection from transmission.<sup>122</sup> However, analysis of the qualitative antibody response revealed lower neutralizing antibody titers in transmitters, suggesting an association between neutralizing activity and intrauterine transmission. In this study, a significant correlation was found between neutralizing titers and antibody avidity, indicating that antibody avidity maturation is critical for production of high levels of neutralizing antibodies during primary CMV infection.<sup>122</sup> In a separate study, higher levels of transplacentally acquired maternal antibodies against glycoprotein B and neutralizing antibodies were observed in infants with symptomatic infection at birth and who went on to develop sequelae.<sup>123</sup>

### Perinatal Infection

In contrast to the poor correlation that exists between CMV excretion during pregnancy and congenital infection, there is a good correlation between maternal shedding in the genital tract and milk and perinatal acquisition. As shown in Table 23-8, in one study,<sup>90</sup> the two most efficient sources of transmission in the perinatal period were infected breast milk, which resulted in a 63% rate of perinatal infection, and the infected genital tract, particularly in late gestation, which was associated with transmission in 26% and 57% of cases (i.e., natal infection). Viral shedding from the pharynx and urinary tract of the mother late in gestation and during the first months post partum has not been associated with perinatal transmission.

As shown in Table 23-4, there is considerable variability in perinatal transmission of CMV throughout the world.<sup>124</sup> The age of the mother and her prior experience with CMV,

which influence the frequency of viral excretion into the genital tract and breast milk, are important factors. Younger seropositive women who breast-feed are at a greater risk for transmitting virus in early infancy, especially in lower socioeconomic groups.<sup>103</sup> It is remarkable that in Japan, Guatemala, Finland, and India, where the rates of CMV excretion within the first year of life are extremely high (39% to 56%), the practice of breast-feeding is almost universal, and most women of childbearing age are seroimmune for CMV.

### Sexual Transmission

Many epidemiologic studies support the classification of CMV as a sexually transmitted infection. This is consistent with excretion of this virus in cervical secretions, vaginal fluid, and semen. In general, in developing areas of the world, 90% to 100% of the population is infected during childhood, even before they are 5 years old. Sexual transmission in these populations plays a minor role as a source of primary CMV infection, but its importance in reinfection is unclear. In developed countries, the infection is acquired at a lower rate, and in some population groups, there is a burst in the prevalence of infection after puberty. Several lines of evidence indicate that sexual transmission of CMV is at least partly responsible for this increase in seroprevalence. Increased seroprevalence of CMV and excretion of virus have been found in women attending sexually transmitted disease clinics and in young male homosexuals.<sup>92-95,125</sup> Handsfield demonstrated that previously infected individuals could be reinfected by a different strain of CMV as assessed by restriction fragment length polymorphism.<sup>125a</sup> Evidence has also been provided for sexual transmission in less promiscuous populations.<sup>94,95</sup> Among the many variables investigated, a significant correlation was found among seropositivity to CMV, greater numbers of lifetime sexual partners, and past or present infection with other sexually transmitted diseases.

### Nosocomial Transmission

Nosocomial CMV infection is an important hazard of blood transfusion and organ transplantation. In compromised hosts such as small premature newborns and bone marrow transplant recipients, transfusion-acquired CMV infection has been associated with serious morbidity and even fatal infection. The association between the acquisition of CMV infection and blood transfusion was first suggested in 1960 by Kreel and co-workers,<sup>126</sup> who described a syndrome characterized by fever and leukocytosis occurring 3 to 8 weeks after open heart surgery. The reports that followed soon after expanded the syndrome to include fever, atypical lymphocytosis, splenomegaly, rash, and lymphadenopathy.<sup>127-131</sup> The term *postperfusion mononucleosis* was then proposed. Prospective studies incriminated blood transfusion as the major risk factor and demonstrated that although the clinical syndrome occurred in approximately 3% of the patients undergoing transfusion, inapparent acquisition of CMV infection ranged from 9% to 58% as determined by seroconversion, a fourfold rise in complement-fixing antibody titers or viral excretion, or both, occurring between 3 and 12 weeks after surgery. It has been estimated that the percentage of blood donors capable of transmitting CMV ranges from

2.5% to 12%. In a study of seronegative children receiving blood for cardiac surgery, the risk of acquiring CMV was calculated to be 2.7% per unit of blood.<sup>128</sup> There is a significant correlation between the risk of acquisition of CMV by patients labeled seronegative and the number of units of blood (total volume) transfused. In one study, the incidence of primary infection increased from 7% among patients receiving 1 unit of blood to 21% among those receiving more than 15 units.<sup>129</sup> For seronegative marrow transplant recipients who receive standard blood products, the risk of CMV infection is between 28% and 57%.<sup>132</sup> Under conditions found in blood banks, CMV inoculated in whole blood persisted for 28 days and in fresh-frozen plasma for 97 days.

The observation that two newborns who received large volumes of fresh blood subsequently developed symptomatic CMV infections led McCracken and associates<sup>133</sup> to suggest an association between blood transfusion and clinically apparent postnatal CMV infection. A subsequent report indicated an association between postnatal CMV infection and exchange transfusions.<sup>134</sup> With exchange transfusions, the risk of infection can reach 50%, which is probably the result of the much larger volume (150 to 200 mL/kg) received by these infants.<sup>134</sup> Intrauterine transfusions have also been implicated in CMV infection of mothers and their infants.

CMV infections resulting from transfusion of blood products can cause significant disease in newborn infants, particularly in premature infants and infants born to women without immunity to CMV. Extremely premature infants born to seropositive mothers are also at increased risk because the transplacental transfer of specific antibodies does not occur until the later stages of gestation. Infected infants with passively acquired anti-CMV antibodies develop milder disease than infected infants without passively acquired antibodies. This observation is a compelling argument for the role of antiviral antibodies in protecting the host against severe disease.

Transmission of CMV by transplantation of an allograft from donors previously infected with CMV represents a major clinical problem in allograft transplantation. Transplantation of a kidney from a seropositive donor into a seronegative recipient results in primary CMV infection in 80% of the patients. The clinical manifestations of the infection vary widely, depending principally on immunosuppressive regimens. Most investigators have found that CMV infection has an adverse effect on the survival of the allograft. CMV is also a major cause of morbidity and mortality in bone marrow recipients.<sup>135-137</sup> Interstitial pneumonitis is the most significant manifestation of the infection; the mortality rate approaches 100% in some series. Between 70% and 100% of heart transplant recipients excrete CMV.<sup>138,139</sup> Primary CMV infection occurs in a high proportion (60%) of patients who are seronegative before surgery. Severe disease is more likely to be associated with primary than with reactivated infection, but primary infection is not associated with an increased risk of rejection of the transplant.<sup>140,141</sup> The demonstration of CMV nucleic acid in kidneys of infected donors and of latent CMV in cells of macrophage-monocyte lineage indicates that the transplanted organs and hematopoietic allografts can serve as the source of virus in transplant recipients.

Nosocomial transmission is possible in the nursery setting, which suggests that workers' hands or contaminated

fomites might be involved.<sup>104-107</sup> CMV has been recovered from objects used in the care of an infected newborn and from surfaces in a daycare center, with recovery of virus for up to 8 hours.<sup>104,105,142</sup> However, the very low rate of CMV infection in newborn infants of seronegative mothers who are not exposed to other important sources such as banked human milk or seropositive blood products indicates that transmission of CMV by means of fomites or workers' hands is rare.

### Transmission to Hospital Workers

Because hospital workers are often women of childbearing age, there has been concern about occupational risk through contact with patients shedding CMV. As illustrated in Table 23-9, most studies carried out during the past decade indicate that the risk is not significantly different from the general population.<sup>143</sup> The studies showing differences in the rate of seroconversion between health care workers and controls did not show that the risks were statistically significant.<sup>144,145</sup>

The risk for hospital personnel is a function of the prevalence of CMV excretion among patients, the prevalence of seronegativity in health care workers, and the degree of their exposure to infected patients. In general, among hospitalized infants and children, viremia occurs in approximately 1% of newborns and 5% to 10% of older infants and toddlers.

Working with hospitalized children inevitably leads to contact with a child shedding CMV; however, it is important that workers who develop a primary infection not assume that their occupational exposure or contact with a specific patient is the source of infection. Three reports illustrate this point well. Yow and co-workers,<sup>146</sup> Wilfert and associates,<sup>147</sup> and Adler and colleagues<sup>148</sup> described health care workers who acquired CMV while pregnant and after attending patients known to be excreting CMV. In each of these reports, assays

of restriction fragment length polymorphisms from CMV isolates demonstrated that the source of CMV for the workers were not the patients under suspicion. With the implementation of universal precautions in the care of hospitalized patients, the risk of nosocomial transmission of CMV to health care workers is expected to be much lower than the risk of acquiring the infection in the community.

### PATHOGENESIS

The disease manifestations that are associated with CMV infections can be conveniently divided into those associated with acute infection and those associated with chronic infections. Considerably more is known about acute infectious syndromes, because acute CMV infections can be temporally related to specific symptoms and associated with specific laboratory abnormalities. Infrequently, acute CMV syndromes can occur in presumably normal individuals and in these cases manifest as an infectious mononucleosis that is indistinguishable clinically from the infectious mononucleosis associated with Epstein-Barr virus infection.<sup>149,150</sup> Normal individuals with symptomatic infections often have increased viral burdens as measured by serologic responses compared with individuals with asymptomatic infections.<sup>151</sup> More commonly, acute CMV infections that result in symptomatic disease occur in immunocompromised hosts. In general, acute CMV syndromes that are associated with clinical disease often share several common characteristics, including occurrence in hosts with depressed cellular immunity, uncontrolled virus replication, multiorgan involvement, end-organ disease caused by direct viral cytopathic effects, and clinical manifestations of disease correlated with virus burden. In patients with invasive CMV infections, such as those in allograft recipients, organ dysfunction and often disease course can be correlated with increasing virus

burden.<sup>152-154</sup> There is usually not an absolute level of viral replication as measured by viral genome copy number in the peripheral blood that is predictive of the onset of an invasive infection and end-organ disease. It appears that increasing levels of virus replication (i.e., genome copy number) is more useful in the identification of individuals at risk for invasive disease and presumably reflects ongoing viral replication with an increasing risk of dissemination.

Chronic disease syndromes associated with CMV include a variety of chronic inflammatory diseases of older populations such as atherosclerotic vascular disease and vascular processes associated with chronic allograft rejection.<sup>155-164</sup> The progressive and late-onset hearing loss associated with congenital CMV infection can be considered in this same category.<sup>165-168</sup> The characteristics of populations experiencing these manifestations of CMV infection are different from those described previously and do not include hosts with global immune dysfunction. Most individuals have normal immunity and allograft recipients undergoing chronic graft rejection may have increased immune responsiveness within the allograft. Viral replication appears to be a prerequisite for disease, but the level of virus replication has not been related to disease. The course of the disease in animal models of CMV-associated vascular disease is that of ongoing inflammation that is enhanced and prolonged by the presence of CMV.<sup>169-172</sup> Inhibition of virus replication early in the course of infection in animal models has been shown to dramatically alter the course of disease, suggesting that virus must seed these areas and establish a persistent infection.<sup>169</sup> The presence of the virus in areas of inflammation increases the expression of soluble mediators of inflammation such as cytokines and chemokines and in some cases, virus-infected cells actively recruit inflammatory cells, including monocytes, into the area of disease.<sup>164,173</sup> The bidirectional interactions between CMV and the host inflammatory response are unique and appear to favor virus persistence, viral gene expression, and likely virus dissemination.

### Cytomegalovirus Infection and Cell-Associated Viremia

An important aspect of the pathogenesis of CMV infection is the route of infection and spread within the host. It is believed that virus is acquired at mucosal sites (i.e., community exposures) or by blood-borne transmission, such as after blood transfusion or transplantation of an infected allograft. Understanding the pathogenesis of these types of infections requires an understanding of the mode of virus transmission and virus dissemination. It is believed that cell-free virus is responsible for community-acquired CMV infection based on recovery of virus from saliva and from cell-free genital tract secretions, but only limited data directly support this claim. The most convincing evidence comes from studies in breast-feeding women that have demonstrated that infectious virus exists in the cell-free fraction of breast milk.<sup>174</sup> This finding suggests that cell-free virus can infect a mucosal surface. Animal models of CMV infection have most commonly used intraperitoneal or subcutaneous inoculations; however, oral infection with cell-free murine CMV has been accomplished (S. Jonjic, University of Rijeka, Rijeka, Croatia, personal communication, 2000).

After infection, local replication, and amplification of virus titer in regional sites, the spread of CMV within an infected host is likely to be cell associated based on findings from immunocompromised patients and experiments using animal models. In mucosal surface infection and blood-borne infections, the mode of spread and dissemination probably is the same, albeit with different kinetics and quantity of infected cells in the vasculature and infected organs. In all but the most severely immunocompromised patients, infectivity that can be demonstrated in the blood compartment is most frequently associated with endothelial cells and polymorphonuclear leukocytes (PMNs) from the buffy coat fraction of peripheral blood.<sup>175-177</sup> PMNs cannot support virus replication but have been shown to carry infectious virus and viral gene products.<sup>178,179</sup> It has been proposed that CMV-infected endothelial cells or fibroblasts can transfer infectious virus to PMNs, and these cells can transmit virus by a microfusion event between virus-containing vesicles and susceptible cells.<sup>178</sup> This mechanism has not been experimentally verified in animal models of CMV infection, but the role of PMNs in transmission of infectious CMV in vivo is accepted, and the correlation between CMV antigen-positive PMNs (antigenemia assay) and disseminated infection provides a diagnostic tool for the identification of patients at risk for invasive infection with CMV.<sup>180-187</sup> Antigen-positive PMNs can be detected in normal hosts infected with CMV, although with a drastically reduced frequency compared with immunocompromised patients, suggesting that even in normal hosts that PMNs may be a common mode of virus dissemination. Other cells within the leukocyte fraction of peripheral blood cells support CMV persistence and transmit infectious virus, including monocyte and macrophages derived by differentiation of blood monocytes.<sup>188-197</sup> Granulocyte-monocyte progenitor cells have been proposed as sites of latency based on in vitro infections and can be detected as antigen-containing cells in immunocompromised patients with disseminated CMV infection.<sup>72,73,189-190,192,198</sup> Macrophages derived from peripheral blood monocytes have been shown to harbor infectious CMV on stimulation with specific cytokines, including TNF- $\alpha$ .<sup>71,76,78</sup> Viral replication and expression of a variety of early and late proteins can be demonstrated in macrophages after infection with recently derived CMV clinical isolates. Another cell lineage believed to be critical for the in vivo spread of CMV is endothelial cells in a variety of microvascular beds. Endothelial cells have been shown to support CMV replication in vitro and infection of these cells results in a variety of cellular responses, including the release of cytokines and chemokines.<sup>70,79,80,191,199-206</sup> Lytic and nonlytic productive infections have been described, suggesting that endothelial cells can respond very differently to infection.<sup>70,200,207,208</sup> Virus infection of endothelial cells is thought to be an initial step for infection of various tissues during CMV dissemination, and endothelial cell infection appears to be critical for the hematogenous spread from infected tissue.<sup>178,191,205</sup> Early studies in transplantation populations described viral antigen-containing endothelial cells circulating in the blood of viremic transplant recipients.<sup>201,209,210</sup> These cells are believed to be infected endothelium that slough into the circulation, presumably because of local infection or inflammation. A similar role for endothelial cells in spread of CMV in the murine model and guinea pig CMV model has been proposed.<sup>204</sup>

## Virus-Encoded Pathogenic Functions

Specific CMV-encoded virulence factors have not been identified. Early studies attempted to correlate restriction fragment length polymorphism of viral isolates from congenitally infected infants with clinical outcome. This genetic analysis proved too crude to allow identification of subtle changes in the viral genome. Numerous studies have reported a possible linkage between polymorphisms in a gene encoding the major envelope glycoprotein gB and disease.<sup>211-214</sup> Most studies have failed to demonstrate any specific linkage between different gB genotypes and disease, and studies using other polymorphisms in several viral genes (UL73, UL74, UL144) have failed to establish any genetic linkage between a specific genotype and disease.<sup>215-218</sup> Although the explanation for the vast polymorphisms in CMVs is unclear, several characteristics of CMV infections, including frequent reinfections with new strains of virus in exposed populations and recombination between strains of virus, are likely reasons for the variability in the nucleotide sequences of different viral isolates.<sup>120,213,219,220</sup> However, there appear to be differences in the biologic behavior of CMVs, such that some strains exhibit extended tropism and can infect endothelial cells, macrophages, and epithelial cells in addition to permissive primary fibroblast cells. This extended tropism is found only in very recently derived isolates of CMV, and after these viruses are repeatedly passaged through fibroblast cells, their extended tropism is quickly lost. It is believed that one or more viral genes are responsible for their extended tropism in vivo and that without the selective pressure of replication in vivo, these genes are lost or mutated. Specific genes that permit extended tropism in vitro have not been identified, but the presence of large numbers of genes that modify the immune response to CMV point to the possibility that these genes can encode a function that inhibits an innate response from cells such as macrophages. Other viral genes encode functional chemokine receptors, viral cytokine-like molecules (vIL-10, vIL-8), and viral anti-apoptotic functions (vICA, UL37), all of which have been proposed to contribute to the in vivo replication and virulence of CMV infections.<sup>65,221-223</sup>

Although defining the function of viral genes in the in vivo replication and spread of CMV has been difficult because of the restricted tropism of CMV to cells of human origin, much information has been gathered from studies in animal models. Using the mouse model of murine CMV infection, several laboratories have identified specific viral genes that appeared to be required for efficient replication and spread in vivo.<sup>195,224-229</sup> Three viral genes encoded by m139, m140, and m141 ORFs of murine CMV (MCMV) have been shown to play a critical role in viral replication in monocytes and macrophages but have little or no effect on the replication of the virus in mouse fibroblasts.<sup>230-233</sup> The in vivo phenotype of viruses that lacked these genes indicated these genes were required for in vivo dissemination and spread of MCMV.<sup>232,234</sup> The mechanism that accounts for restricted replication in monocytes of MCMV with deletions in these specific genes is unknown. The CMV genes that permit replication in monocyte-macrophages has not been definitively identified, but the MCMV genes *M139*, *M140*, and *M141* are homologous to a family of CMV genes (US22 gene family). Another example of a viral gene that directly

influences in vivo tropism and replication of CMV is the MCMV gene *M45*. Endothelial cell tropism of MCMV can be linked to this single viral gene (*M45*), and it is believed that expression of this gene limits resistance of endothelial cells to MCMV-induced apoptosis.<sup>204</sup> Deletion of the homologous reading frame in CMV (UL45) was not associated with the loss of endothelial tropism.<sup>235</sup>

Other genes in MCMV encode functional chemokines, such as the murine cytomegalovirus chemokine 1 (MCK-1) that exhibits activity similar to that of interleukin-8 (IL-8).<sup>232,234</sup> Studies in mice have suggested that the capacity of this gene product to recruit inflammatory cells into a site of virus replication is important for cell-associated virus spread within infected animals.<sup>232</sup> In the absence of this virus-encoded function, virus replication remains localized to the site of infection because of a failure to recruit and infect infiltrating inflammatory cells, limiting viral dissemination.<sup>232</sup> A functionally homologous viral gene in CMV (UL146) may influence the spread of CMV in vivo.<sup>236</sup> The protein encoded by UL146 is a secreted protein that appears to function as a CXCL chemokine (CXCL1) and can induce chemotaxis and degranulation of PMNs.<sup>236</sup> It has been postulated that this viral chemokine could recruit PMNs in vivo and promote CMV dissemination.<sup>234</sup> In severely immunocompromised hosts such as AIDS patients with gastrointestinal and retinal disease from disseminated CMV infection, neutrophil infiltration can be observed in the lamina propria and in the retina.<sup>237-240</sup> Infection of lamina propria macrophages with CMV in vitro results in the induction of IL-8 release from these cells, suggesting that CMV can induce IL-8 release and encode a viral IL-8-like molecule.<sup>241</sup> Such findings are consistent with the proposed mechanism of chemokine expression and CMV dissemination from sites of virus replication. This mechanism of dissemination is consistent with the histopathologic findings in severely immunocompromised patients. However, a neutrophil infiltrate is not an invariant feature of the histopathology of naturally acquired CMV infections, and interactions between other virus-encoded chemokines and chemokine receptors and peripheral blood leukocytes may contribute to virus dissemination. Research findings have demonstrated that CMV engages toll-like receptors with resultant induction of pro-inflammatory cytokines and chemokines cascades.<sup>242</sup> This observation raises the possibility that virus infection alone can recruit cells such as monocytes and PMNs to sites of infection without the requirement of a specific viral chemokine.<sup>242</sup> Other viral genes probably induce host cell genes that facilitate virus replication. Microarray and differential display experiments have demonstrated that CMV infection induces the expression of cyclooxygenase 2 (COX-2), an enzyme required for prostaglandin synthesis and initiation of early steps of inflammation.<sup>55</sup> Subsequent experiments have shown that when COX-2 activity is blocked, CMV replication was blocked.<sup>243</sup> Together, these experiments demonstrated that a CMV-encoded gene could induce a cellular enzyme that facilitated its replication possibly by increasing the inflammatory response to the infection. This host response presumably leads to the recruitment of inflammatory cells into the site of virus replication, thereby promoting infection of infiltrating cells and virus spread.

CMV encodes four G-coupled protein receptor (GPCR)-like molecules in ORFs UL33, UL78, US 27, and US28.<sup>173,244-246</sup>

The US28 gene encodes a GPCR that is constitutively activated and that can also signal after interaction with chemokines, including RANTES, MCP-1, and fractalkine.<sup>173,247-248</sup> Reports have detailed possible roles for this molecule in the spread of CMV *in vivo*, including as a chemokine sink to limit host cell chemotaxis to CMV-infected cells, providing an anti-apoptotic function, recruitment of infected mononuclear cells to the sites of inflammation leading to dissemination of virus, and perhaps even binding of virus or virus-infected cells to chemokine expressing endothelial cells.<sup>246-251</sup> Arterial smooth muscle cells expressing US28 have been shown to migrate down chemokine gradients, thereby providing a mechanism for the localization of CMV-infected cells to sites containing inflammatory cellular infiltrates.<sup>173</sup> Although the role of US28 in CMV-induced vascular disease has been well described and supported by *in vitro* models of smooth muscle cell migration, the importance of US28 in virus dissemination from local site of infection remains to be more completely defined. Together, these and other studies suggest that the large coding sequence of CMV encodes proteins that are essential for efficient replication and for spread within the infected animal but probably have little or no function in the *in vitro* replication of virus.

### Host Immunity and the Pathogenesis of Cytomegalovirus Infections

In normal hosts, innate and adaptive cellular immune responses can limit but not prevent the spread of CMV from secondary sites such as the liver and spleen. The roles of innate and adaptive cellular immune responses in the control of virus replication and spread to other sites have been clearly shown in experimental animal models of CMV infection.<sup>252-258</sup> Increased levels of virus replication follow the loss of either class of cellular immune responses.<sup>253,255</sup> The loss of virus-specific CD4<sup>+</sup> or CD8<sup>+</sup> cytotoxic T lymphocyte (CTL) responses is associated with uncontrolled virus replication and lethal disease in these models.<sup>255</sup> The role of virus-specific antibodies has also been defined in these models and appears to contribute minimally to control of local virus replication but plays a key role in limiting blood-borne dissemination of the virus.<sup>254</sup> This finding is of some interest because in this model of CMV infection, virus spread is almost entirely by cell-associated virus and not cell-free virus, raising several interesting questions, including the mechanisms by which antiviral antibodies restrict virus dissemination.<sup>226</sup> Consistent with the findings in experimental animal models, studies in immunocompromised human hosts have repeatedly demonstrated that loss of normal T lymphocyte responses predisposes the host to CMV infection and, depending on the severity of the immune deficit, can lead to invasive disease resulting in considerable morbidity and mortality.<sup>259-264</sup> Several striking examples of the relationship between immunity and invasive CMV disease have been documented. These include the development of pneumonitis in bone marrow and cardiac allograft recipients, prolonged CMV viremia and end-organ disease such as retinitis in AIDS patients with high viral (i.e., human immunodeficiency virus [HIV]) burdens and low CD4<sup>+</sup> lymphocyte counts, and in fetuses infected *in utero*. Perhaps the most convincing evidence for the critical role of T lymphocyte responses in host resistance to invasive CMV infection were studies in bone

marrow allograft recipients who received *ex vivo* expanded CMV-specific CD8<sup>+</sup> CTL and were protected from invasive CMV infection compared with historical control patients.<sup>262</sup> Another interesting finding from this study was that patients that failed to generate CMV-specific CD4<sup>+</sup> lymphocyte responses failed to generate long-term protection from CMV and developed invasive infections late in the course of transplantation.<sup>262,264</sup> This observation predated studies that showed that a CD4<sup>+</sup> response is required for maintenance of long-term immunity to an infectious agent.<sup>265,266</sup> Effector cells and mediators of the innate immune response have also been shown to be critical for control of CMV infections. Although most studies have used murine models of CMV infections, loss of natural killer (NK) cell activity and invasive CMV infection have been reported.<sup>267,268</sup> In murine models, NK cells and interferons have been shown to play a critical role in resistance to MCMV infection and appear to represent an initial host response that can limit virus replication and spread during the development of a more efficient effector function of the adaptive immune system.<sup>255</sup> In contrast to the role of antiviral antibodies in limiting dissemination of MCMV, the importance of antiviral antibodies in protective responses to CMV remains unclear. Several studies have demonstrated a correlation between antiviral antibody responses, particularly virus-neutralizing antibodies, and patient outcome.<sup>269-273</sup> Studies in solid organ transplant recipients given intravenous immunoglobulins containing anti-CMV antibodies have suggested that virus-specific antibodies can provide some degree of protection from invasive infections.<sup>274-277</sup> In other transplantation populations, such as bone marrow allograft recipients, the efficacy of anti-CMV immunoglobulins has not been proved, and its use varies among transplant centers.<sup>275,276,278,279</sup> Animal models other than mice have also indicated that antiviral antibodies could provide some degree of protection. This is most convincing in a guinea pig model of congenital CMV infection in which passive transfer of anti-guinea pig CMV (gpCMV) antibodies limited maternal disease and disease in infected offspring.<sup>280,281</sup> Available data argue for a role of antiviral antibodies in limiting disease caused by CMV, and in the case of intrauterine infections, antiviral antibodies could freely pass into the fetal circulation and, if protective, could alter the outcome of intrauterine infections.

### Modulation of the Host Immune Response to Cytomegalovirus

Over the past 10 years, several laboratories have identified multiple viral genes whose products interfere with immune recognition and destruction of virus-infected cells. A description of these genes and their modes of action is provided in Table 23-10.

The importance of these genes in the biology of CMV *in vivo* is not completely understood; however, animal models of CMV infection have allowed investigators to determine the importance of homologous genes during virus replication. The results from these studies have indicated that these viral functions actively interfere with virus clearance during acute infection in experimental animals.<sup>258,282,283</sup> Although a complete discussion of these viral genes and their mechanisms of immune evasion is outside the scope of this chapter, several pertinent observations can be made about the

**Table 23–10 Mechanisms of Cytomegalovirus Modulation of Host Immune Responses**

Responses	Viral Gene ORFs <sup>a</sup>	Mechanism

importance of these viral genes in the pathogenesis of CMV infections. These genes do not prevent recognition and control of CMV infections in normal hosts, as evidenced by the limited pathogenicity of this virus in normal individuals and in experimental animal models. Some investigators have argued that the phenotype of these viral genes can only be appreciated in the immunocompromised hosts. Moreover, vast amounts of literature describe the function of immune evasion genes in experimental animals and during acute infection. In most studies, the function of these viral genes has only been evaluated in a limited number of target organs, raising the question of whether some of these genes could be tissue specific. Other investigators have raised the question of whether these genes function to focus the immune response to a limited number of viral antigens, restricting the available antigens for immune recognition. However, these viruses have committed a large amount of their genome to immune evasion functions, the genes are conserved in animal and human CMVs, and experiments using animals have demonstrated that immune evasion functions facilitate a tissue-specific virus replication advantage *in vivo*.<sup>283</sup> These observations suggest that these genes likely play a critical role in the biology of these viruses.

Immune evasion functions encoded by CMVs interfere with innate immune responses and adaptive immune responses to virus-infected cells. Mutations that result in mutation in viral structural proteins and in viral proteins recognized by the immune system also appear to allow escape from immunologic control. Mutations in CMV viral genes encoding targets of dominant CD8<sup>+</sup> CTL responses have been reported.<sup>284</sup> One of the more interesting findings has been the observation that one MCMV gene, *M157*, previously shown to activate NK responses through NK receptor Ly49H in strains of mice that were genetically resistant to MCMV infection, can develop mutations within weeks of infection.<sup>285</sup> Viruses with mutations in *M157* were shown to replicate to higher titers in strains of resistant mice.

This mutational event appears to be caused by immune selection because genetically susceptible strains of mice that do not use this NK cell activation pathway do not generate viruses with mutations in the *m157* gene.<sup>285</sup> Antigenic variation in virion envelope glycoproteins that are targets of virus neutralizing antibodies have been well described. Strain-specific neutralizing antibody responses to the envelope glycoprotein B have been described.<sup>48,286</sup> One study<sup>287</sup> of the polymorphic envelope glycoprotein N suggested that immune selection was responsible for the variation in amino acid sequence of gN derived from different virus isolates. CMVs, including human CMV, can evade immune recognition by a variety of active mechanisms such as immune evasion genes and by more conventional strategies, such as loss of antigenic determinants or loss of key antigens required for activation and recognition by immune cells.

### Pathogenesis of Acute Infections

Very early in the study of CMV infections, disease manifestations associated with congenital and perinatal CMV infections were related to the level of virus excretion, a marker for virus replication.<sup>288</sup> Subsequent studies in allograft recipients and in patients with AIDS have confirmed these findings and have consistently demonstrated that increased levels of CMV replication in these patients are a key predictor of invasive disease. Unchecked virus replication and dissemination leads to multiorgan disease as illustrated by autopsy studies of neonates with congenital CMV infections, allograft recipients, and AIDS patients. Studies using rhesus macaques infected with rhesus CMV (RhCMV) have yielded results consistent with the proposed pathogenesis of human infection and provided a more detailed view of infection with this virus.<sup>289</sup> In these studies, virus given intravenously or by a mucosal route resulted in blood-borne dissemination and widespread infection of a number of organs, including the liver and spleen.<sup>289</sup> The kinetics of the

virus replication were different in the two groups, with a lag in peak virus titers and liver infection occurring in animals inoculated by a mucosal route. This result suggested that a local or regional amplification of virus was required after mucosal infection before blood-borne dissemination to the liver and spleen. This finding is consistent with experimental findings in guinea pigs and mice infected with their respective CMVs.<sup>228,290-292</sup> The rhesus macaques that were inoculated by mucosal exposure remained asymptomatic and failed to exhibit the clinical and laboratory abnormalities that were observed in animals given virus intravenously.<sup>289</sup> Together, these findings parallel clinical and laboratory findings in humans infected with CMV, and human infections that follow parenteral exposure to virus can exhibit clinical and laboratory abnormalities similar to those described in these experimental animal models.

The dissemination of CMV from the liver and spleen to distal sites probably occurs in the normal immunocompetent individual and in the immunocompromised host. However, it is also quite likely that the quantity and duration of the viral dissemination is quantitatively different in these two populations. In contrast to community-acquired CMV infections in normal adults, persistent viral DNAemia as detected by PCR is characteristic of populations with disseminated CMV infections, such as AIDS patients or infants with symptomatic congenital CMV infection.<sup>153,293-299</sup> It appears that the natural history of CMV infection includes local replication at mucosal sites followed by amplification of virus, locally and presumably in regional lymphoid tissue, and spread to the viscera such as liver and spleen. Virus replication in these organs further increases the quantity of viruses, and virus then spreads to distal organs and sites of persistence such as the salivary glands and renal tubules. From observations in humans and in experimental models of infection, symptomatic infection appears to be related to the level of virus replication in sites seeded by the primary viremia, such as the liver and spleen. It follows that parenteral exposure from sources such as contaminated blood are associated with symptomatic infections because a larger viral inoculum is delivered to the organs such as the liver, often in the absence of a developing immune response that would normally be present after infection of a mucosal surface.

### Pathogenesis of Central Nervous System Infections in Congenitally Infected Infants

The disease manifestations of congenital CMV infections include manifestations seen in adult immunocompromised hosts with disseminated CMV infections and include visceral organ involvement, such as hepatitis and, infrequently, pneumonitis and adrenalitis.<sup>300-303</sup> Unique to congenital CMV infection is the presence of CNS disease, a manifestation rarely seen even in the most immunocompromised allograft recipients. CMV encephalitis has been reported in patients with AIDS, but this disease is distinctly different clinically and pathologically from CMV infection of the CNS associated with intrauterine infection. CNS involvement in infants with congenital CMV infections often is associated with ongoing disease, such as progressive hearing loss during the first few years of life, at a time when there is no apparent progression of structural damage in the CNS.<sup>165-168,304</sup> The pathogenesis of CMV CNS infection in the developing fetus

is poorly understood for several reasons, including the lack of a sufficiently large number of autopsy studies. There are no well-developed animal models of CNS infection associated with congenital CMV infection. The MCMV model is useful for the study of many aspects of CMV infection, but congenital infection with MCMV does not occur in mice. The other widely employed small animal model, the guinea pig, can be used to study intrauterine infections, and early reports suggested that CNS infections developed in these animals.<sup>305,306</sup> However, the usefulness of this model for studying CNS infection has not been defined, and because only a limited number of observational studies have been reported, it has been difficult to assign its value as a model. The rhesus macaque offers perhaps the most relevant model for the study of CMV CNS infections for several reasons, including the similarities in brain development shared between macaques and humans. The rhesus CMV is more closely related to CMV than are the rodent and guinea pig CMVs. However, this model is expensive, and these experimental animals are in limited supply because of their use in studies of HIV. For these reasons, our understanding of CNS infection with CMV is limited.

Infection of the developing CNS is associated with a number of structural abnormalities, depending on the age of fetus at the time of CNS infection. Imaging studies of living infants and children with congenital CMV infections and clinical findings consistent with CNS disease have been informative. Commonly observed abnormalities include periventricular calcifications, ventriculomegaly, and loss of white-gray matter demarcation.<sup>307-309</sup> More refined imaging studies have detailed loss of normal brain architecture with loss of normal radial neuronal migration.<sup>310</sup> Limited autopsy studies have confirmed these imaging abnormalities and have demonstrated the presence of inflammatory infiltrates in the parenchyma of the brain.<sup>308</sup> The latter finding is consistent with the presence of increased protein and inflammatory cells in spinal fluid obtained from congenitally infected infants with CNS disease. Together these findings argue for a pathogenic spectrum that likely includes lytic infection of neuronal progenitor cells in the subventricular gray area, vasculitis with loss of supporting vessels in the developing brain, and meningoencephalitis with release of inflammatory mediators. It is unclear why the fetal and newborn brains are more susceptible to CMV infection compared with the adult brain; however, findings from experimental models suggest that the developing cells of the CNS are particularly susceptible to the lytic or possibly the apoptotic effects of CMVs. In animal models, including mice and rhesus macaques, infection of the developing CNS results in widespread lytic virus replication, including neuronal progenitor cells of the subventricular gray area and endothelium.<sup>311-313</sup> Lytic virus replication in this area would lead to loss of normal neuronal development, radial migration, and vascularity of the developing brain. Extravasation of blood from damaged microvasculature would lead to calcifications that are prominent findings in imaging studies of CMV-infected newborn infants. The more severe manifestations of CMV CNS infection can be explained by lytic virus infection of neuronal progenitor cells, glial cells in the CNS, and destruction of supporting vasculature. Intracerebral inoculation of fetal rhesus macaques with RhCMV results in findings similar to those described in severely affected human

infants, suggesting that if CMV enters the CNS early in development, significant structural damage will ensue.

Other infants infected in utero with CMV exhibit clinical findings consistent with CNS involvement, including developmental delays and loss of perceptual functions, but do not have structural damage of the brain that can be detected by routine imaging techniques. At least one autopsy series has suggested that affected infants without calcifications can have neuronal migration deficits manifest as pachygyria and other abnormalities such as cerebellar hypoplasia.<sup>308</sup> The mechanisms leading to loss of normal architecture are unknown but could be related to ongoing inflammation in the CNS because of intrauterine meningoencephalitis. Various inflammatory mediators have been shown to cause loss of neuron and supporting cell function and can modify vascular permeability and endothelial function. Evidence from experimental animal models has suggested that cytokines and chemokines may directly influence neuronal radial migration.<sup>314,315</sup> Ongoing inflammation may result in loss of normal brain architecture from delayed or absent radial migration of neurons destined for the cerebral cortex.

### Pathogenesis of Hearing Loss Associated with Congenital Cytomegalovirus Infection

Hearing loss represents one of the most common long-term sequelae of congenital CMV infection, and its pathogenesis is perhaps the least understood of any manifestation of CMV infection. As discussed in preceding sections, the hearing loss can vary between mild and profound and be unilateral or bilateral, and it can develop or progress after the perinatal period.<sup>165-168,304,316</sup> Hearing impairment may represent the common outcome of CMV infections in different parts of the auditory apparatus or result from infection at different stages in the development of the auditory system. Besides the potential complexity of the disease, several other reasons probably contribute to the lack of understanding of the pathogenesis of hearing loss that follows congenital CMV infection. One of the most apparent is the lack of adequate histopathologic examinations of affected tissue from infected infants. A literature review revealed that only 12 temporal bones from congenitally infected infants have been studied and described in the medical literature. Most of the studies were done without the aid of modern techniques of virus and viral antigen detection and relied almost entirely on conventional histologic examinations. These limitations, together with the lack of adequate information on the maternal and fetal infection, have resulted in the lack of solid clues to the possible mechanisms of virus-induced damage to the auditory system. Hearing loss in CNS infections in adults with AIDS or transplant-related infections is rare and not well described, presumably because these infections differ significantly from congenital CMV infection in the extent of CNS involvement, the underlying diseases, and type of treatment in these immunocompromised patients. Animal models of CMV-induced hearing loss have been developed and have provided some information regarding selected aspects of the hearing loss associated with CMV. In general, however, they have failed to recapitulate the disease, and in some cases, early findings have been difficult to reproduce. Investigators have attempted to combine the limited data from histopathologic studies with natural history

studies of hearing loss from congenitally infected infants with findings from animal studies to develop a model of the pathogenesis of hearing loss associated with congenital CMV infections.

A comprehensive review of temporal bone pathology in infants with congenital CMV infection was published by Strauss.<sup>317,318</sup> The specimens in this series were from infants who died between the ages of 3 weeks and 5 months. A single case report of a 14-year-old patient with severe neuromuscular sequelae resulting from congenital CMV can be found.<sup>319</sup> Findings in the inner ear, cochlea, vestibular system, and auditory or vestibular neural structures were described in all patients. Five of the original nine specimens had evidence of endolabyrinthitis, and virus was isolated from the endolymph in three of the nine specimens.<sup>318</sup> Viral antigen was detected by immunofluorescence in two cases in which routine histology failed to demonstrate viral inclusions.<sup>165</sup> Cochlear and vestibular findings were variable and ranged from rare inclusion bearing cells in or adjacent to the sensory neuroepithelium of the cochlea or vestibular system to more extensive involvement of the nonsensory epithelium. Routine histologic analysis failed to detect viral inclusions in the auditory or vestibular neural structures, but viral antigens were detected in the spiral ganglion when specimens were examined by immunofluorescence.<sup>165</sup> Inflammatory infiltrates were minimal and reported in only three patients in this series.<sup>318</sup> Perhaps the most interesting results were those reported in the examination of tissue from the 14-year-old patient with extensive sequelae from congenital CMV infection. In this patient, extensive cellular degeneration, fibrosis, and calcifications were observed in the cochlea and vestibular systems.<sup>319</sup> Several generalizations can be made from these limited data. First, in all but two of these cases, virus, viral antigens, or histopathologic findings consistent with virus infection were detected in the cochlea or vestibular apparatus. These findings indicate that virus replication could have occurred in the sensory neuroepithelium and nonsensory epithelium and that cellular damage could have resulted from a direct viral cytopathic effect. Virus-induced damage can also result from bystander effects from immune-mediated cytopathology. CMV could induce loss of sensory neuroepithelium in the absence of direct infection of the sensory neuroepithelium but from infection of supporting epithelium followed by host immunopathologic responses. However, an inflammatory infiltrate was seen in only three of nine specimens, an unexpected finding based on the role that the inflammatory response is thought to play in CMV end-organ disease in other patient populations. However, it is well documented that infants with congenital CMV have a delay in the development of immunologic responses to CMV, and it can be argued that findings in the cochlea and vestibular apparatus are consistent with the ineffectual immune responses of congenitally infected infants. An alternative and not exclusive possibility is that infection of the inner ear structures is a late or, in some cases, a postnatal event. The relationship between susceptibility of cells of the sensory neuroepithelium and supporting epithelium to infection with CMV and their developmental status is unknown. These cells could be resistant to CMV infection until late in development. In this case, findings from specimens of the autopsy series described previously may reflect recent infection before host inflammatory responses. Such an

explanation is, however, inconsistent with the course of fetal CMV infection in other parts of the CNS in most of the patients included in autopsy studies. The findings of extensive degenerative changes together with fibrosis and calcifications in the temporal bones from the oldest patient presumably reflect the natural history of CMV labyrinthitis and, depending on the rate at which these changes develop, may explain the progressive nature of hearing loss associated with congenital CMV infection. The loss of neuroepithelium from direct virus-mediated damage or from host-derived inflammation followed by fibrosis is consistent with the profound hearing impairment that develops in some children with congenital CMV infection. Findings in experimental animal models indicate that exaggerated deposition of extracellular matrix is part of the inflammatory response in the inner ear and that this host response possibly leads to the ossification that is observed in animals inoculated in the labyrinth with CMV.<sup>320,321</sup>

Studies in animal models have provided some limited insight into the pathogenesis of hearing loss after congenital CMV infection. Small animal models have provided some information and have mirrored findings in humans. Both virus and inflammation are required for the development of pathology in the inner ear. A study in guinea pigs demonstrated that virus infection in immunocompromised animals was not associated with the typical pathologic findings in virus-infected normal animals.<sup>322</sup> Similarly, blocking virus replication with antiviral compounds or pretreating the animals with virus-neutralizing antibodies limited the development of inner ear pathology.<sup>323-325</sup> From the available studies the pathogenesis of hearing loss associated with congenital CMV infection requires virus replication and a host immune response. Interrupting virus replication or the local host inflammatory response could offer some therapeutic benefit to these patients.

### Nature of Maternal Infection

The nature of the maternal infection is a major pathogenetic factor for congenital CMV infection. Primary infections are more likely to be transmitted to the fetus and are likely to cause more fetal injury than recurrent infections.<sup>326</sup> With primary CMV infection, as in other infections during pregnancy, there appears to be some innate barrier against vertical transmission.<sup>86,327-331</sup> Intrauterine transmission after primary infection occurs in 30% to 40% of cases. How the placenta contains the infection is poorly defined. There have been a few reports of isolated placental involvement in the absence of fetal infection. Current information suggests that gestational age has no apparent influence on the risk of transmission of CMV in utero.<sup>86,327,328,332</sup> However, with regard to the role of gestational age on the expression of disease in the fetus and offspring, infection at an earlier gestational age produces the worst outcome.<sup>86,327,333</sup>

Congenital infection may also result from recurrences of infection.<sup>114-118</sup> The term *recurrence* is used here to represent reactivation of infection or reinfection with the same or a different strain of CMV during pregnancy. Evidence indicates that despite the inability of maternal immunity to prevent transmission of this virus to the fetus, congenital infections that result from recurrent infections are less likely to affect the offspring than those resulting from primary infections.<sup>326</sup>

The risk of congenital CMV infection resulting from a recurrence of infection during pregnancy ranges from a high of 1.5% for a U.S. population of low socioeconomic background to 0.19% for women of middle or upper socioeconomic background from the United States,<sup>86</sup> Great Britain,<sup>328</sup> or Sweden.<sup>334</sup>

In recurrent infection, it is likely that preexisting immunity inhibits the occurrence of viremia, at least to some extent. Cellular immunity may be more important than humoral immunity; however, maternal IgG antibodies are transmitted to the fetus, although their precise role has not been elucidated. Several cases of symptomatic congenital infection have been reported after therapeutic immune suppression, in women with lupus or AIDS, and even in women with intact immune systems.<sup>334-341</sup>

### Perinatal Infection

Naturally acquired perinatal CMV infections result from exposure to infected maternal genital secretions at birth or to breast milk during the first months of postnatal life.<sup>89,90</sup> The presence of CMV at these two sites may be the result of primary or recurrent maternal infection. Iatrogenic CMV infections are acquired predominantly from transfusions of blood or blood products and breast milk from CMV-infected donors. Exposure to CMV in the maternal genital tract has resulted in a 30% to 50% rate of perinatal infection. The transmission from mother to infant through breast milk occurs in 30% to 70% if nursing lasts for more than 1 month.<sup>96,124,174,342-344</sup> After ingestion of the virus, CMV infection is presumably established at a mucosal surface (i.e., buccal, pharyngeal, or esophageal mucosa) or in the salivary glands, for which CMV is known to have a special tropism. Occasionally, perinatal CMV infection and, rarely, congenital CMV infections are associated with pneumonitis. Although it is not proved, it is conceivable that CMV replicates in respiratory mucosa after aspiration of infected secretions or breast milk.

Transmission of CMV by blood transfusion is more likely to occur when large quantities of blood are transfused. The failure to isolate CMV from the blood or blood elements of healthy seropositive blood donors suggests that the virus exists in a latent state, presumably within leukocytes. It has been suggested that CMV becomes reactivated after transfusion, when infected cells encounter the allogeneic stimulus. CMV genomes are activated when transfused to a recipient, particularly if immunologically immature or deficient. Chou and colleagues<sup>345</sup> reported that if the recipient is human leukocyte antigen (HLA) matched with the donor, activation is more likely to occur, presumably because of better survival of infected cells.

### Persistent Viral Excretion

Congenitally and perinatally acquired CMV infections are characterized by chronic viral excretion.<sup>301</sup> Virus is consistently shed into the urine for up to 6 years or longer and into saliva for 2 to 4 years. Not only does excretion persist much longer in these patients than in infected older children and adults, but the quantity of virus excreted is also much greater. Even asymptomatic congenitally or perinatally infected infants excrete quantities of virus that usually exceed those

**Figure 23-2** Quantitative assessment of cytomegalovirus excretion in subjects with congenital symptomatic (triangles) and congenital asymptomatic (circles) infections.

detectable in seriously ill immunocompromised older patients. As shown in Figure 23-2, the highest quantities of virus are excreted during the first 6 months of life. Infants with symptomatic congenital CMV infection excrete significantly larger amounts than those with asymptomatic congenitally or perinatally acquired infections.

## **PATHOLOGY**

### **Overview**

Early reports of histopathologic changes associated with CMV infections relied on a demonstration of classic changes characterized by cytomegaly and nuclear and cytoplasmic inclusions.<sup>300,346</sup> The distinctive features include large cells 20 to 35  $\mu$ m in diameter with a large nucleus containing round, oval, or reniform inclusions. These large inclusions are separated from the nuclear membrane by a clear zone, which gives the inclusion the so-called owl's-eye appearance. The inclusions within the nucleus show DNA positivity by histochemical staining, whereas the cytoplasmic inclusions contain carbohydrates, as evidenced by periodic acid-Schiff positivity. The cytoplasmic inclusions vary from minute dots to distinct rounded bodies 3 to 4  $\mu$ m in diameter. The cytoplasmic inclusions are usually aggregated opposite to the eccentrically placed inclusion-bearing nucleus. Unfortunately, the classic CMV inclusion-bearing cell may be only scattered throughout involved tissue and missed by routine sectioning. This finding has been confirmed when more refined techniques such as in situ DNA hybridization and immunofluorescence using CMV-specific monoclonal antibodies have been used to define the extent of infection with CMV in immunocompromised patients.

Disseminated disease can occur in the infected fetus and congenitally infected infant. CMV can cause a multisystem disease in which almost all major organ systems are involved.<sup>300</sup>

### **Commonly Involved Organ Systems**

#### **Central Nervous System**

Involvement of the CNS is perhaps the most important consequence of fetal infection with CMV. Most descriptions

of the pathology of CNS infection are relevant only to infants with severe CID, which is occasionally fatal.<sup>347-349</sup> The infection can be described grossly as focal encephalitis and periependymitis. The encephalitis can involve cells of the gray matter and white matter and cells within the choroid plexus. Inclusion-bearing cells have been identified in neurons, glia, ependyma, choroid plexus, meninges, and vascular endothelium, and in cells lying free in the ventricles. Rarely, inclusion-bearing cells have been identified in the cerebrospinal fluid.<sup>350</sup> Resolution of acute encephalitis leads to gliosis and calcification. Previous descriptions have emphasized the periventricular location of calcifications; however, these lesions can be located anywhere in the brain.<sup>351,352</sup> CMV has been isolated on a few occasions from cerebrospinal fluid.<sup>353</sup>

Viral inclusion-bearing cells and viral antigen-containing cells can also be found within structures of the inner ear, including the organ of Corti, and in epithelial cells of striae vascularis of the cochlea.<sup>165,354-356</sup> Involvement of the eye, including chorioretinitis, optic neuritis, cataract formation, colobomas, and microphthalmos, has been demonstrated.<sup>165,349</sup> The histopathologic changes associated with retinitis begin as an acute vasculitis that spreads into the choroid through the vascular basement membrane. CMV has been isolated from fluid of the anterior chamber of the eye.<sup>357</sup>

#### **Liver**

Involvement of the liver is common in congenital CMV infections. Clinical evidence of hepatitis as manifested by hepatomegaly, elevated levels of serum transaminases, and direct hyperbilirubinemia is frequently seen in infants with symptomatic congenital infections. Pathologic descriptions of hepatic involvement include mild cholangitis with CMV infections of bile duct cells, intralobular cholestasis, and obstructive cholestasis caused by extramedullary hematopoiesis.<sup>348</sup> Liver calcification has been detected radiologically in infants with congenital infections.<sup>358,359</sup> Clinical and laboratory evidence of liver disease eventually subsides in surviving infants.

#### **Hematopoietic System**

Hematologic abnormalities, including thrombocytopenia, anemia, and extramedullary hematopoieses, are common in

symptomatically infected infants, but these abnormalities almost invariably resolve within the first year of life. The exact mechanism accounting for these disturbances is not certain, although congestive splenomegaly resulting in platelet and red blood cell trapping must play some part in the overall process. Major splenomegaly is common, and congestion, extramedullary hematopoiesis, and diminished size of lymphoid follicles can be seen histologically.

In congenital CMV infections, thrombocytopenia may persist for several months, even years, with or without petechiae. At least in animal models, direct infection of megakaryocytes has been found and postulated as a possible mechanism.<sup>360</sup> Anemia is another feature of symptomatic congenital CMV infection. The presence of indirect hyperbilirubinemia, extramedullary hematopoiesis, and erythroblastemia indicates active hemolysis, but mechanisms for these effects have not been elucidated.

### **Kidneys**

Macroscopically, the kidneys show no alterations. Microscopically, inclusion-bearing cells are commonly seen, especially in the cells lining the distal convoluted tubules and collecting ducts.<sup>361,362</sup> Affected cells may desquamate into the lumina of the tubules and appear in the urine sediment. Inclusions can be found occasionally in Bowman's capsules and proximal tubules. Mononuclear cell infiltration may be present in the peritubular zones of the kidney.

### **Endocrine Glands**

Secretory cells of endocrine glands commonly contain typical CMV inclusions. In the pancreas, the endocrine and exocrine cells are affected.<sup>300</sup> Some reports describe intralobular or periductal mononuclear infiltration, suggesting focal pancreatitis. There is no indication of an association between congenital CMV infection and diabetes mellitus. CMV inclusion-bearing cells have been documented in follicular cells of the thyroid, the adrenal cortex, and the anterior pituitary.

### **Gastrointestinal Tract**

The salivary glands are commonly involved in congenital and perinatal CMV infections. However, there are no reliable figures on the frequency of involvement because the examination of the salivary glands is not always part of autopsies.<sup>362</sup> CMV inclusions have also been described in the mucosal surfaces of the esophagus, stomach, and intestine and in the vessels of ulcerative intestinal lesions.<sup>363</sup>

### **Lungs**

Pulmonary CMV lesions are similar in the newborn and the adult. Microscopically, most inclusion-bearing cells are alveolar cells that lay free in terminal air spaces. In general, there is little inflammatory reaction; however, in the more severe cases, focal interstitial infiltration by lymphocytes and plasma cells can be found.

### **Placenta**

Abnormalities occur in the placentas of most patients with symptomatic CMV infection and are uncommon with subclinical infections.<sup>364</sup> Placentas are not remarkable in size or macroscopic appearance. The most specific feature histologically is the presence of inclusion-bearing cells,

which may be found in endothelial cells, in cells attached to the capillary walls, or in Hofbauer's or stromal cells.<sup>364,365</sup> Other lesions include focal necrosis, which in early gestation shows sparse infiltration by lymphocytes, macrophages, and a few plasma cells. The early lesions manifest as foci of necrosis of the stroma and occasionally of the vessels of the villi. The focus of necrosis is later invaded by inflammatory cells, histiocytes, and fibroblasts. At later gestational ages, these focal lesions become densely cellular, with plasma cells predominating over lymphocytes. Deposition of intracellular and extracellular hemosiderin can be found in stem and terminal villi and is presumably the result of fetal hemorrhage during the necrotizing phase or of maternal intervillous thrombosis. Calcification within villi or on basement membranes has been described as a late manifestation of placental CMV infection.

## **CLINICAL MANIFESTATIONS**

### **Congenital Infection**

Approximately 10% of the estimated 44,000 infants (1% of all livebirths) born annually with congenital CMV infection in the United States have signs and symptoms at birth that would lead the physician to suspect a congenital infection. Only one half of these symptomatic infants have typical generalized CID, characterized mainly by the clinical manifestations given in Table 23-9.<sup>303,366</sup> Another 5% of these infants present with milder or atypical involvement, and 90% are born with subclinical but chronic infection. Because early studies emphasized symptomatic infections, congenital CMV was considered a rare and often fatal disease. In the early reports, many patients were referred to the investigators because of developmental problems; this might have automatically highlighted a group of patients at a higher risk for persistent abnormalities and neurologic damage. The use of more sensitive and specific methods of diagnosis, particularly viral isolation, has allowed prospective longitudinal study of newborns with symptomatic and asymptomatic congenital CMV infections. This has resulted in a better understanding of the infection and its clinical spectrum.

### **Symptomatic Infection**

#### **ACUTE MANIFESTATIONS**

Clinically apparent infections or CID is characterized by involvement of multiple organs, particularly the reticulo-endothelial system and CNS, with or without ocular and auditory damage. Weller and Hanshaw<sup>366</sup> defined the abnormalities found most frequently in infants with symptomatic congenital infection as hepatomegaly, splenomegaly, microcephaly, jaundice, and petechiae. As shown in Table 23-11, petechiae, hepatosplenomegaly, and jaundice are the most common presenting signs.

The magnitude of the prenatal insult is demonstrated by the occurrence of microcephaly with or without cerebral calcification, intrauterine growth retardation, and prematurity.<sup>86,303,307,309,327,367-370</sup> Inguinal hernia in males and chorioretinitis with or without optic atrophy are less common. Clinical findings occasionally include hydrocephalus, hemolytic anemia, and pneumonitis. Among the most severely affected infants, the mortality rate may be as high as 30%.<sup>301</sup> Most

From Boppana S, Pass RF, Britt WS, et al. Symptomatic congenital cytomegalovirus infection: neonatal morbidity and mortality. *Pediatr Infect Dis J* 11:93-99, 1992.

deaths occur in the neonatal period and usually are caused by multiorgan disease with severe hepatic dysfunction, bleeding, disseminated intravascular coagulation, and secondary bacterial infections. When death occurs after the first month but during the first year, it typically is caused by progressive liver disease with severe failure to thrive. Death after the first year usually is restricted to severely neurologically handicapped children and is caused by malnutrition, aspiration pneumonia, and overwhelming infections.

**Hepatomegaly.** This sign, along with splenomegaly, is probably the most common abnormality found in the newborn period in infants born with a symptomatic congenital CMV infection.<sup>370</sup> The liver edge is smooth and nontender and usually measures 4 to 7 cm below the right costal margin. Liver function tests are often abnormal but usually not markedly so. The persistence of hepatomegaly is variable. In some infants, liver enlargement disappears by the age of 2 months. In others, significant enlargement persists throughout the first year of life. However, massive hepatomegaly extending beyond the first 12 months of life is uncharacteristic of CID.

**Splenomegaly.** Enlargement of the spleen exists to a greater or lesser degree in all the common human congenital infections and is especially frequent in congenital CMV infections.<sup>303,370</sup> It may be the only abnormality present at birth. In some instances, splenomegaly and a petechial rash coexist as the only manifestations of the disease. Occasionally, the enlargement is such that the spleen may be felt 10 to 15 cm below the costal margin. Splenomegaly usually persists longer than hepatomegaly does.

**Figure 23-3** Symptomatic congenital cytomegalovirus infection is manifested by microcephaly and petechiae.

**Jaundice.** Jaundice is a common manifestation of congenital CID. The pattern of hyperbilirubinemia may take several forms, ranging from high levels on the first day to undetectable jaundice on the first day with gradual elevation of the bilirubin level to clinically apparent jaundice. The level of jaundice in the early weeks of life may fluctuate considerably.<sup>303,370</sup> In some instances, jaundice is a transient phenomenon, beginning on the first day and disappearing by the end of the first week. More often, however, jaundice tends to persist beyond the time of physiologic jaundice. Transient jaundice may occasionally occur in early infancy with pronounced elevation of bilirubin levels during the third month. Bilirubin levels are high in the direct and the indirect components. Characteristically, the direct component increases after the first few days of life and may constitute as much as 50% of the total bilirubin level. It is rare for the indirect bilirubin component to rise high enough to require an exchange transfusion, but this has been reported.

**Petechiae and Purpura.** There is evidence that CMV has a direct effect on the megakaryocytes of the bone marrow that results in a depression of the platelets and a localized or generalized petechial rash.<sup>360,370</sup> In some patients, the rash is purpuric (Fig. 23-3), not unlike that observed in the expanded rubella syndrome. Unlike the latter infection, however, pinpoint petechiae are a more common manifestation. These petechiae are rarely present at birth but often appear within a few hours thereafter; they may be transient, disappearing within 48 hours. The petechiae may be the only clinical manifestation of CMV infection. More often, however, enlargement of the spleen and liver is associated. The petechiae

may persist for weeks after birth. Crying, coughing, the application of a tourniquet, a lumbar puncture, or restraints of any kind may result in the appearance of petechiae even months after birth. Platelet counts in the first week of life range from less than 10,000 to 125,000, and most counts are in the 20,000 to 60,000 range. Some infants with petechial rashes do not have associated thrombocytopenia.

**Microcephaly.** Microcephaly, usually defined as a head circumference of less than the fifth percentile, affected 14 of 17 patients with CID in the early studies of Medearis in 1964.<sup>371</sup> As tissue culture methods became more widely used and clinical awareness of the infection increased, microcephaly became a less prominent symptom in subsequent series that included mainly infants born with less severe disease. In an examination of 106 surviving patients who were born with symptomatic CMV infection, 53% were microcephalic.<sup>303</sup> Not all infants with microcephaly continue to have head circumferences of less than the third percentile.<sup>370</sup> Microcephaly is the most specific predictor of mental retardation (this is especially true if the head measurement is close to the fifth percentile in an infant of low birth weight). Intracranial calcifications are an indication that the infant will have at least moderate and probably severe mental retardation.

**Ocular Defects.** The principal abnormality related to the eye in CMV infection is chorioretinitis, with strabismus and optic atrophy.<sup>303,367,370</sup> Microphthalmos, cataracts, retinal necrosis and calcification, blindness, anterior chamber and optic disk malformations, and pupillary membrane vestiges have also been described in association with generalized congenital CID. Despite these findings, the presence of abnormalities such as microphthalmos and cataracts is strong presumptive evidence that the disease process is not caused by CMV. Chorioretinitis occurs in approximately 14% of infants born with symptomatic congenital infection.<sup>303,367</sup> Although chorioretinitis occurs less frequently in sympto-

matic congenital CMV than in congenital toxoplasmosis, lesions caused by CMV and *Toxoplasma* cannot be differentiated on the basis of location or appearance.<sup>165,367</sup> *Toxoplasma gondii* and CMV can induce central retinal lesions. Occasionally, the appearance of strabismus with subsequent referral to an ophthalmologist is the means by which chorioretinitis is detected. Any infant with suspected CMV infection or strabismus in early life should be examined carefully for retinal lesions. Chorioretinitis caused by CMV differs from that caused by *Toxoplasma* in that postnatal progression is uncommon.<sup>367</sup>

**Fetal Growth Retardation.** Intrauterine growth retardation, occasionally severe, was reported in 50% of 106 patients with symptomatic congenital CMV infection, whereas prematurity occurred in 34% (see Table 23-11).<sup>303</sup> Infants with asymptomatic congenital infection in general show no intrauterine growth retardation or prematurity, and CMV cannot be considered an important cause of either condition.

**Pneumonitis.** Pneumonitis, a common clinical manifestation of CMV infection after bone marrow and renal transplantation in adults, is not usually a part of the clinical presentation of congenital CMV infection in newborns. Diffuse interstitial pneumonitis occurs in less than 1% of congenitally infected infants, even when the most severely affected cases are considered. As is discussed in greater detail later, CMV-associated pneumonitis is more likely to develop in infants with perinatally acquired CMV infections.<sup>372</sup>

**Dental Defects.** Congenital CMV infection is also associated with a distinct defect of enamel, which seems to affect mainly primary dentition.<sup>373</sup> This defect is more severe in children with the symptomatic form of the infection than in those born with asymptomatic infections (Fig. 23-4).

Clinically, this defect appears on all or most of the teeth and is characterized by generalized yellowish discoloration.

**Figure 23-4** Cytomegalovirus (CMV)-affected teeth. This patient had a clinically severe congenital CMV infection. Notice the fractured borders and opaque and hypocalcified enamel.

The enamel is opaque and moderately soft and tends to chip away from dentin. Affected teeth tend to wear down rapidly, leading to dental caries frequently seen in these children. In our longitudinal studies, this defect of enamel was documented in 27% of 92 children born with symptomatic congenital CMV infection and in 4% of 267 who were born with the subclinical form and who were observed for at least 2 years.<sup>373</sup> These patients usually require extensive orthodontic therapy. It is evident that these defects do not involve permanent teeth to the same degree.

**Deafness.** Sensorineural deafness is the most common handicap caused by congenital CMV infection. Medearis<sup>371</sup> was the first investigator to call attention to the presence of deafness in symptomatic congenitally infected infants. Subsequent reports confirmed this association and provided evidence that CMV can also cause sensorineural hearing loss in children with subclinical congenital infection.<sup>133,165-168,304,309,316,374-381</sup> CMV is now one of the most important causes of deafness in childhood. CMV can replicate in many structures of the inner ear, as demonstrated by typical CMV-induced cytopathology in Reissner's membrane, stria vascularis, and semicircular canals or by CMV-specific immunofluorescence in the organ of Corti and neurons of the eighth nerve.<sup>165,317,318,354-356</sup> The distribution of viral antigens is far more extensive than viral cellular cytolysis. The presence of an inflammatory response suggests the possibility that immune damage in the inner ear may also be a contributing factor.

The frequency and severity of the hearing impairment are worse in patients with symptomatic infection (58%) compared with asymptomatic infection at birth (7.4%). In general, hearing loss is progressive in 50%, is bilateral in 50%, and has a late onset in 20% of cases. The predictors of hearing loss in children with symptomatic congenital CMV infection are intrauterine growth retardation, petechiae, hepatosplenomegaly, thrombocytopenia, and intracerebral calcifications. The presence of microcephaly and other neurologic abnormalities does not predict hearing loss. Using logistic regression analysis, only petechiae and

intrauterine growth retardation are independent predictors of hearing loss.

#### LONG-TERM OUTCOME

The likelihood of survival with normal intellect and hearing after symptomatic congenital CMV infection is small.<sup>133,303,316,367,368,371,375-377,382,383</sup> As shown in Table 23-12, in our prospective studies, one or more handicaps have occurred in almost 90% of the patients with symptomatic congenital infection who survived.<sup>303</sup>

Psychomotor retardation, usually combined with neurologic complications and microcephaly, occurred in almost 70% of the patients. Sensorineural hearing loss was seen in 50%. The hearing loss is bilateral in 67% of patients with hearing loss and is progressive in 54%. Chorioretinitis or optic atrophy occurred in 20% of cases. Expressive language delays independent from hearing loss and mental impairment have also been described. Several studies have searched for clinical predictors of intelligence and developmental outcome and found that microcephaly at birth, development of neurologic problems during the first year of life, ocular lesions (e.g., chorioretinitis), and microcephaly that became apparent after birth were significantly associated with a low IQ and developmental quotient. The best predictor of adverse neurodevelopmental outcome is the presence of cranial computed tomographic (CT) abnormalities detected within the first month of life.<sup>309</sup> In infants with symptomatic congenital CMV infection, abnormal CT findings, particularly intracerebral calcifications, are common (70%). Almost 90% of children with abnormal newborn CT scans develop at least one sequela compared with 29% among those with a normal study.<sup>309</sup> In this particular study, which included 56 children with symptomatic congenital CMV, only 1 child with a normal CT scan had an IQ of less than 70, in contrast to 59% of those with imaging abnormalities. Newborn CT abnormalities were also associated with an abnormal hearing screen at birth and hearing loss on follow-up. None of the neonatal neurologic findings was predictive of an abnormal CT finding.<sup>309</sup> Overall, it can be anticipated that between 90% and 95% of infants with symptomatic

Table 23-12 Sequelae in Children after Congenital Cytomegalovirus Infection

Sequelae	Percent Symptomatic (n/N)	Percent Asymptomatic (n/N)
Sensorineural hearing loss	58 (58/100)	7.4 (22/299)
Bilateral hearing loss	37 (37/100)	2.7 (8/299)
Speech threshold moderate to profound (60-90 dB) <sup>a</sup>	27 (27/100)	1.7 (5/299)
Chorioretinitis	20.4 (19/93)	2.5 (7/281)
IQ <70	55 (33/60)	3.7 (6/159)
Microcephaly, seizures, or paresis/paralysis	51.9 (54/104)	2.7 (9/330)
Microcephaly	37.5 (39/104)	1.8 (6/330)
Seizures	23.1 (24/104)	0.9 (3/330)
Paresis/paralysis	12.5 (13/104)	0 (0/330)
Death <sup>b</sup>	5.8 (6/104)	0.3 (1/330)

<sup>a</sup>For the ear with better hearing.

<sup>b</sup>After the newborn period.

Data from Pass RF, Fowler KB, Boppana S. Progress in cytomegalovirus research. In Landini MP (ed). Proceedings of the Third International Cytomegalovirus Workshop, Bologna, Italy, June 1991. London, Excerpta Medica, 1991, pp 3-10.

congenital infections who survive will develop mild to severe handicaps.

### **Asymptomatic Infection**

As indicated in the previous section, almost 90% of infants with congenital CMV infections have no early clinical manifestations, and their long-term outcome is much better. Nevertheless, there is solid evidence derived from controlled, prospective studies that at least 10% of these infants, and perhaps as many as 15%, are at risk of developing a multitude of developmental abnormalities, such as sensorineural hearing loss, microcephaly, motor defects (e.g., spastic diplegia or quadriplegia), mental retardation, chorioretinitis, dental defects, and others. These abnormalities usually become apparent within the first 2 years of life.<sup>165,167,324,374,375,378,379,384-386</sup> Table 23-12 shows results based on our prospective longitudinal study of 330 patients with asymptomatic congenital infection who were followed by using serial clinical, psychometric, audiometric, and visual assessments.<sup>303</sup> Follow-up studies of patients with inapparent congenital CMV infection have also been done by Kumar and colleagues,<sup>378</sup> Saigal and associates,<sup>375</sup> Melish and Hanshaw,<sup>374</sup> Pearl and co-workers,<sup>380</sup> Williamson and colleagues,<sup>384</sup> Preece and associates,<sup>331</sup> Harris and co-workers,<sup>324</sup> Conboy and colleagues,<sup>381</sup> Ivarsson and associates,<sup>385</sup> Fowler and colleagues,<sup>167</sup> Kashden and co-workers,<sup>386</sup> and Noyola and associates.<sup>387</sup> In general, their findings resemble the results of our study presented in Table 23-12. Most patients in these studies and their controls were from a low socioeconomic background.

The most significant abnormality in children born with subclinical congenital CMV infection is hearing loss. Fowler and associates<sup>167</sup> evaluated 307 children with documented asymptomatic congenital CMV infection and compared their audiometric assessments with 76 uninfected siblings of children with asymptomatic congenital CMV infection and 201 children whose neonatal screen for this infection showed negative results. Sensorineural hearing loss occurred only in children with congenital CMV infection. Among them, 22 (7.2%) had hearing loss. In 11 (50%) of the 22 children, the hearing loss was bilateral. Among the children with hearing loss, further deterioration of hearing occurred in 50% with a median age at first progression of 18 months (range, 2 to 70 months). Delayed onset of sensorineural hearing loss occurred in 18% of the children with the median age of detection at 27 months (range, 25 to 62 months). Fluctuating hearing loss was documented in 22.7% of the children with hearing loss. These results are very similar to those obtained by Williamson and co-workers in Houston.<sup>384</sup> A study in Sweden of more than 10,000 newborns screened for hearing loss and congenital CMV infection found that this congenital infection was the leading cause of sensorineural hearing loss accounting for 40% of the cases with hearing loss.<sup>324</sup> In our group, Hicks and co-workers<sup>388</sup> found 14 cases of congenital CMV infection with sensorineural hearing loss in 12,371 neonates screened for CMV, a rate of approximately 1.1 per 1000 livebirths. The rate was 0.6 per 1000 livebirths when only cases with bilateral loss of 50 dB or greater were considered. These results suggest that CMV infection accounts for at least one third of sensorineural hearing loss in young children.<sup>388</sup> Taken together, these studies indicate that the universal screening for hearing loss in vogue in the United States will detect less than one half of all the cases of

sensorineural hearing loss caused by congenital CMV infection. Because most of these infants are asymptomatic at birth, they are not recognized as being at high risk for hearing loss and are not being further tested to detect late onset hearing loss. The universal screening of neonates for hearing loss needs to be combined with a screening for congenital CMV infections.

Prospective studies of children with subclinical congenital CMV infections have revealed a wide but significant spectrum of neurologic complications.<sup>384</sup> It has been estimated that within the first 2 years of life, 2% to 7% of the infants in this group develop microcephaly with various degrees of mental retardation and neuromuscular defects. How often milder forms of brain damage, such as learning or behavioral difficulties, will occur as these patients grow older is unknown. Studies of the intellectual development of children with asymptomatic congenital CMV infections have shown conflicting results. However, one study evaluated 204 prospectively followed children with asymptomatic congenital CMV infections and 177 uninfected siblings ranging in age from 6 to 203 months.<sup>381</sup> Parents were administered the Developmental Profile, and the children were administered an objective intelligence measure. Results showed that children with asymptomatic congenital CMV infection do not demonstrate intellectual impairment and that they perform similarly to uninfected siblings.

Children with asymptomatic congenital CMV infections are at low risk for developing chorioretinitis. The current estimate is that it occurs in 2% of these children, and like hearing loss, it may not exist at birth.

In summary, these observations underscore the need for longitudinal follow-up of patients with congenital CMV infection regardless of the initial clinical presentation. Careful assessments of perceptual functions (e.g., hearing, visual acuity), psychomotor development, and learning abilities must be made to recognize the full impact of CMV. With early identification of a problem, corrective measures can be instituted to reduce psychosocial and learning problems.

### **Effect of Type of Maternal Infection on Symptoms and Long-Term Outcome**

Studies have clearly demonstrated that preexisting maternal immunity does not prevent CMV from reactivating during pregnancy and cannot reliably prevent transmission in utero nor symptomatic congenital infections.<sup>114-118,120,326,334-341,389,390</sup> A prospective study of young, predominantly African American women with one or more previous deliveries were evaluated to quantify the protection conferred by pre-conception maternal immunity.<sup>391</sup> For the almost 3500 multiparous women who had previously delivered newborns screened for congenital CMV infection and who subsequently became part of this study, the overall rate of congenital CMV infection was 1.3%. Congenital infection occurred in 18 (3.0%) of 604 newborns (95% CI, 1.8% to 4.7%) born to initially seronegative mothers compared with 29 (1.0%) among the 2857 births (95% CI, 0.7% to 1.4%) to immune mothers. Of the initially seronegative women, 23.5% seroconverted for an annualized seroconversion rate of 7.8% per year with 12.7% of these seroconversions resulting in congenital CMV infection. Only 1% of infants born to mothers immune to CMV before conception had congenital infection. These results show that young women who have

immunity to CMV from naturally acquired infections are 69% less likely to have a baby with congenital CMV infections in the future than are those who are initially seronegative. This study also demonstrated a strong relationship between an increased rate of congenital CMV infection and short interval from initial CMV antibody test to subsequent birth among seropositive women. This observation indicates that some of the initially seropositive women had recently experienced primary infection and therefore had increased risk for congenital CMV infection.

It is generally recognized that primary infection has a higher risk of symptomatic infection; however, data that have emerged in recent years, including our own prospective studies, raise the possibility that recurrent maternal infection may result in adverse outcome more frequently than previously thought. In 1999, prospective studies carried out in Sweden<sup>392</sup> and the United States<sup>393</sup> reported the presence of symptomatology at birth and the development of long-term sequelae in children born with congenital CMV infection after a recurrence of maternal infection. Our study<sup>393</sup> included 246 children (1.18%) with congenital CMV infection from the screening of 20,885 neonates. Of the 246 infants, 47 were symptomatic at birth, and 8 (17%) of the 47 were born to mothers with recurrent CMV infection as defined by seropositive status at the time of a previous pregnancy. Demographically, the women in this study have been characterized as predominantly black (93%), single (96%), young (46% ≤20 years old), and without private insurance. A study of this population concluded that in women who are seropositive for CMV, reinfection with different strains of CMV rather than reactivation of the endogenous strain could lead to intrauterine transmission and symptomatic congenital infection. In contrast, the study of women who are predominantly white, married, of middle to high socioeconomic background, and somewhat older has not revealed the occurrence of symptomatic congenital CMV infection as a result of a recurrence of maternal infection.

### Public Health Significance

The public health impact of congenital CMV infection in the United States is significant, as shown in Table 23-13. With an average incidence of 1% and a birth rate of 4 million per annum, approximately 40,000 infants are born each year with congenital CMV infections. Of these, as many as 2800 present with signs and symptoms of infection (e.g., CID). About 336 of them can be expected to die within the first

year, and almost 2160 of the survivors develop handicaps. Another 5580 or so among the subclinically infected develop significant hearing and mental deficits. In addition to the personal and family suffering associated with these conditions, the cost to society for caring for all these children must amount to millions of dollars annually.

### Perinatal Infection

Perinatal infections can be acquired from exposure to virus in the maternal genital tract at delivery, from breast milk, or through multiple blood transfusions.<sup>89,90,96,342,344,394,395</sup> To establish the diagnosis of perinatal CMV infection, the examiner must first exclude congenital infection by showing an absence of viral excretion during the first 2 weeks of life. The incubation period of perinatal CMV infection ranges between 4 and 12 weeks. Although the quantity of virus excreted by infants with perinatal infection is less than that seen with intrauterine acquisition, the infection is also chronic, with viral excretion persisting for years.<sup>301</sup>

Most infants with naturally acquired perinatal infections remain asymptomatic. Most of these infections result from reactivation of maternal virus, and infants therefore are born with variable levels of maternal antibody. Asymptomatic perinatal CMV infection in full-term and otherwise healthy infants does not appear to have an adverse effect on growth, perceptual functions, or motor or psychosocial development. CMV has been incriminated as a cause of pneumonitis in infants younger than 4 months.<sup>90,344,372,396,397</sup> In a study undertaken to define the possible association of CMV and other respiratory pathogens with pneumonitis in young infants, CMV was isolated in 21 (21%) of 104 patients enrolled.<sup>372</sup> Only 3% of 97 hospitalized controls were infected. CMV-associated pneumonitis occurs throughout the year in contrast to the common respiratory virus infections, which occur most often in winter and early spring.

CMV-associated pneumonitis is clinically and radiographically indistinguishable from other types of afebrile pneumonia caused by agents such as *Chlamydia trachomatis* and respiratory syncytial virus. Clinically, patients with CMV-associated pneumonitis have an afebrile course with tachypnea, cough (sometimes paroxysmal), occasional episodes of apnea, coryza, nasal congestion, intercostal retractions, and radiographic evidence of diffuse lower airway obstruction (e.g., air trapping, thickened bronchial walls with prominent pulmonary markings and various degrees of atelectasis). Expiratory wheezing is unusual. Laboratory findings include elevated levels of one or more serum immunoglobulins (especially IgM, in 66% of patients), leukocytosis of more than 12,000 white blood cells/mm<sup>3</sup> (59%), and absolute eosinophilia. The median time of hospitalization is 17 days. Some infants require oxygen therapy and ventilatory assistance. Long-term follow-up of patients with pneumonitis associated with CMV and other respiratory pathogens provides evidence that significant mortality and morbidity do occur irrespective of the etiologic agent.<sup>397</sup>

In premature and ill term infants, Yeager and colleagues<sup>398</sup> found that naturally acquired CMV infection may pose a greater risk. They found that premature infants weighing less than 1500 g at birth who acquired CMV from a maternal source often developed hepatosplenomegaly, neutropenia, lymphocytosis, and thrombocytopenia, coinciding with the

**Table 23-13 Public Health Impact of Congenital Cytomegalovirus Infection in the United States**

Parameter	Estimate
No. of live births per year	4,000,000
Rate of congenital CMV infection (average)	1%
No. of infected infants	40,000
No. of infants symptomatic at birth (5%-7%)	2800
No. with fatal disease (±12%)	336
No. with sequelae (90% of survivors)	2160
No. of infants asymptomatic at birth (93%-95%)	37,200
No. with late sequelae (15%)	5580
Total no. with sequelae or fatal outcome	8076

onset of virus excretion. Frequently, infected patients required longer treatment with oxygen than uninfected patients. In a later study, Paryani and co-workers<sup>399</sup> from the same group reported a prospective study of 55 premature infants, including controls, and suggested that there might be a propensity for an increased incidence of neuromuscular impairments, particularly in premature infants with the onset of CMV excretion during the first 2 months of life. However, sensorineural hearing loss, chorioretinitis, and microcephaly occurred with similar frequency in both groups. Similar findings were reported by Vochem<sup>342</sup> and Maschmann.<sup>344</sup>

Transfusion-acquired perinatal CMV infection can cause significant morbidity and mortality, particularly in premature infants with a birth weight of less than 1500 g born to CMV-seronegative mothers.<sup>134,394,395</sup> The syndrome of post-transfusion CMV infection in premature newborns was characterized by Ballard and co-workers.<sup>400</sup> They isolated CMV from 16 of 51 preterm infants of a mean birth weight of 1000 g and found that 14 of the 16 virus-positive infants had a constellation of symptoms that resembled CID. This recognizable, self-limited syndrome consisted of deterioration of respiratory function, hepatosplenomegaly, unusual gray pallor with disturbing septic appearance, an atypical and an absolute lymphocytosis, thrombocytopenia, and hemolytic anemia. The syndrome was more severe in low-birth-weight infants and occurred 4 to 12 weeks after the transfusion, when the infants were progressing satisfactorily. Although the course of the disease was generally self-limited (lasting 2 to 3 weeks), death occurred in 20% of the ill infants. Subsequent work by Yeager and associates<sup>269</sup> and Adler<sup>401</sup> confirmed these observations. The risk of infection is greater with an increasing number of units of blood transfused. Yeager and associates<sup>269</sup> demonstrated that the risk of infection is related to the serologic status of the donor and that these infections could be prevented by transfusing seronegative newborns with blood from seronegative donors.

## DIAGNOSIS

### Detection of Virus

The diagnosis of congenital CMV infection should be entertained in any newborn with signs of congenital infection or if there is a history of maternal seroconversion or a mononucleosis-like illness during pregnancy. The best test is virus isolation in tissue culture, which is generally accomplished with urine or saliva or with demonstration of CMV genetic material by PCR (Table 23-14).<sup>295,299,346,402-405</sup>

CMV-IgM serology does not have adequate sensitivity or specificity for the diagnosis of congenital CMV infection. With diagnostic methods that detect the virus, viral antigens, and nucleic acids, it is possible to confirm the diagnosis from blood, cerebrospinal fluid, and biopsy material. Of particular interest is the possibility of diagnosis by PCR on blood stored on filter paper.<sup>404</sup> To confirm a congenital CMV infection, demonstration of virus must be attempted in the first 2 weeks of life because viral excretion after that time may represent an infection acquired at birth (natal) by exposure to an infected birth canal or one acquired in the neonatal period by exposure to breast milk or blood products. Although isolation of CMV during the first 2 weeks of life proves a congenital CMV infection, it does not necessarily confirm an etiologic relationship with an existing disease. Urine and saliva are the preferred specimens for culture because they contain larger amounts of virus. The viability of CMV is surprisingly good when specimens are properly stored. For instance, when positive urine specimens (without preservatives) are stored at 4°C for 7 days, the rate of isolation drops to 93%; it drops to only 50% after 1 month of storage.<sup>404</sup> However, storage and transport at ambient temperature or freezing should never be used because infectivity is rapidly and significantly reduced.

**Table 23-14 Diagnostic Methods for Identification of Infants with Congenital Cytomegalovirus Infection**

Method	Advantages	Disadvantages
<b>Detection of Virus or Viral Antigens</b>		
Standard tube culture method	Standard reference method	Takes 2-4 weeks, not suitable for screening
Shell vial assay <sup>83</sup>	Rapid, sensitive, commercially available	Expensive, not suitable for screening
Microtiter plate immunofluorescent antibody assay <sup>84,85</sup>	Rapid, sensitive, reliable, simple, inexpensive	Cell culture based, not commercially available
CMV antigenemia <sup>86</sup>	Rapid and simple	Unknown sensitivity and utility to screen newborns, expensive
<b>Nucleic Acid Amplification Methods</b>		
DNA hybridization assay <sup>87</sup>	Sensitive and reliable	Complicated, need for a radiolabeled probe
PCR amplification methods <sup>88-90</sup>	Simple and can be used to screen large numbers	Utility as a screening assay not proved
<b>Serologic Methods</b>		
Anti-CMV IgM antibody assay	Simple and widely available	Low sensitivity and not reliable for screening

CMV, cytomegalovirus; PCR, polymerase chain reaction.  
Data from Boppana and Fowler, personal communication, 2004.

## Tissue Culture

Standard tissue culture based viral isolation requires inoculation of specimen into monolayers of human fibroblasts. Typically, 2 to 4 weeks may be required for the appearance of the characteristic cytopathic effect. Since 1980, methods for rapid viral diagnosis have become available. Several modifications of the standard tissue culture method combined with immunologic detection of immediate-early CMV-induced antigens have maintained high specificity and sensitivity but allowed the confirmation of diagnosis within 24 hours of inoculation of the clinical specimen.<sup>406-411</sup>

Typically, tissue culture includes the use of monoclonal antibodies to CMV-specific early antigens with low-speed centrifugation of the clinical specimens onto the monolayer of fibroblasts growing on coverslips inside shell vials.<sup>408-410</sup> When this method was evaluated with clinical specimens (i.e., blood; urine; bronchoscopy lavage; lung, liver, and kidney biopsy samples; sputum; and others) obtained primarily from immunosuppressed patients, the sensitivity approached 80%, and the specificity ranged from 80% to 100%. Subsequently, another adaptation of this rapid immunofluorescent assay used 96-well microtiter plates and a monoclonal antibody that is reactive with the major immediate-early human CMV protein polypeptide 72.<sup>411</sup> This rapid assay detected all but 1 of 19 specimens identified by standard virus isolation method from 1676 newborn urine specimens, achieving a sensitivity of 94.5% and a specificity of 100%. This test retained high sensitivity and specificity when saliva instead of urine was tested.<sup>403</sup> This microtiter plate method using saliva or urine samples is the most rapid, simple to perform, and inexpensive alternative to the standard virus isolation method. It is perfectly suitable for mass screening, and there is no drop in sensitivity for specimens at 4° C for up to 3 days. This study also showed that the sensitivity of the microtiter plate method declined rapidly for specimens from older infants and children with congenital CMV infection and from virus-infected children attending daycare centers. It is not recommended for screening or diagnosing CMV infections in older infants and children.

## DNA Hybridization

Rapid diagnosis of CMV can also be accomplished by DNA hybridization.<sup>412-416</sup> However, the methodology is cumbersome because of the need to concentrate virus at high speed centrifugation and the need to extract DNA and hybridize it with a DNA probe labeled with phosphorus 32. The sensitivity and specificity of this method is good when the specimens contain 10<sup>3</sup> or more tissue culture infective doses per milliliter.

## Polymerase Chain Reaction Amplification

Detection of viral DNA by PCR amplification has proven extremely sensitive for the detection of CMV genetic material in a variety of clinical samples, including urine, cerebrospinal fluid, blood, plasma, saliva, and biopsy material.<sup>293,295,299,402,404-405</sup> Using primers directed at major immediate-early protein and late antigen genes, the initial report from Demmler and colleagues<sup>402</sup> found 41 urine specimens positive by PCR

from a total of 44 specimens positive by tissue culture. No positive PCR results were found in 27 urine specimens that were negative by tissue culture.<sup>402</sup> Warren and co-workers<sup>403</sup> used the PCR technique to detect CMV in saliva from children who were between the ages of 1 month and 14 years and who had congenital or perinatal CMV infection and compared the results with a standard tissue culture method and microtiter plate detection of early antigen with tissue culture results as a reference. The sensitivity of PCR was 89.2%, and the specificity was 95.8%. Reproducibility was excellent. If primer selection and amplification conditions are carefully chosen, PCR can give results comparable to standard tissue culture test. Some advantages include the minute amount of specimen and the fact that infectious virus is not required, allowing for retrospective diagnosis of CMV infection if the appropriate specimens are available.<sup>404</sup> Nelson and colleagues<sup>295</sup> showed that PCR detection of CMV DNA in serum was a sensitive, specific, and rapid method for diagnosis of infants with symptomatic congenital CMV infection. The PCR detected CMV DNA in the serum of 18 infants with symptomatic infection, 1 of 2 with asymptomatic infection, and 0 of 32 controls. An exciting new development is the use of real-time PCR to detect and quantitate CMV DNA in dried blood spots obtained from a drop of neonatal blood applied to the IsoCode card (Schleicher and Schuell, Inc., Keene, NH) at the time of the newborn metabolic screen. IsoCode cards are preferred for this application because of ease of isolation of DNA from peripheral blood without the use of a lysis procedure.<sup>404</sup> Swedish investigators were able to detect CMV DNA in dried blood specimens of 13 (81%) of 16 infants with congenital CMV infection.<sup>404</sup> Italian investigators using a similar method obtained a sensitivity of 100% and a specificity of 98.5% in a study of 205 neonates, including 14 with congenital infections.<sup>417</sup> Both groups of investigators used a nested PCR method to detect CMV DNA in dried blood specimens, which adds to the complexity of the assay, reducing its potential use as a screening assay. Advantages of PCR-based methods to screen newborn infants include no need for tissue culture facilities and a minute amount of specimens. Once dried, the samples on filter paper are no longer infectious, reducing the biohazard risk. They are easy to ship and transport without occupational exposure to infectious material. They offer the possibility to quantitate CMV DNA in PCR-positive samples and the possibility for automation. They are available for retrospective diagnosis when appropriate specimens are available, and they can be stored at room temperature for many years.

## Antigenemia

An assay to detect CMV antigenemia by means of monoclonal antibodies to pp65 in PMNs has shown good sensitivity compared with conventional methods (e.g., serology, culture) for the diagnosis of CMV disease in immunocompromised adult subjects.<sup>183,299,418-420</sup> Revello and colleagues<sup>299,421</sup> examined pp65 antigenemia, viremia, and DNAemia in peripheral blood leukocytes from 75 infants born to mothers who had primary CMV infection during pregnancy. The results of this study showed that compared with virus isolation from newborn urine, the sensitivity of PCR, antigenemia, and viremia were 100%, 42.5%, and 28%, respectively. The specificity of the three assays was 100%.

## Detection of Immune Response

With congenital CMV infection, antibody production begins in utero and is continued probably during the life span of the host. Antibodies are also produced for prolonged periods after postnatally acquired infections.

### Detection of IgG Antibodies

Serologic tests that measure IgG antibody are readily available and are easier to perform than are most virologic methods. However, their correct interpretation is complicated by the presence of antibodies (IgG class) that are normally transmitted from the mother to the fetus.<sup>288</sup> A negative antibody titer in cord and maternal sera is sufficient evidence to exclude the diagnosis of congenital CMV infection. In uninfected infants born to seropositive mothers, IgG antibodies serially decrease with a half-life of approximately 1 month and disappear when the children are between 4 and 9 months old. In contrast, in infected infants, IgG antibody levels persist for long periods at comparable or sometimes higher levels than in their mothers. CMV infections are commonly acquired during the neonatal period mostly from maternal sources (e.g., milk, genital secretions) and blood or blood products. When neonatal infections are transmitted from the mother, the distinction from congenital involvement is not possible by routine serologic means. In both situations, IgG antibody titers tend to remain stable for many months. A neonatal infection in the face of a negative maternal IgG antibody titer should point to transmission from other sources, such as a blood transfusion or nosocomial infection.

Many serologic assays have been described and evaluated for the detection of CMV IgG antibodies. Among these, complement fixation, enzyme-linked immunosorbent assay (ELISA), anticomplement immunofluorescence, radioimmunoassay, and indirect hemagglutination are adequate.

### Detection of IgM Antibodies

Infected fetuses usually produce specific IgM antibodies. IgM antibodies are not transferred by the placenta, and their presence in cord or neonatal blood represents a fetal antibody response. There are a number of different means to test for IgM antibodies, but before deciding on the use of any particular test, it is important to know its specificity, sensitivity, and reproducibility. None has reached a level of specificity and sensitivity to match the virologic assays described in the previous section.

The solid-phase radioimmunoassay RIA described by Griffiths and Kangro<sup>422</sup> is among the best, with a reported sensitivity of 89% and a specificity of 100% for diagnosis of congenital CMV infections. With the IgM ELISA, the specificity was almost 95% with a sensitivity of approximately 70% when evaluating congenitally infected infants.<sup>423</sup> The IgM capture ELISA and radioimmunoassay have not fared much better when testing for congenital CMV infection. Modifications of the IgM tests yet to be appropriately tested in newborns include an ELISA test that uses purified recombinant CMV polypeptides shown to be highly immunogenic as the antigens for the assay.<sup>424</sup> Another version with proven greater sensitivity in blood donors, pregnant women, and transplant recipients with active CMV infection is a Western blot test for IgM antibodies against viral structural polypeptides pp150 and pp52.<sup>425</sup> Until IgM antibody tests

are better perfected for general use, clinicians should not rely solely on one of these assays to diagnose congenital CMV infection. Continued research in this area may provide a simple and generally available method for rapid, definitive diagnosis of congenital infections in ill and asymptomatic neonates.

## Diagnosis of Cytomegalovirus Infection during Pregnancy

### Clinical Signs and Symptoms

Most primary CMV infections in immunocompetent hosts are subclinical and infections occurring in pregnant women are no exception. Less than 5% of pregnant women with proven primary CMV infections are symptomatic with an even smaller percentage manifesting mononucleosis-like syndrome. No clinical manifestations are expected with recurrent infections (i.e., reactivations or reinfections).

### Laboratory Markers

The diagnosis of primary CMV infection can be easily confirmed by documenting seroconversion (i.e., the de novo appearance of virus-specific IgG antibodies in a pregnant woman who was seronegative). In the absence of serologic screening, this is seldom available in clinical practice. The presence of IgG antibodies denotes past infection from 2 weeks to many years in duration.

### IgM Assays

Of the several tests that have undergone evaluation, the ELISA-IgM capture method seems to provide the best specificity (95%) and sensitivity (100%). The IgM antibody response varies widely from one patient to another. Seropositivity can be detected up to 16 weeks, but it is unusual to last more than 1 year. It is typical to see sharp drops in titers within the first 2 to 3 months of infection.

Recombinant IgM assays have been developed based on recombinant CMV proteins and peptides. Structural and nonstructural CMV-encoded proteins react with IgM antibodies. The detection of specific IgM antibodies can be accomplished by Western blot, immunoblot, or microparticle enzyme immunoassay.<sup>426,427</sup> With the immunoblot assay, the sensitivity was 100%, and the specificity was 98%.<sup>426</sup> The microparticle enzyme immunoassay had sensitivity and specificity of greater than 95%.<sup>427</sup>

### IgG Avidity Assay

The IgG avidity assay is based on the observation that IgG antibodies of low avidity are present during the first months after the onset of infection. With time, IgG antibodies of increasingly higher avidity are produced and eventually only IgG of high avidity is detected in individuals with long-standing CMV infection. The results of the avidity test are reported as an index representing the percentage of IgG antibody bound to the antigen after denaturation treatment with 6M urea.<sup>299,428,429</sup> Similar approaches have been reported for other infectious agents. In one study, an avidity index value of approximately 20% was obtained in serum samples collected within 3 months after onset of primary infection, in contrast to an avidity index of 78% in sera from individuals with remote infection (Fig. 23-5).<sup>430</sup>

**Figure 23-5** Kinetics of IgG avidity index. (From Revello MG, Gerna G. Diagnosis and management of human cytomegalovirus infection in the mother, fetus, and newborn infant. *Clin Microbiol Rev* 15:680-715, 2002.)

In determining the risk of congenital CMV, a moderate to high avidity index obtained before the 18th week of gestation<sup>429,431</sup> has a negative predictive value of 100%. When the avidity index is determined between 21 and 23 weeks' gestation, the negative predictive value dropped to 91%.<sup>431</sup> The explanation for this observation is that some of the women who transmitted the infection in utero had acquired the infection at a very early gestational age. One important limitation of the IgG avidity test is the lack of standardization. In one study, the ability of these IgG avidity assays to identify primary CMV infection almost reached 100%, whereas the ability to exclude a recent infection ranged from 20% to 96%.

### Viral Cultures

CMV excretion from multiple sites such as urine, saliva, and genital secretions is common and can last weeks to several months after a primary infection. Unfortunately, the same occurs with reinfections and reactivations, making this diagnostic approach useless. Viremia, as determined by conventional tissue culture methods, is too insensitive to confirm the diagnosis of primary infection in immunocompetent hosts.

### Other Viral Tests

Other diagnostic methods with greater sensitivity and specificity include the determination of antigenemia (number of pp65-positive peripheral blood leukocytes); quantification of CMV DNA in whole blood (DNAemia), leukocytes (leuko-DNAemia), or plasma; and determination of immediate-early and late mRNA (RNAemia) in blood.<sup>299,432</sup> Some of these assays are commercially available. The data supporting their diagnostic value are derived largely from studies in immunosuppressed patients with primary CMV infections, reactivations, and dissemination of infection and evaluation of antiviral treatments. One study of immunocompetent adults, including a large proportion of pregnant women with primary CMV infection, showed that pp65 antigenemia was detected in 57% of patients examined within the first month after the onset of primary infection.<sup>433</sup> The rate of positive results dropped to 25% a month later and to 0% 5 months later. Viremia was detected in 26% of patients during the first month only. Leuko-DNAemia (by PCR test) was detected in 100% of patients tested during the first

month, in 89% of those tested on the second month, and in 47% of those tested 3 months after the onset of primary infection. DNAemia lasted 4 to 6 months in 26% of patients, and no patient remained positive beyond 6 months from the onset of infection. None of these three assays was positive for patients with old CMV infection, including nine subjects with proven recurrences. The results of this study<sup>433</sup> indicate that antigenemia and DNAemia when run on blood specimens can rapidly and specifically diagnose and provide an approximate date of onset for primary infection in pregnant women. The detection of immediate-early mRNA has been evaluated as a diagnostic tool for primary CMV infection in healthy individuals.<sup>434,435</sup> This test was consistently negative in all subjects with old or recurrent CMV infection. In contrast, all subjects within the first month of a primary infection tested positive. The proportion of positive results declined over time with all patients testing negative after 6 months of the onset of CMV infection. The kinetics of this test resemble that of DNA detection and, in at least one comparison, the immediate-early mRNA test was slightly more sensitive in the early phase of primary CMV infection.<sup>435</sup>

### Maternal Laboratory Tests of Fetal Infection

In utero transmission of CMV infection occurs in approximately 40% of primary infections acquired during pregnancy. No reliable tests can define transmission of infection to the fetus. Moreover, there are no maternal prognostic markers of fetal infection with a recurrence of maternal infection. One study showed that reinfection with a different strain of CMV, as measured by new antibody specificity against epitopes of glycoprotein H, was capable of causing symptomatic congenital CMV infection. The methodology used in this study is far from becoming a standard laboratory assay.

### Prenatal Diagnosis

The prenatal diagnosis of CMV is possible by testing fetal blood obtained by cordocentesis and amniotic fluid obtained by amniocentesis. Fetal blood can be used for determination of specific IgM antibodies and direct viral markers. IgM antibodies can be detected only after 20 weeks' gestation, but because of low sensitivity (approximately 50%), the test has very limited diagnostic value.<sup>436-438</sup> However, studies of viral

load in fetal blood show that the sensitivity of antigenemia was approximately 58%; of viremia, 55%; and of leuko-DNAemia, 82%. The specificity is 100% for the three assays.<sup>299</sup> In one study, PCR in fetal blood had a sensitivity of 41%, but viral culture had a sensitivity of only 7%. With the use of fetal blood, even the most sensitive assays miss almost 15% to 20% of infected fetuses.

Results in amniotic fluid are far better, and this method is the standard for prenatal diagnosis. Viral isolation in tissue culture has a sensitivity of approximately 60%, whereas the sensitivity of PCR can reach 100%. The specificity of both assays is excellent.<sup>436,439-442</sup> A quantitative PCR method has shown that when the amniotic fluid contains  $10^5$  or more genome equivalents of CMV DNA, the risk of symptomatic congenital CMV infection is significantly higher than when the viral load is  $10^3$  genome equivalents or less.<sup>443-445</sup>

A confounding factor in prenatal diagnosis is the gestational age at the time of amniocentesis or cordocentesis. After a primary maternal infection, it may take weeks to months for transplacental transmission of CMV to occur. An interval of 7 weeks between maternal onset of infection and diagnostic tests for fetal infection has been suggested as a reasonable interval by some investigators.<sup>439,440,446</sup> Gestational age at the time of testing is important, because the sensitivity can be as low as 30% when amniotic fluid is obtained before the 21st week of gestation, and it can be 100% if the test is performed after 21 weeks' gestation.<sup>437,438,442,447-452</sup>

When counseling pregnant women, it is important to remember that 80% to 90% of children with congenital CMV infection escape CNS sequelae. In the absence of specific antiviral treatment, the only alternatives available after a prenatal diagnosis of congenital CMV infection are to terminate the pregnancy or do nothing. The presence or absence of ultrasonographic evidence of fetal abnormalities should be taken into consideration during counseling of women at risk.

### Diagnosis of Perinatally Acquired Infections

For perinatally acquired infections, viral culture and CMV DNA detection by PCR using urine and saliva are the preferred diagnostic methods, but CMV excretion does not begin until 3 to 12 weeks after exposure.<sup>89,288</sup> For diagnostic specificity, it is imperative to have a negative result from urine or saliva specimens collected within the first 2 weeks of life. In early infancy, antibody assays have the same limitations described earlier for infants with congenital CMV infection. The desire to differentiate between congenital and perinatal CMV infections stems from the fact that their risks for acute morbidity and for long-term sequelae are very different.

## DIFFERENTIAL DIAGNOSIS

During the newborn period, the constellation of hepatosplenomegaly, petechiae, and direct hyperbilirubinemia with or without pneumonitis, microcephaly, and ocular and neurologic abnormalities that characterize CID is common to several disease entities, including other congenital infections such as congenital rubella syndrome, toxoplasmosis, syphilis, neonatal herpes simplex virus infections, and less likely,

hepatitis B and varicella virus infections.<sup>370</sup> The differential diagnosis of symptomatic congenital CMV infection also includes bacterial sepsis and noninfectious disorders such as hemolytic diseases related to Rh or ABO incompatibilities or red blood cell defects, metabolic disorders such as galactosemia and tyrosinemia, immune thrombocytopenia, histiocytosis X, congenital leukemia, and others. The list of diseases that must be considered in the differential diagnosis becomes broader as the clinical manifestations diminish in severity.

Infections may coexist in the same patient. Consequently, the laboratory workup for differential diagnosis must be thorough.

### Congenital Rubella Syndrome

Congenital rubella has been virtually eliminated in the United States after the successful immunization program adopted years ago. Although symptomatic congenital rubella and CMV infections share many signs and symptoms, central cataracts, congenital heart defects, raised purpuric rather than petechial rash, salt-and-pepper lesions as opposed to chorioretinitis, and the absence of cerebral calcifications are more likely to occur with congenital rubella syndrome than with CID.<sup>370</sup>

### Congenital Toxoplasmosis

Almost all of the manifestations observed in CID have been described for symptomatic congenital toxoplasmosis. Some differences merit discussion.<sup>370</sup> For instance, the calcifications of toxoplasmosis are generally scattered throughout the cerebral cortex, whereas the calcifications of CID tend to occur in the periventricular areas. The rash associated with toxoplasmosis is usually maculopapular but is not petechial or purpuric. Chorioretinitis in the two diseases cannot be differentiated on the basis of appearance or distribution. However, it is more likely that chorioretinitis related to CMV is associated with other major clinical manifestations, such as microcephaly. Not uncommonly, the chorioretinitis of toxoplasmosis is an isolated finding.

### Congenital Syphilis

The most consistent signs of early congenital syphilis are osteochondritis and epiphysitis on the radiograph of the long bones.<sup>370</sup> These occur in approximately 90% of infected patients and are more likely to appear in patients who become symptomatic in the first week of life. Rhinitis, sometimes associated with laryngitis, is another common manifestation of congenital syphilis; it is often followed by a dark red maculopapular, spotted rash. Lesions of the skin and mucous membranes are also seen. Hepatosplenomegaly occurs but is less common in early syphilis than in CID. Calcifications of the brain are not characteristic of congenital syphilis. However, choroiditis may be seen.

### Neonatal Herpes Simplex Virus Infections

Congenital herpes simplex virus infections are less common than neonatal herpes simplex virus infections, but they are more likely to pose a diagnostic dilemma because they may

resemble CID. Microcephaly, intracranial calcifications, chorioretinitis with and without optic atrophy and hepatosplenomegaly are common clinical manifestations of intrauterine herpes simplex virus infections. The presence of skin vesicles or scarring present at birth is valuable for the differential diagnosis. The more common form of herpes simplex virus infection, neonatal infection, is acquired during parturition and does not usually manifest as an acute disease until the infants are 5 to 21 days old. Unlike the situation in typical CID, the infant is well during most of the first week of life. When illness does occur, it may be accompanied by seizures, encephalitis, respiratory distress, bleeding disorders, and vesicular lesions that tend to cluster. The presence of skin and mucous membranous lesions is valuable for the differential diagnosis of CID.

## TREATMENT

### Chemotherapy

A small number of systemically administered antiviral agents have been used in therapeutic trials of serious, life-threatening or sight-threatening CMV disease. Two antiviral agents, ganciclovir and foscarnet, are licensed for this purpose in immunocompromised patients. Foscarnet inhibits viral replication by inhibiting viral DNA polymerase, and ganciclovir acts as a chain terminator during elongation of the newly synthesized viral DNA.<sup>453-457</sup>

The Collaborative Antiviral Study Group (CASG) under the auspices of the National Institute of Allergy and Infectious Diseases first conducted a phase II pharmacokinetic-pharmacodynamic study that established the safe dose of ganciclovir to be used in young infants and demonstrated an antiviral effect with suppression of viruria.<sup>453</sup> A phase III, randomized, controlled study followed in newborn infants with symptomatic congenital infection involving the CNS.<sup>456</sup> A total of 100 patients were enrolled. Those in the ganciclovir treatment arm received doses of 6 mg/kg administered intravenously every 12 hours for 6 weeks of treatment. The primary end point was improved hearing (as assessed by brain-stem-evoked response) between baseline and 6 months of follow-up or, for those with normal hearing at enrollment, preservation of normal hearing at follow-up. Twenty-one (84%) of 25 ganciclovir-treated patients had hearing improvement or maintained normal hearing at 6 months, compared with 10 (59%) of 17 in the no-treatment group ( $P = .06$ ). At 6 months of follow-up, none (0 of 25) of the ganciclovir-treated infants had hearing deterioration, compared with 7 (41%) of 17 in the no-treatment group ( $P < .01$ ). Alternatively, 5 (21%) of 24 of ganciclovir recipients had worsening in hearing in their best ear between baseline and 1 year or longer, compared with 13 (68%) of 19 in the no-treatment group ( $P < .01$ ).

As in the previous phase II study, the most significant toxicity in the treated group was neutropenia, with 29 (63%) of 46 patients developing moderate to severe neutropenia compared with 9 (21%) of 43 of the no-treatment group ( $P < .01$ ). One half of the patients with neutropenia required dosage adjustment and 12% had discontinuation of therapy. This study demonstrates that 6 weeks of intravenous ganciclovir in symptomatic congenital CMV-infected infants

prevents worsening of hearing loss at 6 months and 1 year of follow-up. Treated patients had a more rapid resolution of their liver function abnormalities and improvements in short-term growth and head circumference compared with controls. There are no reports on the therapeutic efficacy of combined therapy (i.e., foscarnet-ganciclovir). The CASG is conducting a phase I/II pharmacokinetic-pharmacodynamic study of valganciclovir, the orally bioavailable prodrug of ganciclovir, to determine the dose necessary to achieve a safe and effective concentration of ganciclovir in the bloodstream.

Intravenous ganciclovir treatment at a dose of 6 mg/kg that is administered every 12 hours for 42 days can be recommended for infants with proven symptomatic congenital CMV infection, particularly for those with no evidence of hearing loss. Although the phase III study sponsored by the CASG did not include infants without CNS involvement, the data suggest that treatment may speed the resolution of liver abnormalities. The decision to treat should be carefully discussed with parents and caregivers because treatment often requires a substantial commitment, including 42 days of intravenous therapy (preferably in the hospital), the use of secure intravenous access, and frequent blood sampling to check for ganciclovir toxicity. Anecdotal reports do not support the use of hyperimmune immunoglobulin or antiviral treatment with ganciclovir or foscarnet for treating the fetus in utero.

### Passive Immunization

Hyperimmune plasma and immunoglobulin have been used with some success as prophylaxis for primary CMV infections in immunosuppressed transplant recipients. A meta-analysis of randomized, controlled trials of immunoglobulin as prophylaxis for CMV disease in adult transplant recipients found a significant beneficial effect.<sup>458</sup> Studies are being conducted to determine if a humanized monoclonal antibody, such as the one that binds to gH of CMV, is more efficacious for the prevention or treatment in patients at high risk for CMV infection.<sup>459</sup> It is unlikely that passive immunoprophylaxis will ever work for treatment of congenital infections because the cases are identified weeks and months after infection occurred in utero. However, it might be a means of preventing primary CMV infection and disease associated with transfusion-acquired infections in premature infants. No controlled studies are available.

### Vaccines

In the United States, congenital CMV infection is a significant public health problem. It is the leading cause of sensorineural hearing loss and the leading infectious cause of brain damage in children.<sup>460</sup> Not surprisingly, the Institute of Medicine of the National Academy of Sciences concluded that a vaccine to prevent congenital CMV infection should be a top priority. Despite 30 years of research efforts, no such vaccine is available. The prevailing thought is that both neutralizing antibodies and cell-mediated immunity are necessary for prevention. Of the CMV proteins, gB, gH, pp65, and pp150 can induce neutralizing and CTL responses.<sup>460-465</sup>

The strategies for vaccine development include live-attenuated vaccine (i.e., Towne strain). This vaccine induces

a significant antibody response and cell-mediated immunity, as determined by lymphoproliferative response. In CMV-seronegative recipients of kidneys from seropositive donors, this vaccine reduced disease severity but did not prevent infection.<sup>461</sup> It also protected against a low-dose virulent CMV challenge in normal volunteers. In a later trial, this vaccine failed to decrease the rate of acquisition of CMV in parents of children in daycare. The magnitude of the induced immune response was 10-fold lower than that generated by natural infection.<sup>463</sup> The Towne vaccine is not excreted by vaccinees.

### Recombinant Virus Vaccine

The genome of the virulent Toledo strain of CMV, divided into four fragments, was inserted in the genetic background of the attenuated Towne strain, creating four chimeras. The ability of these four recombinant virus strains to generate antibody and cell-mediated immune responses in the absence of clinical side effects is being evaluated in a phase I study.<sup>461</sup>

### Subunit Vaccines

A CMV vaccine based on the envelope glycoprotein gB combined with a novel adjuvant (MF59) was tested in a double-blind, placebo-controlled trial of seronegative adult volunteers.<sup>464</sup> Results showed that after three doses, the antibody responses to gB and neutralizing antibodies exceeded the levels in seropositive control subjects. Cell-mediated immunity was not evaluated. The major target of the cell-mediated immune response is pp65. In an effort to elicit this response, a study<sup>465</sup> made use of the nonreplicating canarypox expression vector in which CMV pp65 has been inserted. A phase I trial on seronegative volunteers found that pp65-specific CTLs were elicited after only two vaccinations. An antibody response to pp65 was also demonstrated. In this preliminary study, the canarypox CMV pp65 recombinant vaccine seems to generate an immune response similar to that provided by natural infection.<sup>465</sup> A canarypox CMV recombinant that contained gB did not induce neutralizing antibodies. It is possible to explore the immunogenicity of a vaccine combining canarypox CMV (pp65) with gB with an appropriate adjuvant such as MF59. This combination may generate sufficient CTLs and neutralizing antibodies to protect against CMV disease.

Other potential avenues for the development of CMV vaccine include peptide vaccines and DNA vaccines. All candidate vaccines must demonstrate that immunogenicity provides protection.

## PREVENTION

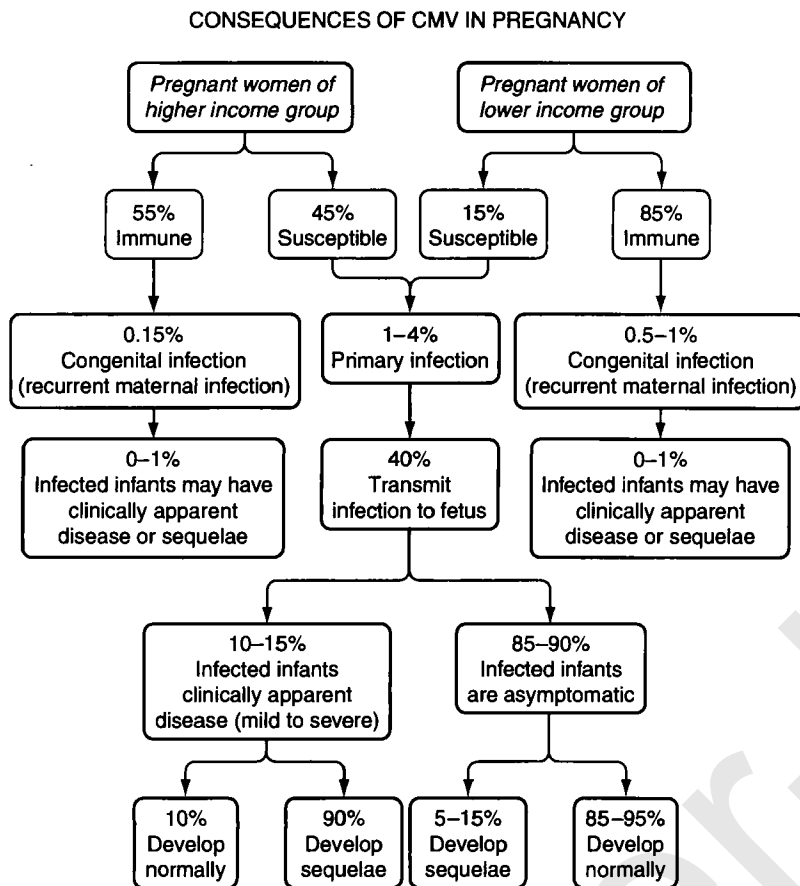

CMV usually is not very contagious, and its horizontal transmission requires direct contact with infected material, such as secretions that contain the virus and, less likely, fomites.<sup>97-113,466</sup> With the exception of a few small studies that were designed to prevent infection through blood and blood products and grafted organs, no broad-based strategies for preventing the transmission of this virus have been tested.<sup>269,395,467,468</sup> Although there are still no effective means of preventing congenital CMV infections or most perinatally acquired CMV infections, a few common sense recommendations can be made.

## Pregnant Women

An average of 2% of susceptible pregnant women acquire CMV infection during pregnancy in the United States; most of them have no symptoms, and only 40% of the episodes result in fetal infection (Fig. 23-6).<sup>469</sup> Because there is no effective drug therapy and the risk of fetal morbidity is low, several investigators have concluded that routine serologic screening of pregnant women for primary CMV infections during pregnancy is of limited value.<sup>328,470</sup> However, reliable and inexpensive serologic tests are available, and women of childbearing age can be informed of their immune status.<sup>471</sup> Those who are seronegative should be able to make informed decisions about the risks of CMV. Primary CMV infection should be suspected in pregnant women with symptoms compatible with a heterophil-negative, mononucleosis-like syndrome. To more precisely define a recent asymptomatic primary CMV infection, serologic tests such as IgM capture ELISA, IgG avidity index, and DNAemia (PCR) could be used. There are no reliable means to determine whether intrauterine transmission has occurred after symptomatic or subclinical primary infection in early gestation or to assess the relatively small number of fetuses at risk of disease. The sensitivity and specificity of prenatal diagnosis by testing fetal blood obtained by cordocentesis or amniotic fluid PCR and viral culture are good after 20 weeks' gestation. There is still limited information to serve as a basis for recommendations regarding termination of pregnancy after a primary CMV infection acquired in early gestation. Similarly, there is no conclusive information regarding how long conception should be delayed after documented primary infection is acquired in a woman of childbearing age. Viral excretion is not a good indicator because virus is shed into saliva for weeks or months after infection and into urine and the cervix for months or years.

The data on which to base recommendations for prevention of congenital CMV infection after recurrent maternal infection are even more inadequate. Preexisting immunity does not prevent the virus from reactivating or reinfection, nor does it effectively control the occasional spread to the fetus.<sup>326</sup> Preexisting maternal immunity affords significant protection to the fetus. However, evidence that in some high-risk populations reinfections with antigenically different virus can cause fetal disease and long-term sequelae may temper this statement. There are no techniques for identifying women with reactivation of CMV that result in intrauterine transmission. Because the risk of transmission is very low (see Fig. 23-6) and the risk of fetal disease even lower, women known to be seropositive before conception do not need to be virologically or serologically tested, nor do they need to be unduly worried about the very low risk of adverse effects on the fetus.

The principal sources of CMV infection among women of childbearing age are exposure to children excreting CMV and sexual contacts. Recommendations for prevention of sexual transmission of CMV are beyond the scope of this review. Suffice it to say that they are similar to those advocated for the prevention of other, more common sexually transmitted infections. As for the risk from exposure to children, at greater risk are susceptible pregnant mothers of CMV-infected children who attend daycare centers.<sup>97,98,102,106-108,110-113</sup> Hand washing and simple hygienic measures that are routine

**Figure 23-6** Characteristics of cytomegalovirus infection in pregnancy. (From Stagno S, Whitley RJ. Herpesvirus infection of pregnancy. *N Engl J Med* 313:1270-1274, 1985.)

for hospital care can be recommended, but it is unrealistic to expect all mothers to comply.

Because CMV has been found to be endemic in the day-care setting and is found everywhere in hospitals, questions often arise about the occupational risks to pregnant personnel in these facilities. Although hospital workers do not appear to be at increased risk for CMV infection,<sup>109,143,145,148</sup> personnel who work in daycare centers are.<sup>97,98,102,104,105,110</sup> In the hospital, routine procedures for hand washing and infection control should make nonparenteral acquisition of CMV infections less likely than in the community. Although most patients who shed CMV are asymptomatic and go unrecognized, when caring for known CMV-excreting patients, these routine measures should be combined with a special recommendation that pregnant caretakers be especially careful in handling such patients.<sup>143</sup> In the daycare setting, where hygiene is difficult at best, these preventive measures may be more difficult to implement. Although there is still debate about the need for routine serologic screening of female personnel and daycare workers, I believe that it should be recommended for potentially childbearing women whose occupation exposes them to CMV. Knowing their immune status can be helpful in counseling pregnant women at risk. Those found to be seropositive can be strongly reassured. Those found to be serosusceptible should be provided with information on prevention measures and reassured that common sense steps such as hand washing and avoiding contact with secretions should prevent acquisition of infection.<sup>143</sup> Attempts to identify all congenitally CMV-

infected children and children excreting this virus in the workplace so that seronegative workers and parents can avoid contact with them pose serious logistic problems and would require frequent periodic testing.

### Nosocomial Infection

Hospitalized patients who receive blood products and organ transplants are at risk for nosocomial CMV infection. Because the role of organ transplantation in transmission of CMV is insignificant in the newborn period, it is not discussed here. Transfusion of blood products can be an important source of perinatal CMV infections. The use of blood products from seronegative donors prevents the transmission of CMV and the subsequent risk of disease.<sup>132,269,395,401</sup> However, this method is not practical in areas where most of the donor population is seropositive. The availability of seronegative donors and the additional cost involved in serologic screening and processing the blood must be evaluated by regional blood banks.

The use of deglycerolized, frozen red blood cells and the use of filters to remove leukocytes are also effective means of eliminating post-transfusion CMV infection in adult dialysis patients and in newborns, even in low-birth-weight infants.<sup>132,468,472</sup> Both methods result in a significant disruption and depletion of leukocytes.

Many hospitals are using one of these three approaches to prevent transfusion-acquired perinatal CMV infections.<sup>473</sup> It is up to the local hospital and blood bank to determine

whether transfusion-associated CMV disease is a problem and which method to choose. However, many nurseries have adopted the policy that all transfusions of blood or blood products should be with seronegative blood, irrespective of the infant's birth weight and maternal immune status.

The absence of CMV infection in premature infants born to seronegative mothers and who receive only seronegative blood products suggests that spread of CMV from hands of personnel or from fomites must be rare. Until more information is available, the only logical recommendation is hand washing and routine infection control measures.

Rarely is perinatal infection through breast milk a cause for concern, at least for full-term newborns who receive their mother's milk.<sup>90,96</sup> Premature infants, who generally do not receive sufficient quantities of specific transplacental antibodies, are at higher risk for morbidity.<sup>342,344</sup> We must also be cautious with expressed banked milk and wet nurses because CMV-infected milk might inadvertently be given to infants born to seronegative women. Storage of naturally infected breast milk at  $-20^{\circ}\text{C}$  (freezer temperature) significantly reduces but does not eliminate infectivity.<sup>474</sup> Heat treatment of breast milk at  $72^{\circ}\text{C}$  for 10 seconds eliminates all infectious viruses without affecting the nutritional and immunologic properties of milk.<sup>342</sup>

## The Viruses 784

Morphology and Classification  
Characteristics and Host Systems  
Antigenic Characteristics

## Epidemiology and Transmission 787

General Considerations  
Transplacental Transmission  
Ascending Infection and Contact Infection during Birth  
Neonatal Infection  
Host Range  
Geographic Distribution and Season

## Pathogenesis 792

Events during Pathogenesis  
Factors That Affect Pathogenesis

## Pathology 793

General Considerations  
Polioviruses  
Coxsackieviruses A  
Coxsackieviruses B  
Echoviruses

## Clinical Manifestations 795

Abortion  
Congenital Malformations  
Prematurity and Stillbirth  
Neonatal Infection

## Diagnosis and Differential Diagnosis 810

Clinical Diagnosis  
Laboratory Diagnosis  
Differential Diagnosis

## Prognosis 811

Polioviruses  
Nonpolio Enteroviruses

## Therapy 812

Specific Therapy  
Nonspecific Therapy

## Prevention 813

Immunization  
Other Measures

Enteroviruses (i.e., coxsackieviruses, echoviruses, newer enteroviruses, and polioviruses) and parechoviruses are responsible for significant and frequent human illnesses, with protean clinical manifestations.<sup>1-14</sup> Enteroviruses and parechoviruses are two genera of the Picornaviridae.<sup>13-16</sup> Enteroviruses were first categorized together and named in 1957 by a committee sponsored by the National Foundation for Infantile Paralysis<sup>17</sup>; the human alimentary tract was believed to be the natural habitat of these agents. Enteroviruses and parechoviruses are grouped together because of similarities in physical, biochemical, and molecular properties,

as well as shared features in their epidemiology and pathogenesis and the many disease syndromes that they cause.

Congenital and neonatal infections have been linked with many different enteroviruses and parechoviruses. Representatives of all four major enterovirus groups, as well as parechoviruses 1 and 2, have been associated with disease in the neonate.<sup>1-14,18-32</sup>

Poliomyelitis, the first enteroviral disease to be recognized and the most important one, has had a long history.<sup>33</sup> The earliest record is an Egyptian stele of the 18th dynasty (1580 to 1350 BC), which shows a young priest with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis.<sup>34,35</sup> Underwood,<sup>36</sup> a London pediatrician, published the first medical description in 1789 in his *Treatise on Diseases of Children*. During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of "infantile paralysis." The authors were greatly puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the latter part of the 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman<sup>37</sup> worked out the basic principles of the epidemiology.

The virus was first isolated in monkeys by Landsteiner and Popper in 1908.<sup>38</sup> The availability of a laboratory animal assay system opened up many avenues of research that in the ensuing 40 years led to the demonstration that an unrecognized intestinal infection was common and that paralytic disease was a relatively uncommon event.

Coxsackieviruses and echoviruses have had a shorter history. Epidemic pleurodynia was first clinically described in northern Germany in 1735 by Hannaeus<sup>3,39</sup> more than 200 years before the coxsackieviral cause of this disease was discovered. In 1948, Dalldorf and Sickles<sup>40</sup> first reported the isolation of a coxsackievirus by using suckling mouse inoculation.

In 1949, Enders and associates<sup>41</sup> reported the growth of poliovirus type 2 in tissue culture, and their techniques paved the way for the recovery of a large number of other cytopathic viruses. Most of these "new" viruses failed to produce illness in laboratory animals. Because the relationships of many of these newly recovered agents to human disease were unknown, they were called orphan viruses.<sup>4</sup> Later, several agents were grouped together and called enteric cytopathogenic human orphan viruses, or echoviruses. Some studies<sup>13-16</sup> of the viral genome of echoviruses 22 and 23 found that they were distinctly different from other enteroviruses, and they have been placed in the new genus, parechovirus.

Live-attenuated oral poliovirus vaccines (OPV) became available 40 years ago, and the most notable advance during the past 20 years has been the dramatic reduction in world-

wide poliomyelitis because of immunization with OPV and efforts of the global immunization initiative.<sup>42-47</sup> The last case of confirmed paralytic polio in the Western Hemisphere occurred in 1991.<sup>42</sup>

Aside from the polio immunization successes, there have been few major advances or new modes of treatment for enteroviral diseases. However, the use of nucleic acid detection systems for enteroviral diagnosis has progressed over the past 15 years, and rapid diagnosis of meningitis and other enteroviral illnesses has become possible.<sup>31,48-64</sup> There has been progress in the development of specific anti-enteroviral drugs.<sup>65-67</sup>

## THE VIRUSES

### Morphology and Classification

The enteroviruses are single-stranded RNA viruses belonging to the Picornaviridae (from *pico*, meaning “small”). They are grouped together because they share certain physical, biochemical, and molecular properties.<sup>11,13,15 68-78</sup> In electron micrographs, the virus is seen as a 30-nm particle consisting of a naked protein capsid that constitutes 70% to 75% of the mass; each particle has a dense central core (nucleoid) of RNA. Enterovirus capsids are composed of four structural proteins: VP1, VP2, VP3, and VP4. The capsid shell has icosahedral symmetry with 20 triangular faces and 12 vertices. The shell is formed by VP1, VP2, and VP3; VP4 lies on its inner surface.

The three surface proteins (VP1, VP2, VP3) have no sequence homology, but they have the same topology.<sup>15</sup> They form an eight-stranded, antiparallel  $\beta$  barrel that is wedge shaped and composed of two antiparallel  $\beta$  sheets. The amino acid sequences in the loops that connect the  $\beta$  strands and the N- and C-terminal sequences that extend from the  $\beta$ -barrel domain of VP1, VP2, and VP3 give each enterovirus its distinct antigenicity.

The coat proteins protect the RNA genome from nucleases and are important determinants of host range and tropism. They determine antigenicity, and they deliver the RNA genome into the cytoplasm of new host cells.

The genome of enteroviruses is a single-stranded, positive-strand RNA molecule.<sup>71</sup> It contains a 5' noncoding region, which is followed by a single long open reading frame, a

short 3' noncoding region, and a poly(A) tail. The four capsid proteins (VP1 through VP4) and seven nonstructural proteins (2A, 2B, 2C, 3A, 3B, 3C, and 3D) result from a cleaved, long polyprotein that was translated from genomic RNA.

Viral components and complete virions are formed in the cytoplasm of infected cells. If the rate of virus assembly is rapid and many particles are formed in one area, crystallization may occur.

The original classification of human enteroviruses is shown in Table 24-1. The enteroviral subgroups were differentiated from each other by their different effects in tissue cultures and in animals. Although these differentiating factors are still useful, many strains have been isolated that do not conform to such rigid specificities. For example, several coxsackievirus A strains grow and have a cytopathic effect in monkey kidney tissue cultures, and some echovirus strains cause paralysis in mice. Since 1974, newly identified enteroviral types were assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Prototype enteroviral strains Fermon, Toluca-1, J670/71, and BrCr were assigned enteroviral numbers 68 through 71, respectively. Sequencing studies of the VP1 protein of “untypeable” strains have identified at least six new enteroviral types.<sup>78</sup> Definitive identification of enteroviral types is made by neutralization with type-specific antiserum.

Because studies of the viral genomes of echoviruses 22 and 23 found that they were distinctly different from other enteroviruses, they were placed in the new genus, parechovirus; they are parechoviruses types 1 and 2.<sup>14-16</sup> The parechoviruses contain only three capsid polypeptides: VP1, VP2, and VP0, which is the uncleaved precursor to VP2 plus VP4.

Complete or partial genetic sequence data are available from all enteroviruses.<sup>71-75</sup> In general, sequence comparisons partially support the classic subgrouping of enteroviruses as provided in Table 24-1. However, in many instances, genetic relationships do not correlate with the original subdivisions.<sup>13,64,71,77</sup> All prototype human enterovirus strains fall into one of five genomically identified clusters.<sup>13,64,71,76,77</sup> Presented in Table 24-2 is the species designation by genetic analysis for the original enteroviral types.

The cellular receptors and co-receptors for attachment in the replication cycle for selected enteroviruses and parechoviruses are presented in Table 24-3. After attachment, the replication cycle takes 5 to 10 hours and occurs in the cytoplasm.

Table 24-1 Human Enteroviruses: Animal and Tissue Culture Spectrum

Virus <sup>a</sup>	Antigenic Types <sup>b</sup>	Cytopathic Effect		Illness and Pathology	
		Monkey Kidney Culture	Human Tissue Culture	Suckling Mouse	Monkey
Polioviruses	1-3	+	+	-	+
Coxsackieviruses A	1-24 <sup>c</sup>	-	-	+	-
Coxsackieviruses B	1-6	+	+	+	-
Echoviruses	1-34 <sup>d</sup>	+	±	-	-

<sup>a</sup>Many enteroviral strains have been isolated that do not conform to these categories.

<sup>b</sup>New types, beginning with type 68, were assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68 through 71 were identified.

<sup>c</sup>Type 23 was found to be the same as echovirus 9.

<sup>d</sup>Echovirus 10 was reclassified as a reovirus; echovirus 26 was reclassified as a rhinovirus; echoviruses 22 and 23 have been reclassified as parechoviruses.

## Characteristics and Host Systems

Enteroviruses are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures ( $-20^{\circ}\text{C}$ ).<sup>11,13,35,69,70</sup> They are rapidly inactivated by heat ( $>56^{\circ}\text{C}$ ), formaldehyde, chlorination, and ultraviolet light but are resistant to 70% alcohol, 5% Lysol, quaternary ammonium compounds, ether, deoxycholate, and detergents that are effective against lipid-containing viruses.

Enteroviral strains grow rapidly when adapted to susceptible host systems and cause cytopathology in 3 to 7 days. The typical tissue culture cytopathic effect is shown in Figure 24-1; characteristic pathologic findings in mice are shown in Figures 24-2 and 24-3. Final titers of virus recovered in the laboratory vary markedly among different viral strains and the host systems employed; usually, concentrations of  $10^3$  to  $10^7$  infectious doses per 0.1 mL of tissue culture fluid or tissue homogenate are obtained. Unadapted viral strains frequently require long periods of incubation in tissue cultures or suckling mice before visible evidence of growth is observed.

**Table 24-2 Genomic Classification of Enteroviruses**

Species Designation	Original Enteroviral Type
Poliovirus (PV)	Poliovirus types 1, 2, 3
Human enterovirus A (HEV A)	Enterovirus type 71, Coxsackievirus A types 2-8, 10, 12, 14, 16
Human enterovirus B (HEV-B)	Coxsackievirus type A9 Coxsackievirus types B1-6 Echovirus types 1-9, 11-21, 24-27, 29-33
Human enterovirus C (HEV-C)	Enterovirus type 69 Coxsackievirus A types 1, 11, 13, 15, 17-22, 24
Human enterovirus D (HEV-D)	Enterovirus types 68, 70

**Table 24-3 Cell Receptors and Co-receptors for Selected Enteroviruses and Parechoviruses**

Virus Type	Receptor	Co-receptor
Polioviruses 1-3	Poliovirus receptor (PVR, CD155)	
Coxsackievirus A13, A18	Intercellular adhesion molecule-1 (ICAM-1)	
Coxsackievirus A21	Decay-accelerating factor (CD55)	ICAM-1
Coxsackievirus A9	$\alpha_v\beta_3$ (vitronectin receptor)	
Coxsackievirus B1-6	Coxsackievirus-adenovirus receptor (CAR) or decay-accelerating factor (CD55)	$\alpha_v\beta_6$ integrin
Echoviruses 1, 8	$\alpha_2\beta_1$ integrin (V1a-2)	$\beta_2$ -microglobulin
Echoviruses 3, 6, 7, 11-13, 20, 21, 29, 33	Decay-accelerating factor (CD55)	$\beta_2$ -microglobulin
Enteroviruses 70	Decay-accelerating factor (CD55)	
Parechovirus 1	$\alpha_v\beta_1$ , $\alpha_v\beta_3$ (vitronectin receptor)	

Data from Racaniello VR. Picornaviridae: the viruses and their replication. *In* Knipe DM, Howley PM (eds). *Fields Virology*, vol. 1. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 685-722.

Blind passage is occasionally necessary for cytopathic effects to become apparent.

Although many different primary and secondary tissue culture systems support the growth of various enteroviruses, it is generally accepted that primary rhesus monkey kidney cultures have the most inclusive spectrum. Other simian kidney tissue cultures, although less commonly used, also have the same broad spectrum.<sup>79</sup> Tissue cultures of human origin have a more limited spectrum, but several echovirus types have had more consistent primary isolation in human embryonic lung fibroblastic cell strains than in monkey kidney cultures.<sup>80-82</sup>

Most coxsackievirus A types do not grow and produce a cytopathic effect in simian kidney tissue cultures. However, most coxsackievirus A types (except A1, A19, and A22) replicate in the RD cell line derived from a human rhabdomyosarcoma.<sup>83</sup> A satisfactory system for the primary recovery of enteroviruses from clinical specimens would include primary rhesus, cynomolgus, or African green monkey kidney tissue cultures; a diploid, human embryonic lung fibroblast cell strain; the RD cell line; and the intraperitoneal and intracerebral inoculation of suckling mice younger than 24 hours old. Optimally, blind passage should be carried out in the tissue culture systems.

## Antigenic Characteristics

Although some minor cross-reactions exist between several coxsackievirus and echovirus types, common group antigens of diagnostic importance are not well defined.<sup>11,13,35,69</sup> Heat treatment of virions and the use of synthetic peptides have produced antigens with broad enteroviral reactivity.<sup>84,85</sup> These antigens have been used in enzyme-linked immunosorbent assay (ELISA) and complement fixation tests to determine IgG and IgM enteroviral antibodies and for antigen detection. In one study, Terletskaia-Ladwig and colleagues<sup>85</sup> identified patients infected with enteroviruses with the use of an IgM enzyme immunoassay (EIA). This test employed heat-treated coxsackievirus B5 and echovirus 9 as antigens, and it identified patients infected with echoviruses 4, 11, and 30. The sensitivity of the test was 35%. In another study using heat-treated virus or synthetic peptides, the respective sensitivities were 67% and 62%.<sup>84</sup> However, both tests lacked specificity. Intratypic strain differences are common occurrences, and some strains (i.e., prime strains) are neutralized

**Figure 24-1** Fetal rhesus monkey kidney tissue culture (HL-8). **A**, Uninoculated tissue culture. **B**, Echovirus 11 cytopathic effect.

poorly by antisera to prototype viruses. In animals, however, these prime strains induce antibodies that neutralize the specific prototype viruses.

Identification of polioviral, coxsackieviral, and echoviral types by neutralization in suckling mice or tissue cultures with antiserum pools is relatively well defined. Neutralization is induced by the epitopes on structural proteins VP1, VP2, and VP3; in particular, several epitopes are clustered on VP1. Prime strains do cause diagnostic difficulties because frequently they are not neutralized by the reference antisera, which is a particular problem with echoviruses 4, 9,

and 11 and with enterovirus 71. If these types or other possible prime strains are suspected, this problem sometimes can be overcome by employing antisera in less-diluted concentrations or using antisera prepared against several different strains of problem viruses. Kubo and associates<sup>77</sup> were able to type enteroviral isolates not identified by neutralization by nucleotide sequence analysis of the VP4 gene. They specifically identified prime strains of echovirus 18 and enterovirus 71. Sequence analysis of the VP1 gene also is useful for typing enteroviral prime strains not identified by neutralization.<sup>86</sup>

## EPIDEMIOLOGY AND TRANSMISSION

### General Considerations

Enteroviruses are spread from person to person by fecal-oral and possibly by oral-oral (respiratory) routes.<sup>1-11,87</sup> Swimming and wading pools may serve as a means of spread of enteroviruses during the summer.<sup>88</sup> Oral-oral transmission by way of the contaminated hands of health care personnel and transmission by fomites have been documented on a long-term care pediatric ward.<sup>89</sup> Enteroviruses have been recovered from trapped flies, and this carriage probably contributes to the spread of human infections, particularly in lower socioeconomic populations that have poor sanitary facilities.<sup>90-92</sup>

Children are the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits facilitate spread. Spread is from child to child (by feces to skin to mouth) and then within family groups. Recovery of enteroviruses is inversely related to age; the prevalence of specific antibodies is directly related to age. The incidence of infections and the prevalence of antibodies do not differ between boys and girls.

### Transplacental Transmission

#### Polioviruses

Poliovirus infections in pregnancy can result in abortion, stillbirth, neonatal disease, or no evidence of fetal involvement.<sup>93</sup> Gresser and associates<sup>94</sup> have shown that the human amniotic membrane in organ culture can be infected, resulting in a persistent low-grade infection. It has been observed on many occasions that maternal poliomyelitis occurring late in pregnancy has resulted in transplacental transmission of the virus to the fetus in utero.<sup>95-116</sup> The evidence that transplacental passage of virus occurs in early pregnancy is meager. Schaeffer and colleagues<sup>98</sup> were able to recover virus from

the placenta and the fetus after a spontaneous abortion in a 24-year-old woman with poliomyelitis.

Although attenuated poliovirus vaccines have been given to pregnant women, there has never been a search for the transplacental passage of vaccine virus.<sup>117-119</sup> Viremia occurs after oral administration of polio vaccine, and occasionally, this virus probably is passed transplacentally to the fetus.<sup>120-127</sup>

#### Coxsackieviruses

Several investigators have studied coxsackievirus infections in pregnant animals and the transplacental passage of virus to the fetus. Dalldorf and Gifford<sup>128</sup> studied two strains of coxsackievirus B1 and one of coxsackievirus A8 in gravid mice. In only one instance (coxsackievirus B1) were they able to recover virus from a fetus. They thought that this result was inconclusive because they were unable to recover virus in five other instances. Berger and Roulet<sup>129</sup> observed muscle lesions in the young of gravid mice infected with coxsackieviruses A1 and B1. Selzer<sup>130</sup> studied several viruses in gravid mice; coxsackievirus A9 was found in the placentas of two mice but in no fetuses, and coxsackievirus A18 was not recovered from fetuses or placentas. Selzer<sup>130</sup> found that coxsackieviruses B3 and B4 passed the placental barrier. Soike<sup>131</sup> also observed that in the last week of pregnancy, coxsackievirus B3 reached fetal mice transplacentally. Modlin and Crumpacker<sup>132</sup> reported that infection in late gestational mice was more severe than that occurring in early pregnancy and that transplacental infection of the fetus occurred transiently during the maternal infection. Flamm<sup>133</sup> observed that coxsackievirus A9, when injected intravenously in rabbits, reached the blastocyst early in pregnancy and the amniotic fluid later in pregnancy. He also demonstrated congenital infection in mice with coxsackievirus A1.<sup>134</sup>

Palmer and co-workers<sup>135</sup> studied the gestational outcome in pregnant mice inoculated intravenously with Theiler's murine encephalomyelitis virus, a murine enterovirus. In early gestational infections they found a high rate of placental

and fetal abnormalities. The rates of fetal abnormalities and placental infection were greater than the rate of fetal viral infection, suggesting that the adverse effects of the viral infections were direct and indirect. Gestational infection could result in virus passage to the fetus and fetal damage or in placental compromise with indirect fetal damage.

In another study using the same murine model with Theiler's murine encephalomyelitis virus, Abzug<sup>136</sup> found that maternal factors (i.e., compromised uteroplacental blood flow, concomitant infection, and advanced age) increased the risk of transplacental fetal infection.

In humans, the transplacental passage of coxsackieviruses at term has been documented on several occasions. Benirschke<sup>137</sup> studied the placentas in three cases of congenital coxsackievirus B disease and could find no histologic evidence of infection. In 1956, Kibrick and Benirschke<sup>138</sup> reported the first case of intrauterine infection with coxsackievirus B3. In this instance, the infant was delivered by cesarean section and had clinical evidence of infection several hours after birth. Brightman and colleagues<sup>139</sup> recovered coxsackievirus B5 from the placenta and rectum of a premature infant. No histologic abnormalities of the placenta were identified. Other evidence of intrauterine infection has been presented for coxsackieviruses A4 and B2 through B6.<sup>140-148</sup>

Evidence for intrauterine infection during the first and second trimesters of pregnancy with coxsackieviruses is less clear. Burch and co-workers<sup>149</sup> reported the results of immunofluorescent studies of two fetuses of 5 months' gestation and one fetus of 6 months' gestation; the 6-month-old fetus had evidence of coxsackievirus B4 myocarditis, one 5-month-old fetus showed signs of coxsackievirus B3 infection, and the other 5-month-old fetus showed evidence of coxsackievirus B2, B3, and B4 infections. Basso and associates<sup>143</sup> recovered coxsackievirus B2 from the placenta, liver, and brain of a fetus after a spontaneous abortion at 3 months' gestation. Plager and co-workers found no evidence of intrauterine viral transmission of coxsackievirus B5 infections during the first and second trimesters of pregnancy.<sup>150</sup>

Euscher and associates<sup>151</sup> detected coxsackievirus RNA in placental tissue from six of seven newborn infants with respiratory difficulties and other manifestations at birth. Of these infants, one died shortly after birth, and the other six suffered neurodevelopmental delays. The placentas of 10 normal infants were examined for coxsackievirus RNA, and results of these studies were negative. Three of the placentas from the affected infants showed focal chronic villitis, two showed focal hemorrhagic endovasculitis, and one showed focal calcifications. In addition to respiratory distress, two neonates had rashes, two had seizures, two had thrombocytopenia, and one had intraventricular hemorrhage.

### **Echoviruses, Enteroviruses, and Parechoviruses**

Less is known about transplacental passage of echoviruses than about that of coxsackieviruses and polioviruses. Echovirus infections are regular occurrences in all populations. Women in all stages of pregnancy are frequently infected, and viremia is commonly seen in these infections.<sup>152</sup> In particular, epidemic disease related to echovirus 9 has been studied epidemiologically and serologically.<sup>153-155</sup> In these studies, a search for teratogenesis has been made, but no definitive virologic investigations have been carried out; asymptomatic transplacental infection might have occurred.

Cherry and colleagues<sup>141</sup> cultured samples from 590 newborns during a period of enteroviral prevalence without isolating an echovirus. Antepartum serologic study of a group of 55 mothers in this study showed that 5 (9%) were actively infected with echovirus 17 during the 6-week period before delivery. In two other large nursery studies, there was no suggestion of intrauterine echovirus infections.<sup>156,157</sup>

Berkovich and Smithwick<sup>158</sup> described a newborn without clinical illness who had specific IgM parechovirus 1 antibody in the cord blood, suggesting intrauterine infection with this virus. Hughes and colleagues<sup>159</sup> reported a newborn with echovirus 14 infection who had a markedly elevated level of IgM (190 mg/dL) on the sixth day of life. It seems likely that this infant was also infected in utero. Echoviruses 6, 7, 9, 11, 19, 27, and 33 have been identified in cases of transplacentally acquired infections.<sup>143,160-168</sup>

Chow and associates<sup>169</sup> described a 1300-g fetus, which was stillborn after 26 weeks' gestation, with unilateral hydrocephalus, hepatosplenomegaly, fibrotic peritonitis, and meconium staining. Enterovirus 71 was isolated from the amniotic fluid, and the same virus was identified by polymerase chain reaction (PCR) in the cord blood and by immunohistochemical staining in the fetal midbrain and liver. Otonkoski and coworkers<sup>170</sup> reported the occurrence of neonatal type 1 diabetes after a possible maternal echovirus 6 infection.

### **Ascending Infection and Contact Infection during Birth**

Definitive evidence is lacking for ascending infection or contact infection with enteroviruses during birth. In prospective studies of genital herpes simplex and cytomegaloviral infections, there have been no enteroviral isolations.<sup>171,172</sup> These results suggest that ascending infections with enteroviruses, if they occur at all, are rare. However, Reyes and associates<sup>173</sup> recovered coxsackievirus B5 from the cervix of four third-trimester pregnant women. Three of the four positive cultures were obtained 3 weeks or more before delivery. In the fourth case, the cervical culture was obtained the day before delivery, and the child was delivered by cesarean section. All of the infants were healthy, but unfortunately, culture for virus was possible only from the infant delivered by cesarean section; the result was negative. In an earlier study, Reyes and colleagues<sup>164</sup> reported a child who died of a disseminated echovirus 11 infection. The illness had its onset on the third day of life, and the virus was recovered from the mother's cervix at that time.

Enteroviral infection during the birth process seems probable. The fecal carriage rate of enteroviruses in asymptomatic adult patients varies between 0% and 6% or higher in different population groups.<sup>174-176</sup> Cherry and associates<sup>141</sup> found that in 2 (4%) of 55 mothers, enteroviruses were present in the feces shortly after delivery. Katz,<sup>177</sup> in a discussion of a child with neonatal coxsackievirus B4 infection, suggested that the infant might have inhaled maternally excreted organisms during birth. The fact that this child had pneumonia tends to support the contention. Infections occurring 2 to 7 days after birth could have been acquired during passage through the birth canal.

## Neonatal Infection

Neonatal infections and illnesses from enteroviruses are relatively common.<sup>178</sup> Transmission of enteroviruses to newborns is similar to that for populations of older people. The main factor in the spread of virus is human-to-human contact.

During the summer and fall of 1981 in Rochester, New York, 666 neonates were cultured for enteroviruses within 24 hours of birth and then weekly for 1 month.<sup>164</sup> The incidence of acquisition of nonpolio enteroviral infections during this period was 12.8%. Two risk factors were identified: lower socioeconomic status and lack of breast-feeding.

## Polioviruses

Clinical poliomyelitis is rare in neonates, but the infection rate before the vaccine era was never determined. It is probable that the rarity of neonatal poliomyelitis was not related to lack of viral transmission but reflected the protection from disease offered by specific, transplacentally transmitted polioviral antibodies. From experience gained in vaccine studies, it is apparent that infants with passively acquired antibody can be regularly infected.<sup>179-191</sup>

In 1955, Bates<sup>110</sup> reviewed the literature on poliomyelitis in infants younger than 1 month. He described six infants who apparently were not infected by their mothers and who had had other likely contacts. A neighbor was the contact in one case, siblings in two cases, nursery nurses in two cases, and an uncle in the sixth case. In most other infants, the mother had had poliomyelitis shortly before the child was born and probably was the contact. The mode of transmission—intrauterine, during birth, or postnatal contact—is unknown.

Bergeisen and colleagues<sup>192</sup> reported a case of paralytic poliomyelitis from a type 3 vaccine viral strain. They suggested that the source of this virus might have been the child of the neonate's baby sitter, who was vaccinated about 2 weeks before the onset of the illness.

## Coxsackieviruses

Several epidemics with coxsackieviruses B in newborn nurseries have been studied. Brightman and co-workers<sup>139</sup> observed an epidemic of coxsackievirus B5 in a premature nursery. Their data suggested that the virus was introduced into this nursery by an infant with a clinically inapparent infection who had been infected in utero. Secondary infections occurred in 12 infants and two nurses. The timing of the secondary cases suggested that three generations of infection had occurred and that the nurses had been infected during the second generation. The investigators suggested that the infection had spread from infant to infant and from infant to nurse.

Javett and colleagues<sup>193</sup> documented an acute epidemic of myocarditis associated with coxsackievirus B3 infection in a Johannesburg maternity home. Unfortunately, no epidemiologic investigation or search for asymptomatic infected infants was performed. However, analysis of the onset dates of the illnesses indicated that single infections occurred for five generations and then five children became ill within a 3-day period.

Kipps and colleagues<sup>194</sup> carried out epidemiologic investigations in two coxsackievirus B3 nursery epidemics. In the first epidemic, the initial infection was probably transmitted from a mother to her child; this infant was then the source

of five secondary cases in newborns and one illness in a nurse. Infants with four of the five secondary cases were located on one side of the nursery, but only one cot was close to the cot of the index patient, and this cot did not adjoin the cots of the three other infants with contact cases. In the second outbreak, an infant who also was infected by his mother probably introduced the virus into the nursery. Infants with the three secondary cases were geographically far removed from the one with the primary case of infection.

There have been many other instances of isolated nursery infections and small outbreaks with coxsackieviruses, and it seems that the most consistent source of original nursery infection is transmission from a mother to her child,<sup>193-253</sup> but introduction of virus into the nursery by personnel also occurs.<sup>233,234</sup>

## Echoviruses and Parechoviruses

Although many outbreaks of echovirus infections have been observed in newborn nurseries, information on viral transmission is incomplete.<sup>30,235-265</sup> Cramblett and co-workers<sup>235</sup> reported an outbreak of echovirus 11 disease in four infants in an intensive care nursery. All infants were in enclosed incubators, and three patients became ill within 24 hours; the fourth child became ill 4 days later. Echovirus 11 was recovered from two members of the nursery staff. These data suggest that transmission from personnel to infants occurred because of inadequate hand washing. In another outbreak in an intensive care unit, the initial patient was transferred to the nursery because of severe echovirus 11 disease.<sup>250</sup> After transfer, infection occurred in the senior house officer and a psychologist in the unit. It was inferred by the investigators that spread by respiratory droplets to nine other infants occurred from these infected personnel.

In a maternity unit outbreak of echovirus 11 involving six secondary cases,<sup>257</sup> infection spread through close contact between the infected newborns and the nurses. In another reported nosocomial echovirus 11 outbreak, infants in an intermediate care unit for more than 2 days were more likely to become infected than those who were there for less than 2 days. Illness was also associated with gavage feeding, mouth care, and being a twin.<sup>258</sup>

Modlin<sup>260</sup> reviewed reports of 16 nursery outbreaks involving 206 ill infants. In only 4 of the 16 outbreaks was the source identified, and in all 4, the primary case was an infant who acquired infection vertically from its mother. After introduction of an infected newborn into a nursery, spread to other infants by personnel is common.<sup>262-265</sup> Risk factors for nursery transmission as described by Rabkin and co-workers<sup>262</sup> were "lower gestational age or birth weight; antibiotic or transfusion therapy; nasogastric intubation or feeding; proximity in the nursery to the index patient; and care by the same nurse during the same shift as the index patient."

Wilson and associates<sup>264</sup> reported an intensive care nursery epidemic in which respiratory syncytial virus and echovirus 7 infections occurred concurrently. This epidemic persisted from January to June 1984 despite an aggressive isolation cohorting program. A major factor in persistence was asymptomatic infections with both viruses.

Sato and associates<sup>266</sup> reported a point-source outbreak of echovirus 33 infection in nine newborns related to one nursery over a 10-day period. The primary case was born to

a mother who was febrile and who had a high echovirus 33 neutralizing antibody titer in a convalescent-phase serum specimen.

Jack and colleagues<sup>236</sup> observed the endemic occurrence of asymptomatic infection with parechovirus 1 in a nursery during an 8-month period. A total of 44 infants were infected during this time, and nursery infection occurred when there was no known activity of parechovirus 1 in the community at large. The investigators believed that the endemic viral infection was spread by fecal contamination of hands of nursery personnel.

Nakao and colleagues<sup>246</sup> and Berkovich and Pangan<sup>237</sup> also documented parechovirus 1 infections in nurseries. Like Jack and colleagues,<sup>236</sup> they observed that the infections seemed to be endemic to the nurseries rather than related to community epidemics.

### Host Range

It is the general opinion that humans are the only natural hosts of enteroviruses.<sup>87</sup> However, enteroviruses have been recovered in nature from sewage,<sup>91</sup> flies,<sup>90-92</sup> swine,<sup>267,268</sup> dogs,<sup>269,270</sup> a calf,<sup>271</sup> a budgerigar (i.e., small Australian parakeet),<sup>272</sup> a fox,<sup>273</sup> mussels,<sup>274</sup> and oysters.<sup>275</sup> Serologic evidence of infection with enteroviruses similar to human strains has been found in chimpanzees,<sup>276</sup> cattle,<sup>277</sup> rabbits,<sup>278</sup> a fox,<sup>279</sup> a chipmunk,<sup>280</sup> and a marmot.<sup>251</sup> It is probable that infection of these animals was the result of their direct contact with an infected human or infected human excreta. Although enteroviruses do not multiply in flies, they appear to be a possible significant vector in situations of poor sanitation and heavy human infection. The contamination of shellfish is also intriguing<sup>274,275,279-284</sup> because in addition to their possible role in human infection, they offer a source of enteroviral storage during cold weather. Contaminated foods are another possible source of human infection.<sup>284</sup>

### Geographic Distribution and Season

Enteroviruses have a worldwide distribution.<sup>1,11,87,285,286</sup> Neutralizing antibodies for specific viral types have been found in serologic surveys throughout the world, and most strains have been recovered in worldwide isolation studies. In any one area, there are frequent fluctuations in predominant types. Epidemics probably depend on new susceptible persons in the population rather than on reinfections; they may be localized and sporadic and may vary in cause from place to place in the same year. Pandemic waves of infection also occur.

In temperate climates, enteroviral infections occur primarily in the summer and fall, but in the tropics, they are prevalent all year.<sup>11,87,287</sup> A basic concept in understanding their epidemiology is the far greater frequency of unrecognized infection than that of clinical disease. This is illustrated by poliomyelitis, which remained an epidemiologic mystery until it was appreciated that unrecognized infections were the main source of contagion. Serologic surveys were instrumental in elucidating the problem. In populations living in conditions of poor sanitation and hygiene, epidemics do not occur; but wide dissemination of polioviruses has been confirmed by demonstrating the presence of specific antibodies to all three types in nearly 100% of children by the age of 5 years.

Epidemics of poliomyelitis first began to appear in Europe and the United States during the latter part of the 19th century; they continued with increasing frequency in the economically advanced countries until the introduction of effective vaccines in the 1950s and 1960s.<sup>33,34,288,289</sup> The evolution from endemic to epidemic follows a characteristic pattern, beginning with collections of a few cases, then endemic rates that are higher than usual, followed by severe epidemics with high attack rates.

The age group attacked in endemic areas and in early epidemics is the youngest one; more than 90% of paralytic cases begin in children younger than 5 years. After a pattern of epidemicity begins, it is irreversible unless preventive vaccination is carried out. Because epidemics recur over a period of years, there is a shift in age incidence such that relatively fewer cases are in the youngest children; the peak often occurs in the 5- to 14-year-old group, and an increasing proportion is in young adults. These changes are correlated with socioeconomic factors and improved standards of hygiene; when children are protected from immunizing infections in the first few years of life, the pool of susceptible persons builds up, and introduction of a virulent strain often is followed by an epidemic.<sup>290</sup> Extensive use of vaccines in the past 4 decades has resulted in elimination of paralytic poliomyelitis from large geographic areas, but the disease remains endemic in various parts of the world. Although seasonal periodicity is distinct in temperate climates, some viral activity does take place during the winter.<sup>291</sup> Infection and acquisition of postinfection immunity occur with greater intensity and at earlier ages among crowded, economically deprived populations with less efficient sanitation facilities.

Molecular techniques have allowed the study of genotypes of specific viral types in populations over time.<sup>292-295</sup> For example, Mulders and colleagues<sup>295</sup> studied the molecular epidemiology of wild poliovirus type 1 in Europe, the Middle East, and the Indian subcontinent. They found four major genotypes circulating. Two genotypes were found predominantly in Eastern Europe, a third genotype was circulating mainly in Egypt, and the fourth genotype was widely dispersed. All four genotypes were found in Pakistan.

The epidemiologic behavior of coxsackieviruses and echoviruses parallels that of polioviruses; unrecognized infections far outnumber those with distinctive symptoms. The agents are disseminated widely throughout the world, and outbreaks related to one or another type of virus occur regularly. These outbreaks tend to be localized, with different agents being prevalent in different years. In the late 1950s, however, echovirus 9 had a far wider circulation, sweeping through a large part of the world and infecting children and young adults. This behavior has been repeated occasionally with other enteroviruses; after a long absence, a particular agent returns and circulates among the susceptible persons of different ages who have been born since the previous epidemic occurred. Other agents remain endemic in a given area, surfacing as sporadic cases and occasionally as small outbreaks. Multiple types are frequently active at the same time, although one agent commonly predominates in a given locality.

There are no available data on the incidence of symptomatic congenital and neonatal enteroviral infections. From the frequency of reports in the literature, it appears that severe neonatal disease caused by enteroviruses decreased

Table 24-4 Predominant Types of Nonpolio Enteroviral Isolations in the United States, 1961-1999

Year	Five Most Common Viral Types per Year <sup>a</sup>				
	First	Second	Third	Fourth	Fifth
1961	Coxsackievirus B5	Coxsackievirus B2	Coxsackievirus B4	Echovirus 11	Echovirus 9

<sup>a</sup>Most patients from whom viruses were isolated had neurologic illnesses.

<sup>b</sup>Third and fourth place tie.

Data from Cherry JD. Enteroviruses and parechoviruses. In Feigin RD, Cherry JD, Demmler GJ, Kaplan SL (eds). *Textbook of Pediatric Infectious Diseases*, 5th ed. Philadelphia, WB Saunders, 2004, p 1989.

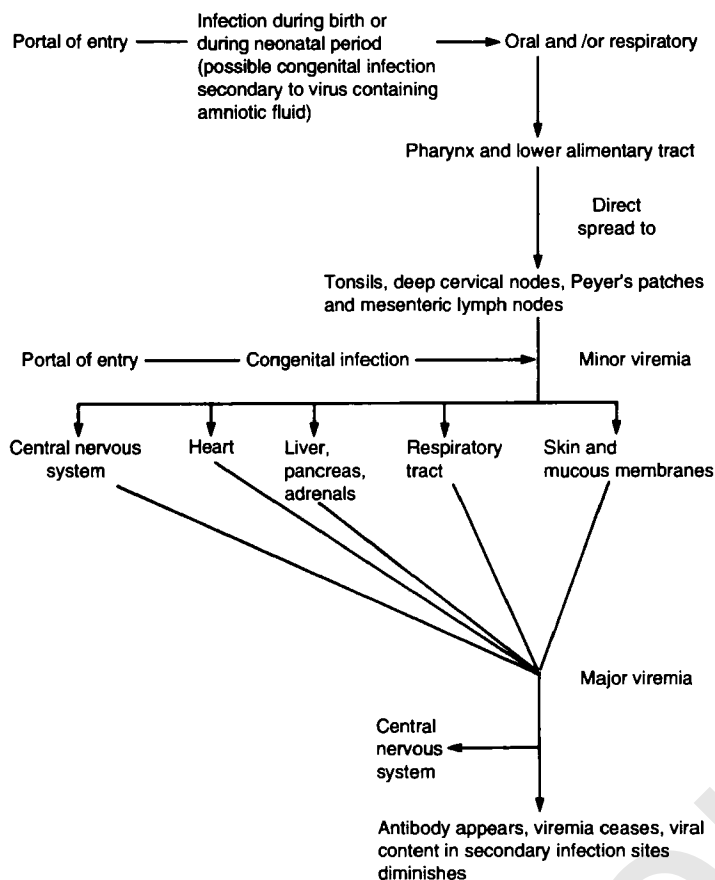

slightly during the late 1960s and early 1970s and then became more common again. Shown in Table 24-4 are the five most prevalent nonpolio enterovirus isolations per year in the United States from 1961 through 1999. Most patients from whom viruses were isolated had neurologic illnesses. It is possible that other enteroviruses were also prevalent but did not produce clinical disease severe enough to cause physicians to submit specimens for study. Many coxsackievirus A infections, even in the epidemic situation, probably went undiagnosed because suckling mouse inoculation was not performed. Although 62 nonpolio enteroviral types and 2 parechovirus types have been identified, in the 39 years covered in Table 24-4, only 24 different virus types have been reported. In the earlier years, echovirus 9 was the most common type; echoviruses 6 and 11 and coxsackieviruses B2 and B4 were the next most common types. Since 1990, echoviruses 30 and 11 have been the most common circulating

viral types. In 1999, three of the five most common viral types (echoviruses 14, 16, and 25) were new to the list.

Similar data are available for the most common enteroviral isolates in Spain from 1988 to 1997 and Belgium from 1980 to 1994.<sup>296,297</sup> The most common enterovirus isolated in both countries was echovirus 30. In 1997 and 1998, major epidemic disease caused by enterovirus 71 occurred in Taiwan, Malaysia, Australia, and Japan.<sup>298-302</sup>

An analysis of the Centers for Disease Control and Prevention nonpolio enterovirus data for 14 years found that early isolates in a particular year were predictive of isolates for the remainder of that year.<sup>303</sup> The six most common isolates during March, April, and May were predictive of 59% of the total isolates during July through December of the same year.

Although the use of live polioviral vaccine has eliminated epidemic poliomyelitis in the United States, it is hard to

**Figure 24-4** The pathogenesis of congenital and neonatal enteroviral infections.

determine what the effect of polio vaccine viruses has been on enteroviral ecology. In 1970, polioviruses accounted for only 6% of the total enteroviral isolations from patients with neurologic illnesses.<sup>304</sup> Although the figures are not directly comparable, more than one third of the enteroviral isolations in 1962 from similar patients were polioviruses.<sup>305</sup> However, Horstmann and associates<sup>306</sup> studied specimens from sewage and asymptomatic children during the vaccine era and found that the number of yearly polioviral isolations (presumably vaccine strains) was greater than the number of nonpolio enteroviruses. The prevalence of vaccine viruses did not seem to affect the seasonal epidemiology of other enteroviruses.

## **PATHOGENESIS**

### **Events during Pathogenesis**

Congenital infections with enteroviruses result from transplacental passage of virus to fetus. The method of transport from mother to fetus is poorly understood. Maternal viremia during enteroviral infections is common, and because virus has been recovered from the placenta on several occasions, it is probable that active infection of the placenta also occurs. Benirschke<sup>137</sup> found no histologic evidence of placental disease in three cases of established transplacentally acquired coxsackievirus B infections. Batcup and associates<sup>307</sup> found diffuse perivillous fibrin deposition with villous necrosis and inflammatory cell infiltration of the placenta in a woman who

2 weeks earlier, at 33 weeks' gestation, had coxsackievirus A9 meningitis. The woman was delivered of a macerated, stillborn infant. At birth, virus was recovered from the placenta but not from the stillborn infant.

It is assumed that infection in the fetus results from hematogenous dissemination initiated in the involved placenta. It is also possible that some in utero infection results from the ingestion of virus contained in amniotic fluid; in this situation, primary fetal infection involves the pharynx and lower alimentary tract. The portal of entry of infection during the birth process and the neonatal period is similar to that for older children and adults.

Figure 24-4 shows a schematic diagram of the events of pathogenesis. After initial acquisition of virus by the oral or respiratory route, implantation occurs in the pharynx and the lower alimentary tract. Within 1 day, the infection extends to the regional lymph nodes. On about the third day, minor viremia occurs, resulting in involvement of many secondary infection sites. In congenital infections, infection is initiated during the minor viremia phase. Multiplication of virus in secondary sites coincides with the onset of clinical symptoms. Illness can vary from minor to fatal infections. Major viremia occurs during the period of multiplication of virus in the secondary infection sites; this period usually lasts from the third to the seventh days of infection. In many echovirus and coxsackievirus infections, central nervous system involvement apparently occurs at the same time as other secondary organ involvement. This occasionally appears to happen with polioviral infections; however, more commonly, the central nervous system symptoms of poliomyelitis are delayed,

suggesting that seeding occurred later in association with the major viremia.

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on about the seventh day. However, infection continues in the lower intestinal tract for prolonged periods.

### Factors That Affect Pathogenesis

The pathogenesis and pathology of enterovirus infections depend on the virulence, tropism, and inoculum concentration of virus, as well as on many specific host factors. Enteroviruses have marked differences in tropism and virulence. Although some generalizations can be made in regard to tropism, there are marked differences even among strains of specific viral types. Differences in virulence of specific enteroviral types may be the result of recombination among enteroviruses or point mutations.<sup>308-310</sup>

Enterovirus infections of the fetus and neonate are thought to be more severe than similar infections in older individuals. This is undoubtedly true for coxsackievirus B infections and probably also true for coxsackievirus A, echovirus, and poliovirus infections. Although the reasons for this increased severity are largely unknown, several aspects of neonatal immune mechanisms offer clues. The similarity of coxsackievirus B infections in suckling mice to those in human neonates has provided a useful animal model. Heineberg and co-workers<sup>311</sup> compared coxsackievirus B1 infections in 24-hour-old suckling mice with similar infections in older mice. They observed that adult mice produced interferon in all infected tissues, whereas in suckling mice, only small amounts of interferon were identified in the liver. They thought that the difference in outcome of coxsackievirus B1 infections in suckling and older mice could be explained by the inability of the cells of the immature animal to elaborate interferon.

Others thought that the increased susceptibility of suckling mice to severe coxsackievirus infections was related to the transplacentally acquired, increased concentrations of adrenocortical hormones.<sup>312,313</sup> Kunin<sup>314</sup> suggested that the difference in age-specific susceptibility might be explained at the cellular level. He showed that a variety of tissues of newborn mice bound coxsackievirus B3, whereas tissues of adult mice were virtually inactive in this regard.<sup>314,315</sup> It has been suggested that the progressive loss of receptor-containing cells or of receptor sites on persisting cells with increasing age might be the mechanism that accounts for infections of lesser severity in older animals. Teisner and Haahr<sup>316</sup> suggested that the increased susceptibility of suckling mice to severe and fatal coxsackievirus infections might be from physiologic hypothermia and poikilothermia during the first week of life.

In the past, it was assumed that specific pathology in various organs and tissues in enteroviral infections was caused by the direct cytopathic effect and tropism of a particular virus. However, a large number of studies using murine myocarditis model systems have suggested that host immune responses contribute to the pathology.<sup>13,308,317-332</sup> These studies suggest that T cell-mediated processes and virus-induced autoimmunity cause acute and chronic tissue damage. Other studies suggest that the primary viral cytopathic effect is

responsible for tissue damage and that various T cell responses are a response to the damage, not the cause.<sup>333</sup> From my review of various murine myocarditis model systems, it is apparent that the genetics of the hosts and of the viral strains determine the likelihood of autoimmune, cell-mediated cellular damage.<sup>308,317-320,322-325,327,329,331</sup> However, none of the model systems is appropriate for the evaluation of the pathogenesis of neonatal myocarditis. Although available studies suggest that enterovirus-induced myocarditis in older children and adults occasionally may have a delayed cell-mediated component, the short incubation period and fulminant nature of neonatal disease, as well as the similar infection in suckling mice, suggest that autoimmune factors are not major in the pathogenesis of myocarditis in neonates.

During the past 40 years, the clinical manifestations caused by several enteroviral serotypes have changed. For example, echovirus 11 infections initially were associated with exanthem and aseptic meningitis in children. They later were found to cause severe sepsis-like illnesses in neonates. These phenotypic changes in disease expression may be the result of recombination among enteroviruses.<sup>310,334</sup>

## PATHOLOGY

### General Considerations

Great variations in the clinical signs of congenital and neonatal enterovirus infections are paralleled by wide variations in pathology. Because pathologic material usually is available only from patients with fatal illnesses, the discussion in this section considers only the more severe enteroviral manifestations. It is worth emphasizing, however, that these fatal infections account for only a small portion of all congenital and neonatal enterovirus infections. The pathologic findings in infants with milder infections, such as nonspecific febrile illness, have not been described.

### Polioviruses

The pathologic findings in fatal neonatal poliomyelitis are similar to those seen in disease of older children and adults.<sup>19,102,108,109,111</sup> The major findings have involved the central nervous system, specifically the anterior horns of the spinal cord and the motor nuclei of the cranial nerves. Involvement is usually irregularly distributed and asymmetric. Microscopically, the anterior horn cells show neuronal destruction, gliosis, and perivascular small round cell infiltration. Myocarditis has also been observed,<sup>102</sup> characterized by focal necrosis of muscle fibers and various degrees of cellular infiltration.

### Coxsackieviruses A

Records of neonatal illnesses associated with coxsackieviruses A are rare.<sup>335-337</sup> Gold and co-workers,<sup>336</sup> in a study of sudden unexpected death in infants, recovered coxsackievirus A4 from the brains of three children. Histologic abnormalities were not identified in the brains or spinal cords of these patients. Baker and Phillips<sup>337</sup> reported the death of twins in association with coxsackievirus A3 intrauterine infections; the first twin was stillborn, and the second twin died when 2 days old of viral pneumonia.

**Figure 24-5** Coxsackievirus B4 myocarditis in a 9-day-old infant. Notice the myocardial necrosis and mononuclear cellular infiltration.

**Figure 24-6** Coxsackievirus B4 encephalitis in a 9-day-old infant. Notice the focal infiltrate of mononuclear and glial cells.

Eisenhut and associates<sup>338</sup> described a full-term neonate with coxsackievirus A9 infection with meningitis, myocarditis, and disseminated intravascular coagulation who died on the seventh day of life.

### Coxsackieviruses B

Of the enteroviruses, coxsackieviruses B have been most frequently associated with severe and catastrophic neonatal disease. The most common findings in these cases have been myocarditis or meningoencephalitis, or both. Involvement of the adrenals, pancreas, liver, and lungs has occurred.

#### Heart

Grossly, the heart is usually enlarged, with dilatation of the chambers and flabby musculature.<sup>138,147,193,195,204</sup> Microscopically, the pericardium frequently contains some inflammatory cells; and thickening, edema, and focal infiltrations of inflammatory cells may be found in the endocardium. The myocardium (Fig. 24-5) is congested and contains infiltrations of inflammatory cells (i.e., lymphocytes, mononuclear cells, reticulum cells, histiocytes, plasma cells, and polymorphonuclear and eosinophil leukocytes). Involvement of the myocardium is often patchy and focal but occasionally is diffuse. The muscle shows loss of striation, edema, and eosinophilic degeneration. Muscle necrosis without extensive cellular infiltration is common.

### Brain and Spinal Cord

The meninges are congested, edematous, and occasionally mildly infiltrated with inflammatory cells.<sup>138,147,177,195,201,204,339</sup> Lesions in the brain and spinal cord are focal rather than diffuse but frequently involve many different areas. The lesions consist of areas of eosinophilic degeneration of cortical cells, clusters of mononuclear and glial cells (Fig. 24-6), and perivascular cuffing. Occasionally, areas of liquefaction necrosis unassociated with inflammation are seen.

#### Other Organs

The lungs commonly have areas of mild focal pneumonitis with peribronchiolar mononuclear cellular infiltrations.<sup>138,177,195,201,340-342</sup> Massive pulmonary hemorrhage has been observed. The liver is frequently engorged and occasionally contains isolated foci of liver cell necrosis and mononuclear cell infiltrations. A neonate with a coxsackievirus B1 infection developed a sepsis-like illness on the fourth day of life with severe hepatitis and subsequently developed progressive liver calcifications.<sup>342</sup> In the pancreas, infiltration of mononuclear cells, lymphocytes, and plasma cells has been observed, and occasional focal degeneration of the islet cells occurs. Congestion has been observed in the adrenal glands, with mild to severe cortical necrosis and infiltration of inflammatory cells.

## Echoviruses

In an earlier period, although frequently responsible for neonatal illnesses, echoviruses were rarely associated with fatal infections. During the past 30 years, however, there have been many reports of fatal illnesses in newborns from echovirus type 11.<sup>30,162,165,257,343-348</sup> In virtually all cases, the major pathologic finding was massive hepatic necrosis; other findings included hemorrhagic necrosis of the adrenal glands, hemorrhage in other organs, myocardial necrosis, and acute tubular necrosis of the kidneys. Wang and colleagues<sup>348</sup> studied four neonates (three with echovirus 11 and one with echovirus 5 infections) with fulminant hepatic failure and observed two histopathologic patterns associated with minimal inflammation but extensive hemorrhagic necrosis. One pattern indicated ongoing endothelial injury with endotheliitis and fibrinoid necrosis. The second pattern, which was seen in the two neonates who initially survived, was that of veno-occlusive disease. Virus has not been identified in hepatocytes. Extensive myositis of the strap muscles of the neck occurred in one case.<sup>347</sup> Massive hepatic necrosis has also occurred in infections with echoviruses 3, 5, 6, 7, 9, 14, 19, 20, and 21.<sup>159,160,254,343,349-353</sup> Wreghitt and associates<sup>354</sup> described a neonate with a fatal echovirus 7 infection. This infant was found to have massive disseminated intravascular coagulation, with bleeding in the adrenal glands, renal medulla, liver, and cerebellum.

At autopsy, one infant with echovirus 6 infection was found to have cloudy and thickened leptomeninges, liver necrosis, adrenal and renal hemorrhage, and mild interstitial pneumonitis.<sup>343</sup> One infant with echovirus 9 infection had an enlarged and congested liver with marked central necrosis,<sup>350</sup> and another with this virus had interstitial pneumonitis without liver involvement.<sup>161</sup> Three infants with echovirus 11 infections had renal and adrenal hemorrhage and small-vessel thrombi in the renal medulla and in the medulla and the inner cortex of the adrenal glands.<sup>250</sup> In these patients, the livers were normal. Two infants, one with echovirus 6 and the other with echovirus 31 infection, had only extensive pneumonias.<sup>256,355</sup>

## CLINICAL MANIFESTATIONS

### Abortion

#### *Polioviruses*

Poliomyelitis is associated with an increased incidence of abortion. Horn<sup>93</sup> reported 43 abortions in 325 pregnancies complicated by maternal poliomyelitis. Abortion was directly related to the severity of the maternal illness, including the degree of fever during the acute phase of illness. However, abortion also was associated with mild, nonparalytic poliomyelitis. Schaeffer and colleagues<sup>98</sup> studied the placenta and abortus 12 days after the onset of illness in a mother. Poliovirus type 1 was isolated from the placenta and the fetal tissues.

Other investigators<sup>356-360</sup> have reported an increased incidence of abortions in cases of maternal poliomyelitis. Siegel and Greenberg<sup>112</sup> noticed that fetal death occurred in 14 (46.7%) of 30 instances of maternal poliomyelitis during the first trimester. Kaye and colleagues<sup>360</sup> reviewed the literature

in 1953 and found 19 abortions in 101 cases of poliomyelitis in pregnancy. In a small study in Evanston Hospital in Illinois, the abortion rate associated with maternal poliomyelitis was little different from the expected rate.<sup>357</sup> In a study of 310 pregnant women who received trivalent oral poliovirus vaccine, there was no increase in abortions above the expected rate.<sup>118</sup> In a later study in Finland that involved about 9000 pregnant women immunized with oral poliovirus vaccine, there was no evidence of an increase in stillbirths.<sup>361</sup>

#### *Coxsackieviruses*

Although in the late 1950s and early 1960s there were extensive outbreaks of illness caused by coxsackievirus A16, there was no evidence of adverse outcomes of pregnancy related to this virus. Because infections with other coxsackieviruses rarely involve large segments of the population, rate studies have not been performed.

Frisk and Diderholm<sup>362</sup> found that 33% of women with abortions had IgM antibody to coxsackieviruses B, whereas only 8% of controls had similar antibody. In a second, larger study, the same research group confirmed their original findings.<sup>363</sup>

#### *Echoviruses*

There is no available evidence suggesting that echovirus infections during pregnancy are a cause of spontaneous abortion. Landsman and associates<sup>155</sup> studied 2631 pregnancies during an epidemic of echovirus 9 and could find no difference in antibody to echovirus 9 between mothers who aborted and those who delivered term infants. A similar study in Finland revealed no increase in the abortion rate among mothers infected in early pregnancy with echovirus 9.<sup>153</sup>

## Congenital Malformations

#### *Polioviruses*

The congenital malformation rate associated with poliovirus infection as determined in the NIH-sponsored Collaborative Perinatal Research Project of 45,000 pregnancies was 4.1%.<sup>364</sup> Although isolated instances of congenital malformation and maternal poliomyelitis have been reported, there is little statistical evidence demonstrating that polioviruses are teratogens. In their review of the literature, Kaye and colleagues<sup>360</sup> identified six anomalies in 101 infants born to mothers with poliomyelitis during pregnancy. In the reviews of Horn,<sup>93</sup> Bates,<sup>110</sup> and Siegel and Greenberg,<sup>112</sup> there was no evidence of maternal poliovirus infection-induced anomalies.

The possibility of congenital anomalies associated with attenuated oral poliovirus vaccine has also been studied.<sup>117,118,361,365-367</sup> Pearson and co-workers<sup>117</sup> studied the fetal malformation rate in a community in which a large vaccine field trial had been carried out; although it is probable that pregnant women became infected with vaccine virus by secondary spread, there was no community increase in fetal malformations. Prem and associates<sup>118</sup> studied the infants of 69 women who received attenuated vaccine before 20 weeks' gestation and found that none had anomalies. In contrast, the rate of congenital defects in Blackburn, England, increased coincident with mass vaccination with trivalent poliomyelitis vaccine.<sup>365</sup> However, there is no evidence of cause and effect related to this observation. Connelly and

colleagues<sup>366</sup> commented on a child with a unique renal disease acquired in utero. The child's mother had received oral polio vaccine during the second month of pregnancy.

In February 1985, a mass vaccination program with live oral poliovirus vaccine was carried out in Finland.<sup>367</sup> Although pregnant women received vaccine, there was no evidence that vaccine virus had a harmful effect on developing fetuses.

### **Coxsackieviruses**

In a large prospective study, Brown<sup>368-370</sup> and colleagues (Evans<sup>371,372</sup> and Karunas<sup>373</sup>) made a serologic search for selected maternal enteroviral infections in association with congenital malformations. In one study,<sup>373</sup> serum samples from 22,935 women had been collected. From this group, serum samples from 630 mothers of infants with anomalies and from 1164 mothers of children without defects were carefully studied. Specifically, serologic evidence was sought for infection during the first trimester and last 6 months of pregnancy with coxsackieviruses B1 through B5 and A9 and with echoviruses 6 and 9. In this study, infants were examined for 113 specific abnormalities; these anomalies were grouped into 12 categories for analysis. The investigators demonstrated a positive correlation between maternal infection and infant anomaly with coxsackieviruses B2 through B4 and A9. The overall first-trimester infection rate with coxsackievirus B4 was significantly higher in patients with anomalies than that in controls. Maternal coxsackievirus B2 infection throughout pregnancy, coxsackievirus B4 infections during the first trimester of pregnancy, and infection with at least one of the five coxsackieviruses B during pregnancy were all associated with urogenital anomalies. Coxsackievirus A9 infection was associated with digestive anomalies, and coxsackieviruses B3 and B4 were associated with cardiovascular defects. When coxsackieviruses B were analyzed as a group (B1 to B5), there was an overall association with congenital heart disease; the likelihood of cardiovascular anomalies was increased when maternal infection with two or more coxsackieviruses B occurred. In this study, the mothers had been instructed to keep illness diary sheets. There was no correlation between reported maternal clinical illnesses and serologic evidence of infection with the selected enteroviruses. This suggests that many infections that may have been causally related to the anomalies were asymptomatic. A disturbing finding in this study was the lack of seasonal occurrence of the births of children with specific defects. Because enteroviral transmission is most common in the summer and fall, the birth rate of children with malformations should have been greatest in the spring and summer if coxsackieviruses were a major cause of malformation.

In the NIH-sponsored Collaborative Perinatal Research Project, Elizan and co-workers<sup>374</sup> were unable to find any relationships between maternal infections with coxsackieviruses B and congenital central nervous system malformations. Scattered case reports in the literature describe congenital anomalies associated with maternal coxsackievirus infections. Makower and colleagues<sup>140</sup> reported a child with congenital malformations who was born at 32 weeks' gestation and from whom a coxsackievirus A4 strain was recovered from the meconium. The child's mother had been well throughout pregnancy, except for a febrile illness during the first month. The relationship of the viral infection to the congenital malformations or to the prematurity is uncertain.

Gauntt and associates<sup>375</sup> studied the ventricular fluids from 28 newborn infants with severe congenital anatomic defects of the central nervous system. In four infants (two with hydranencephaly, one with an occipital meningocele, and one with aqueductal stenosis), neutralizing antibody to one or more coxsackievirus B types was found in the fluid. In one case, IgM-neutralizing antibody to coxsackievirus B6 was found. The investigators concluded that their data suggested the possibility of an association between congenital infections with coxsackieviruses B and severe central nervous system defects.

### **Echoviruses**

In the large prospective study of Brown and Karunas,<sup>373</sup> the possible association of maternal infections with echoviruses 6 and 9 and congenital malformations was examined. Maternal infection with these selected echoviruses apparently was not associated with any anomaly. In three other studies,<sup>153-155</sup> no association was found between maternal echovirus 9 infection and congenital malformation.

## **Prematurity and Stillbirth**

### **Polioviruses**

In the study by Horn<sup>93</sup> of 325 pregnancies, nine infants died in utero. In each instance, the mother was critically ill with poliomyelitis. Horn<sup>93</sup> also observed that 45 infants weighed less than 6 pounds, and 17 of these had a birth weight of less than 5 pounds. These low-birth-weight infants were born predominantly to mothers who had had poliomyelitis early in pregnancy. A similar finding was reported by Aycock.<sup>96,376</sup> In New York City, Siegel and Greenberg<sup>112</sup> also documented an increase in prematurity after maternal poliomyelitis infection. This was specifically related to maternal paralytic poliomyelitis. There has been no observation of stillbirth or prematurity in relation to vaccine administration.<sup>361</sup>

### **Coxsackieviruses**

Bates reported a fetus of 8 months' gestational age who was stillborn and had calcific pancarditis and hydrops fetalis at autopsy.<sup>144</sup> Fluorescent antibody study revealed coxsackievirus B3 antigen in the myocardium. Burch and colleagues<sup>149</sup> described three stillborn infants who had fluorescent antibody evidence of coxsackievirus B myocarditis, one each with coxsackieviruses B2, B3, or B4. They also reported a premature boy who had histologic and immunofluorescent evidence of cardiac infection with coxsackieviruses B2 through B4; he lived only 24 hours. A macerated stillborn girl was delivered 2 weeks after the occurrence of aseptic meningitis caused by coxsackievirus A9 in a 27-year-old woman.<sup>307</sup> Virus was recovered from the placenta but not from the infant. Coxsackievirus B6 has been recovered from the brain, liver, and placenta of a stillborn infant.<sup>143</sup>

### **Echoviruses and Enteroviruses**

Freedman<sup>377</sup> reported the occurrence of a full-term, fresh stillbirth in a woman infected with echovirus 11. Because the infant had no pathologic or virologic evidence of infection, he attributed the event to a secondary consequence of maternal infection from fever and dehydration rather than

**Table 24–5 Major Manifestations of Neonatal Nonpolio Enteroviral and Parechoviral Infections**

Specific Involvement	Common	Rare
Inapparent infection	Par 1	Cox A9, B1, B2, B4, B5 Echo 3, 5, 9, 11, 13, 14, 20, 30, 31

primary transplacental infection. Echovirus 27 has been associated with intrauterine death on two occasions.<sup>143,166</sup>

In an extensive study of neonatal enteroviral infections in Milwaukee in 1979, Piraino and associates<sup>165</sup> found that 12 of 19 stillbirths occurred from July through October coincident with a major outbreak of enterovirus disease. Echovirus 11 was the main agent isolated during this period. A 1300-g fetus, stillborn after 26 weeks' gestation, had hydrocephalus, fibrotic peritonitis, and hepatosplenomegaly and was found to have an enterovirus 71 infection by PCR and immunohistochemical study.<sup>169</sup>

## Neonatal Infection

### *Nonpolio Enteroviruses and Parechoviruses*

Illnesses caused by nonpolio enteroviruses and parechoviruses are discussed by clinical classification (Table 24-5) in the following sections.

#### INAPPARENT INFECTION

Although it is probable that inapparent infections in neonates occasionally occur with many *different enteroviruses*, there is little documentation of this assumption. Cherry and

co-workers<sup>141</sup> studied 590 normal newborns during a 6-month period and found only one infection without clinical signs of illness. This was a child infected in utero or immediately thereafter with coxsackievirus B2. The mother had an upper respiratory illness 10 days before delivery. In a similar but more comprehensive study, Jenista and associates<sup>178</sup> failed to isolate any enteroviruses from cultures from 666 newborns on the first postpartum day. However, during weekly cultures during the month after birth, 75 enteroviruses were isolated. Symptomatic enteroviral disease occurred in 21% (16 of 75).

During a survey of perinatal virus infections, 44 infants were found to be infected with parechovirus 1 during the study period from May to December 1966.<sup>236</sup> The virus prevalence and the incidence of new infections during this period were fairly uniform. No illness was attributed to parechovirus 1 infection, and the virus disappeared from the nursery in mid-December 1966. Inapparent infections with parechovirus 1 have been reported on two other occasions.<sup>237,246</sup> Infections without evidence of illness have occurred with coxsackieviruses A9, B1, B4, and B5 and with echoviruses 3, 5, 9, 11, 13, 14, 20, 30, and 31.<sup>9,156,157,178,210, 250, 256, 340,378-381</sup>

#### MILD, NONSPECIFIC FEBRILE ILLNESS

In a review of 338 enteroviral infections in early infancy, 9% were classified as nonspecific febrile illnesses.<sup>378</sup> Illness may be sporadic in nature or part of an outbreak with a specific viral type. In the latter situation, clinical manifestations vary depending on the viral type; some infants have aseptic meningitis and other signs and symptoms, and some have only nonspecific fever. Coxsackievirus B5 and echovirus types 5, 11, and 33 have been those found most commonly in nonspecific fevers; other agents identified have included coxsackieviruses A9, A16, and B1 through B4 and echoviruses 4, 7, 9, and 17.\*

Mild, nonspecific febrile illness occurs most commonly in full-term infants after uneventful pregnancies and deliveries without complications. Illness can occur at any time during the first month of life. When the onset occurs after the infant is 7 days old, a careful history frequently reveals a trivial illness in a family member. The onset of illness is characterized by mild irritability and fever, which is usually in the range of 38° C to 39° C, but higher temperatures occasionally occur. Poor feeding is frequently observed. One or two episodes of vomiting or diarrhea, or both, may occur in some infants. The usual duration of illness is 2 to 4 days.

Routine laboratory study is not helpful, but cerebrospinal fluid (CSF) examination may reveal an increased protein concentration and leukocyte count indicative of aseptic meningitis. Although, by definition, illness in this category is mild, the degree of viral infection may be extensive. When looked for, virus may be isolated from the blood, urine, and spinal fluid of infants with mild illnesses.<sup>211,379</sup>

#### SEPSIS-LIKE ILLNESS

The major diagnostic problem in neonatal enteroviral infections is differentiation of bacterial from viral disease. Even in the infant with mild, nonspecific fever, bacterial

disease must be strongly considered. The sepsis-like illness described here is always alarming. This illness is characterized by fever, poor feeding, abdominal distention, irritability, rash, lethargy, and hypotonia.<sup>340,385-387</sup> Other findings include diarrhea, vomiting, seizures, shock, disseminated intravascular coagulation, thrombocytopenia, hepatomegaly, jaundice, and apnea. The onset of illness is introduced by irritability, poor feeding, and fever and followed within 24 hours by other manifestations. In a group of 27 neonates, Lake and associates<sup>286</sup> observed that 54% had temperatures of 39° C or higher. The duration of fever varies from 1 to 8 days, most commonly 3 to 4 days. Barre and colleagues<sup>388</sup> reported a 3-day-old boy with an enterovirus-associated hemophagocytic syndrome. This neonate presented with a typical sepsis-like picture with fever, hepatosplenomegaly, coagulopathy, thrombocytopenia, and anemia. This child recovered and had no hemophagocytic relapses.

Sepsis-like illness is common. Morens<sup>378</sup> described its occurrence in one fifth of 338 enteroviral infections in infants. In an attempt to differentiate bacterial from viral disease, Lake and co-workers<sup>340</sup> studied 27 infants with enteroviral infections. White blood cell counts were not helpful because the total count, the number of neutrophils, and the number of band form neutrophils were elevated in most instances. Of most importance were historical data. Most mothers had evidence of a recent febrile, viral-like illness. Other factors often associated with bacterial sepsis, such as prolonged rupture of membranes, prematurity, and low Apgar scores, were unusual in the enteroviral infection group.

Sepsis-like illness has been identified most often with coxsackieviruses B2 through B5 and echovirus types 5, 11, and 16; other viruses detected include coxsackieviruses A9 and B1; echoviruses 2, 3, 4, 6, 9, 14, 19, and 21; and parechovirus 1.\*

Since the early 1980s, echovirus 11 has been associated most frequently with fatal septic events, with hepatic necrosis, and disseminated intravascular coagulation.<sup>30,163-165,257,344-348,354</sup>

#### RESPIRATORY ILLNESS

Respiratory complaints are generally overshadowed by other manifestations of neonatal enteroviral disease. Only 7% of 338 enteroviral infections in early infancy were classified as respiratory illness.<sup>378</sup> Except for echoviruses 11 and parechovirus 1, respiratory illness associated with enteroviruses has been sporadic.<sup>237,239</sup>

Hercik and co-workers<sup>239</sup> reported an epidemic of respiratory illness in 22 newborns associated with echovirus 11 infection. All of these infants had rhinitis and pharyngitis, 50% had laryngitis, and 32% had interstitial pneumonitis. Berkovich and Pangan<sup>237</sup> studied respiratory illnesses in premature infants and reported 64 with illness, 18 of whom had virologic or serologic evidence of parechovirus 1 infection. Many had high but constant levels of serum antibody to parechovirus 1. Some of the 18 infants were probably also infected with parechovirus 1. The children with proven parechovirus 1 infections could not be clinically differentiated from those without evidence of parechovirus 1 infection. Ninety percent of the infants had coryza, and 39% had radiographic evidence of pneumonia.

\*See references 29, 141, 165, 196, 207, 211, 229, 230, 238, 240-242, 249-251, 379, 382, 384.

\*See references 28-30, 160, 161, 163-165, 168, 214, 234, 235, 243, 247, 250, 251, 257, 338, 340, 342, 344-346, 348, 350, 351, 354, 383, 385, 389-394.

**Herpangina.** Chawarewong and associates<sup>396</sup> described several infants with herpangina and coxsackievirus A5 infection. A vesicular lesion on an erythematous base on a tonsillar pillar in a 6-day-old infant with coxsackievirus B2 meningitis has also been reported.<sup>397</sup> Two 1-month-old infants were described in an outbreak of herpangina due to coxsackievirus B3 in a welfare home in Japan.<sup>398</sup>

**Coryza.** Several agents have been associated with coryza: coxsackievirus A9 and echoviruses 11, 17, 19, and 22.<sup>158,239,243,246,399</sup>

**Pharyngitis.** Pharyngitis is uncommon in neonatal enteroviral infections. In more than 50 infants with enteroviral infections studied by Linnemann and colleagues<sup>383</sup> and Lake and associates,<sup>340</sup> pharyngitis did not occur. Suzuki and co-workers<sup>400</sup> observed pharyngitis in 3 of 42 neonates with echovirus 11 infections. In contrast, in the same study, 67% of children 1 month to 4 years old had pharyngitis. Pharyngitis has been associated with coxsackievirus B4 and with echoviruses 11, 17, and 18.<sup>207,239,253,400,401</sup>

**Laryngotracheobronchitis or Bronchitis.** A few enteroviruses have been identified in cases of laryngotracheobronchitis or bronchitis: coxsackieviruses B1 and B4 and echovirus 11.<sup>239,402</sup> Specific clinical descriptions of laryngotracheobronchitis or bronchitis associated with enteroviral infections are scanty. Hercík and co-workers<sup>239</sup> observed laryngitis in 11 and croup in 4 of 22 neonates during an echovirus 11 outbreak. All of the affected infants had upper respiratory tract findings, vomiting, and lethargy. Many were also cyanotic and had hepatosplenomegaly.

**Pneumonia.** Pneumonia as the main manifestation of neonatal enteroviral infection is rare. Morens<sup>378</sup> documented only seven instances of pneumonia in 338 neonatal enteroviral infections. Outbreaks of pneumonia in neonates have been reported with echovirus 11 and parechovirus 1.<sup>237,239</sup> Pneumonia resulting from other enteroviruses is a sporadic event and has been reported for the following nonpolio enteroviruses: coxsackieviruses A9 and B4 and echoviruses 9, 17, and 31.

During a nursery echovirus 11 outbreak, 7 of 22 neonates had pneumonia.<sup>239</sup> All infants had signs of upper respiratory infection and general signs of sepsis-like illness. In infants with pneumonia associated with an echovirus 22 nursery epidemic, coryza, cough, and dyspnea were early signs.<sup>237</sup> The illnesses tended to be protracted, with radiographic changes persisting for 10 to 100 days.

**Cloud Baby.** Eichenwald and associates<sup>248</sup> recovered echovirus 20 from four full-term infants younger than 8 days. Although these infants apparently were well, it was found that they were extensively colonized with staphylococci and that they disseminated these organisms into the air around them. Because of this ability to disseminate staphylococci, they were called *cloud babies*. The investigators believed that these cloud babies contributed to the epidemic spread of staphylococci in the nursery. Because active staphylococcal dissemination occurred only during the time that echovirus 20 could be recovered from the nasopharynx, it was theorized that viral-bacterial synergism occurred.

#### GASTROINTESTINAL MANIFESTATIONS

Significant gastrointestinal illness occurs in about 7% of enteroviral infections during infancy.<sup>378</sup>

**Vomiting or Diarrhea.** Vomiting and diarrhea are common but usually just part of the overall illness complex and not the major manifestations. In 1958, Eichenwald and colleagues<sup>244</sup> described epidemic diarrhea associated with echovirus 18 infections.

In 22 infants with epidemic respiratory disease caused by echovirus 11, all had vomiting as a manifestation of the illness.<sup>239</sup> Linnemann and colleagues<sup>383</sup> reported vomiting in 36% and diarrhea in 7% of neonates with echoviral infections. In another study, Lake and associates<sup>340</sup> found diarrhea in 81% and vomiting in 33% of neonates with nonpolio enteroviral infections. Vomiting and diarrhea in neonates have been associated with coxsackieviruses B1, B2, and B5; echoviruses 4 through 6, 8, 9, 11, 16, 17, 18, 19, and 21; parechovirus 1; and enterovirus 71.\*

**Hepatitis.** Morens<sup>378</sup> observed that 2% of neonates with clinically severe enteroviral disease had hepatitis. Lake and colleagues<sup>340</sup> found that 37% of neonates with enteroviral infections had hepatomegaly, and hepatosplenomegaly was observed by Hercík and associates<sup>239</sup> in 12 of 22 newborns with echovirus 11 respiratory illnesses.

Severe hepatitis, frequently with hepatic necrosis, has been associated with echoviruses 5, 6, 7, 9, 11, 14, 19, 20, and 21.<sup>159,160,263,343,344,347-350,353,406,407</sup> In 1980, Modlin<sup>254</sup> reported four fatal echovirus 11 illnesses in premature infants. All had hepatitis, disseminated intravascular coagulation, thrombocytopenia, lethargy, poor feeding, and jaundice. Since 1980, there have been many reports of sepsis-like illness with fatal hepatitis related to echovirus 11.<sup>30,163,165,257,345,347,348,351</sup>

Coxsackieviruses B1, B4, and other B types have been associated with neonatal hepatitis.<sup>12,29,203,216,342,393-395</sup> Abzug<sup>408</sup> reviewed medical records of 16 neonates with hepatitis and coagulopathy and found a case-fatality rate of 31%. All of the five patients who died had myocarditis, and three had encephalitis.

**Pancreatitis.** Pancreatitis was recognized in three of four newborns with coxsackievirus B5 meningitis<sup>200</sup> and in coxsackievirus B3 and B4 infections at autopsy.<sup>197</sup> In other fatal coxsackievirus B infections, pancreatic involvement has been identified, but clinical manifestations have rarely been observed.

**Necrotizing Enterocolitis.** Lake and associates<sup>340</sup> described three infants with necrotizing enterocolitis. Coxsackievirus B3 was recovered from two of these infants and coxsackievirus B2 from the third. Parechovirus 1 was associated with a necrotizing enterocolitis outbreak.<sup>409</sup>

#### CARDIOVASCULAR MANIFESTATIONS

In contrast with enteroviral cardiac disease in children and adults, in which pericarditis is common, neonatal disease virtually always involves the heart muscle.<sup>†</sup> Most cases of neonatal myocarditis are related to coxsackievirus B infections, and nursery outbreaks have occurred on several occasions. In 1961, Kibrick<sup>20</sup> reviewed the clinical findings in 45 cases of neonatal myocarditis; his findings are summarized in

\*See references 157, 211, 214, 234, 238-240, 242-244, 247, 383, 385, 403-405.

†See references 6, 12, 28, 29, 138, 144, 147-149, 163, 165, 193-196, 201-206, 208-210, 213, 215, 218, 220, 221, 223, 225, 227-229, 341, 345, 346, 393-395, 410-414, 416.

Diarrhea	8

Modified from Kibrick S. Viral infections of the fetus and newborn. *Perspect Virol* 2:140, 1961.

Table 24-6. Many of the early experiences, particularly in South Africa, involved catastrophic nursery epidemics. Since the observation in 1972 of five newborns with echovirus 11 infections and myocarditis, there have been no further reports of nursery epidemics.<sup>412</sup>

The illness as described by Kibrick<sup>20</sup> most commonly had an abrupt onset and was characterized by listlessness, anorexia, and fever. A biphasic pattern was observed in about one third of the patients. Progression was rapid, and signs of circulatory failure appeared within 2 days. If death did not occur, recovery was occasionally rapid but usually occurred gradually during an extended period. Most patients had cardiac findings, such as tachycardia, cardiomegaly, electrocardiographic changes, and transitory systolic murmurs. Many patients showed signs of respiratory distress and cyanosis. About one third of the infants had signs suggesting neurologic involvement. Of the 45 patients analyzed by Kibrick, only 12 survived.

In the echovirus 11 nursery outbreak reported by Drew,<sup>414</sup> 5 of 10 infants had tachycardia out of proportion to their fevers. Three of these infants had electrocardiograms, supra-ventricular tachycardia occurred in all, and ST segment depression was observed in two of the records. Supraventricular tachycardia has also been seen in patients with coxsackievirus B infections.<sup>210</sup> Echovirus 19 has been associated with myocarditis.<sup>399</sup>

Neonatal myocarditis related to enteroviruses has been less common than it was 4 decades ago. In his review, Morens<sup>378</sup> reported only two instances among 248 severe neonatal enteroviral illnesses.

#### EXANTHEM

Exanthem as a manifestation of neonatal enteroviral infection has occurred with coxsackieviruses B1, B3, and B5; echoviruses 4, 5, 7, 9, 11, 16, 17, 18, and 21; and parechovirus 1.\* In most instances, rash is just a minor manifestation of moderate to severe neonatal disease. Of 27 infants studied by Lake and colleagues, 41% had exanthem.<sup>340</sup> Similarly,

Linnemann and co-workers<sup>383</sup> reported exanthem in 4 of 14 neonates with echoviral infections.

Cutaneous manifestations usually have their onset between the third and fifth day of illness. The rash is usually macular or maculopapular, and petechial lesions occasionally are seen. Surprisingly, vesicular lesions have been reported only once with coxsackievirus B3 infection and once with enterovirus 71 infection in neonates. Theodoridan and associates<sup>417</sup> described a full-term newborn boy with vesicular lesions at birth. PCR revealed coxsackievirus B3. A 1-month-old infant with enterovirus 71 infection and hand-foot-and-mouth syndrome has been reported.<sup>418</sup> Hall and associates<sup>385</sup> reported two neonates with echovirus 16 infections in which the illnesses were similar to roseola. The patients had fevers for 2 and 3 days, defervescence, and then the appearance of maculopapular rashes.

#### NEUROLOGIC MANIFESTATIONS

**Meningitis and Meningoencephalitis.** As shown in Table 24-5, meningitis and meningoencephalitis have been associated with coxsackieviruses B1 through B5 and with many echoviruses.\* In most instances, the differentiation of meningitis from meningoencephalitis is difficult in neonates. Meningoencephalitis is common in infants with sepsis-like illness, and autopsy studies reveal many infants with disseminated viral disease (e.g., heart, liver, adrenals) in addition to central nervous system involvement. In the review of Morens,<sup>378</sup> 50% of the neonates with enteroviral infections had encephalitis or meningitis.

The initial clinical findings in neonatal meningitis or meningoencephalitis are similar to those in nonspecific febrile illness or sepsis-like illness. Most often, the child is quite normal and then becomes febrile, anorectic, and lethargic. Jaundice frequently affects newborns, and vomiting occurs in neonates of all ages. Less common findings include apnea, tremulousness, and general increased tonicities. Seizures occasionally occur.

CSF examination reveals considerable variation in protein, glucose, and cellular values. In seven newborns with meningitis related to coxsackievirus B5 studied by Swender and associates,<sup>234</sup> the mean CSF protein value was 244 mg/dL, and the highest value was 480 mg/dL. The mean CSF glucose value was 57 mg/dL, and one of the seven had pronounced hypoglycorrhachia (12 mg/dL). The mean CSF leukocyte count for the seven infants was 1069 cells/mm<sup>3</sup>, with 67% polymorphonuclear cells. The highest cell count was 4526 cells/mm<sup>3</sup>, with 85% polymorphonuclear cells. In another study involving 28 children younger than 2 months in whom coxsackievirus B5 was the implicated pathogen, 36% of the infants had CSF leukocyte counts of 500 cells/mm<sup>3</sup> or more.<sup>391</sup> In this same study, only 13% of the infants had CSF protein values of 120 mg/dL or more; 12% of the infants had glucose values of less than 40 mg/dL.

The CSF findings in cases of neonatal nonpolio enteroviral infections are frequently similar to those in bacterial disease. In particular, the most consistent finding in bacterial disease, hypoglycorrhachia, affects about 10% of newborns with enteroviral meningitis.<sup>234,340,382,391,419</sup>

\*See references 28, 29, 147, 158, 161, 165, 198, 212, 224, 235, 238, 240, 243, 383, 385-387, 393, 399, 412, 415, 417.

\*See references 28-30, 149, 157, 165, 212, 228, 234, 235, 238, 242, 247, 257, 259, 338, 339, 346, 380, 386, 387, 391, 395, 397, 403, 405, 409, 412, 415-437.

**Paralysis.** Johnson and associates<sup>420</sup> reported a 1-month-old boy with a right facial paralysis and loss of abdominal reflexes. The facial paralysis persisted through convalescence; the reflexes returned to normal within 2 weeks. The boy was infected with coxsackievirus B2. A 1-month-old boy with hand-foot-and-mouth syndrome and bilateral lower limb weakness due to enterovirus 71 infection has been described.<sup>418</sup>

#### SUDDEN INFANT DEATH

Balduzzi and Greendyke<sup>335</sup> recovered coxsackievirus A5 from the stool of a 1-month-old child after sudden infant death. In a similar investigation of sudden infant death, Gold and co-workers<sup>336</sup> recovered coxsackievirus A4 from the brains of three infants. Coxsackievirus A8 was recovered from the stool of a child in whom anorexia was diagnosed on the day before death. Coxsackievirus B3 was recovered at autopsy from an infant who died suddenly on the eighth day of life.<sup>335</sup> Morens and associates<sup>6</sup> reported eight cases of sudden infant death associated with enteroviral infection; parechovirus 1 was found on two occasions. In five instances of cot death in one study, echovirus 11 was isolated from the lungs in two children, from the myocardium in one, and from the nose or feces in the other two.<sup>344</sup>

Grangeot-Keros and co-workers<sup>438</sup> looked for evidence of enteroviral infections using PCR and an IgM immunoassay in cases of sudden and unexplained infant deaths. They divided their infant death population into two groups. One group had clinical, biologic, or histologic signs of viral infection, and the other group had no indicators of an antecedent infection. Fifty-four percent of infants with evidence of a preceding infection had PCR evidence of an enterovirus in samples from the respiratory tract or lung, or both, whereas none of those without evidence of a prior infection had similar positive PCR findings. Their IgM antibody studies supported their PCR findings.

### Manifestations of Polioviruses

#### GENERAL CONSIDERATIONS

Polioviral infection in children classically results in a spectrum of clinical illness. As described by Paul<sup>439</sup> and accepted by others, 90% to 95% of infections in non-neonatal children are inapparent, 4% to 8% are abortive, and 1% to 2% are frank cases of poliomyelitis. Whether neonatal polioviral infection is acquired in utero, during birth, or after birth, it appears that the more severe manifestations of clinical illness are similar to those of older children. However, the available reports in the literature suggest that the frequencies of occurrence of inapparent, abortive, and frank cases are quite different from those in older children. Most reports describe severely affected infants.<sup>95,98-106,108-116</sup> Asymptomatic infection does occur, however.<sup>96,97</sup>

In the excellent review by Bates<sup>110</sup> in 1955, 58 cases of clinically overt poliomyelitis in infants younger than 1 month were described. Although complete data were not available on many of the cases, 51 had paralysis or died from their disease, or both. Of the total number of infants for whom there were clinical data, only one had nonparalytic disease. Because follow-up observation was recorded for only a short time in many infants, the evaluation of residual paralysis (presence or absence) may not be reliable. Pertinent clinical data from the study by Bates are presented in Table 24-7, and

these data show that more than one half of the cases resulted from maternal disease. Because others have identified congenital infection without symptomatic maternal infection, it is probable that infection in the mothers was the source for an even greater percentage of the neonatal illnesses. Because the incubation period of neonatal poliomyelitis has not been determined, it is difficult to know how many infants were infected in utero. Most illnesses occurring within the first 5 days of life probably were congenital. Most neonates had symptoms of fever, anorexia or dysphagia, and listlessness. Almost one half the infants described in this review died, and of those surviving, 48% had residual paralysis.

#### INAPPARENT INFECTION

Shelokov and Habel<sup>97</sup> followed a virologically proven infected newborn without signs of illness. The infant was normal when 1 year old. Wingate and co-workers<sup>107</sup> studied an infant delivered by cesarean section from a woman with poliomyelitis who died 1 hour after delivery. Her infant was treated with gamma globulin intramuscularly at the postnatal age of 21 hours. He remained asymptomatic; poliovirus 1 was recovered from a stool specimen on the fifth day of life.

#### INFECTION ACQUIRED IN UTERO

Elliott and colleagues<sup>111</sup> described an infant girl in whom "complete flaccidity" was observed at birth. This child's mother had mild paralytic poliomyelitis, with the onset of minor illness occurring 19 days before the infant's birth. Fetal movements had ceased 6 days before delivery, suggesting that paralysis had occurred at this time. On examination, the infant was severely atonic; when supported under the back, she was passively opisthotonic. Respiratory efforts were

Adapted from Bates T. Poliomyelitis in pregnancy, fetus, and newborn. *Am J Dis Child* 90:189, 1955.

abortive and confined to accessory muscles, and laryngoscopy revealed complete flaccidity in the larynx.

Johnson and Stimson<sup>104</sup> reported a case in which the mother's probable abortive infection occurred 6 weeks before the birth of the infant. The newborn was initially thought to be normal but apparently had no medical examination until the fourth day of life. At that time, the physician diagnosed a right hemiplegia. On the next day, a more complete examination revealed a lateral bulging of the right abdomen accompanied by crying and the maintenance of the lower extremities in a frog-leg position. Adduction and flexion at the hips were weak, and the knee and ankle jerks were absent. Laboratory studies were unremarkable except for the examination of the CSF, which revealed 20 lymphocytes/mm<sup>3</sup> and a protein concentration of 169 mg/dL. During a 6-month period, this child's paralysis gradually improved and resulted in only residual weakness of the left lower extremity.

Paresis of the left arm occurred in another child with apparent transplacentally acquired poliomyelitis shortly after birth.<sup>114</sup> The 2-day-old infant was quadriplegic, but patellar reflexes were present, and there were no respiratory or swallowing difficulties. This child had pneumonia when 3 weeks old, but general neurologic improvement occurred. Examination when the infant was 8 weeks old revealed bilateral atrophy of the shoulder girdle muscles. The CSF in this case revealed 63 leukocytes/mm<sup>3</sup>, with 29% of them polymorphonuclear cells, and a protein value of 128 mg/dL.

All three of the infants previously discussed were apparently infected in utero several days before birth. Their symptoms were exclusively neurologic; fever, irritability, and vomiting did not occur.

#### POSTNATALLY ACQUIRED INFECTION

In contrast to infections acquired in utero, those acquired postnatally are more typical of classic poliomyelitis. Shelokov and Weinstein<sup>99</sup> described a child who was asymptomatic at birth. Onset of minor symptoms in the mother occurred 3 weeks before delivery, and major symptoms occurred 1 day before delivery. On the sixth day of life, the infant became suddenly ill with watery diarrhea. He looked grayish and pale. On the next day, he was irritable, lethargic, and limp and had a temperature of 38° C. Mild opisthotonos and weakness of both lower extremities developed. He was responsive to sound, light, and touch. The CSF had an elevated protein level and an increased number of leukocytes. His condition worsened during a total period of 3 days, and then gradual improvement began. At 1 year, he had severe residual paralysis of the right leg and moderate weakness in the left leg.

Baskin and associates<sup>102</sup> described two infants with neonatal poliomyelitis. The first child, whose mother had severe poliomyelitis at the time of delivery, was well for 3 days and then developed a temperature of 38.3° C. On the fifth day of life, the boy became listless and cyanotic. CSF examination revealed a protein level of 300 mg/dL and 108 leukocytes/mm<sup>3</sup>. His condition worsened, and extreme flaccidity, irregular respiration, and progressive cyanosis developed; he died on the seventh day of life. The second infant was a boy who was well until he was 8 days old, but he then became listless and developed a temperature of 38.3° C. During the next 5 days, he developed flaccid quadriplegia; irregular, rapid, and shallow respirations; and an inability to swallow. The child died on

the 14th day of life. His mother had developed acute poliomyelitis 6 days before the onset of his symptoms.

Abramson and colleagues<sup>108</sup> reported four children with neonatal poliomyelitis, two of whom died. In three of the children, the illnesses were typical of acute poliomyelitis seen in older children; they were similar to the cases of Baskin and associates<sup>102</sup> described previously. The fourth child died at 13 days of age with generalized paralysis. The onset of his illness was difficult to define, and he was never febrile. Swarts and Kercher<sup>109</sup> also described a child whose illness had an insidious onset. When 10 days old, the child gradually became lethargic and anorectic and regurgitated formula through his nose. On the next day, flaccid quadriplegia developed. Winsser and associates<sup>115</sup> and Bates<sup>110</sup> reported infants with acute poliomyelitis with clinical illnesses similar to those that occur in older individuals.

#### VACCINE VIRAL INFECTIONS

Administration of oral polio vaccines to newborns has been carried out in numerous studies.<sup>118,179-191</sup> Vaccine viral infection occurs in newborns with all three types of poliovirus, although the rate of infection is less than that for immunized older children. This rate is governed by the dose of virus, transplacentally acquired maternal antibody, and antibody acquired from colostrum and breast milk. Although clinical illness rarely has resulted from attenuated polioviral infections in older children and adults, there is only one specific report of paralytic poliomyelitis in a newborn associated with infection with a vaccine viral strain.<sup>192</sup> In that case, the possible source for the infection was the recently vaccinated child of the baby-sitter. In a review of 118 cases of vaccine-associated paralytic poliomyelitis in the United States between 1980 and 1992, the age of patients ranged from 1 month to 69 years, but details about neonates were not presented.<sup>444</sup>

#### Manifestations of Specific Nonpolio Enteroviruses

##### COXSACKIEVIRUSES

**Coxsackievirus A.** There have been few reports of neonatal coxsackievirus A infections. Baker and Phillips<sup>337</sup> reported a small-for-gestational-age infant with pneumonia and a sepsis-like illness with disseminated intravascular coagulation. This newborn died on the second day of life, and when cultured, the CSF grew coxsackievirus A3. Balduzzi and Greendyke<sup>335</sup> recovered a coxsackievirus A5 from the stool of a 1-month-old child with sudden infant death. In a similar investigation of sudden infant death, Gold and co-workers<sup>336</sup> recovered coxsackievirus A4 from the brains of three infants. Coxsackievirus A8 was also recovered from the stool of a child in whom anorexia was observed on the day before death. Berkovich and Kibrick<sup>242</sup> reported a 3-day-old neonate with nonspecific febrile illness (38.3° C) who was infected with coxsackievirus A9. Coxsackievirus A9 was also recovered from an 11-day-old infant with rhinitis, lethargy, anorexia, and fever.<sup>243</sup> This illness lasted 3 days. Jack and associates<sup>236</sup> described a 3-day-old newborn with fever, cyanosis, and respiratory distress who died on the seventh day of life; an autopsy revealed bronchopneumonia. Coxsackievirus A9 was isolated from the feces on the fourth and sixth days of life.

Lake and associates<sup>340</sup> reported two neonates with coxsackievirus A9 infections, but no clinical details were

presented. Jenista and co-workers<sup>178</sup> recovered coxsackievirus A9 strains from seven nonhospitalized neonates who were thought to be well. In the Netherlands, a neonate with coxsackievirus A9 illness had pericarditis, meningitis, pneumonitis, and hepatitis; he recovered completely.<sup>410</sup> Krajdén and Middleton<sup>28</sup> described a neonate with a sepsis-like illness who died. Coxsackievirus A9 was recovered from the liver and lung. Morens<sup>378</sup> also reported a death associated with this same virus type. Eisenhut and colleagues<sup>338</sup> reported an outbreak that included four neonates with coxsackievirus A9 infections. One infant who had meningitis, myocarditis, and disseminated intravascular coagulation died. A second neonate had vomiting, rhinitis, and abdominal distention, and two neonates had asymptomatic infections. Forty-eight of 598 neonates admitted to a regular nursery in Bangkok, Thailand, in the spring of 1977 had herpangina.<sup>394</sup> Coxsackievirus A5 was isolated from nine specimens from the afflicted infants, and a rise in the serum antibody titer was identified in 10 instances. Helin and colleagues<sup>424</sup> described 16 newborns with aseptic meningitis caused by coxsackievirus A14. During a 2.5-year follow-up period, they all developed normally, and no sequelae were identified. Coxsackievirus A16 was recovered from one newborn with nonspecific illness; his mother had had hand-foot-and-mouth syndrome 4 days previously.<sup>230</sup>

**Coxsackievirus B1.** Coxsackievirus B1 has only occasionally been recovered from newborns (Table 24-8). Eckert and co-workers<sup>402</sup> recovered a coxsackievirus B1 strain from the stool of a 1-month-old boy with bronchitis. Jahn and Cherry<sup>211</sup> described a 4-day-old infant who became febrile and lethargic. This illness persisted for 5 days without other signs or symptoms. An examination of the CSF showed a slight increase in the number of leukocytes, and most were mono-

nuclear cells. Coxsackievirus B1 was recovered from the throat, stool, urine, and serum.

Wright and colleagues<sup>216</sup> reported an infant fatality associated with coxsackievirus B1 infection. This premature boy was well until he was 4 days old, when he had two episodes of cyanosis and apnea. After this, he became anorexic and listless and lost the Moro reflex. On the ninth day of life, he had shallow respirations, hepatomegaly, jaundice, petechiae, and thrombocytopenia. He was edematous and lethargic, and he had a temperature of 34.5° C, a pulse rate of 130 beats per minute, and a respiratory rate of 20 breaths per minute. He became weaker, unresponsive, and apneic and died. Positive laboratory findings included the following values: less than 10,000 platelets/mm<sup>3</sup>, 283 mg of CSF protein/dL; 20.5 mg of serum bilirubin/dL; and 100 units of serum aspartate aminotransferase. Autopsy revealed hepatic necrosis, meningoencephalitis, and myocarditis. Coxsackievirus B1 was recovered from the throat, urine, liver, lung, kidney, and brain.

Twin boys with a sepsis-like illness with hepatitis and disseminated intravascular coagulation have been reported.<sup>29</sup> The first twin died on the 16th day of life, and the second twin survived. Another set of twins had coxsackievirus B1 infections shortly after birth; one twin had myocarditis, and the other had hepatitis with subsequent progressive liver calcifications.<sup>342</sup> A third set of twins had coxsackievirus B1 infections with illness that began when they were 5 days old.<sup>395</sup> One twin had disseminated intravascular coagulation, and the other had meningitis. Three other newborns with fatal sepsis-like illnesses with hepatitis have been described.<sup>393,394</sup>

Isacsohn<sup>233</sup> described four severe cases of neonatal illnesses due to coxsackievirus B1; three of the four neonates died. Of the three fatalities, one was caused by myocarditis, and the other two resulted from multiorgan dysfunction. The surviving

infant had hepatitis, congestive heart failure, thrombocytopenia, and residual neurologic damage.

McLean and colleagues<sup>214</sup> described a male newborn who had a temperature of 39° C, vomiting, and diarrhea on the fourth day of life. When 6 days old, he appeared gray and mottled and developed shallow respirations. He died on the seventh day of life after increased respiratory distress (90 breaths per minute), hepatomegaly, generalized edema, and cardiac enlargement. Coxsackievirus B1 was recovered from the heart and brain.

Gear<sup>217</sup> studied an extensive epidemic of Bornholm disease related to coxsackievirus B1 in Johannesburg in the summer of 1960 to 1961. After the first coxsackievirus B1 isolations, the medical officers of the area were on the alert for nursery infections and the prevention of nursery epidemics. Despite careful isolation procedures, Gear<sup>217</sup> reported that infection "was introduced into all the large maternity homes in Johannesburg." About 20 cases of neonatal myocarditis were documented, as were three deaths. The isolation procedures apparently prevented secondary nursery cases.

Volakova and Jandasek<sup>218</sup> reported epidemic myocarditis related to coxsackievirus B1. Cherry and Jahn<sup>224</sup> described a child with a mild febrile exanthematous illness, which had its onset within 10 minutes of birth.

**Coxsackievirus B2.** The reported instances of coxsackievirus B2 infections in neonates are provided Table 24-8. In most instances, the infants had myocarditis or neurologic manifestations. Eleven of 12 of the infants with myocarditis died. The one child with myocarditis who survived was reexamined when 2 years old and was found to be normal.<sup>219</sup> This child's mother became ill with sore throat, coryza, and malaise on the day after delivery. When 3 days old, the child became febrile (38.9° C) and had periods of apnea and cardiac irregularities. The cry was "pained." The electrocardiogram showed a left-sided heart pattern in the V leads and T wave abnormalities. The child's symptoms lasted less than 48 hours. Coxsackievirus B2 was isolated from the nose, urine, throat, and CSF of the child and from the mother's stool. The mother breast-fed the infant (while she wore a mask) during her illness. A later specimen of breast milk was cultured for virus without successful recovery of an agent.

Puschak<sup>142</sup> reported a child who became febrile (39.5° C) 8 hours after birth. During the next 9 days, the infant's temperature fluctuated between 36.7° C and 38.9° C. The patient had no other symptoms. Serologic evidence of coxsackievirus B2 infection was found.

Johnson and associates<sup>420</sup> described a 1-month-old infant with aseptic meningitis who developed a persistent right facial paralysis. In a study of undifferentiated diarrheal syndromes, Ramos-Alvarez<sup>404</sup> observed a child with coxsackievirus B2 infection. Eilard and associates<sup>382</sup> reported a nursery outbreak in which 12 infants were infected. All had aseptic meningitis, and 2 also had myocarditis. One of the two infants died on the 13th day of life. One child with thrombocytopenia and respiratory failure died.<sup>340</sup>

**Coxsackievirus B3.** Neonatal infections with coxsackievirus B3 are summarized in Table 24-8. Most reported cases have been severe illnesses with myocarditis or meningoencephalitis, or both. One case involved sudden infant death,<sup>335</sup> in which coxsackievirus B3 was recovered from a pool of organs from an infant who died on the eighth day of life.

Tuuteri and co-workers<sup>229</sup> studied a nursery outbreak of coxsackievirus B3 infection. Seven children had mild disease characterized by anorexia, listlessness, and fever, and two infants had fatal myocarditis. Of the 57 reported neonatal infections with coxsackievirus B3, 30 deaths occurred, and most were associated with myocarditis and sepsis-like illness. Three infants had febrile illnesses with meningitis and were reported to have suffered no residual effects; long-term follow-up is not available, however.<sup>145,212</sup>

Isacsohn and colleagues<sup>233</sup> reported two neonates with multiorgan dysfunction who survived. A full-term boy delivered by caesarean section had scattered vesicular lesions at birth.<sup>417</sup> New lesions appeared over a 5-day period, and the rash lasted for 10 days. The child had no other symptoms, and the mother had no febrile illness during pregnancy.

Chesney and associates<sup>419</sup> studied a 3-week-old girl with meningoencephalitis. This child had hypoglycorrhachia; the CSF glucose value on the sixth day of illness was 23 mg/dL, with a corresponding blood glucose level of 78 mg/dL. As described in another review,<sup>340</sup> two infants who died had thrombocytopenia and respiratory failure; a clinical picture suggestive of necrotizing enterocolitis also was observed.

During a 5-year period in Toronto, Krajden and Middleton<sup>28</sup> assessed 24 neonates with enteroviral infections who were admitted to the Hospital for Sick Children. Nine children were infected with coxsackievirus B3; of these, two infants had meningitis, three had myocarditis, and four had a sepsis-like illness. Of this group, one infant with meningitis, one with myocarditis, and all with sepsis-like illness died. All the neonates with sepsis-like illness had clinical evidence of multiorgan involvement; they had respiratory distress, hepatomegaly, hemorrhagic manifestations, and congestive heart failure. Two neonates with herpangina and coxsackievirus B3 infections were described in an outbreak involving 25 infants.<sup>398</sup>

**Coxsackievirus B4.** Table 24-8 summarizes coxsackievirus B4 neonatal infections. Most were severe and frequently were fatal illnesses with neurologic and cardiac involvement. An infant with less severe disease was described by Sieber and associates.<sup>207</sup> This child was well until 6 days after delivery, when he developed pharyngitis, diarrhea, and gradually increasing lethargy. This was followed by fever for 36 hours. No other signs or symptoms were observed, and the child was well when 11 days old. He had virologic and serologic evidence of coxsackievirus B4 infection.

Winsser and Altieri<sup>197</sup> studied an infant who suddenly became cyanotic and convulsed and died at 2 days of age. At autopsy, the only findings were bronchopneumonia, congestive splenomegaly, and chronic, interstitial pancreatitis. Coxsackievirus B4 was isolated from the spleen.

Barson and associates<sup>411</sup> reported the survival of an infant with myocarditis. Cardiac calcification was revealed on radiographs when the child was 4 weeks old, and the electrocardiogram revealed a left bundle branch block. When the child was 7 months old, the conduction defect remained, but the myocardial calcification had resolved.

**Coxsackievirus B5.** The spectrum of neonatal infection with coxsackievirus B5 is greater than that with the other coxsackieviruses B. Studies are summarized in Table 24-8. Meningitis and encephalitis are common neonatal mani-

festations of coxsackievirus B5 infection.\* Nursery epidemics have been observed. Rantakallio and associates<sup>231</sup> studied 17 infants in one nursery with aseptic meningitis. None of the infants was severely ill. All had fever, with a temperature of 38° C to 40° C. Eleven of the 17 neonates were boys. Signs included irritability, nuchal rigidity, increased tone, anorexia, opisthotonos, whimpering, loose stools, and diminution of alertness. In another nursery outbreak, Farmer and Patten<sup>380</sup> found 28 infected infants. Of the group of 28, 15 had aseptic meningitis, 4 had diarrhea, and 9 had no signs of illness. Six years later, the 15 children who had had meningitis were studied. Thirteen were found to be physically normal and to have normal intelligence. Two children had intelligence levels below the mean for the group and had residual spasticity. At the time of the initial illness, these two infants and one additional child were twitching, irritable, or jittery.

Swender and associates<sup>234</sup> studied seven cases of aseptic meningitis in an intensive care nursery during a 6-week period during the summer of 1972. Two of the infants had apnea. One of the infants had a CSF glucose level of 12 mg/dL. During a community outbreak of coxsackievirus B5 infections, Marier and colleagues<sup>391</sup> studied 32 infants with aseptic meningitis. In this group, 36% had CSF leukocyte counts of 500 cells/mm<sup>3</sup> or higher, and in 19%, neutrophils accounted for 50% or more of the count. In 12% of patients, the CSF glucose level was less than 40 mg/dL. Thirty-eight percent of the infants had blood leukocyte counts of 15,000 cells/mm<sup>3</sup> or higher values.

Of particular interest is the observation of exanthem in four reports. Cherry and co-workers<sup>415</sup> described a 3-week-old boy with fever, a maculopapular rash, and enlarged cervical and postauricular lymph nodes. Examination of the CSF revealed 141 leukocytes/mm<sup>3</sup>, of which 84% were lymphocytes, and a protein value of 100 mg/dL. An electrocardiogram was normal. In this child, the rash appeared before the fever. Coxsackievirus B5 was isolated from the pharynx and the CSF. Nogen and Lepow<sup>212</sup> reported an infant with a similar illness. This child had a nonspecific erythematous papular rash on the face and scalp. One week later, he became febrile and irritable. The CSF contained 440 white blood cells/mm<sup>3</sup>, and 96% of them were mononuclear. Virus was isolated from the feces, throat, and CSF.

Artenstein and associates<sup>198</sup> reported a 23-day-old girl with a fever and an erythematous macular rash that spread from the scalp to the entire body, except the palms and soles, and lasted 4 days. Coxsackievirus B5 was recovered from the stool, but no evidence of serum antibody to this virus was found. McLean and co-workers<sup>147</sup> also described a child with a papular rash on the trunk and limbs that was present at birth. On the fourth day of life, the rash had disappeared, but the patient then developed a temperature of 39.4° C. Irritability, twitching, and fullness of the anterior fontanelle were observed, and CSF examination showed meningitis. During an 8-day period, the child had repeated episodes of vomiting and diarrhea. On the 11th day of life, the infant had hyperpnea, tachycardia, and an enlarging liver. The child died on the 13th day of life. Autopsy revealed extensive encephalitis and focal myocardial necrosis. Virus was recovered from the brain, heart, lungs, and liver.

It appears that neonatal infection with coxsackievirus B5 is less likely to be fatal than infection with the other coxsackieviruses B. Only 6 of 36 infants described in Table 24-8 died. In contrast to coxsackieviruses B2, B3, and B4, coxsackievirus B5 appears to be more neurotropic than cardiotropic.

#### ECHOVIRUSES

**Echovirus 1.** Dömök and Molnár<sup>228</sup> described aseptic meningitis related to echovirus 1.

**Echovirus 2.** Krajden and Middleton<sup>28</sup> described three infants with echovirus 2 infections. Two of the neonates had meningitis and recovered. The third child, who died, had a sepsis-like illness. Virus was isolated from the CSF, lung, liver, and urine. One other neonate with echovirus 2 infection has been observed, but no details are available.<sup>340</sup>

**Echovirus 3.** In the summer of 1970, Haynes and co-workers<sup>421</sup> studied an epidemic of infection caused by echovirus 3. Three infected neonates were observed, all of whom had meningitis. One child, a full-term girl, developed tonic seizures and an inability to suck on the third day of life. The serum bilirubin level was 28 mg/dL. Shortly thereafter, the child became cyanotic, flaccid, and apneic and developed a bulging anterior fontanelle; she was in shock. She received assisted ventilation with a respirator for 3 days. When the child was 1 month old, severe neurologic damage with developing hydrocephalus was obvious. Echovirus 3 was recovered from the CSF, and the CSF protein level was 880 mg/dL on the sixth day of life.

The other two infants in this study apparently had uncomplicated aseptic meningitis. The CSF findings in one child revealed 1826 white blood cells/mm<sup>3</sup>, and 91% of them were polymorphonuclear cells. The other child had 320 cells/mm<sup>3</sup>, 98% of which were polymorphonuclear cells.

A 4-day-old infant from whom echovirus 3 was recovered from the CSF has been reported.<sup>28</sup> This child had fewer than 3 white blood cells/mm<sup>3</sup> in the CSF. Other neonates with echovirus 3 infection have been observed, but no details are available.<sup>178,340</sup>

**Echovirus 4.** Linnemann and associates<sup>383</sup> studied 11 infants with echovirus 4 infections. All infants had fevers, and most were irritable. Four infants had a fine maculopapular rash, which was located on the face or abdomen, or both. In two children, the extremities were also involved. Other neonates with echovirus 4 infections have been reported, but details of their illness are not available.<sup>178,340</sup>

**Echovirus 5.** There have been six reports of neonatal illnesses associated with echovirus 5 infections.<sup>340,348,379,432</sup> In one nursery epidemic, six infants were involved.<sup>241</sup> All infants had fever (38.3° C to 39.7° C) that lasted 4 to 8 days. Two neonates had tachycardia that was disproportionately rapid when compared with the degree of fever, but in neither was there evidence of myocarditis. Four infants had splenomegaly and enlarged lymph nodes; these findings persisted for several weeks.

In 1966 (July to October), an epidemic of echovirus 5 infection involved 23% of the infants in the maternity unit at the Royal Air Force Hospital in Changi, Singapore.<sup>240</sup> Fifty-six infants were symptomatically infected, and 10 were asymptotically infected. Those who were ill were 2 to 12 days old at the onset of disease. All 56 symptomatic infants

\*See references 28, 139, 147, 149, 200, 202, 231, 232, 234, 380, 391, and 423.

had fever; 87% of them had a temperature of 38.3° C or greater. The mean duration of fever was 3.5 days, with a range of 2 to 7 days. Twenty infants had a faint erythematous macular rash that was most prominent on the limbs and buttocks but also occurred on the trunk and face. The rash, which began 24 to 36 hours after the beginning of fever, lasted 48 hours. Diarrhea occurred in 17 infants, 4 of whom passed blood and mucus. Vomiting was observed in about one half the neonates. All infants apparently recovered completely.

One newborn girl had a nonspecific, biphasic febrile illness.<sup>327</sup> Echovirus 5 was recovered from the CSF, but the cell count, protein level, and glucose value were normal.

Another study included a 9-day-old infant with aseptic meningitis.<sup>432</sup> During an epidemiologic investigation in Rochester, New York, 13 of 75 enteroviral isolates were echovirus 5.<sup>178</sup> Six of the infants were asymptomatic; no clinical details of the other seven patients were presented. A neonate with sepsis-like illness and hepatic failure died 9 days after birth.<sup>348</sup>

**Echovirus 6.** Sanders and Cramblett<sup>243</sup> reported a boy who was well until 9 days old, when he developed a fever (38° C), severe diarrhea, and dehydration. His white blood cell count was 27,900 cells/mm<sup>3</sup>, and virologic and serologic evidence of echovirus 6 infection was found. Treatment consisted of intravenous hydration, to which there was a good response. Krous and colleagues<sup>343</sup> described an infant who died on the ninth day of life with a sepsis-like illness. The child had meningitis, disseminated intravascular coagulation, hepatic necrosis, and adrenal and renal hemorrhage. Ventura and associates<sup>348</sup> reported the death of a full-term neonate with sepsis-like syndrome who at postmortem examination had massive hepatic necrosis, adrenal hemorrhagic necrosis, renal medullary hemorrhage, hemorrhagic noninflammatory pneumonia, and severe encephalomalacia. Yen and co-workers<sup>168</sup> reported a premature boy who developed a sepsis-like illness on the fifth day of life. This infant had hepatic failure and was treated with intravenous immune globulin. He recovered gradually, but on the 62nd day of life, he died of a nosocomial *Enterobacter cloacae* infection. Echovirus type 6 has been associated with neonatal illness on two other occasions, but no clinical details are available.<sup>340,383</sup>

**Echovirus 7.** Piraino and colleagues<sup>165</sup> reported three infants with echovirus 7 infections. All three had fever, one had respiratory distress and exanthem, and one had irritability and loose stools. Two neonates with fatal sepsis-like illnesses with massive disseminated intravascular coagulation have been reported.<sup>263,354</sup> One neonate with severe hepatitis was treated with pleconaril and survived.<sup>407</sup>

**Echovirus 8.** In a search for etiologic associations in infantile diarrhea, Ramos-Alvarez<sup>404</sup> identified one neonate from whom echovirus 8 was recovered from the stool. The antibody titer to this virus rose fourfold.

**Echovirus 9.** Echovirus 9 is the most prevalent of all the enteroviruses (see Table 24-4). From 1955 to 1958, epidemic waves of infection spread throughout the world.<sup>445</sup> Since that time, echovirus 9 has been a common cause of human illness. Despite its prevalence and its frequent association with epidemic disease, descriptions of neonatal illness are uncommon. Unlike experiences with several other enteroviruses, new-

born nursery epidemics caused by echovirus 9 have not often been described.

Neonatal echovirus 9 experiences are provided in Table 24-9. Moscovici and Maisel<sup>156</sup> described an asymptomatic infant with echovirus 9 infection. When echovirus 9 was prevalent in Erie County, New York, during the summer of 1971, seven neonatal cases were observed.<sup>403</sup> Four children had aseptic meningitis, but only moderate elevations of CSF protein values and white blood cells were observed. One child, a 15-day-old infant, had radiologic evidence of bronchopneumonia, and two infants had gastroenteritis. Rawls and co-workers<sup>350</sup> described an infant who was well until the seventh day of life, when progressive lethargy, anorexia, and irritability developed. The child became moribund, and jaundice, scattered petechiae, and hypothermia were observed. The pulse rate was 90 beats per minute, the respiratory rate was 40 breaths per minute, and the liver was enlarged. The infant died 3 days after the onset of symptoms. Echovirus 9 was recovered from the lung, brain, and CSF. Cho and colleagues<sup>389</sup> described a similar severe neonatal illness in a child from whom echovirus 9 was recovered from the CSF. This child was hypothermic and hypotonic on the third day of life. He had bilateral pneumonia and leukopenia. After a stormy course, which included an exchange transfusion for suspected sepsis and mechanical ventilation for apnea, he eventually recovered.

A child who became febrile (38.3° C), irritable, and anorectic on the sixth day of life was described by Jahn and Cherry.<sup>211</sup> This child became asymptomatic within 2 days; echovirus 9 was recovered from the throat, feces, serum, and CSF. Eichenwald and Kostevalov<sup>157</sup> reported two children with mild irritability, fever, and diarrhea and a third child with diarrhea and convulsions in whom laboratory findings showed aseptic meningitis. Haynes and colleagues<sup>422</sup> studied a large outbreak of meningoencephalitis caused by echovirus 9 and described nine children who were 2 weeks to 2 months old. Cheeseman and associates<sup>161</sup> studied a neonate with fatal interstitial pneumonia, and Krajden and Middleton<sup>28</sup> reported a 4-day-old infant from whom echovirus 9 was recovered from the CSF. This child had fewer than 3 white blood cells/mm<sup>3</sup> in the CSF.

**Echovirus 11.** Neonatal illness associated with echovirus 11 infection has been interesting and varied. Reported cases are

listed in Table 24-10. Eleven of the reports involved nursery outbreaks, and in five reports, the neonatal cases were part of a larger community epidemic. Miller and associates<sup>238</sup> studied an epidemic of aseptic meningitis and other acute febrile illnesses in New Haven, Connecticut, in the summer of 1965. This epidemic was unique in that one half of the patients with meningitis from whom virus was isolated were younger than 6 months. The echovirus 11 in this epidemic was a prime strain. Three neonatal illnesses were reported. One of the patients, a 1-month-old infant, was initially irritable and feverish and had diarrhea. Chest radiographs revealed bilateral

pneumonitis. A generalized, discrete maculopapular rash, which lasted 24 hours, was seen on the third day of illness. Fever persisted for 6 days. A 12-day-old girl had fever (39.4°C) lasting 1 day but no other findings. Echovirus 11 was recovered from her throat. Another 1-month-old infant had aseptic meningitis.

Sanders and Cramblett<sup>243</sup> described two infants with diarrhea. Both infants were acutely ill; one was jaundiced and irritable and had feeding difficulty. In another study, two infants with echovirus 11 infections had diarrhea.<sup>242</sup> One infant had a temperature of 39.3°C and a “stuffy nose,” and

the other had a temperature of 39.8° C and aseptic meningitis. Cramblett and co-workers<sup>235</sup> observed an outbreak of nosocomial infections caused by echovirus 11 in a neonatal intensive care unit. In a 1-month-old, premature infant with frequent apneic episodes, the CSF contained 2200 white blood cells/mm<sup>3</sup>, 89% of them polymorphonuclear cells, and the protein level was 280 mg/dL. The infant made a gradual recovery. Echovirus 11 was isolated from the CSF and stool. In another premature infant, apneic episodes and bradycardia suddenly began on the 20th day of life. Fever developed, the apneic spells continued, and digitalis therapy was necessary because of congestive heart failure. Examination of the CSF revealed aseptic meningitis, and echovirus 11 was recovered from the CSF, throat, and stool. A third child with aseptic meningitis had an exanthem. The disease began suddenly, and the child had shallow respirations and poor skin color. On the next day, generalized seizures occurred, and a maculopapular rash developed on the trunk, extremities, and face. The patient made a gradual recovery. A fourth child had a severe, nonspecific febrile illness.

A particularly noteworthy finding in neonatal echovirus 11 infection has been severe sepsis-like illness with hepatitis or hepatic necrosis, disseminated intravascular coagulation, and extensive hemorrhagic manifestations.<sup>162-164,250,251,254,343-348,351</sup> During the past 15 years, more than 40 such cases have been described, and most of the illnesses have been fatal.

Hercik and co-workers<sup>239</sup> reported an epidemic of respiratory illness in 22 newborns. Six of the infants were severely ill, and one subsequently died. The incubation period varied from 17 hours to 9 days, with an average of 3 days. Seven infants had an interstitial pneumonia, and all had rhinitis, pharyngitis, and vomiting. Toce and Keenan<sup>167</sup> reported two newborns with respiratory distress and pneumonia at birth. Both infants died of their echovirus 11 infections. Tarcan and colleagues<sup>433</sup> described a 5-day-old boy who developed fever and diarrhea. He developed a maculopapular rash on the face, generalized petechiae and hemorrhagic bullae, and pancytopenia due to bone marrow failure. This infant was treated with intravenous immune globulin and recovered.

**Echovirus 13.** Before 2000, infection with echovirus 13 was rare in neonates. The virus was isolated from one asymptomatic infant in a neonatal surveillance study.<sup>178</sup> In 2001 in the United States, echovirus 13 was the leading cause of aseptic meningitis, and during 2001 and 2002, aseptic meningitis outbreaks with this agent occurred in a number of countries.<sup>440-443</sup> A substantial number of cases were infants who were 3 months old or younger.<sup>440</sup> A 28-day-old boy in Tennessee had aseptic meningitis and hepatitis.<sup>441</sup> Neonatal cases were reported in Israel and Spain, but details were not presented.<sup>442,443</sup>

**Echovirus 14.** Hughes and colleagues<sup>159</sup> reported an infant boy who became febrile (38° C) and had cyanotic episodes on the third day of life. When 4 days old, his temperature was 38.9° C, and he experienced recurrent apneic spells. Liver enlargement, hypothermia, bradycardia, periodic breathing, and spontaneous ecchymoses developed, and the infant died on the seventh day of life. Laboratory studies revealed the presence of leukopenia and thrombocytopenia, and autopsy showed severe hepatic necrosis. Drouhet<sup>446</sup> described a child with aseptic meningitis and echovirus 14 infection, and

Hinuma and associates<sup>381</sup> reported four newborns with apparent asymptomatic echovirus 14 infections.

**Echovirus 16.** In 1974, Hall and colleagues<sup>385</sup> studied five neonates with echovirus 16 infections. All five infants were admitted to the hospital because sepsis was suspected. Four of five were febrile, all were lethargic and irritable, and two had abdominal distention. Three of the neonates had erythematous maculopapular exanthems, and in two, the rash appeared after or with defervescence. Leukocyte counts in four infants revealed an increased percentage of band form neutrophils. Two neonates had aseptic meningitis. Lake and associates<sup>340</sup> observed three infants with echovirus 16 infections. In their study, clinical findings were not itemized by virus type, but it is inferred that sepsis-like illnesses occurred.

**Echovirus 17.** Neonatal infection with echovirus 17 has been observed by three investigators. Cherry and co-workers<sup>141</sup> reported two ill infants. A 19-day-old infant developed otitis media 5 days after his mother had a flulike illness. Echovirus 17 was isolated from his feces, and serologic evidence of echovirus 17 infection was found in the infant and the mother. The second child had a nonspecific febrile illness at the age of 4 weeks, which was severe enough to require hospitalization. Virus was isolated from the infant's throat, feces, and serum.

Sanders and Cramblett<sup>243</sup> described two neonates with exanthem associated with echovirus 17. The first child, a 3-week-old girl, became drowsy, anorectic, and febrile. She had a fine maculopapular rash on the trunk, a slightly injected pharynx, and a few petechiae on the soft palate. She remained febrile for 5 days. Echovirus 17 was recovered from the CSF and the feces. The second infant became ill when 3 weeks old. His symptoms were mild rhinitis and cough followed by lethargy and refusal to eat. Four days after the onset of symptoms, his temperature was 39° C, and his respiratory rate was 60 breaths per minute. A fine maculopapular rash appeared on the trunk, and radiographs revealed an infiltrate in the right lung. The patient's course was uneventful, and he was much improved 12 days after the onset of symptoms.

Faulkner and van Rooyen<sup>247</sup> described an outbreak of echovirus 17 infection with illness in a nursery in mid-August of 1971. Seven infants were involved, including one with aseptic meningitis who was 7 weeks old. All the infants had fever, four had central nervous system signs, three had abdominal distention, four had diarrhea, and three had a rash. One other infant from another community was also studied by the investigators. This child had a febrile pneumonitis when 3.5 weeks old. The findings abated in 5 days, but the child suddenly died 6 days later. Autopsy revealed interstitial pneumonitis with extensive edema and scattered petechial hemorrhages of the viscera. Echovirus 17 was isolated from the liver, lung, spleen, and kidney.

**Echovirus 18.** In 1958, Eichenwald and colleagues<sup>244</sup> described epidemic diarrhea associated with echovirus 18 infections. In a nursery unit of premature infants, 12 of 21 were mildly ill. Neither temperature elevation nor hypothermia occurred. Six infants were lethargic and listless, and two developed moderate abdominal distention. The diarrhea lasted 1 to 5 days; there were five or six watery, greenish stools per day, occasionally expelled explosively. In two

infants, a small amount of blood was seen in the stools, but there was no mucus or pus cells. Five other infants in another nursery had similar diarrheal illness. Echovirus 18 was recovered from all ill infants.

Medearis and co-workers<sup>401</sup> reported a 3-week-old girl with fever, irritability, lethargy, pharyngitis, and postnasal drainage. Admitted to the hospital because of apneic spells, she developed a generalized erythematous blotchy macular rash and had frequent stools. The illness lasted about 7 days. Echovirus 18 was recovered from the blood, throat, and feces. Berkovich and Kibrick<sup>242</sup> found echovirus 18 in the stool of a 12-day-old twin infant with fever and a red throat. The relationship of echovirus 18 to the illness is uncertain because the patient's twin was infected with echovirus 11, and the patient also had serologic evidence of echovirus 11 infection. The fever and red throat may have been caused by echovirus 11 rather than echovirus 18 infection. Wilfert and associates<sup>425</sup> observed a 9-day-old infant with aseptic meningitis.

**Echovirus 19.** Cramblett and co-workers<sup>399</sup> described two neonates with echovirus 19 infections. One child had an upper respiratory infection, cough, and paroxysmal atrial tachycardia. The other child also had an upper respiratory infection, but in addition to echovirus 19 infection, coxsackievirus B4 was recovered from the throat of this infant. Butterfield and associates<sup>245</sup> isolated echovirus 19 post mortem from the brain, lung, heart, liver, spleen, lymph nodes, and intestine of a premature infant who had cystic emphysema. The relationship between the generalized viral infection and the pulmonary disease is not understood.

Philip and Larson<sup>160</sup> reported three catastrophic neonatal echovirus 19 infections, which resulted in hepatic necrosis and massive terminal hemorrhage. One infant, infected in utero, was symptomatic at birth. The Apgar score was 3, and multiple petechiae were observed. The infant had generalized ecchymoses and apneic episodes and died when 3.5 hours old. Thrombocytopenia was identified, and echovirus 19 was isolated from the brain, liver, spleen, and lymph nodes. The other two infants who died of echovirus 19 infection were twins. They were normal during the first 3 days of life but then became mildly cyanotic and lethargic. Shortly thereafter, apneic episodes occurred, and jaundice and petechiae developed. Both twins became oliguric, and they died on the eighth and ninth days of life, with severe gastrointestinal bleeding. Both twins were thrombocytopenic, and virus was recovered from systemic sites in both. Two similar catastrophic cases have been described.<sup>406</sup>

Purdham and associates<sup>255</sup> reported an outbreak of echovirus 19 in a neonatal unit in which 12 infants were affected. Eleven infants were febrile, 10 were irritable, 7 had marked abdominal distention with decreased bowel sounds, and 5 had apneic episodes. Bacon and Sims<sup>392</sup> described two neonates with sepsis-like illness. The infants were cyanotic with peripheral circulatory failure. In another study involving the same echovirus 19 epidemic, five infants younger than 3 months were reported.<sup>390</sup> All had sepsis-like illness with hypotonia and peripheral circulatory failure. Two infants had aseptic meningitis, and two others had diarrhea.

**Echovirus 20.** Eichenwald and Kostevalov<sup>157</sup> recovered echovirus 20 from four asymptomatic infants younger than 8 days (see "Cloud Baby"). Five neonates with severe illness

due to echovirus 20 have also been described.<sup>352,353</sup> All had hepatitis, and two died.

**Echovirus 21.** Jack and co-workers<sup>236</sup> recovered echovirus 21 from the feces of a 7-day-old infant with jaundice and diarrhea. No other details of the child's illness are available. Chonmaitree and associates<sup>412</sup> studied a 19-day-old infant with aseptic meningitis and rash, and Georgieff and colleagues<sup>351</sup> reported a newborn with fulminant hepatitis. Lake and colleagues<sup>340</sup> also mentioned one infected infant but presented no specific details.

**Echovirus 25.** Linnemann and colleagues<sup>383</sup> reported one neonate with echovirus 25 infection. They gave no virus-specific details except that fever and irritability occurred.

**Echovirus 30.** Matsumoto and associates<sup>428</sup> described a nursery outbreak involving 11 infants during a 2-week period. All the neonates had aseptic meningitis, and all recovered. Two symptomatic and six asymptomatic neonates were reported in the Rochester, New York, surveillance study.<sup>178</sup>

**Echovirus 31.** McDonald and associates<sup>256</sup> described three neonates in an intensive care nursery with echovirus 31 infections. One infant had a fatal encephalitis-like illness, with hypertonicity, hyperreflexia, and apneic spells. The other two infants also experienced apneic spells, and in addition, one had pneumonia and meningitis.

**Echovirus 33.** In a study of epidemic illness related to echovirus 33 disease in the Netherlands, Kapsenberg<sup>249</sup> stated that 7- to 8-day-old neonates in a maternity ward had a febrile illness. No further data were presented.

#### ENTEROVIRUS 71

Schmidt and colleagues<sup>426</sup> mentioned one 3-week-old infant with meningitis and enterovirus 71 infection. Chonmaitree and colleagues<sup>405</sup> described one 9-day-old neonate with aseptic meningitis and one 14-day-old infant with gastroenteritis from enterovirus 71. Chen and associates<sup>418</sup> reported a child with bilateral lower limbs weakness in association with the hand-foot-and-mouth syndrome.

#### PARECHOVIRUSES

**Parechovirus 1.** Parechovirus 1 has been associated with three epidemics of nursery infections. During a survey of perinatal virus infections, 44 infants were found to be infected with parechovirus 1 during a study period from May to December 1966.<sup>236</sup> The virus prevalence and the incidence of new infections during this period were fairly uniform. No illness was attributed to parechovirus 1 infection, and the virus disappeared from the nursery in mid-December of 1966. Berkovich and Pangan<sup>237</sup> studied respiratory illnesses in premature infants and reported 64 infants with illness, 18 of whom had virologic or serologic evidence of parechovirus 1 infection. Many had high but constant levels of serum antibody to parechovirus 1. Some of these infants were probably also infected with parechovirus 1. The children with proven parechovirus 1 infections could not be clinically differentiated from those without evidence of parechovirus 1 infection. Of 18 infants with documented parechovirus 1 infections, 90% had coryza, 39% had pneumonia, and 11% had morbilliform rash or conjunctivitis, or both. In contrast to the studies of Jack and co-workers,<sup>236</sup> only 3 of 35 asymptomatic infants were found to be infected

with parechovirus 1. Nakao and associates<sup>246</sup> recovered parechovirus 1 from 29 premature infants. Many of the infected infants were asymptomatic, and those who were ill had only mild symptoms of coryza, cough, and diarrhea. Jenista and colleagues<sup>178</sup> described 17 parechovirus 1 infections in nonhospitalized neonates. Clinical details were not presented, but it appears that all of these infants were asymptomatic. Parechovirus 1 infection was associated with a nosocomial necrotizing enterocolitis outbreak.<sup>409</sup>

**Parechovirus 2.** Ehrnst and Eriksson<sup>437</sup> reported a 1-month-old girl with encephalopathy resulting from a nosocomial parechovirus 2 infection. No further details of this case were provided.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

### Clinical Diagnosis

The clinical differentiation of neonatal infectious diseases frequently seems to be an impossible task. Although it is true that treatable bacterial and viral illnesses should always be considered and treated first, it is also true that when all the circumstances of a particular neonatal illness are considered, enterovirus diseases can be suspected on clinical grounds. The most important factors in clinical diagnosis are season of the year, geographic location, exposure, incubation period, and clinical symptoms.

In temperate climates, enteroviral prevalence is distinctly seasonal, and disease is usually seen in the summer and fall. Neonatal enterovirus disease is unlikely in the winter. In the tropics, enteroviruses are prevalent throughout the year, and the season therefore is not helpful diagnostically.

As with all infectious illnesses, knowledge of exposure and incubation time is important. A careful history of maternal illness is vital, particularly the symptoms of maternal illness. For example, nonspecific mild febrile illness in the mother that occurs in the summer and fall should warn of the possibility of more severe neonatal illness. More specific findings in the mother (e.g., aseptic meningitis, pleurodynia, herpangina, pericarditis, myocarditis) should alert the clinician to look for more specific enteroviral illnesses. Minor illness in nursery personnel during enteroviral seasons and the short incubation period of enteroviral infections should be taken into consideration. Manifestations of neonatal nonpolio enteroviral infections are given in Table 24-5.

### Laboratory Diagnosis

#### Virus Isolation

Most viral diagnostic laboratories have facilities for the recovery of most enteroviruses that cause congenital and neonatal illness. Three tissue culture systems—primary rhesus, cynomolgus, or African green monkey kidney tissue culture; a diploid, human embryonic lung fibroblast cell strain; and the RD cell line—allow the isolation of all polioviruses, coxsackieviruses B, echoviruses, newer enteroviruses, parechoviruses, and many coxsackieviruses A. In a 1988 study in which Buffalo green monkey kidney cells and subpassages of primary human embryonic kidney cells were used in addition to primary monkey kidney and human diploid

fibroblast (MRC-5) cells, the enterovirus recovery rate was increased by 11%.<sup>447</sup> For a complete diagnostic isolation spectrum, suckling mouse inoculation should also be performed. Optimally, at least one blind passage should be carried out in each of the culture systems.

Proper selection and handling of specimens are most important in the isolation of viruses from ill neonates. Because infection in neonates tends to be generalized, collection of material from multiple sites is important. Specimens should be taken from any or all of the following: nasopharynx, throat, stool, blood, urine, CSF, and any other body fluids that are available. Swabs from the nose, throat, and rectum should be placed in a transport medium.

Transport medium provides a protective protein, neutral pH, and antibiotics for control of microbial contamination and, most importantly, prevents desiccation. Many viral transport and storage media are commercially available or are prepared readily in the laboratory; their utility has been reviewed elsewhere.<sup>448</sup> Convenient and practical collection devices, such as the Culturette (Becton-Dickinson, Cockeysville, Md) or Virocult (Medical Wire and Equipment Co., Victory Gardens, NY), consist of a swab, usually Dacron or rayon, on a plastic or aluminum shaft accompanied by a self-contained transport medium (Stuart or Amies) and are routinely available in most hospitals for bacteriologic culture. Calcium alginate swabs, which are toxic to herpes simplex virus, and wooden shafts, which may be toxic for viruses and the cell culture system itself, should not be used. Saline or holding media that contain serum also should be avoided. Useful liquid transport media (2-mL aliquots in screw-capped vials) consist of tryptose phosphate broth with 0.5% bovine albumin; Hanks' balanced salt solution with 5% gelatin or 10% bovine albumin; or buffered sucrose phosphate (0.2 M, 2-SP),<sup>448,449</sup> which has been used as a combined transport for viral, chlamydial, and mycoplasmal culture requests and is appropriate for long-term frozen storage of specimens and isolates.<sup>450</sup>

Fluid specimens should be collected in sterile vials. Specimens of autopsy material are best collected in vials that contain transport medium. In general, specimens should be refrigerated immediately after collection and during transportation to the laboratory. Specimens should not be exposed to sunlight during transportation. If an extended period is likely to elapse before a specimen can be processed in the laboratory, it is advisable to ship and store it frozen.

Contrary to popular belief, evidence of enteroviral growth from tissue cultures takes only a few days in many cases and less than a week in most.<sup>451</sup> The use of the spin amplification, shell vial technique, and monoclonal antibodies has significantly reduced the time for detection of enteroviral cultures.<sup>59,452</sup> After isolation of an enterovirus, identification of its type is conventionally done by neutralization, which is unfortunately an expensive and lengthy process.

#### Rapid Virus Identification

Because of the number of different serotypes of enteroviruses, the use of immunofluorescence, agglutination, counter-immunoelectrophoresis, and ELISA techniques for the direct detection of antigen in suspected enteroviral infections has not been useful. Nucleic acid techniques with cDNA and RNA probes have been useful for the direct identification of enteroviruses.<sup>76,453-456</sup> Of most importance has been the

development of numerous PCR techniques. Since 1990, innumerable reports have described enteroviral PCR methods and their use in identifying enterovirus RNA in clinical specimens.<sup>49-62,457-465</sup> PCR has proved most useful for the direct identification of enteroviruses in the CSF of patients with meningitis. Compared with culture of CSF specimens, PCR is more rapid and sensitive, and the specificity is equal.

PCR also has proved useful in the identification of enteroviruses in blood, urine, and throat specimens.<sup>31,51,56,58,459,460</sup> Particularly impressive are the findings of Byington and associates.<sup>51</sup> Using PCR on specimens of blood and CSF, they found that more than 25% of infants admitted to the hospital for suspected sepsis in 1997 had nonpolio enterovirus infections. Based on this study and the work of Adr oletti and co-workers,<sup>52</sup> I believe the general workup for febrile neonates hospitalized for possible sepsis should include PCR for enteroviruses in blood and CSF. This is most important during enterovirus season (summer and fall in temperate climates), but because enteroviral circulation continues all year, it is reasonable to also perform PCR in the off seasons. Although PCR detects enterovirus RNA, the specific enteroviral type is not identified. Because of this shortcoming, I recommend that conventional culture should be performed along with PCR.

PCR has also identified enteroviruses in frozen and formalin-fixed biopsy and autopsy specimens of myocardium.<sup>51,56,58,459,460</sup> In one study, enteroviruses were identified in myocardial tissue from four neonates who died of myocarditis.<sup>460</sup> In one case, the specimen was obtained during life by a right ventricular endomyocardial biopsy, and in the other three, frozen or formalin-fixed autopsy samples were used. Most PCR methods can detect one tissue culture infective dose of enterovirus in CSF, stool, or throat specimen.<sup>459</sup> Polioviruses can be separated from other enteroviruses, and poliovirus vaccine strains can be rapidly identified by PCR.<sup>461-466</sup>

Enteroviral RNA has been identified in numerous tissue specimens from patients with chronic medical conditions, such as idiopathic dilated cardiomyopathy. However, the possibility of lack of specificity (false-positive results) is a concern.

### Serology

Except in special circumstances, the use of serologic techniques in the primary diagnosis of suspected neonatal enterovirus infections is impractical. Standard serologic study depends on the demonstration of an antibody titer rise to a specific virus as an indication of infection with that agent. Although hemagglutination inhibition, ELISA, and complement fixation tests take only a short time to perform, these tests can be done only after the collection of a second, convalescent-phase blood specimen. These tests are also impractical in searching for the cause of a specific illness in a child because there are so many antigenically different enteroviruses. As discussed in "Antigenic Characteristics," group antigens can be produced that allow serologic diagnosis by IgM EIA and complement fixation, but these tests lack specificity.<sup>84,85,467</sup>

In the evaluation of an infant with a suspected enterovirus infection, serum should be collected as soon as possible after the onset of illness and then again 2 to 4 weeks later. This serum should be stored frozen. In most clinical situ-

ations, it is not necessary to carry out serologic tests on the collected serum because demonstration of an antibody titer rise in the serum of an infant from whom a specific virus has been isolated from a body fluid is obviously superfluous. However, collected serum can be useful diagnostically if the prevalence of specific enteroviruses in a community is known. In this situation, it is relatively easy to look for antibody titer changes to a selected number of viral types. More rapid diagnosis using a single serum sample is possible if a search for specific IgM enteroviral antibody is made.<sup>207,468-476</sup>

Unfortunately, enterovirus IgM antibody tests are not commercially available. Commercial laboratories do offer enteroviral complement fixation antibody panels. However, these tests are expensive, and their results in the clinical setting are almost always meaningless unless acute-phase and convalescent-phase sera are analyzed.

### Histology

There are no specific histologic findings in enteroviral infections, such as those seen in cytomegalovirus or herpes simplex viral infections. However, tissues can be examined for specific enteroviral antigens by immunofluorescent study and by PCR.<sup>149,457,477,478</sup>

### Differential Diagnosis

The differential diagnosis of congenital and neonatal enterovirus infections depends on the clinical manifestations. In general, the most important illness categories are generalized bacterial sepsis or meningitis, congenital heart disease, and congenital and neonatal infections with other viruses.

Hypothermia and hyperthermia associated with non-specific signs such as lethargy and poor appetite are common in neonatal enteroviral infections; they are also the presenting manifestations in bacterial sepsis. Proper bacterial cultures are essential. Differentiation between congenital heart disease and neonatal myocarditis is frequently difficult. However, the occurrence of fever or hypothermia, generalized lethargy and weakness, and characteristic electrocardiographic changes should suggest a viral cause.

Congenital infections with rubella virus, cytomegalovirus, *Toxoplasma gondii*, or *Treponema pallidum* are frequently associated with intrauterine growth retardation; this is not usual with enterovirus infections. Generalized herpes simplex infections are clinically similar to severe infections with several enteroviruses; in herpes infections, skin lesions are common, and a scraping of a lesion and a culture should allow a rapid diagnosis. In infants with signs of central nervous system involvement, it is particularly important to consider herpes simplex virus infection as a possible cause because infection with this agent is treatable and early treatment is essential. In infants with meningitis, proper cultures and PCR testing are essential because the CSF findings in bacterial and viral illnesses are frequently similar.

## PROGNOSIS

### Polioviruses

As substantiated in the review by Bates<sup>110</sup> and the summary in Table 24-7, poliovirus infections in neonates are generally

severe. Of the 44 cases with available follow-up data, there were 21 deaths; of the survivors, 12 had residual paralyses. Because infant survivors of poliomyelitis are susceptible to infection by the other two types of poliovirus, they should receive polio vaccine.

### Nonpolio Enteroviruses

It is apparent that the immediate prognosis for patients with coxsackievirus and echovirus infections is related to the specific manifestations. Mortality rates are highest for infants with myocarditis, encephalitis, or sepsis-like illness with liver involvement. Differences in the severity of illness depend on viral type and strain variations. In general, infections with coxsackieviruses B1 to B4 and with echovirus 11 appear to carry the most ominous initial prognoses.

There is a surprising dearth of information related to long-term sequelae of neonatal coxsackievirus and echovirus infections. Gear,<sup>195</sup> in a 4-year follow-up study, found no evidence of permanent cardiac damage in several children who had coxsackievirus B myocarditis. For children with aseptic meningitis, there is little available evidence of neurologic damage. One of five infants studied by Nogen and Lepow,<sup>212</sup> from whom virus was recovered from the CSF, was suspected of having brain damage. Cho and colleagues<sup>389</sup> reported that a child who had had severe neonatal echovirus 9 disease was developing normally at 1 year of age. Tuuteri and associates<sup>229</sup> reported that two children who had had clinically mild neonatal coxsackievirus B3 infections were thriving when seen at 1 year of age. After an epidemic of mild febrile disease related to echovirus 5, 51 children were examined at 1 year of age and found to be normal.<sup>240</sup>

Farmer and colleagues<sup>423</sup> did a careful follow-up study of 15 children who had meningoencephalitis related to coxsackievirus B5 during the neonatal period. When 6 years old, two of the children were found to have developed spasticity, and their intelligence was below the mean for the study group as a whole and below the mean of a carefully selected control group. Three children who had myocarditis and meningoencephalitis had no cardiac sequelae at the age of 6 years. Sells and associates<sup>427</sup> described neurologic impairment at later follow-up study of some children who had central nervous system enteroviral infections during the first year of life.

In a study in which nine children with enteroviral meningitis during the first 3 months of life were compared with nine matched control children, Wilfert and associates<sup>432</sup> found that the receptive language functioning of patients was significantly less than that of the controls. Head circumference, hearing, and intellectual function were similar for patients and controls. Bergman and colleagues<sup>431</sup> reported an extensive study in which 33 survivors of enteroviral meningitis during infancy were compared with their siblings. In this comprehensive study, none of the survivors had major neurologic sequelae, and they performed as well as their siblings on a large number of cognitive, achievement, perceptual-motor skills, and language tests. Rantakallio and co-workers<sup>413</sup> found that 16 of 17 patients with neonatal meningitis related to coxsackievirus B5 had normal neurologic development on follow-up. The one exception was a child with suspected intrauterine myocarditis. In another study, 16 newborns with meningitis related to coxsackievirus A14 were normal 2.5 years later.

The most alarming report is that of Eichenwald,<sup>479</sup> who gave details of a 5-year follow-up study of infants who had had neonatal diarrhea associated with echovirus 18 infection.<sup>244</sup> Thirteen of 16 infants who had had an echovirus 18 infection during the neonatal period showed neurologic damage; these children had an IQ of less than 70, spasticity, deafness, blindness, or a combination of these effects.

In most instances, the antibody response of neonates after enterovirus infection is good. It is therefore to be expected that one attack of infection with a particular viral type provides immunity to the specific agent in the future. From the evidence derived from polio vaccine studies, it is probable that reinfection with all enteroviruses is common, but that after an initial antibody response, a secondary inapparent infection occurs and is confined to the gastrointestinal tract.

## THERAPY

### Specific Therapy

No specific therapy for any enterovirus infection is approved for use in the United States. In severe, catastrophic and generalized neonatal infection, it is likely that the infant received no specific antibody for the particular virus from the mother. In this situation, it is probably advisable to administer human immune serum globulin to the infant. Dagan and associates<sup>480</sup> examined three lots of human serum globulin and found the presence of neutralizing antibodies to several commonly circulating and infrequently circulating enteroviruses. Although there is no evidence that this therapy is beneficial in treating acute neonatal infections, there is evidence of some success in the treatment of chronic enteroviral infections in agammaglobulinemic patients.<sup>481</sup> Because it was found by Hammond and co-workers<sup>482</sup> that a single dose of intramuscular immunoglobulin resulted in little change in circulating neutralizing antibodies to coxsackievirus B4 and echovirus 11 in seven infants, it seems advisable when therapy is decided on to use high-dose intravenous immune globulin. One neonate with disseminated echovirus 11 infection with hepatitis, pneumonitis, meningitis, disseminated intravascular coagulation, decreased renal function, and anemia survived after receiving a large dose of intravenous immune globulin and supportive care.<sup>483</sup>

Abzug and colleagues<sup>484</sup> performed a small but controlled study in which nine enterovirus-infected neonates received intravenous immune globulin and seven similarly infected infants received supportive care. In this study, there was no significant difference in clinical scores, antibody values, or magnitude of viremia and viruria in those treated compared with the control infants. However, five infants received intravenous immune globulin with a high neutralizing antibody titer ( $\geq 1:800$ ) to their individual viral isolates, and they had a more rapid cessation of viremia and viruria.

Jantusch and associates<sup>485</sup> reported an infant with a disseminated echovirus 11 infection who survived after maternal plasma transfusions. The role, if any, of these transfusions in the infant's recovery is unknown, and this form of therapy cannot be recommended. A neonate with an echovirus 11 infection-induced fulminant hepatitis survived after orthotopic liver transplantation.<sup>486</sup>

Many anticoronavirus drugs and biologicals have been studied during the past 30 years.<sup>65,66</sup> The antiviral drug pleconaril offers promise for the treatment of enteroviral infections.<sup>65,395,407,487-489</sup> This drug is a novel compound that integrates into the capsid of enteroviruses. It prevents the virus from attaching to cellular receptors and therefore prevents uncoating and subsequent release of viral RNA into the host cell. In a double-blinded, placebo-controlled study of 39 patients with enteroviral meningitis, a statistically significant shortening of the disease duration was noted from 9.5 days in controls to 4.0 days in drug recipients.<sup>65</sup> Pleconaril also has been used on a compassionate-release basis in the treatment of patients with life-threatening infection.<sup>489</sup> Several categories of enteroviral illnesses have been treated: chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild-type or vaccine associated), encephalitis, and bone marrow transplant patients. Favorable clinical responses were observed in 22 of 36 treated patients, including 12 of 18 patients with chronic meningoencephalitis. However, in the absence of controls, the extent to which the favorable outcomes can be attributed to pleconaril is unknown.

In severe illnesses, such as neonatal myocarditis or encephalitis, it is frequently tempting to administer corticosteroids. Although some investigators thought this approach was beneficial in treating coxsackievirus myocarditis, I believe that corticosteroids should not be given during acute enterovirus infections. The deleterious effects of these agents in coxsackievirus infections of mice<sup>490</sup> are particularly persuasive. Immunosuppressive therapy for myocarditis of unknown origin with prednisone and cyclosporine or azathioprine was evaluated in a controlled trial of 111 adults, and no beneficial effect was observed.<sup>491</sup>

Because the possibility of bacterial sepsis cannot be ruled out in most instances of neonatal enteroviral infections, antibiotics should be administered for the most likely potential pathogens. Care in antibiotic selection and administration is urged so that drug toxicity is not added to the problems of the patient. In neonates with meningitis or meningoencephalitis and in some infants with sepsis-like illnesses, the possibility of herpes simplex virus infections should be strongly considered, and empirical treatment with intravenous acyclovir should be instituted after obtaining appropriate herpesvirus studies.

## Nonspecific Therapy

### *Mild, Nonspecific Febrile Illness*

In infants in whom fever is the only symptom, careful observation is most important. Many infants who eventually become severely ill have 2 to 3 days of fever initially without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented, if possible.

### *Sepsis-like Illness*

In infants with severe sepsis-like illness, the major problems are shock, hepatitis and hepatic necrosis, and disseminated intravascular coagulation. For shock, attention should be directed toward treating hypotension and acidosis and ensuring adequate oxygenation.

For hepatitis, oral neomycin (25 mg/kg every 6 hours) or other nonabsorbable antibiotics to suppress intestinal bacterial flora may be helpful. The administration of blood (i.e., exchange transfusion) and vitamin K may be useful when bleeding occurs because of liver dysfunction. Heparin therapy should be considered when disseminated intravascular coagulation occurs.

### *Myocarditis*

There is no specific therapy for myocarditis. However, congestive heart failure and arrhythmias should be treated by the usual methods. In administering digitalis preparations to infants with enteroviral myocarditis, careful attention to the initial dosage is most important because the heart is often extremely sensitive; frequently, only small amounts of digoxin are necessary.

### *Meningoencephalitis*

In patients with meningoencephalitis, convulsions, cerebral edema, and disturbances of fluid and electrolyte balance occur frequently and respond to treatment. Seizures are best treated with phenobarbital, phenytoin (Dilantin), or lorazepam. Cerebral edema can be treated with urea, mannitol, or large doses of corticosteroids. However, it seems unwise to use corticosteroids in active enterovirus infections because the potential benefits may be outweighed by deleterious effects. Fluids should be monitored closely, and frequent determinations of serum electrolyte levels should be made because inappropriate antidiuretic hormone secretion is common.

### *Paralytic Poliomyelitis*

Infants should be observed carefully for evidence of respiratory paralysis. If respiratory failure occurs, the early use of a positive-pressure ventilator is essential. In newborns, this is better performed without tracheotomy. Careful attention to pooling of secretions is important. Blood gas levels should be monitored frequently. Passive exercises of all involved extremities should be started if the infant has been afebrile for 3 days.

## PREVENTION

### Immunization

Congenital and neonatal poliomyelitis should be illnesses of historical interest only. However, because segments of populations in a few regions of the world have not been adequately immunized with polioviral vaccines, clinical poliomyelitis will continue to occur. In adequately immunized populations, congenital and neonatal poliomyelitis has been eliminated.

Attenuated viral vaccines for other enteroviruses are not available. However, if a virulent enteroviral type became prevalent, it is probable that a specific vaccine for active immunization could be developed.

Passive protection with intramuscular immune globulin (0.15 to 0.5 mL/kg) or perhaps intravenous immune globulin can be useful in preventing disease.<sup>482,492-494</sup> In practice, however, this approach seems to be worthwhile only in sudden and virulent nursery outbreaks. For example, if several cases

of myocarditis occurred in a nursery, it would seem wise to administer immune globulin to all infants in the nursery. Pooled human immune globulin in most instances can be expected to contain antibodies against coxsackievirus types B1 through B5 and echovirus 11. This procedure could offer protection to infants without transplacentally acquired specific antibody who had not yet become infected.

### Other Measures

Careful attention to routine nursery infection control procedures is important in preventing and controlling epidemics of enteroviral diseases. Nursery personnel should exercise strict care in washing their hands after handling each infant. It is also important to restrict the nursery area to personnel who are free of even minor illnesses.

Nursery infection, when it occurs, is best controlled in units that follow a cohort system. When illness occurs, the infant in question should be immediately isolated, and the nursery should be closed to all new admissions.

Scientific and medical knowledge about the genetic composition, molecular structure, pathogenesis, and natural history of infection has dramatically increased over the past decade for the hepatotropic viruses (Table 25-1). Six viral agents have been documented or suspected to cause hepatitis as the primary clinical manifestation of infection in children and adults: hepatitis A virus (HAV); hepatitis B virus (HBV);

hepatitis C virus (HCV); hepatitis D virus (HDV), an agent found to infect only patients simultaneously infected with HBV; hepatitis E virus (HEV); and hepatitis G virus (HGV), also known as GB virus type C (GB being the initials of the patient from whom the prototype virus in this group was first isolated). Fortunately, these viruses rarely cause transplacental in utero infection. As a result of the almost universal inoculation of the vaginally born infant with maternal blood, vaginal secretions, and stool, however, most of these agents may be transmitted perinatally (at the time of labor and delivery) when present in the mother.

This chapter reviews the characteristics of each of these viruses, pathogenesis and transmission of the disease, nature of the clinical illness, and diagnosis, therapy, and prevention of the infection.

## HEPATITIS A

### The Virus

HAV was first identified in the stool of a patient with the acute phase of hepatitis A (Fig. 25-1).<sup>8</sup> Although the size (27 nm in diameter), density, and structure (genetic organization, absence of lipid envelope) are similar to those of enteroviruses, HAV does not share any cross-reactive antigens, nucleic acid, or protein sequences with the enteroviruses.<sup>2,19</sup> It is classified as a picornavirus within the genus *Hepatitisvirus*.<sup>4</sup> The positive-sense, single-stranded RNA is 7.5 kilobases long and is composed of a single open reading frame, coding for at least four structural (VP1, VP2, VP3, and VP4) and seven nonstructural proteins (including an RNA polymerase and a protease).<sup>3</sup> The structural proteins are cleaved from a single precursor protein by the viral protease, with the capsid proteins VP1 and VP3 representing the antigenic structure against which neutralizing antibody is directed.<sup>4</sup> Although only one serotype is known to exist, genetic variability derives from isolates around the world, which have been categorized into four human genotypes.<sup>3</sup> HAV has been cultured in a variety of human and nonhuman primate cells in vitro.<sup>32</sup>

### Pathogenesis

Virus is ingested, enters the gastrointestinal tract, and is transported from the gut to the liver where hepatocyte entry occurs.<sup>4</sup> The cellular receptor involved in viral uptake is a membrane glycoprotein of unknown function.<sup>26</sup> The pathogenesis of HAV-mediated liver injury is not well understood. HAV can be detected in the liver, bile, blood, and stool as early as 2 weeks after exposure following release of virions from hepatocytes into both bile and blood. HAV replication may occur within the hepatocyte without evidence of cell

Table 25–1 Hepatitis Viruses

Virus	Virus Structure	Primary Route of Neonatal Infection	Transmission in Children and Adults
HAV (picornavirus, genus <i>Hepatovirus</i> )	SS RNA, nonenveloped	Perinatal	Fecal-oral
HBV ( <i>Hepadnavirus</i> )	DS circular DNA, enveloped	Perinatal	Blood-borne
HCV (flavivirus, genus <i>Hepacivirus</i> )	SS RNA, enveloped	Perinatal	Blood-borne
HDV ( <i>Deltavirus</i> )	SS, circular RNA (HBV envelope)	Not reported	Blood-borne
HEV (provisionally togavirus)	SS RNA, nonenveloped	In utero; perinatal	Fecal-oral
HGV (flavivirus)	SS RNA, nonenveloped	In utero; perinatal	Blood-borne, sexual

DS, double-stranded; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HGV, hepatitis G virus (GB virus type C); SS, single-stranded.

**Figure 25–1** Hepatitis A virus (HAV) particles. Electron micrograph of the 27-nm HAV virions in a stool specimen. (Reprinted with permission from Feinstone SM, Kapikian AZ, Purcell RH. Hepatitis A: detection by immune electron microscopy of a viruslike antigen associated with acute illness. *Science* 182:1026. Copyright 1973 by the American Association for the Advancement of Science.)

injury; most tissue-cultured strains of HAV are not cytotoxic. Some clinical or environmental isolates are clearly cytopathic, however.<sup>5</sup> The role of the immune system in clearing the infection is poorly understood. The anti-HAV immune response in adults consists of specific cellular and humoral responses.<sup>28,34</sup> Hepatocyte injury is thought to be a result of cytotoxic T cell responses.<sup>34</sup>

In one study of 11 acutely infected adults,<sup>20</sup> for the first 70 days after the appearance of jaundice, virus titers in serum were detectable in the range of  $1 \times 10^3$  to  $3 \times 10^4$  genome equivalents per mL. During the subsequent 4 months, the viral load generally decreased, although in 4 patients, the load increased after an apparent earlier decline, despite the presence of circulating antibody. In 3 patients, virus could be detected in blood for longer than 6 months. In these patients,

anti-HAV immunoglobulin M (IgM) and total anti-HAV antibody also were measured, in addition to liver function testing. A correlation was found between peak serum virus and peak serum aminotransferase levels; however, peak anti-HAV IgM levels did not correlate with a decreasing viral load. Instead, viral loads decreased with increasing total anti-HAV antibody, suggesting a greater role for anti-HAV IgG, or specific antibody in the context of an ongoing cellular response, which was not assessed in these patients. Primate model evidence suggests that virus particles excreted into the bile and intestine may again be absorbed through the gut and transported back to the liver in an enterohepatic circulation, providing a mechanism for autoinoculation.<sup>4</sup>

The biochemical and histologic changes in hepatitis occur with the onset of the anti-HAV immune response. The histopathologic findings in HAV infection are nonspecific and include focal hepatocellular necrosis with balloon degeneration and hepatocyte regeneration, accompanied by a predominantly mononuclear inflammatory infiltrate. The areas of most marked inflammation are periportal.

### Transmission

Hepatitis A is spread by the fecal-oral route. Transmission occurs by direct contact with a person with an acute HAV infection, such as an infected infant in a daycare center environment, or by ingestion of contaminated food and water.<sup>4,18,24</sup> The stool is highly contagious; in prospective evaluations of fecal excretion in symptomatic older children and adults, as well as in experimental animals, investigators found stool containing up to  $10^8$  HAV genome equivalents per mL.<sup>16,31</sup> Following infection, children may excrete virus for a more prolonged period than has been noted in adults; investigators unexpectedly also found HCV DNA in the stool during the second week of illness more often in children than in adults.<sup>31</sup> Excretion in the stool may be particularly prolonged in neonates. HAV RNA was detected in neonatal stool samples for 4 to 5 months in 23% of babies diagnosed with HAV infection.<sup>22</sup> In addition to prolonged excretion in clinically silent infection, transmission is facilitated by the fact that the quantity of virus in stool is highest before HAV-mediated illness becomes clinically detectable in children and adults, before the development of elevated serum concentrations of transaminases or bilirubin.<sup>21,31</sup> To further facilitate transmission, HAV is known to be stable in stool specimens for prolonged periods, as documented by animal infection following inoculation by

HAV-containing stool that had been dried and stored at 77°F for 30 days.<sup>17</sup>

In addition to fecal-oral transmission, parenteral transmission of HAV also is possible, both by blood transfusion and by injection drug use, because viremia has been well documented to occur with acute HAV infection.<sup>4,16,22</sup>

With respect to maternal-infant transmission of HAV, an early study of acute icteric hepatitis during pregnancy assessed six women with acute hepatitis A. All six women were symptomatic with jaundice at the time of hospitalization for delivery and had markedly increased serum alanine aminotransferase (ALT) levels. Clinical or laboratory signs of hepatitis did not develop in any of the infants born to mothers with acute hepatitis A during pregnancy, presumably owing to the fact that viral shedding had decreased substantially by the time clinical symptoms appeared.<sup>33</sup> Perinatal transmission, however, was documented in a neonate in the course of an investigation of a nursery outbreak of HAV, finding that the infant's mother had been diagnosed with an acute HAV infection 10 days before delivery.<sup>35</sup> Perinatal transmission also has been documented in infants born to mothers diagnosed with infection at 4 months before delivery<sup>7</sup> or at the time of delivery.<sup>30</sup> In both of these reports, the infants were asymptomatic for the first weeks of life, with documentation in one report<sup>30</sup> of the absence of HAV RNA in cord blood. Other reports have documented intrauterine transmission with fetal infection associated with polyhydramnios and ascites at 27 weeks of gestation, following maternal infection at 20 weeks of gestation.<sup>15</sup> Prospectively collected epidemiologic data on the true incidence of neonatal HAV infection following maternal infection, acquired either in utero or perinatally at the time of delivery, are not available.

Although a neonate may become infected from transfusion or from vertical transmission as outlined, spread within nurseries to other infants and health care workers also has been documented. Outbreaks of HAV infection once the virus was introduced into the nursery have been reported.<sup>13,22,25</sup>

No cases of transmission from breast milk as the sole means of exposure of the neonate to infectious virus have been reported.

### Clinical Illness

Although biopsy-proven clinical HAV infection in a neonate has been reported,<sup>7</sup> the true incidence of clinical disease in HAV-infected neonates is unknown, because no prospective evaluation in exposed neonates has been possible. In infants and children, particularly those younger than 3 years of age, less than 20% are clinically symptomatic following infection<sup>9,10,12</sup>—far lower than in adults, of whom between 76% and 97% have clinical illness, with icterus in 40% to 70%.<sup>4,14</sup> The average incubation period from exposure to onset of symptoms is 30 days, with a range of 15 to 50 days. Nonspecific signs and symptoms associated with infection include fever, anorexia, nausea, myalgia, diarrhea, and abdominal discomfort. In adults, these symptoms may be present 5 to 7 days before the onset of jaundice. Duration of disease varies considerably, averaging 30 days in adults, but is shorter in children. Elevated values on liver function tests and abnormalities on liver biopsy, however, may persist in

some cases for several months.<sup>4</sup> Approximately 100 cases of fulminant HAV infection with liver failure occur each year in the United States, representing less than 1% of cases of HAV infection. Acute liver failure occurs more often in older adults or in those with underlying liver disease but has been reported in children as well.<sup>6,23,27</sup>

Chronic, lifelong infection, as has been documented for HBV and HCV, has not been shown to occur with HAV infection.

### Laboratory Diagnosis

Hepatitis A is diagnosed in the laboratory by demonstration of serum antibodies to HAV (anti-HAV) by a number of different enzyme immunoassays or radioimmunoassays. The most commonly used test to diagnose HAV infection is the determination of anti-HAV IgM, which is virtually always present at the first sign of clinical disease and persists for 4 to 6 months. The sensitivity and specificity of anti-HAV IgM assay were reported to be 100% and 99%, respectively, in one community outbreak,<sup>29</sup> but similar data are not available for the accuracy of the test in the neonate. Anti-HAV IgG remains detectable for years following infection. Research laboratories also can detect virus in blood or stool by means of reverse transcriptase–polymerase chain reaction (RT-PCR) tests or by *in situ* hybridization techniques on biopsy samples.

### Therapy

No approved antiviral agents are available for treatment of hepatitis A infection. This state of affairs is likely to be a consequence of the widespread availability of effective vaccines and the self-limited nature of this infection.

### Prevention of Infection

For infants born to mothers whose symptoms began between 2 weeks before to 1 week after delivery, current recommendations are to administer a single intramuscular injection of immune serum globulin (ISG), 0.02 mL/kg, to the infant, although the efficacy of ISG in this situation has not been documented.<sup>1</sup>

Prevention of infection in infants and health care workers in a nursery outbreak consists of strict infection control measures to prevent fecal-oral transmission of virus from infected infants to susceptible infants. For health care workers, previous immunization with one of the U.S. Food and Drug Administration (FDA)–approved HAV vaccines should be protective for those who are inadvertently exposed to an infected neonate, parent, or sibling and should prevent further nosocomial transmission within the nursery. If an outbreak of hepatitis A is documented in the nursery, post-exposure prophylaxis with ISG (0.02 mL/kg) should provide sufficient anti-HAV antibody to prevent or modify illness in non-HAV-immunized, exposed health care workers, or in neonates who may have had close exposure to infectious secretions. No data are available to support the use of vaccine alone for postexposure prophylaxis.<sup>1</sup> Because HAV vaccines have not been tested in the neonate, immune prophylaxis is the only available preventive measure for this population following documented exposure.

## HEPATITIS B

### The Virus

HBV is a *hepadnavirus*, an enveloped virus that contains a partially double-stranded DNA molecule approximately 3200 nucleotides in length.<sup>96</sup> Although viruses with genetic organization and morphologic structure similar to those of HBV have been identified in birds and other mammals, the host range of HBV is limited to humans, gorillas, and chimpanzees.

The life cycle of HBV is largely understood because of extensive studies in animal models with species-specific hepadnaviruses. Early after infection, the virus infects primarily hepatocytes but also may infect cells of the kidney and pancreas and mononuclear cells. Although the hepatocyte cell surface receptor for HBV remains unknown, several possibilities are under investigation.<sup>64</sup> Following membrane fusion, the virus nucleocapsid ultimately arrives in the nucleus, where the partially double-stranded DNA molecule becomes covalently closed, circular DNA through the action of host cellular DNA repair enzymes, which not only complete the DNA strand but also release the attached viral polymerase.<sup>52,64</sup> This double-stranded DNA may then be associated with cellular histone proteins to form stable minichromosomes, which may represent a feature of intracellular stability of the virus, with implications for viral latency.<sup>64</sup> The double-stranded DNA also serves as the template for host RNA polymerase II, which provides the RNA required for translation to viral proteins and creates the pregenomic RNA destined for encapsidation in the process of forming new viral progeny.

The HBV DNA genome codes for four families of polypeptides (corresponding to overlapping open reading frames): the pre-S/S region proteins, the pre-C/C/e-antigen proteins, the P gene polymerase product, and the X gene product, HBx protein. The pre-S/S region codes for three envelope proteins that exist as both glycosylated and nonglycosylated forms: the large L (pre-S1) protein, the medium (middle) M (pre-S2) protein, and the small S (S, or major) protein.<sup>51,54,64,91,96,103</sup> The serum of patients with acute hepatitis B contains three morphologically distinct forms of virus or viral antigen (Fig. 25-2). These forms are distinct particles that can be readily aggregated by reaction with serum containing specific antibody against the hepatitis B surface antigen (HBsAg). The first particle to be described, and the most common form in the serum, is a spherical 22-nm particle composed of multiple subunits of the S envelope protein.<sup>11</sup> In addition, long microfilaments with the same 22-nm diameter as for the spherical particles can be seen scattered throughout an electron microscopic field. The third particle is a large spherical particle, 42 nm in diameter, with an outer shell and a dense inner core, which represents the complete infectious virus particle. The 22-nm particles are formed from HBsAg composed of 90% S (major) protein, with minor components of the medium and large proteins. About 70% of HBsAg protein on the filamentous and 42-nm particles consists of the S protein.<sup>64</sup>

The pre-C/C open reading frame provides the genetic material for the core protein (P21), which is serologically recognized by the host as HBeAg and is the major protein in the core, or nucleocapsid. The pre-C region also codes for a soluble antigen, detected in the blood as HBeAg.

**Figure 25-2** Hepatitis B virus (HBV) particles. Electron micrograph from a patient with acute HBV infection demonstrates three circulating particles: 20-nm structures and filamentous structures containing HBsAg envelope proteins (primarily the S, or major protein, but no HBV viral genome); and the 47-nm infectious virion structures containing both envelope proteins and nucleocapsid containing genomic HBV DNA. HBsAg, hepatitis B surface antigen. (Courtesy of Dr. June Almeida.)

The pol gene is the longest-segment open reading frame, coding for a multifunctional 90-kilodalton (kDa) polymerase protein, which has the ability to act as reverse transcriptase (creating double-stranded DNA, which is present in infectious virions), an RNase, and a DNA polymerase.

The X open reading frame leads to the formation of the 154-amino-acid-long nonstructural, regulatory HBx protein. The function of HBx is not well understood,<sup>40</sup> but it appears to be involved as a transactivator for a number of viral and cellular gene promoters, possibly in events that lead to dysregulation of cellular functions. These occurrences over time are believed to be factors leading to the development of hepatocellular carcinoma.

The core protein self-assembles into capsids in the cytoplasm, incorporating pregenomic single-stranded HBV RNA. Following assembly of the capsid, however, the RNA is transcribed back into DNA by the multifunctional pol gene polymerase (also called the Pol protein, or P protein), exhibiting reverse transcriptase activity. Within the nucleocapsid, the pregenomic RNA is then degraded by this enzyme, and the viral polymerase subsequently completes the formation of the final double-stranded HBV DNA, and then attaches covalently to the 3' end of the minus-strand DNA, to complete the formation of the nucleocapsid. These completed nucleocapsids are then capable of associating with cell membranes, binding to envelope proteins, and subsequent release.<sup>64</sup>

Possibly because of the extensive worldwide distribution of HBV, some diversity exists in its DNA sequences and the

antigenicity of HBsAg.<sup>112</sup> Classically, three antigenic epitopes on HBsAg have been distinguished: a, d/y, and w/r.<sup>48,110,111</sup> The a antigen is common to HBsAg molecules derived from all strains of HBV and is a major neutralizing epitope. Because vaccination with HBsAg usually results in the development of antibodies to the a epitope, any form of HBsAg can be used to produce neutralizing antibodies. HBsAg usually is exclusively d or y and w or r, leading to serologic designations of ayw, ayr, adw, and adr. With the development of monoclonal antibodies to HBsAg and genetic sequencing data, more subtle differences in serotypes of HBsAg have become apparent; for example, four distinct subgroups have been identified within the ayw group.<sup>112</sup> The antigenic differences among viral isolates are of epidemiologic interest, although clinical outcomes of HBV infection as they relate to strain differences are currently under study.

## Pathogenesis

HBV is noncytopathic to the hepatocyte. The pathogenesis of disease is closely associated with the appearance of the host immune response, most prominently that of circulating HBV-specific cytotoxic T cells.<sup>52,81,85</sup> The breadth and intensity of the response to the HBV antigenic epitopes have been correlated with the ability to clear the virus. In addition to direct cytotoxic mechanisms, HBV-specific T cells have the ability to decrease viral replication by noncytolytic mechanisms, primarily involving IFN- $\gamma$ , which leads to an enhanced immune response both within the hepatocyte and with respect to recruitment of additional immune-competent (CD4<sup>+</sup> and natural killer [NK]) cells.<sup>87,113</sup> Accumulating evidence suggests that even in adults who recover clinically from the infection, persisting, perhaps lifelong HBV infection, is the rule, accompanied by a strong and continuing T cell response.<sup>86</sup> The actual immune parameters that are responsible for the persistent, chronic infection seen in neonates, however, have not been investigated in detail.

Acute infection in adults may be either asymptomatic or symptomatic, in the latter case accompanied by biochemical and histologic evidence of hepatitis. The pathogenesis of infection has been broadly separated into four categories: immune tolerance, immune/active clearance, nonreplicative, and reactivation.<sup>108</sup> Greater than 90% of neonatal infections result in chronic infection, whereas only 5% of infections in adults become persistent. Immune tolerance in the neonate may result either from cellular immune system immaturity or from suppression of immune responses. Immune suppression leading to chronic infection may either be specific to HBV, possibly linked to the transplacental passage of soluble HBeAg, or be a nonspecific function of the fetal immune suppression that normally occurs during gestation.

The serum concentration of HBV DNA varies markedly from patient to patient with different states of chronic HBV disease. Asymptomatic HBsAg-positive chronic carriers with little or no hepatocellular injury usually have very high concentrations of serum HBV DNA, validating the concept of immune tolerance, with poor host regulation of viral replication and minimal host-mediated injury to hepatocytes. On the other hand, persons who remain HBsAg positive but have ongoing evidence of hepatocellular injury, as assessed by serum aminotransferases and liver biopsy, will have a

20% chance of developing cirrhosis with their chronic HBV infection.

In general, circulating HBeAg in adults denotes a higher load of circulating virus, with less host control of the infection and less host-mediated damage to hepatocytes. Over time, a certain percentage of adults will revert from HBeAg seropositivity to anti-HBe seropositivity, usually accompanied acutely by increased liver inflammation.<sup>106</sup> One study showed that the vertical transmission rate of HBV infection was increased in women who were HBeAg positive, suggesting a correlation between viral load and transmission rates.<sup>77</sup> Of those with perinatal infection, the period of immune tolerance may last for the first 2 decades or longer.<sup>108</sup> Although HBeAg positivity may correlate with less inflammation, the risk of hepatocellular carcinoma is highest in those who are HBeAg positive, suggesting that altered molecular control of cellular function in HBV infected hepatocytes may correlate with the development of cancer.<sup>40</sup>

In addition to being present as extrachromosomal, covalently closed, double-stranded DNA, HBV DNA also may become integrated into host chromosomes and can be found within the chromosomes of most hepatocellular tumors. The viral DNA usually has been severely rearranged, with deletions, duplications, inversions, and insertions.<sup>75</sup> The role of HBV in carcinogenesis is not well defined and may be a function of random genetic integration events that facilitate the development of uncontrolled tumor growth through genetic expression of HBV enhancers or promoters within critical human genes, or may reflect a biologic effect of one of the HBV proteins, such as HBx, which may prevent mechanisms of cell homeostasis from operating normally. As the chronic infection progresses over many years, the lifetime risk of the development of hepatocellular carcinoma is estimated to be 40% to 50%.<sup>38,61</sup>

Following inoculation of a susceptible host with infectious virions, HBsAg appears in the bloodstream within 1 to 6 months during the acute phase of infection, correlating with high levels of circulating virus and contagiousness. A high risk of vertical transmission of HBV from mother to infant is present during the acute infection. In older children and adults, HBV-specific CD8<sup>+</sup> and CD4<sup>+</sup> lymphocytes clear the production of virus by both cytolytic and noncytolytic mechanisms.<sup>88</sup> In the neonate, the most common response following perinatal exposure is a chronic asymptomatic hepatitis with the histologic features of unresolved or persistent hepatitis.

Limited data exist on the hepatocellular characteristics of infection in the newborn or during the first year of life. Early studies by Schweitzer and colleagues demonstrated that in 13 of 17 HBsAg-positive infants, no signs of acute clinical hepatitis were present.<sup>93</sup> Physical findings for 12 infants with persistent antigenemia remained normal. In one child, hepatomegaly and splenomegaly were detected at 15 months of age. Liver biopsy specimens were obtained from 10 HBsAg-positive infants between 3 and 27 months of age; results from 8 of the 10 infants documented intact lobular architecture with no suggestion of nodular regeneration or fibrosis. Some liver cells were hydropic and polyhedral, giving a cobblestone appearance to the liver lobule. Liver cell nuclei were slightly enlarged, and small foci of liver cell necrosis were present. Only one liver biopsy specimen had increased amounts of fibrosis, but no bridging between portal areas was apparent.

## Transmission

Transmission to the neonate most often occurs at the time of delivery, but some evidence suggests that some neonates may already be infected in utero, with virus present in cord blood at birth.<sup>84</sup> In Taiwan, where the prevalence of HBsAg positivity in the population is 5% to 20%, a high frequency of vertical transmission of HBsAg from asymptomatic carrier mothers was documented before the routine use of hepatitis B immune globulin (HBIG) and HBV vaccines. In natural history studies by Stevens and co-workers, HBsAg antigenemia was eventually documented in 63 infants born to 158 carrier mothers.<sup>100</sup> Fifty-one of these infants became HBsAg positive within the first 6 months of life. Furthermore, within this group, 21 of 103 infants born to carrier mothers had a positive cord blood sample for HBsAg, suggesting a high rate of in utero transmission. A relationship also was documented in this study between the level of the mother's viremia and the development of infection in the infant. This strikingly high frequency of transmission of the hepatitis virus noted in Taiwan also has been observed in other Asian and African populations.

A high incidence of maternal transmission of HBV from asymptomatic carrier mothers to infants also was reported in 1975 by investigators in Japan.<sup>76</sup> In a study of 5993 mothers in five municipal hospitals in Tokyo, 139 (2.3%) were positive for HBsAg. These women were judged to be asymptomatic carriers by three criteria: (1) HBsAg was present in a high titer (1:512 or greater) as determined by the immune adherence hemagglutination method; (2) the women were free of clinical liver disease; and (3) no laboratory-tested abnormalities of liver function were present. Of the infants born to the 139 HBsAg-positive mothers, none had congenital malformations. Of note, none of 59 cord blood specimens tested by the technique of immune adherence hemagglutination were positive for HBsAg. Outcomes in 11 infants of HBsAg-positive mothers were studied in follow-up evaluations. In 8 of these 11, HBsAg appeared in the serum within 6 months; 3 remained HBsAg negative for 7 to 14 months. In view of the lack of HBsAg in cord blood in this study, perinatal transmission, rather than in utero transmission appears to have been the major route of neonatal infection in this population studied in Japan.

Another early report from Japan<sup>77</sup> documented the presence of e antigen (a marker of higher viral load and less vigorous host response to HBV) in the blood of 10 asymptomatic carrier mothers, all 10 of whose infants became HBsAg positive. The infants born to mothers whose sera contained antibodies to e antigen (anti-e) did not become HBsAg positive. The importance of e antigen as a determinant in the transmission of HBV was confirmed in a prospective trial of pregnant women who were chronic carriers of HBsAg. Of the 70 pregnant women who delivered, 38 were HBeAg positive. Thirty-seven of the 38 HBeAg-positive mother-infant pairs were followed for 5 months or more. By 5 months, 26 of the 37 infants (70.3%) born to HBeAg-positive mothers were HBsAg positive.<sup>63</sup> Another study from Taiwan further supported the correlation between the presence of HBeAg in the serum of HBsAg carrier mothers and infection in their newborns: 85% of infants born to HBeAg-positive women became infected with HBV during the first year of life, and no vertical transmission was documented in HBeAg-

negative mothers.<sup>101</sup> Circulating HBV DNA was measured during pregnancy in chronically infected pregnant women in Sweden, both HBeAg positive ( $n = 9$ ) and HbeAg negative ( $n = 46$ ).<sup>99</sup> Not unexpectedly, viral load was higher in HbeAg-positive women than in those who were HbeAg negative; the three infants who acquired the infection all were born to HBeAg-positive mothers.

In the United States, the rate of transmission of HBsAg from asymptomatic carrier mothers to their children appears to be lower. Schweitzer and colleagues found that only 1 of 21 infants born to HBsAg-positive mothers became positive for HBsAg.<sup>94</sup> In this study, HBsAg was found in the cord blood in 9 of 18 specimens, but none of these infants became HBsAg positive. The authors concluded that the presence of HBsAg in the cord blood bore no relationship to the development of antigenemia in the infant of an asymptomatic carrier mother. In Denmark, Skinhoj and co-workers<sup>98</sup> found no infections among 28 infants studied for 3 to 5 months after birth to asymptomatic carrier mothers.

In a recent study from China, a high rate of in utero transmission was again suggested in the population studied.<sup>117</sup> Among 59 infants born to HBV chronic carrier mothers, in utero transmission was documented in 40% by HBV DNA detected in peripherally drawn venous blood shortly after birth.

A fetal pulmonary or gastrointestinal route of infection in utero is theoretically possible in infants who may not be infected through a hematogenous route. Investigators in one study found HBsAg in 33% of amniotic fluid samples and in 95% of gastric aspirates from the newborn infants.<sup>63</sup> HBV DNA was found by PCR assay of amniotic fluid from 48% of chronic carrier mothers, although contamination of amniotic fluid from maternal blood may have been possible.<sup>117</sup>

Thus, in Taiwan, Japan, and China, the risk of infants acquiring hepatitis B from asymptomatic carrier mothers by perinatal as well as in utero routes appears to be high, whereas in the United States and other countries, the risk of acquiring neonatal hepatitis from HBsAg carrier mothers appears to be lower. It is not clear what role genetically determined immune responses, or socioeconomic or cultural conditions, may play in the epidemiology of transmission from mother to infant.

No evidence is available to suggest that the clinical course in the pregnant woman in whom acute hepatitis B develops during pregnancy is different from that in women who are not pregnant.<sup>49</sup> With acute infection during the first part of pregnancy, however, clearance of HBV virions usually occurs by the time of delivery. For those women with infection later in pregnancy who are HBsAg positive at the time of delivery, the rate of perinatal acquisition of infection in the infant is similar to the rate found in infants born to mothers with chronic infection. In the United States, Schweitzer and co-workers assessed the presence of HBsAg in 56 mother-infant pairs; the mothers had acute viral hepatitis during pregnancy or within 6 months after delivery.<sup>92,94</sup> This study indicated that HBsAg was transmitted from mother to infant by 10 of 26 mothers who had HBsAg-positive hepatitis. Of interest, infection was transmitted from 8 of 17 mothers whose hepatitis developed within 2 months after delivery. The investigators demonstrated that the frequency of HBV transmission from mother to infant is high (76%) when

acute hepatitis B occurs in the third trimester or early in the postpartum period and low (10%) when hepatitis occurs in the first two trimesters of pregnancy.

Although infants may theoretically be infected through breast milk, which is known to contain virus,<sup>41,67,104</sup> this mode of transmission does not appear to add additional risk for the infant beyond other exposures from a chronically infected mother.<sup>55,84</sup> Infants who receive appropriate prophylaxis following delivery should be allowed to breast-feed.<sup>1</sup> For parents who refuse appropriate prophylaxis, or in situations in which prophylaxis is not available, the added risks of neonatal infection beyond those from exposures to HBV during the pregnancy and birth are minimal, particularly when balanced with the nutritional and immunologic benefits from breast milk.

### Clinical Illness

A majority of infants who become positive for HBsAg after mother-to-infant transmission remain anicteric, show no signs of acute clinical hepatitis, and remain HBsAg positive for an extended period. The natural history of neonatal infection is best described by studies in which ongoing exposures to HBV from the community are minimal, giving the best insight into the evolution of virus-child interactions. A natural history study was recently published from England in which 73 infants diagnosed with perinatal infection were born to HBsAg-, HBeAg-positive mothers (comprising 53 women from the Indian subcontinent and 9 Asian, 6 African-Caribbean, and 5 white women).<sup>42</sup> These infants either were born before the era of routine perinatal prophylaxis ( $n = 51$ ) or were prophylaxis failures ( $n = 22$ ). The mean duration of follow-up was 10 years (range 2 to 20 years). All children were clinically well; none had evidence of liver enlargement by palpation or ultrasound examination. All were of normal height and weight. Of the 73 children, 3 had cleared HBsAg and had become seropositive for anti-HBs at follow-up testing. Sixty-five percent of children were seropositive for HBeAg, and 30% had seroconverted to become anti-HBe positive by an average of 10 years of age (range 4 to 19 years). Four of the five (80%) white children seroconverted, compared with 18 of the 50 (36%) children from the Indian subcontinent, with no seroconversions noted in the 9 Asian children. This finding of different rates of HBeAg seroreversion in different ethnic groups also has been reported by other investigators.<sup>43</sup>

Half of the Indian subcontinent children and two thirds of the Asian children had normal values for serum ALT. Elevated aminotransferase values tended to be stable over the period of follow-up evaluation. Liver biopsy samples were available in 48% of the children. In these children, 30% of biopsy specimens showed minimal or no inflammation, 63% showed mild hepatitis, and 6% demonstrated moderately severe hepatitis, as graded by Ishak scoring. Two children with moderately severe changes had "incomplete cirrhosis." No association was found between the severity of the histopathologic changes and age, gender, or ethnic origin. A weak association was found between elevation of liver function tests and the degree of inflammation present. Children who were HBeAg positive also were shown to have the highest levels of circulating HBV DNA.

Although none of the children in this series became clinically symptomatic, in earlier reports mild, self-limited

hepatitis with variable elevations of ALT and abnormalities on liver biopsy were reported.<sup>95</sup> In the study carried out in Taiwan, however, in which 158 women who were carriers of HBsAg gave birth to 63 antigen-positive infants (40%), all of the infants remained healthy, without signs or symptoms of hepatitis.<sup>100</sup>

Although the vast majority of infants have benign clinical disease, fulminant hepatitis has been reported, particularly in infants born to HBeAg-negative mothers, although it may also occur in infants born to mothers who are HBeAg positive.<sup>43,45,59,60</sup>

Neonatal infection with HBV has been suggested to play a dominant role in the development of primary hepatocellular carcinoma in later life.<sup>38</sup> A progression of events from vertical HBV transmission leading to chronic infection, resulting in cirrhosis and hepatocellular carcinoma in adult life, has been implicated to explain findings in Senegal, West Africa, where primary hepatocellular carcinoma is a major cause of death among young adult men.<sup>62</sup> The finding that mothers of patients with hepatocellular carcinoma were positive for HBsAg four times more frequently than the fathers suggested that the virus was acquired from the mother by vertical transmission. The development of hepatocellular carcinoma also may relate to an associated high incidence of HBeAg positivity in HBsAg carriers in particular geographic regions. In the United States, only 3% to 5% of HBsAg carriers also are HBeAg positive, and hepatocellular carcinoma is uncommon, whereas 30% of HBsAg carriers also are HBeAg positive in Taiwan, Japan, and Uganda; these countries have a very high incidence of hepatocellular carcinoma. In several studies, between 37% and 90% of patients with hepatocellular carcinoma were HBsAg positive; these rates were 10 times higher than that in matched controls living in the same area.<sup>105</sup> Furthermore, preliminary data from Taiwan suggest that perinatal HBV prophylaxis programs, now in their third decade, have been associated with the decrease in hepatocellular carcinoma in the age groups immunized.<sup>46</sup>

In summary, it is evident that a majority of infants who become HBsAg positive by mother-to-infant transmission are clinically healthy, but they may have persistently elevated values on liver function tests, and approximately 5% will have moderately severe histopathologic changes on liver biopsy. These changes are not well predicted by the clinical or HBV serologic status, or by liver function testing. Late complications include cirrhosis and hepatocellular carcinoma.<sup>52,61</sup> Clinical illness in adults has recently been reviewed.<sup>52,108</sup>

### Laboratory Diagnosis

The availability of reliable, reproducible methods for a variety of antigens and antibodies associated with HBV infection has played a major role in the accumulation of knowledge on the epidemiology and clinical relevance of HBV. These tests are widely available from both hospitals and regional reference laboratories. The patterns of HBV viral products and host responses in both acute, resolved infection and in chronic infection are summarized in Figure 25-3.<sup>96</sup>

HBsAg was one of the first detected virus-associated antigens. At present, most clinical laboratories use variations of the enzyme-linked immunoassay (EIA) methods or radioimmunoassay (RIA) and to detect HBsAg. HBsAg is

**Figure 25-3** Viral and host serologic markers and clinical correlates of hepatitis B virus (HBV) infection. **A**, Acute infection with appropriate host response and resolution of infection. **B**, Chronic infection. (Data from Servoss JC, Friedman LS. Serologic and molecular diagnosis of hepatitis B virus. *Clin Liver Dis* 2004;8[2]:267-81.)

synthesized during viral replication and also may be synthesized from HBV DNA sequences integrated into the chromosomes of hepatocytes in the absence of viral production.<sup>107</sup> In general, the presence of HBsAg is an indication of active viral infection. Approximately 90% of adults will be HBsAg positive using a conventional enzyme-linked immunosorbent assay (ELISA) for HBsAg during the first 2 weeks of symptomatic acute viral hepatitis B. A single negative assay result early in the course of infection may represent a false-negative result, because the antigen concentration may be below the sensitivity of the immunoassays. Repeating the assay several weeks later may yield a positive result. In acute infection, the levels of HBsAg begins to fall 4 to 6 months after exposure.<sup>96</sup> In the neonate, HBsAg may be present at birth, as a consequence of in utero infection, or may not be detectable for several months following perinatal or postnatal inoculation. For infants born to chronically infected mothers who are provided immunoprophylaxis, HBsAg (and anti-HBs) should be checked at 9 to 15 months of age, or 1 to 3 months following completion of the primary immunization series.<sup>1</sup>

Anti-HBs antibody testing is widely available, usually performed by EIA or RIA techniques. This circulating antibody is directed against epitopes on the S protein of the pre-S/S ORF gene product. In self-limited HBV infections, it usually is assumed that the patient is no longer infectious after anti-HBs is detectable. With the development of more sensitive assays for HBsAg and anti-HBs, patients with self-limited infection may be transiently HBsAg and anti-HBs positive simultaneously.<sup>97</sup> Most patients with chronic HBV infections will never be anti-HBs positive. Conversely, less than 10% of chronic carriers have anti-HBs antibodies.<sup>97</sup> Anti-HBs positivity usually implies that an HBV infection has resolved or that the patient has mounted an antibody response to the hepatitis B vaccine. In persons with natural infection, anti-HBc also is positive. Evidence that an adult may both have anti-HBs and be intermittently positive for small amounts of HBV DNA suggests that anti-HBs is a marker for clinical cure, rather than for sterilizing immunity.<sup>52,88</sup>

Anti-HBc is formed against the nucleocapsid core protein during the course of infection. It is most commonly detected by EIA or RIA. Early in the infection, anti-HBc antibodies

are predominantly of the IgM class and have been used to diagnose acute infection in adults. Symptomatic adults are anti-HBc positive 2 weeks after symptoms begin, and virtually all patients with asymptomatic HBV infections are anti-HBc positive at the time when other virus-associated antigens are detectable and the ALT rises. With time, the titer of anti-HBc IgM declines as the titer of anti-HBc IgG rises. At 6 months following infection, a majority of patients' anti-HBc antibodies are IgG, although a minority may have detectable anti-HBc IgM for up to 2 years. The anti-HBc antibody titer slowly declines but remains detectable for many years after self-limited infection. The anti-HBc titer usually remains high during the course of chronic infection. During recovery from an acute infection, the anti-HBc IgM may be detected in serum several weeks after infection at a time when the HBsAg is decreasing and no longer detectable in serum, and while anti-HBs is increasing but is not yet detectable in serum. The newborn infant's anti-HBc response following perinatal infection has not been prospectively studied. Of note is the fact that immunized infants born to mothers not infected by hepatitis B may be transiently positive for HBsAg from the vaccine but should not be positive for anti-HBc. In infants born to mothers with chronic infection, transplacental, maternal anti-HBc should be detectable for up to the first several months of life. In addition, in infants born to chronically infected mothers, passive immunization with hepatitis B immune globulin also may provide anti-HBc detectable in the infant's serum. Continued presence of anti-HBc at 12 to 18 months in these infants, however, should raise the suspicion of perinatal infection with HBV.

Both HBeAg and anti-HBe are detectable by both EIA and RIA. The HBeAg usually is detectable in adults when viral replication is occurring with little host response to limit the production of virions. Later in the course of infection, particularly in certain ethnic groups, a seroconversion from HBeAg to anti-HBe may be accompanied by decreasing viral titers, or even the eventual clearance of virus. The concentration of virus usually is higher in HBeAg-positive sera than in HBeAg-negative sera. The absence of HBeAg positivity, however, does not exclude the potential infectivity of HBsAg-positive sera in patients with HBV infections either caused by standard strains or caused by those with mutations

in the precore region in which HBeAg is not produced.<sup>65,66,83</sup> At present, although the immunoassays for HBeAg and anti-HBe are readily available to the practitioner, the clinical use of these assays is limited to guiding antiviral therapy in helping to identify an HBeAg-to-anti-HBe seroconversion in the chronic HBV carrier. No other management decisions can be reliably based on these tests at this time. The decision of whether to perform immunoprophylaxis of a newborn of an HBsAg-positive mother with HBIG and HBV vaccine should not depend on her HBeAg/anti-HBe status, because vertical transmission may occur in either setting.

HBV DNA can be measured in commercial reference laboratories by a variety of techniques, either *qualitative* assays that detect the presence or absence of HBV DNA or *quantitative* HBV DNA assays. Techniques include signal amplification following molecular hybridization (including hybrid capture and branched-DNA methods) or nucleic acid target amplification (PCR and transcription-mediated amplification [TMA] techniques).<sup>79,80</sup> These tests most often are used to monitor response to antiviral therapy, rather than to diagnose an HBV infection.

HBV genotypes also can be determined in reference laboratories by using immunoassay and nucleic acid sequencing techniques. These assays most often are interpreted in conjunction with a pretreatment laboratory assessment, because different genotypes may respond differently to various antiviral and immune therapies.

Many other tests for hepatitis B virus and other techniques to measure HBV antigens, HBV antibody, and specific lymphocyte responses to various HBV epitopes have existed for several years. New molecular techniques are being used to provide more insight into the pathogenesis of infection, and to allow investigators to track response to antiviral therapy more closely.

## Therapy

Therapy for HBV infection has not been studied systematically in the neonate. In older children, therapy is undertaken in those with biopsy evidence of liver disease.<sup>43</sup> Therapy for hepatitis B includes interferon- $\alpha$  (including pegylated formulations) and lamivudine and adefovir, the nucleoside analogues that act as polymerase inhibitors. In children, multiple studies have been conducted using interferon- $\alpha$ , with overall encouraging results. Response rates as high as 58% were noted in some studies.<sup>39,43</sup> In adults and children with chronic hepatitis B infection, lamivudine treatment has been associated with a rapid and profound decrease in serum HBV DNA levels, normalization of aminotransferase levels, and in adults, reversal of some histologic changes seen in liver biopsy specimens, with reduction in fibrosis and cirrhosis.<sup>52,56,58,61</sup> Unfortunately, emergence of lamivudine resistance may occur within 6 months of therapy, linked to nucleic acid mutations in the HBV genome.<sup>79,96</sup> Adefovir has been studied in both HBeAg-negative<sup>53</sup> and HBeAg-positive<sup>70</sup> adults. Limited data exist on adefovir therapy in children with chronic HBV infection, but no recommendations can yet be made. Other nucleotide analogues are currently investigational. The concept of multiple drug therapy to decrease the risk of the development of resistance also has been suggested.

In addition, pegylated interferon- $\alpha$ , used alone or in combination with lamivudine in adults, provided a better

antiviral response than lamivudine alone, and the combination of lamivudine plus peginterferon- $\alpha$  did not significantly improve the outcome of infection beyond that achieved by peginterferon- $\alpha$  alone.<sup>71</sup> In two smaller studies involving 19 and 20 children, respectively, interferon- $\alpha$  plus lamivudine was used for treatment in (1) children who were noted to be interferon- $\alpha$  nonresponders, demonstrating a response rate of 37%,<sup>89</sup> and (2) those who were treatment naïve, resulting in a response rate of 55%.<sup>90</sup>

The decision of which child to treat is still evolving, and incorporates both the safety, side effects, tolerability, as well as efficacy in children who usually are asymptomatic with their HBV infections.<sup>39,43</sup>

## Prevention of Infection

Prophylaxis for the HBV-exposed neonate may consist of passive immunization with hepatitis B immune globulin (HBIG), active immunization with HBV vaccines, or antiviral therapy with lamivudine, or a combination of these treatments. The role of HBIG in preventing vertical transmission of HBV to infants born to HBV carrier mothers has been well documented, but HBIG is currently being replaced by vaccine in some countries, particularly in infants born to mothers considered at low risk of transmitting the infection.<sup>69,74,115</sup> HBIG is used routinely with vaccine for all infants born to HbsAg-positive mothers in the United States.<sup>1</sup>

HBIG is derived from plasma collected from persons who have recovered from HBV infection and is processed to eliminate risk of infection from HIV or HCV.<sup>44</sup> The success of HBIG alone in preventing vertical transmission was documented in Taiwan by demonstrating a decrease in neonatal HBV infection from 92% in infants born to HBSAg- and HBEAg-positive mothers to 26% in infants given 0.5 mL of HBIG at birth, 3 months, and 6 months.<sup>36</sup> In an effort to further decrease transmission, subsequent studies employed both passive protection (HBIG) and active immunization with HBV vaccine. Immune serum globulin (ISG) is not considered to have sufficient antibody to HBV to be a reasonable substitute for HBIG for passive prophylaxis in the newborn.

The first hepatitis B vaccines were originally approved in the United States in 1981. They were composed of purified HBsAg from plasma of chronic carriers and were documented to be immunogenic and protective in infants born to chronic carrier mothers.<sup>37,57,68,72,73,114,116</sup> These vaccines were replaced a few years later by the currently available vaccines, all of which use recombinant DNA technology in *Saccharomyces cerevisiae* to produce HBsAg and are safer than but just as effective as previously available vaccines.<sup>69,74,82,102</sup> Currently available data on long-term protection suggest that booster doses of HBV vaccines may not be necessary for children who received either plasma-derived or recombinant vaccines, although the relevant studies were conducted largely in countries in which hepatitis B is endemic.

Current recommendations to achieve protection of the infant from vertically transmitted infection begin with universal screening of all pregnant women for the HBV carrier state. For infants born in the United States to women who are identified as chronic carriers (regardless of HBeAg serologic status), both HBIG (0.5 mL) and an initial dose of one of the FDA-approved hepatitis B vaccines (Recombivax

HB [Merck], 5 µg; or Engerix-B [GSK], 10 µg) should be administered at different sites, within 12 hours of birth.

For premature infants born at less than 2000 g whose mothers are HbsAg positive, the initial dose of vaccine at birth should not be considered as part of the immunizing series and should be regarded as just an additional dose. For infants born to women who are not HBV carriers, the first dose of vaccine should be provided in the neonatal period, not necessarily within 12 hours of birth. For women who have not been screened, vaccine should be administered within the first 12 hours of life while maternal testing is under way. If maternal testing indicates that the mother is a chronic HBV carrier, then HBIG should be administered as quickly as possible, preferably within 48 hours of birth, but may be given within 7 days of birth. For infants born at less than 2000 g whose mothers did not undergo screening or were screened too late for results to be available within 12 hours of birth, a dose of HBIG should be given in addition to vaccine, rather than waiting for the maternal HBV status to be determined. For infants born to HBSAg-positive mothers, follow-up testing should be performed for HBsAg and anti-HBs at 9 to 15 months of age, after completion of the series of immunizations for HBV. Testing of the infant shortly after vaccine administration may yield a positive result for HBsAg as a result of vaccination, rather than of infection. Detailed recommendations for immunization of neonates are available from the American Academy of Pediatrics<sup>1</sup> and the ACIP.<sup>44</sup>

In situations in which a chronic carrier mother has premature rupture of the membranes, the delivery management should not be altered in order to deliver the infant to provide prophylaxis, because no data are available to support an increased risk of HBV infection to the infant before delivery in this situation.<sup>50</sup>

Mutations in the viral genome responsible for the production of HBsAg with an altered antigenic structure are known to exist. These relatively rare mutations create HBV virions that are not neutralized by the immunity created with HBV immunization<sup>47,78</sup>; the clinical consequences in persons infected by these altered HBV virions are therefore not altered with available HBV vaccines.

The current recommendation to prevent HBV infection in infants born to mothers with chronic hepatitis also should apply to infants born to mothers who become infected by HBV in the last trimester of pregnancy and are HBsAg positive at the time of delivery, because risk of vertical transmission appears to be similar in both situations. Large-scale trials to document efficacy of HBIG and HBV vaccine in these infants do not exist, however.

In addition to providing immune prophylaxis with HBIG and vaccine to infants, lamivudine also has been used for treatment in mothers with high viral loads during the last month of pregnancy in an effort to reduce the risk of vertical transmission. Although the average viral load decreased in women who received lamivudine, one of eight infants who also received immune prophylaxis became infected with HBV.<sup>109</sup> At this time, antiviral therapy during the last month of pregnancy cannot be routinely recommended.

Intervention strategies with hepatitis vaccine and HBIG for the newborn infant, based on maternal screening for HBV infection and the gestational age of the infant, are summarized in Table 25-2.

## HEPATITIS C

### The Virus

After the development of definitive assays for both HAV and HBV in the mid-1970s, it became clear that other agents also were responsible for post-transfusion hepatitis, sporadic hepatitis, and occasional epidemics of maternally transmitted hepatitis.<sup>119</sup> Following the discovery of the virus by means of a “blind” recombinant immunoscreening approach, HCV was recognized as the agent most commonly responsible for parenterally transmitted non-A, non-B virus infection.<sup>122</sup> HCV is a single-stranded enveloped RNA virus approximately 9600 nucleotides long, belonging to the Flaviviridae family.<sup>146,149</sup> The single strand of positive-sense RNA codes for a single open reading frame, producing a single polypeptide of approximately 3000 amino acids that is cleaved into three *structural* proteins—core, E1, E2—and seven *non-structural* proteins—p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. Structural proteins E1 and E2 are involved in the viral envelope and are likely to be involved in cell receptor binding. Nonstructural proteins provide various intracellular functions, including a protease used to cleave a portion of the polypeptide into active components, a helicase, and an RNA-dependent RNA polymerase.

Entry into the cell follows attachment of the virus by means of the E2 envelope protein to CD81, a cell surface protein expressed on hepatocytes and other cells.<sup>147</sup> Following entry, events of viral replication and release are not well understood. Viral uncoating occurs, with release of viral RNA into the cytoplasm and subsequent translation into the polypeptide as well as the production of negative-sense RNA, from which further copies of RNA for virus production can be made. Core protein, formed from the first 191 amino acids of the polypeptide, polymerizes to form the icosahedral HCV nucleocapsid, which combines with positive-sense RNA to form virions, which then incorporate the envelope proteins E1 and E2 before release. The E2 protein genome contains a hypervariable region (HVR-1) that permits ongoing change in antigenic structure of the E2 protein, providing a mechanism by which HCV may continually elude targeted host defenses,<sup>156</sup> similar to that seen in HIV infections. The viral RNA polymerase lacks the “proofreading” capabilities normally found in mammalian polymerases, thereby facilitating ongoing base replacement and altered tertiary structure of the E2 protein.

Worldwide, six major genotypes exist, although each genotype comprises hundreds to thousands of subtypes resulting from the high mutation rates during virus replication. These subtypes are called *quasispecies* and provide some insight into the unique ability of this virus to continually alter its immunologically recognizable epitopes. In general, the genotypes of HCV are used as epidemiologic tools, but they also appear to respond differently to antiviral therapies.

### Pathogenesis

Most of the information gathered on the pathogenesis of disease is based on primate models of infection, because cell culture systems and small animal models do not currently exist.<sup>132</sup> Following infection, the virus primarily enters

Table 25–2 Hepatitis B Neonatal Intervention Strategies Based on Maternal HBV Screening Status

Maternal HBV Status	Interpretation	Laboratory Evaluation at Birth and during Infancy	Infant Treatment
HBsAg negative	Mother is not considered infectious; no risk to the neonate	None required	<i>All newborn infants:</i> standard 3-dose immunization regimen with hepatitis B vaccine recommended: dose 1 given soon after birth, up to 2 months of age; dose 2 given at least 4 weeks after dose 1; dose 3 given at least 16 weeks after dose 1, and at least 8 weeks after dose 2, with last dose no earlier than 24 weeks of age
HBsAg positive	Mother is infectious; significant risk of neonatal infection	HBsAg on peripheral venous blood sampling to diagnose intrauterine infection (and less likely benefit from perinatal intervention); test infant for anti-HBs and HBsAg at 9-15 months of age for outcome of intervention	<i>All infants:</i> HBIG 0.5 mL within 12 hours of birth, in addition to the first dose of hepatitis B vaccine, also given within 12 hours of birth; second and third doses of vaccine for infants with birth weight 2000 g or greater, as above <i>Preterm infants less than 2000 g birth weight:</i> initial birth dose should not be counted as one of immunizing series because of an immature response to vaccine; subsequent 3 immunizations in primary immunizing series for these infants should start at age 1 month
HBsAg status unknown	Mother's infectious status unknown; do maternal HBsAg testing as soon as possible	None required at birth In infants whose mothers are subsequently found to be HBsAg positive, testing for anti-HBs and HBsAg at 9-15 months of age is recommended	<i>Full-term infants:</i> give first dose of hepatitis B vaccine within 12 hours of birth; if maternal HBsAg is positive, give HBIG 0.5 mL as soon as possible, within 7 days of age; if maternal HBsAg is negative, HBIG is not needed; subsequent doses as for HBsAg negative <i>Preterm infants less than 2000 g birth weight:</i> if maternal HBsAg status cannot be determined within 12 hours of birth, give HBIG in addition to hepatitis vaccine within 12 hours of birth; provide subsequent 3 hepatitis B immunizations for primary series, starting at 1 month of age, as above for preterm infants

HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

hepatocytes, although viral replication also may occur in other cell types, including dendritic cells and B cells. The virus is not cytopathic, similar to HBV. Within 10 to 14 weeks following inoculation, acute hepatitis develops, although virus can be detected in the liver many weeks before clinically evident disease. At the onset of illness, liver function test results become abnormal, and HCV-specific T cells appear in the liver.<sup>121,124,138,140,149</sup>

In a study of outcome in five persons following needle-stick exposure, viremia could first be detected within 1 to 2 weeks after exposure.<sup>158</sup> Clearance of virus occurred in only

one subject in this study and was not seen until after the appearance of HCV-specific CD8<sup>+</sup> T cells accompanied by a strong HCV-specific CD4<sup>+</sup> response. Clinical hepatitis occurred at the time of appearance of CD8<sup>+</sup> T cells, although elevation of liver enzymes occurred as early as 2 weeks after exposure in persons who remained asymptomatic. In persons in whom persistent infection did not develop, no CD8<sup>+</sup>-specific response was detected, although in some, strong CD4<sup>+</sup> T cell responses initially developed that subsequently faded during the 23 to 92 weeks of follow-up evaluation. Of note, the production of IFN- $\gamma$  led to a

100,000-fold drop in circulating virus titer, suggesting that the noncytolytic mechanisms of T cell control of intracellular virus replication in HBV infections may be similar in HCV.

Other studies have documented strong CD8<sup>+</sup> T cell responses to multiple different epitopes of HCV among human subjects with resolution of infection.<sup>137</sup> The responses differed in the specific HCV epitopes recognized, suggesting that no single neutralizing epitope exists, and that a response to multiple epitopes simultaneously is more likely to lead to clearance of virus. Persons with persisting infection had responses that were weaker and more narrowly focused. Similar data exist in the chimpanzee model, suggesting that CD8<sup>+</sup> T cell responses, seen in cells resident within the liver, constitute an important component of the immune response.<sup>121,149,155,159</sup> Within the liver, complex interactions between virally infected cells and HCV-specific CD8<sup>+</sup> and CD4<sup>+</sup> T cells occur, leading to both cytolytic, destructive changes in hepatocytes and interferon production. With an extremely high replication rate of greater than 10<sup>10</sup> virions per day, as well as rapid rates of mutation, the ever-changing antigenic structure provides a moving target for the immune system. The HCV-specific antibody, which is used to diagnose infection, recognizes epitopes on the various quasispecies of HCV virions, many of which may no longer exist in the circulation at the time antibody is detected. Likewise, epitopes that elicit a cellular immune response also are changing, providing a difficult challenge to the cellular immune system to find and neutralize virally infected cells. It is not difficult to understand that chronic infection develops in 80% of infected adults.

### Transmission

HCV is primarily transmitted parenterally: by needlestick exposure (from reused needles in medical settings from the past decades, or in intravenous drug abuse) and by blood transfusion before screening of donated blood beginning in 1992. The infection may be transmitted vertically from chronically infected mother to infant, although the rate of infection in newborns is only about 3% to 7%.<sup>152</sup> Infection appears to be most often acquired perinatally, although some controversy exists as about what proportion of neonates might be infected in utero. The assessment of in utero infection usually is made by confirming the presence of HCV RNA by RT-PCR assay in cord blood. Inapparent contamination of the cord with maternal blood, however, may lead to false-positive results. In some of these situations, contamination is supported by follow-up studies in infants that failed to detect either HCV RNA by RT-PCR assay, or evidence of productive infection as assessed by the later appearance of anti-HCV antibody. In some studies, a rare infant who is negative for HCV by PCR assay at birth may become transiently positive during the first year of life without evidence of anti-HCV antibody at that time, or when tested later at follow-up evaluation. These observations of transient viremia may be explained either by false-positive test results or by inoculation and subsequent clearance of HCV in the infant without evidence of productive infection.

Many studies of vertical transmission have recently been published describing the rate of infection in the newborn and factors that may influence transmission.<sup>123,126,150,152,157,160</sup> The vast majority of infants who develop infection are born

to viremic mothers; the viral load in the mother has been a significant factor in transmission in most studies in which viral load was determined, with the presence of greater than 10<sup>6</sup> genome equivalents per mL resulting in greater risk of transmission.<sup>128,130</sup> HIV co-infection has been associated with increased rates of HCV transmission four to five times higher than in women who are not also HIV infected.<sup>126,129,142,154,160</sup> Some investigators also have noted infantile hypoxia and intrapartum exposure to maternal blood as assessed by a history of perineal or vaginal laceration as additional risk factors.<sup>157</sup>

At present, universal screening during pregnancy for HCV is not recommended<sup>118,145</sup>; however, pregnant women at high risk for infection should be screened. Risk factors include HIV or HBV infection, parenteral drug abuse, transfusion or transplantation before 1992, presence of chronic infection with HCV/HBV/HIV in a sexual partner, attendance at a chronic dialysis unit or association with staff of such units, elevated values on liver function tests, and history of body piercing.<sup>133</sup> Although most authorities do not advocate cesarean section for delivery in cases of maternal infection, some studies suggest a higher rate of transmission with vaginal delivery.<sup>150</sup> One analysis predicted the cost-effectiveness of cesarean section if the perinatal transmission rate in a group of HCV-positive pregnant women is at least 7.7%, estimating a reduction in transmission of more than 77%.<sup>148</sup>

Although breast milk may contain HCV DNA, breast-feeding does not appear to carry additional risk to the term infant born to a mother with HCV infection. Therefore, no restrictions should be placed on routine breast-feeding by the HCV-positive mother.<sup>139,153</sup>

Recommendations for testing the infant for evidence of vertical transmission, based on maternal laboratory screening tests for HCV infection, are summarized in Table 25-3.

### Clinical Illness

HCV infection most often is asymptomatic in infants with perinatally acquired HCV.<sup>134,151</sup> Most infections in children are either found by screening those with exposure to HCV (receipt of blood products prior to 1992 or born to mothers with chronic HCV infection) or noted incidentally on examinations and laboratory testing unrelated to hepatitis. Long-term follow-up evaluation of 62 perinatally infected infants, defined by presence of HCV RNA in serum and presence of anti-HCV antibody beyond 18 months of age, suggests that chronic infection will develop in greater than 80%.<sup>151</sup> Elevated values on liver function tests were present in 93%, and liver biopsies performed in 11 asymptomatic children all demonstrated only mild abnormalities. Therefore, it is likely that a majority of infants will have not overt manifestations of infection, and that the first clinical symptoms attributable to HCV infection will appear in the third and fourth decades of life, when cirrhosis begins to produce clinical symptoms.<sup>136</sup> Unlike in HBV infections, in which the degree of abnormality of liver function tests correlates roughly with the degree of liver damage, the fluctuating host response in HCV infection suggests that liver function tests are not helpful in assessing the development of aggressive hepatitis and cirrhosis. Normal findings on these tests may simply reflect a period in which the child's immune surveillance has not yet recognized new quasi-

**Table 25-3 Hepatitis C Management Strategy for Infants Born to Mothers Screened for HCV Due to Risk Factors**

Maternal HCV Status	Interpretation	Laboratory Evaluation at Birth and during Infancy	Infant Treatment
Anti-HCV negative	Mother not considered infectious; no risk to neonate unless mother was infected within 6 months before testing and had not yet seroconverted at time of screening; for recent high-risk exposures for mother, request additional plasma HCV RT-PCR testing on mother at delivery	None required for infants born to mothers who are anti-HCV negative (or with negative result on HCV RT-PCR assay if obtained)	None
Anti-HCV positive	Mother has been previously infected and has an 80% chance of being chronically infected and persistently viremic with HCV Check maternal plasma HCV by RT-PCR assay; if result is positive, mother is infectious (5% risk of HCV vertical transmission), particularly if she also is HIV positive (30% risk of HCV vertical transmission)	No routine testing at birth; infant should be tested for anti-HCV antibody at 12 to 18 months of age Maternal, transplacental antibody should be reliably cleared by the infant at that time if no neonatal infection has occurred; if anti-HCV is present at age 12 to 18 months, do plasma HCV RT-PCR testing in infant; if result is positive, infant has been infected If anti-HCV test result is positive at age 18 months, and plasma HCV RT-PCR assay result is negative, repeat anti-HCV and HCV PCR testing every 6 months until both are negative (no infection) or both are positive (infection)	No HCV vaccine available; no effective immune globulin to prevent HCV transmission to neonate

anti-HCV, antibody to hepatitis C virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; RT-PCR, reverse transcriptase–polymerase chain reaction.

species within hepatocytes, and no acute inflammatory host response is present at that moment. Yet significant damage to the liver may have already occurred. Similarly, highly elevated liver function test values may reflect an ongoing immunologic response, with a liver that previously incurred minimal inflammatory changes.

Of perinatally infected children, about 20% have been documented to clear their infection during childhood—a higher proportion than in children who acquired infection through transfusion.<sup>134</sup> Of perinatally infected children who cleared their infection, liver inflammation as assessed by liver function tests was greater than in those who remained chronically infected. This finding suggests that greater host recognition of viral infection accompanied by liver damage may be a predictor of subsequent cure.<sup>151</sup> Routine liver biopsy in children with HCV is not currently recommended.<sup>1,135</sup>

In adults, jaundice will develop as part of the clinical presentation in only 20% of those with acute HCV infections.<sup>141</sup> Some patients will have a nonspecific prodrome of fatigue, lethargy, low-grade fever, nausea and vomiting, and abdominal discomfort beginning approximately 2 months

following exposure (2 to 12 weeks), and lasting from 2 to 12 weeks. Of those adults who are clinically symptomatic, approximately 50% will clear the infection; of those who have clinically asymptomatic infection, the infection will become chronic in 80%.<sup>140</sup> The interval from acute infection to the development of cirrhosis may be 30 years or longer. Severe complications of cirrhosis will occur in 15% to 20% of chronically infected persons.<sup>136</sup> With HCV infection outbreaks associated with contaminated blood products, long-term follow-up evaluation suggests that the great majority of chronically infected adults have minimal cirrhosis as confirmed by biopsy performed 20 years after infection. Alcohol use and co-infection with other viruses causing hepatitis are associated with an acceleration of the inflammatory process. The genotype of HCV causing the infection does not appear to play a major role in the clinical course or progression of infection.<sup>132</sup>

Chronic HCV infection in adults also is a risk factor for the development of hepatocellular carcinoma. An HCV-attributable risk of 1% to 4% per year has been reported for persons in whom cirrhosis also developed.<sup>136</sup>

The status of HCV viral infection in pregnancy has been studied. Published reports suggest a decrease in the level of aminotransferases as the pregnancy progresses, as well as some variability in the viral load.<sup>123,131</sup>

### Laboratory Diagnosis

The diagnosis of an HCV infection is based on the detection of anti-HCV antibodies, which reflect a host humoral response to a wide range of HCV viral antigens as measured by enzyme immunoassay (EIA). Unlike in HAV or HBV infection, however, the presence of antibody does not document recovery from infection, or lack of contagiousness. As in HIV infection, the EIAs are very sensitive, but serologic confirmation of infection also is available with the more specific recombinant immunoblot assay (RIBA), which detects the host response to specific viral products within infected cells. Current-generation EIA and RIBA tests are more sensitive and specific than previous tests, allowing more accuracy in diagnosis. The third-generation EIA tests detect antibodies to recombinant and synthetic peptides representing the core and NS3, NS4, and NS5 regions and are 99% specific.<sup>127,143</sup> RIBAs also are highly specific in measuring host antibody reactions to each of a number of specific HCV antigens, including two synthetic peptides, 5-1-1(p) and c100(p), from the NS4 region of the HCV genome; c33-c recombinant antigen derived from the NS3 region; c22(p) from the core portion of HCV; and the product of the NS5 region of the HCV genome.

Routine confirmation of positive third-generation EIA results with RIBA usually is not required to document infection.<sup>143</sup> Antibodies to HCV antigens develop as early as 2 to 4 weeks after infection; however, some HCV-infected persons, including neonates, may not seroconvert for up to 6 months or longer following the assumed time of exposure.

The diagnosis of active, chronic infection also relies on detection of HCV RNA, because the virus cannot be cultured. Both qualitative (nonquantitative) and quantitative assays are commercially available. Qualitative systems generally are more sensitive and include RT-PCR or TMA techniques, which can detect as few as 50 HCV genome copies per mL of blood. Quantitative assays, useful in following response to antiviral therapy, include PCR, TMA, and branched-DNA amplification techniques.<sup>143</sup> The quantity of HCV nucleic acid detected in serum in chronic infection appears to wax and wane, probably in response to the state of immunologic recognition by the host. When the host recognizes specific HCV epitopes and produces specific antibody and cellular immunity against that particular strain of circulating virus (quasispecies), it often will disappear from the circulation—only to be replaced by other quasispecies of HCV as the hypervariable genes continue to mutate to produce antigenically distinct epitopes, which then are no longer recognized by the host. At certain times during a chronic infection, the viral load of organisms detected in the serum may drop below the level of detection, producing a false-negative result. With time and further mutation during viral replication, however, new quasispecies will appear and will again be detected by assays for HCV RNA in chronically infected patients.

Additional tests that generally are not helpful in management of patients include RNA sequencing assays, to determine the genotype of infecting strain of HCV, and HCV core antigen levels (which correlate with HCV RNA levels).

Transplacentally acquired antibody in babies who are not documented to have chronic infection usually becomes undetectable during the first year of life. Antibody has not been detected in infants at 18 months of age but has been found in some infants up to 15 months of age.<sup>120,126</sup> Diagnosis of transplacental infection can be made by detecting persisting anti-HCV antibody at 18 months of age, with infection confirmed by qualitative PCR testing for HCV RNA. Although the presence of antibody before the age of 18 months may still represent maternal antibody, the presence of HCV RNA at any age suggests inoculation, if not infection. Clinicians may wish to test for HCV RNA (qualitative) in infants born to mothers with chronic HCV infection as early as 6 months of life, but if the result is positive, the test should be repeated at the age of 9 to 12 months to confirm vertical transmission.

### Therapy

As with HBV infection in the newborn, the infection is clinically benign during the first years of life; therapy with either interferon- $\alpha$  or specific anti-HCV antivirals in the infant is more likely to cause unacceptable adverse reactions in these asymptomatic babies than it is to provide any long-term benefit in preventing cirrhosis or hepatocellular carcinoma. In general, therapy is not necessary during infancy. In view of the variability in clinical progression of disease during childhood, however, a liver biopsy in the school-aged child may help the clinician in assessing the risks versus benefits of anti-HCV therapy during childhood.

Interferon- $\alpha$  has been FDA approved for use in children with hepatitis C infection in children from 3 to 16 years of age. All children in pediatric clinical trials were biopsied before enrollment; all trials required some histologic evidence of hepatitis. Virologic response rates in children varied, ranging from 33% to 45%, with a consistently lower response rate for genotype 1.<sup>135</sup> Interferon- $\alpha$  in combination with ribavirin also has received FDA approval<sup>125</sup> for the same age group based on data from 118 children, with virologic response to genotype 1 ( $n = 92$ ) of 36% and a response to non-1 genotypes of 81% ( $n = 26$ ).

In adults, pegylated interferon- $\alpha$  in combination with ribavirin has produced the best overall virologic response among FDA-approved therapies, with response rates of about 55%.<sup>144</sup> Clinical trials of peginterferon are under way in children.

### Prevention of Infection

No HCV vaccines have been approved for use in humans. No therapeutic trials in pregnancy have been undertaken during the last trimester to reduce the viral load at the time of delivery in an attempt to decrease the rate of vertical transmission. No immune globulins or antivirals have been used for the newborn infant to prevent the development of infection in those perinatally exposed to HCV.

## HEPATITIS D

### The Virus

Rizzetto and colleagues first noted that clinical deterioration of chronic HBV infection was associated with the appearance of a new (delta) antigen in the liver and antibody in the serum to this antigen.<sup>170</sup> This delta agent was subsequently isolated and analyzed and its nucleic acid cloned and sequenced.<sup>162,165,171</sup> HDV (delta agent) is a 37-nm negative-sense single-stranded RNA agent that requires co-infection with HBV. The unique circular RNA genome is only 1700 nucleotides long. HDV is unrelated to known animal RNA viruses but shares some similarities with plant viruses.<sup>161,163,169</sup> Reclassification of HDV as a new genus, *Deltavirus*, has been proposed.

### Pathogenesis

Little is known about HDV infection. Cell entry is thought to be mediated by an HBsAg-associated cellular receptor. Once inside the cell, host cell RNA polymerase transcribes viral RNA by mechanisms that are poorly understood, because no RNA-dependent RNA polymerase activity usually exists for host enzymes.<sup>161</sup> HDV has multiple open reading frames, but only one, ORF5, leads to the production of a single, identifiable HDV protein. This protein can take two forms—HDAg-S (short) and HDAg-L (long), which contains an additional 19 amino acids and serves a different function. HDAg-S is involved in HDV RNA replication by stimulating transcription of viral nucleic acid by the host enzyme; HDAg-L is involved in virion assembly.<sup>161,163</sup> Genetic heterogeneity is well documented with HDV: Three genotypes, as well as numerous quasispecies within each genotype, have been described.<sup>163</sup> The RNA genome is capable of self-cleavage and self-ligation in the process of creating circular RNA; therefore, it is classified as a ribozyme. The virus uses the HBV S protein (HBsAg) as a coat protein, packaging the HDV RNA/HDAg within infectious virions. The virus may be directly cytotoxic to the hepatocyte.

Investigation of the immunologic response to HDV acute infection in patients chronically infected by HBV suggests clearance of HDV by CD4<sup>+</sup> helper T cells, which have been documented to respond to at least four specific viral epitopes.<sup>168</sup> Patients with HDV hepatitis in whom chronic HDV infections subsequently developed lacked these specific cellular responses. Recently, a set of HDV epitopes eliciting specific anti-HDV CD8<sup>+</sup> T cell responses were found in patients with evidence of past HDV infection, suggesting that cellular immune responses to HDV may be similar to those seen with HBV infection.<sup>164</sup>

The histopathology of hepatitis delta virus infection has been studied in carriers of HBsAg with serial biopsies in adults with acute HDV hepatitis associated with chronic infection. No feature distinguished HDV histopathology from other types of viral hepatitis. Portal and periportal inflammation with piecemeal necrosis was documented, often accompanied by cirrhosis. Biopsies also documented focal, confluent, and bridging necrosis. In patients with chronic HBV infection who are co-infected with HDV, more rapid progression to cirrhosis may occur, particularly in certain population groups.<sup>169</sup> HDV co-infection does not

appear to confer additional risk of hepatocellular carcinoma, however.<sup>169</sup>

Overall, approximately 5% of persons infected chronically with HBV worldwide are co-infected with HDV, resulting in a public health burden of 15 million cases of HDV infection. As the epidemiology of hepatitis D is better understood, the worldwide distribution and clinical significance of HDV are becoming appreciated. HDV is present in 40% to 60% of all cases of fulminant HBV infection.

### Transmission

HDV infection in adults in the developed world occurs primarily in association with parenteral drug abuse, although sexual transmission and intrafamilial transmission also may occur.<sup>166</sup> In underdeveloped areas within Africa and South America, the seroprevalence of HDV is much higher, although it may vary considerably even within regions of a single country. In these areas, identified risk factors include living in a household with an index case, sexual contact, and spread through open skin lesions in children.<sup>169</sup> In utero or vertical transmission of HDV from mother to neonate has not been reported.

### Clinical Illness

HDV infections occur in three clinical settings: (1) acute HDV hepatitis with acute HBV hepatitis, (2) acute HDV hepatitis with chronic HBV hepatitis, and (3) chronic HDV hepatitis with chronic HBV hepatitis. The incidence, transmission, and clinical consequence of HDV infection in newborns and young children have not been defined.

### Laboratory Diagnosis

Commercial anti-HDV EIA tests are widely available, including an anti-HDV IgM test. In acute self-limited HDV hepatitis, the IgM anti-HDV antibody is only transiently positive; therefore, serial samples may be necessary to confirm the diagnosis. In any HBsAg-positive, anti-HBc IgM antibody-negative patient who has acute hepatitis, a screening test for IgM anti-HDV antibody may help rule out concurrent HDV superinfection. In chronic HDV hepatitis, anti-HDV IgM or high-titer anti-HDV IgG antibodies are detectable. Serial samples that are positive for anti-HDV antibody confirm that the infection is chronic and not acute. In addition to detection of antibody, HDV antigen (HDAg) can be detected in serum by immunoblot technique in a majority of patients with chronic HDV infection. The most sensitive test for HDV infection is an assay for HDV RNA using RT-PCR, which also is commercially available.

### Therapy

The only treatment that proved effective in HDV/HBV co-infection in adults is high-dose, prolonged therapy with interferon- $\alpha$ .<sup>167</sup> Courses of interferon longer than 1 year have been used in some patients.<sup>163</sup> No treatment has been used in children.

## Prevention of Infection

The prevention of hepatitis D is accomplished through the prevention of hepatitis B, because available evidence does not suggest that HDV can infect a person who is HBsAg negative. Perinatal transmission has not yet been documented; accordingly, the need for intervention during pregnancy has not yet been defined.

## HEPATITIS E

### The Virus

HEV is a 7500-base, positive-sense, single-stranded RNA whose sequence is unique among those of other known viruses, most closely resembling that of togaviruses. The viral genome consists of three open reading frames, which code for at least five nonstructural and capsid proteins, including a protease, a helicase, and an RNA-dependent RNA polymerase. This virus is 27 to 32 nm in diameter and can be found in stool by immune electron microscopy during the acute phase of the infection. The virus does not have a lipid membrane and is labile to high salt concentrations and freezing but appears to be able to persist in sewage.<sup>186,188</sup>

### Pathogenesis

HEV infection is found worldwide. Like HAV, this virus is a major cause of waterborne epidemics of acute hepatitis under conditions of poor sanitation. Infections occur predominantly in Asia, Africa, and Mexico. Recently developed EIAs for anti-HEV have detected antibodies to HEV-related antigens in 1% to 2% of U.S. volunteer blood donors, indicating that HEV also may be endemic in the United States. Most people infected with HEV are older than those infected with HAV, with seroepidemiologic investigations suggesting a peak incidence of infection between the ages of 15 and 40 years. Published data suggest negligible intra-familial transmission from index cases identified during outbreaks of HEV infection, providing support for a more prominent role in exposure from contaminated water supplies.<sup>172</sup> Early childhood transmission, presumably through direct contact, also has been documented to occur.<sup>180</sup>

Very little is known about the pathophysiology of HEV infection in humans, although primate models have successfully been used to study productive infections. The virus first appears in the liver, followed by viremia, and subsequently by shedding of the virus in feces. Liver injury occurs with elevated serum aminotransferases and develops at the time of appearance of anti-HEV IgM antibody. Evidence of liver inflammation is accompanied by biopsy evidence of injury, but without the presence of significant clinical illness in the primate model. No chronic infection has been described in humans. In animal models and in humans, the severity of the disease may be genotype dependent. Passively administered neutralizing antibody to HEV capsid antigens is successful in preventing infection following challenge in the cynomolgus primate model.<sup>187</sup> Little is known about the human cellular immune response to HEV infection.

A number of studies of the natural history of hepatitis in pregnancy have documented HEV to play a dominant role in the progression to fulminant hepatic failure and death.<sup>181,184,185</sup> The pathogenesis of aggressive infection in pregnancy is not well understood.

### Transmission

Hepatitis E virus (HEV) usually is transmitted to children and adults by the fecal-oral route.<sup>173,174</sup> With respect to the neonate, limited data point to in utero infection as suggested by the presence of specific HEV IgM in cord blood, as well as by the detection of virus by PCR assay.<sup>182,185</sup> In one report from India of a series of eight infants born to mothers with evidence of acute HEV infection in the third trimester, five infants had PCR evidence of in utero infection<sup>182</sup>; of these, four had elevated values of liver aminotransferases, and three had anti-HEV IgM. Two of these five neonates died, with postmortem examination in one infant documenting hepatic necrosis.

In another report, also from India, three of six neonates born to mothers with acute HEV infection during the third trimester of pregnancy were PCR positive for HEV. Two of these three infants also were anti-HEV IgM positive in cord blood. One of these infants had intrauterine growth retardation and elevated values on liver function tests at the time of birth but recovered clinically from the illness.<sup>185</sup>

Prospectively collected, uncontrolled data on HEV transmission from mothers to infants in Saudi Arabia documented HEV RNA in colostrum of infected mothers. Of 57 pregnant women documented to be HEV seropositive for viral RNA during the last trimester, 6 experienced symptomatic liver disease in the perinatal period. Clinical hepatitis developed in 4 infants born to these 6 women by 6 to 8 weeks of age. None of these infants were breast-fed, because of maternal illness. All other infants born to HEV RNA-positive mothers were breast-fed for a mean of 3.6 months. Hepatitis did not develop in any of these infants. Therefore, available data suggest that breast-feeding does not increase the transmission of virus from mother to infant.<sup>176</sup>

### Clinical Illness

The incubation period following exposure in children and adults is between 15 and 60 days. The clinical manifestations of illness usually are mild, with nausea, vomiting, and epigastric pain, followed by the onset of jaundice. Clinical symptoms and aminotransferase elevation usually resolve within 1 to 6 weeks.<sup>183,188</sup> In the animal model, clinical symptoms are dependent on the inoculum of virus.<sup>177</sup> Excretion generally continues for a few weeks following onset of illness.<sup>175</sup> Chronic HEV infection has not been documented.

### Laboratory Diagnosis

Acute infection may be diagnosed by the presence of anti-HEV IgM, whereas past infection may be documented by the presence of anti-HEV IgG. Assays for both immunoglobulins are available commercially in reference laboratories.<sup>175,179</sup>

## Therapy

Clinical studies of antiviral therapy in animal models or humans have not been reported. Nevertheless, antiviral therapy might provide benefit to specific populations, including pregnant women, in whom more serious disease may develop.

## Prevention of Infection

Postexposure, passive administration of immune globulin does not appear to reduce the incidence of disease.<sup>183</sup> Based on the ability to passively neutralize virus and to prevent infection in animal models, vaccines have been developed for HEV infection. A vaccine that contains an epitope spanning all genotypes is now in clinical trials in Nepal.<sup>178</sup>

## HEPATITIS G

### The Virus

HGV, also known as GB virus type C (GBV-C), was identified in 1995 from the blood of hepatitis patients who had no other identifiable causes of viral hepatitis.<sup>192</sup> Since its discovery, however, no further association has been found with hepatitis as a clinical syndrome attributable to this virus—hence the preference of some experts for the name GBV-C.<sup>197</sup> The virus is classified as a flavivirus, containing a 9.4-kilobase single strand of positive-sense RNA. The single polyprotein encoded by the single open reading frame in the genome has approximately 30% homology with HCV. The polyprotein is cleaved into at least eight proteins, including two envelope proteins (E1, E2) and six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, NS5B), analogous to HCV. Unlike the genes that code for the HCV E2 protein, however, a hyper-variable region does not appear to exist in HGV.<sup>197</sup>

### Pathogenesis

In an attempt to define the HGV-attributable liver infection in patients known to be chronically infected with the virus because of persistent serum HGV RNA, investigators assayed HGV RNA in both liver and serum from patients undergoing liver transplantation (for a variety of underlying disorders) who were known to be infected either with HGV alone, infected with HCV alone, or coinfecting with both viruses.<sup>193</sup> The investigators found a mean liver-to-serum ratio of HCV, known to be hepatotropic, of greater than 10<sup>2</sup>, whereas the mean liver-to-serum ratio in HGV patients was only 0.3, leading to the conclusions that HGV was not hepatotropic and that HGV RNA found in the liver was related to blood circulation rather than to hepatocyte infection. Indeed, HGV has not been found to be pathogenic in any study in which patients were known to be infected.<sup>196</sup> Anti-HGV antibody was found in 13% of blood donors in the midwestern United States who passed the standard laboratory and questionnaire screening tests to permit donation. Furthermore, in 2% of these donors, HGV RNA was detected.

In epidemiologic studies worldwide, the prevalence of antibodies to HGV E2 protein varies, ranging from 20% in South Africa to 3% in the Philippines.<sup>194</sup> In studies in which

both HGV RNA and anti-HGV antibody directed against the E2 protein are assayed, both are never found together in the same patient.<sup>194,197</sup>

### Transmission

HGV has been shown to be transmitted by exposure to infected blood and blood products, by sexual exposure, and from mother to newborn infant.<sup>196</sup> In Sweden, three studies investigated vertical transmission, including one study of HIV-infected mothers. Of seven infants born to mothers not infected with HIV, one infant became HGV RNA positive in serum at 3 months, with persisting viremia during 42 months of follow-up and no evidence of liver disease.<sup>191</sup> In another investigation, 16 of 20 mothers (80%) with HGV viremia transmitted the infection, as documented by the presence of HGV RNA in their infants.<sup>198</sup> The time to acquisition of viremia in the infants was not well defined, but occurred in a majority of infants by 3 to 6 months of age. Symptomatic hepatitis did not develop in any of the infants. In mothers with HGV and HIV coinfection, the vertical transmission rate of HGV was assessed in the era prior to maternal antiretroviral antenatal prophylaxis. Of 17 mothers identified with HGV infection, 3 were viremic with HGV at the time of delivery, and 14 had anti-HGV antibody. None of the anti-HGV-antibody positive women had detectable serum HGV RNA. Only one of the infants born to the mothers with HGV viremia transmitted the infection to her infant; HIV was not co-transmitted to this infant.<sup>190</sup> HGV did not appear to influence the rate of transmission of HIV, noted to be 20% in this study.

The role of breast-feeding in transmission was investigated in one study, documenting the lack of detectable HGV RNA in the breast milk of 15 viremic women.<sup>195</sup> Nevertheless, the vertical transmission rate in this study was 20%, as assessed by HGV RNA in the infants. Because breast milk may not play a significant role in vertical transmission of HGV, and the consequences of neonatal chronic infection are not defined, breast-feeding should not be discouraged in women known to be HGV infected.

### Laboratory Diagnosis

Most commercial laboratories do not offer routine testing for HGV. An EIA for antibody to the E2 protein has been developed to detect past infection, however, and is used in epidemiologic investigations.<sup>196</sup> HGV RNA can be detected by RT-PCR assay, which is available in some reference laboratories. Because the virus is not known to cause disease, recommendations for routine screening for HGV infection in any population, including blood donors, have not been made.

## HISTORICAL BACKGROUND

Infections caused by herpes simplex viruses (HSVs) were recognized by the ancient Greeks. The word *herpes*, meaning “to creep or crawl,” was used to describe skin lesions. Herodotus associated mouth ulcers and lip vesicles with fever<sup>1</sup> and called this event *herpes febrilis*. Genital herpetic infections were first described by Astruc, a physician to French royalty.<sup>2</sup> The transmissibility of these viruses was established unequivocally by passage of virus from lip and genital lesions of humans to the cornea or the scarified skin of the rabbit.<sup>3</sup> During the early 20th century, diseases associated with HSV infections became more clearly defined by numerous clinical and pathologic case reports.

Neonatal HSV infection was identified as a distinct disease 70 years ago. The first written descriptions of neonatal HSV infections were attributed to Hass, who described the histopathologic findings of a fatal case, and to Batignani, who described a newborn child with HSV keratitis.<sup>4,5</sup> During subsequent decades, our understanding of neonatal HSV

infections was based on histopathologic descriptions of the disease, which indicated a broad spectrum of organ involvement in infants.

An important scientific breakthrough occurred in the mid-1960s, when Nahmias and Dowdle<sup>6</sup> demonstrated two antigenic types of HSV. The development of viral typing methods provided the tools required to clarify the epidemiology of these infections. HSV infections “above the belt,” primarily of the lip and oropharynx, were found in most cases to be caused by HSV type 1 (HSV-1). Infections “below the belt,” particularly genital infections, were usually caused by HSV type 2 (HSV-2). The finding that genital HSV infections and neonatal HSV infections were most often caused by HSV-2 suggested a cause-and-effect relationship between these two disease entities. This causal relationship was strengthened by detection of the virus in the maternal genital tract at the time of delivery, indicating that acquisition of the virus by the infant occurs by contact with infected genital secretions during birth.

During the past 25 years, our knowledge of the epidemiology, natural history, and pathogenesis of neonatal HSV infections has been enhanced greatly. The development of antiviral therapy represents a significant advance in the management of infected children, providing the opportunity to decrease mortality and reduce the morbidity associated with these infections. Neonatal HSV infection is more amenable to prevention and treatment than many other pathogens because it is acquired most often at birth rather than during gestation. As our understanding of the epidemiology of HSV infections has improved, postnatal acquisition of HSV-1 has been documented from nonmaternal sources, and more cases caused by HSV-1 infections of the maternal genital tract have been identified. New perspectives on the changing presentations of neonatal HSV infection, the obstacles to diagnosis, and the value of antiviral therapy are topics addressed in this chapter.

## HERPES SIMPLEX VIRUS

### Structure

The biologic, molecular, antigenic, and epidemiologic characteristics of HSV-1 and HSV-2 have been the subject of numerous publications. Reviews highlight the importance of these organisms as models for viral replication and as pathogens in human infection.<sup>7,8</sup>

The HSVs are members of a family of large DNA viruses that contain centrally located, linear, double-stranded DNA. Other members of the herpesvirus family include cytomegalovirus, varicella-zoster virus, Epstein-Barr virus, and human herpesviruses 6A, 6B, 7, and 8.<sup>7,8</sup> As a family, these viruses are virtually indistinguishable from each other by electron

microscopy. The viral DNA is packaged inside a protein structure, the capsid, which confers icosahedral symmetry to the virus. The capsid consists of 162 capsomers and is surrounded by a tightly adherent membrane known as the tegument. An envelope consisting of glycoproteins, lipids, and polyamines loosely surrounds the capsid and tegument. The glycoproteins mediate attachment of the virus to cells.

The HSV genome consists of about 150,000 base pairs.<sup>7</sup> The DNA encodes for more than 80 polypeptides. The genome consists of two components, L and S, each of which contains unique sequences that can invert, which leads to four isomers. Viral DNA extracted from virions or infected cells consists of four equal populations differing solely with respect to the relative orientation of these two unique components.

The DNAs of HSV-1 and HSV-2 are colinear with respect to the order of genes encoding viral proteins. The percent homology of base pairs that constitute each gene varies from higher to lesser degrees of conservation. There is considerable overlap in the cross-reactivity between HSV-1 and HSV-2 glycoproteins, although unique regions of these gene products exist for each virus.<sup>9,10</sup> The two viral types can be distinguished by using restriction enzyme analysis of viral DNA, which allows precise epidemiologic investigations of virus transmission.

## Replication

Replication of HSV is characterized by the expression of three gene classes: alpha, beta, and gamma. These genes are expressed temporally and in a cascade sequence.<sup>7</sup> Although herpesvirus genes carry transcriptional and translational signals similar to those of other DNA viruses that infect higher eukaryotic cells, the messenger RNAs arising from most genes are not spliced. The information density is lower than that encoded in the genes of smaller viruses. This relatively low density of genetic information is important in that it permits insertion and deletion of genes in the HSV genome without significant alteration of the genomic architecture. This point is relevant because it provides an opportunity for the use of genetically engineered herpesviruses as vaccines or vectors for antigen delivery.<sup>11</sup>

Alpha genes are expressed at immediate-early times after infection and are responsible for the initiation of replication. These genes are transcribed in infected cells in the absence of viral protein synthesis. Products of the beta genes, or early genes, include the enzymes necessary for viral replication, such as HSV thymidine kinase, and the regulatory proteins. These genes require functional alpha gene products for expression. The onset of expression of beta genes coincides with a decline in the rate of expression of alpha genes and an irreversible shutoff of host cellular macromolecular protein synthesis. Structural proteins are usually of the gamma, or late, gene class. The gamma genes are heterogeneous and are differentiated from beta genes solely by their requirement for viral DNA synthesis for maximal expression. Most glycoproteins are expressed as late genes. In addition to its regulatory and structural genes, the virus encodes genes that allow initial evasion of the host response, including gene products that block interferon- $\alpha$  and interferon- $\beta$  responses. HSV-1 and HSV-2 also express an immediate-early protein, ICP47, that mediates the downregulation of major histocompatibility complex class I molecules.<sup>12</sup>

Replication of viral DNA occurs in the nucleus of the cell. Assembly of the virus begins with formation of nucleocapsids in the nucleus, followed by acquisition of the envelope at cytoplasmic locations. Virus is transported through the cytoskeleton to the plasma membrane, where progeny virions are released.

HSV specifies at least 11, and probably several more, glycoproteins. The glycoproteins have been designated as B, C, D, E, G, H, I, J, K, L, and M.<sup>9</sup> Glycoprotein D (gD) is required for infectivity and is the most potent inducer of neutralizing antibodies; glycoprotein B (gB) is required for infectivity and also induces neutralizing antibodies; glycoprotein C (gC) binds to the C3b component of complement; and glycoprotein E (gE) binds to the Fc portion of IgG. The amino acid sequences of the glycoprotein G (gG) produced by HSV-1 and HSV-2 are sufficiently different to elicit antibody responses that are specific for each virus type. The fact that the antibody response to the two G molecules exhibits minimal cross-reactivity has provided the basis for serologic methods that can be used to detect recent or past HSV-2 infection in individuals who have also been infected with HSV-1.<sup>13-16</sup>

The close antigenic relatedness between HSV-1 and HSV-2 interferes with the serologic diagnosis of these infections using standard serologic assays. These methods do not distinguish between individuals who have had past infection with HSV-1 only, past infection with HSV-2 only, or dual infection. Although laboratory reports often indicate antibody titers to each virus, the methods used by some commercial laboratories are based on use of crude antigen and do not eliminate the detection of cross-reactive antibodies. Commercial type-specific tests based on glycoprotein G are available in some laboratories and must be used for diagnosis of HSV-2 infection.<sup>15</sup> Clinicians must be knowledgeable regarding the type of testing performed by their referral laboratory to correctly interpret results.

## Latency and Reactivation

All of the herpesviruses have a characteristic ability to establish latency, by mechanisms that remain unidentified, to persist in this latent state for various intervals of time and to reactivate, causing virus excretion at mucosal or other sites. After infection, the viral DNA persists in the host for the entire lifetime of the individual.

The biologic phenomenon of latency has been recognized and described since the beginning of the 20th century, particularly the association of HSV latency with neurons. In 1905, Cushing<sup>17</sup> observed that patients treated for trigeminal neuralgia by sectioning a branch of the trigeminal nerve developed herpetic lesions along the innervated areas of the sectioned branch. This specific association of HSV with the trigeminal ganglion was suggested by Goodpasture.<sup>18</sup> Past observations have demonstrated that microvascular surgery of the trigeminal nerve tract to alleviate pain associated with tic douloureux resulted in recurrent lesions in more than 90% of seropositive individuals.<sup>19,20</sup>

Accumulated experience in animal models and from clinical observations suggests that inoculation of virus at the portal of entry, usually oral or genital mucosal tissue, results in infection of sensory nerve endings, and the virus is transported to the dorsal root ganglia. Replication at the site of

inoculation enhances access of the virus to ganglia but is usually not associated with signs of mucocutaneous disease. Only a fraction of new infections with HSV-1 and HSV-2 are associated with clinically recognizable disease. When reactivation is triggered at oral or genital sites, the virus is transported back down axons to mucocutaneous sites. Replication and shedding of infectious virus occur at these sites. Recognizing that excretion of infectious virus during reactivation is not usually associated with clinical signs of recurrent herpes lesions is essential for understanding the transmission of HSV to newborns. Clinically silent reactivations are much more common than recurrent lesions. Reactivation, with or without symptoms, appears in the presence of humoral and cell-mediated immunity. Reactivation is spontaneous, although symptomatic recurrences have been associated with physical or emotional stress, exposure to ultraviolet light, tissue damage, and suppression of the immune system. Persistence of viral DNA has been documented in neuronal tissue of animal models and humans.<sup>7,8,21-23</sup>

Animal model studies indicate that the transport of virus to the ganglia is by retrograde axonal flow.<sup>24</sup> After transport, virus replicates for several days in sensory ganglia that innervate the sites of inoculation. After latency is established in sensory ganglia, virus cannot be eradicated from the infected cells. Because the latent virus does not multiply, it is not susceptible to drugs, such as acyclovir, that affect viral DNA synthesis. Our understanding of the mechanisms by which HSV establishes a latent state and persists in this form remains limited, and this is a subject of intense research interest.

## EPIDEMIOLOGY

### Nature of Infection

Although many routes of infection have been suggested, transmission of HSV most often occurs as a consequence of intimate, person-to-person contact. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Infection with HSV-1, generally limited to the oropharynx, can be transmitted by respiratory droplets or through direct contact of a susceptible individual with infected secretions. Acquisition often occurs during childhood.

Primary HSV-1 infection in the young child is usually asymptomatic, but clinical illness is associated with HSV gingivostomatitis. Primary infection in young adults has been associated with only pharyngitis or with a mononucleosis-like syndrome. Seroprevalence studies have demonstrated that acquisition of HSV-1 infection, like that of other herpesvirus infections, is related to socioeconomic factors. Antibodies, indicative of past infection, are found early in life among individuals of lower socioeconomic groups, presumably reflecting the crowded living conditions that provide a greater opportunity for direct contact with infected individuals. As many as 75% to 90% of individuals from lower socioeconomic populations develop antibodies to HSV-1 by the end of the first decade of life.<sup>8,25-27</sup> In middle and upper middle socioeconomic groups, only 30% to 40% of individuals are seropositive by the middle of the second decade of life.<sup>8</sup> A change in seroprevalence rates of HSV-1 has been recognized in the past few decades, which reflects a

delay in acquisition of infection until later in life. The increase in the reported number of cases of genital herpes caused by HSV-2 may be related to a lower prevalence of prior HSV-1 infection in young adults. These individuals would not have the partial protection against HSV-2 infection that is probably conferred by cross-reactive HSV-1 immunity. Investigators have found that a substantial percentage of cases of genital HSV infection are caused by HSV-1 in certain populations.<sup>28</sup>

Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found until the age of onset of sexual activity.<sup>26</sup> A progressive increase in infection rates with HSV-2 in all populations begins in adolescence. Until recently, the precise seroprevalence of antibodies to HSV-2 had been difficult to determine because of cross-reactivity with HSV-1 antigens. During the late 1980s, seroepidemiologic studies performed using type-specific antigen for HSV-2 (glycoprotein G-2) identified antibodies to this virus in approximately 25% to 35% of middle-class women in several geographic areas of the United States.<sup>14,29-31</sup> Based on national health surveys, the seroprevalence of HSV-2 in the United States from 1988 to 1994 was 21.9% for individuals 12 years old or older.<sup>31</sup> Among those with serologic evidence of infection, fewer than 10% had a history of genital herpes symptoms. This seroprevalence represented a 30% increase compared with data collected from 1976 to 1980. HSV seroprevalence is highly variable and depends on geographic region, sex, age, race, and high-risk behaviors.<sup>32</sup> The increasing prevalence of genital HSV-1 infection in some countries suggests that use of type-specific tests for HSV-1 and HSV-2 may be helpful in determining the true incidence of genital HSV infections.<sup>28</sup>

The molecular epidemiology of HSV infections can be determined by restriction enzyme analysis of viral DNA obtained from infected individuals. Viruses have identical profiles when they are from the same host or are epidemiologically related.<sup>33</sup> In a few circumstances, however, it has been demonstrated that superinfection or exogenous reinfection with a new strain of HSV is possible. Such occurrences are uncommon in the nonimmunocompromised host with recurrent genital HSV infection.<sup>33-35</sup> Differences in the restriction endonuclease patterns of viral DNAs, indicating exogenous infections, are more common in immunocompromised individuals who are exposed to different HSVs, such as patients with acquired immunodeficiency syndrome (AIDS).

### Maternal Infection

Infection with HSV-2, which reactivates and is shed at genital sites, is common in the pregnant woman. Using assays to detect type-specific antibodies to HSV-2, seroepidemiologic investigations have demonstrated that approximately one in five pregnant women has had HSV-2 infection.<sup>30,36-40</sup> Given the capacity of HSV to establish latency, the presence of antibodies is a marker of persistent infection of the host with the virus. The incidence of infection in women of upper socioeconomic class was 30% or higher in three large studies.<sup>38,40,41</sup> These investigations have demonstrated that most women with serologic evidence of HSV-2 infection have no history of symptomatic primary or recurrent disease. New HSV-2 infections also appear to be acquired during pregnancy with a frequency that is comparable to seroconversion rates among

nonpregnant women, and these infections usually occur without clinical signs or symptoms.<sup>37-41</sup>

Evaluation of pregnant women and their partners has demonstrated that women can remain susceptible to HSV-2 despite prolonged sexual contact with a partner who has known genital herpes.<sup>39</sup> One in 10 women in this study were found to be at unsuspected risk for acquiring HSV-2 infection during pregnancy as a result of contact with a partner whose HSV-2 infection was asymptomatic.

Most maternal infections are clinically silent during gestation. However, infection during gestation may manifest in several clinical syndromes. An uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated disease. As first reported by Flewett and co-workers<sup>42</sup> in 1969 and by others<sup>43,44</sup> subsequently, infection has been documented to involve multiple visceral sites in addition to cutaneous ones. In a limited number of cases, dissemination after primary oropharyngeal or genital infection has led to severe manifestations of disease, including necrotizing hepatitis with or without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. Although only a few patients have suffered from disseminated infection, the mortality rate for these pregnant women is more than 50%. Fetal deaths were described in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Surviving fetuses were delivered by cesarean section during the acute illness or at term, and none had evidence of neonatal HSV infection.

Earlier studies described an association of maternal primary infection before 20 weeks' gestation with spontaneous abortion in some women.<sup>45</sup> Although the original incidence of spontaneous abortion after a symptomatic primary infection during gestation was thought to be as high as 25%, this estimate was not substantiated by prospective studies and was erroneous because of the small number of women followed. More precise data obtained from a prospective analysis of susceptible women demonstrated that 2% or more acquired infection but that acquisition of infection was not associated with a risk of spontaneous abortion.<sup>46</sup> With the exception of rare case reports,<sup>47</sup> primary infection that develops later in gestation is not generally associated with premature rupture of membranes or premature termination of pregnancy.<sup>47</sup>

Localized genital infection, whether it is associated with lesions or remains asymptomatic, is the most common form of HSV infection during pregnancy. Overall, prospective investigations using cytologic and virologic screening indicate that genital herpes occurs with a frequency of about 1% in women tested at any time during gestation.<sup>38,46</sup> Most of these infections were classified as recurrent when HSV-2-specific serologic evaluation was done concurrently. Transmission of infection to the infant is most frequently related to the actual shedding of virus at the time of delivery. Because HSV infection of the infant is usually the consequence of contact with infected maternal genital secretions at the time of delivery, the incidence of viral excretion at this point has been of particular interest. The reported incidence of viral excretion at delivery is 0.01% to 0.39% for all women, regardless of their history of genital herpes.<sup>38,41</sup>

Several prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a

known history of genital herpes. These women represent a subset of the population of women with HSV-2 infection because they had characteristic genital lesions from which virus was isolated. In a predominantly white, middle-class population, symptomatic recurrent infection occurred during pregnancy in 84% of pregnant women with a history of symptomatic disease.<sup>48</sup> Viral shedding from the cervix occurred in only 0.56% of symptomatic infections and 0.66% of asymptomatic infections. These data are similar to those obtained for other populations.<sup>29</sup> The incidence of cervical shedding in asymptomatic pregnant women has been reported to vary from 0.2% to 7.4%, depending on the numbers of cultures that were obtained between symptomatic episodes. Overall, these data indicate that the frequency of cervical shedding is low, which may reduce the risk of transmission of virus to the infant when the infection is recurrent. The frequency of shedding does not appear to vary by trimester during gestation. No increased incidence of premature onset of labor was apparent in these prospective studies of women with reactivation of HSV-2 infection.

The most important fact about maternal transmission is that most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infections during the pregnancy and at the time of delivery. These women usually have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash and account for 60% to 80% of all women whose infants become infected.<sup>49-51</sup> Among women delivering children who developed neonatal HSV infection, only 27% had a history of or evidence of recurrent lesions indicative of HSV infection during the current pregnancy.<sup>50</sup> One half of these women reported genital HSV infection in their sexual partners.

### Factors Influencing Transmission of Infection to the Fetus

The development of serologic assays that distinguish antibodies to HSV-1 from those elicited by HSV-2 infection has allowed an accurate analysis of risks related to perinatal transmission of HSV.<sup>13-16</sup> The category of maternal genital infection at the time of delivery influences the frequency of neonatal acquisition of infection. Maternal infections are classified as caused by HSV-1 or HSV-2 and as newly acquired or recurrent. These categories of maternal infection status are based on laboratory criteria and are independent of clinical signs. Women with recurrent infections are those who have preexisting antibodies to the virus type that is isolated from the genital tract, which is usually HSV-2. Most women classified as having recurrent infection have no history of symptomatic genital herpes. Infections that are newly acquired, which have been referred to as *first-episode* infections, are further categorized as *primary* or *first episode*, *nonprimary* based on type-specific serologic testing. This differentiation is made whether clinical signs are present or not. *Primary infections* are those in which the mother is experiencing a new infection with HSV-1 or HSV-2 and has not already been infected with the other virus type. These mothers are seronegative for any HSV antibodies (i.e., HSV-1 or HSV-2 negative) at the onset of infection. *Nonprimary infections* are those in which the mother has a new infection with one virus type, usually HSV-2, but has antibodies to the other virus type, usually HSV-1, because of an infection that

was acquired previously. As transmission has been studied using type-specific serologic methods, it has become obvious that attempts to distinguish primary and recurrent disease by clinical criteria are not reliable. Serologic classification is an important advance because many "new" genital herpes infections in pregnancy represent the first symptomatic episode of infection acquired at some time in the past. In one study designed to evaluate acyclovir therapy, pregnant women who were thought to have recent acquisition of HSV-2 based on symptoms had all been infected previously. These women were experiencing genital symptoms, caused by the reactivation of latent virus, for the first time.<sup>52</sup>

A hierarchy of risk of transmission has emerged using laboratory tools to classify maternal infection. Infants born to mothers who have true primary infections at the time of delivery are at highest risk, with transmission rates of 50% or higher.<sup>46,51</sup> Those born to mothers with new infections that are first episode but nonprimary appear to be at lower risk; transmission rates are estimated to be about 30%. The lowest risk of neonatal acquisition occurs when the mother has active infection caused by shedding of virus acquired before the pregnancy or at stages of gestation before the onset of labor. The estimated attack rate for neonatal herpes among these infants is less than 2%. This estimate is reliable because it is based on the cumulative experience from large, prospective studies of pregnant women in which viral shedding was evaluated at delivery, regardless of the mother's history of genital herpes or contact with a partner with suspected or documented genital herpes.

The reasons for the higher risk of transmission to the infant when the mother has a new infection can be attributed to differences in the quantity and duration of viral shedding in the mother and in the transfer of passive antibodies from the mother to the infant before delivery. Primary infection is associated with larger quantities of virus replicating in the genital tract ( $>10^6$  viral particles per 0.2 mL of inoculum) and a period of viral excretion that may persist for an average of 3 weeks.<sup>53</sup> Many women with new infections have no symptoms but shed virus in high titers. In some mothers, these infections cause signs of systemic illness, including fever, malaise, and myalgias. In a small percentage of cases, significant complications, such as urinary retention and aseptic meningitis, occur. In contrast, virus is shed for an average of only 2 to 5 days and at lower concentrations (approximately  $10^2$  to  $10^3$  viral particles per 0.2 mL of inoculum) in women with symptomatic recurrent genital infections. Asymptomatic reactivation is also associated with short periods of viral replication, often less than 24 to 48 hours. One of the most important observations about HSV infections that has emerged from the evaluation of pregnant women is that new HSV-1 and HSV-2 infections often occur without any of the manifestations that were originally described as the classic findings in primary and recurrent genital herpes.

In parallel with the classification of maternal infection, the mother's antibody status to HSV at delivery appears to be an additional factor that influences the likelihood of transmission and probably affects the clinical course of neonatal herpes. Transplacental maternal neutralizing antibodies appear to have a protective, or at least an ameliorative, effect on acquisition of infection for infants inadvertently exposed to virus.<sup>54</sup> Maternal primary infection late in gestation

may not result in significant passage of maternal antibodies across the placenta to the fetus. Based on available evidence, the highest risk of transmission from mothers with newly acquired genital herpes is observed when the infant is born before the transfer of passive antibodies to HSV-1 or HSV-2, when the infant is exposed at delivery or within the first few days of life.<sup>46,50,55</sup>

The duration of ruptured membranes has also been described as an indicator of risk for acquisition of neonatal infection. Observations of a small cohort of women with symptomatic genital herpes indicated that prolonged rupture of membranes ( $>6$  hours) increased the risk of acquisition of virus, perhaps as a consequence of ascending infection from the cervix.<sup>45</sup> It is recommended that women with active genital lesions at the time of onset of labor be delivered by cesarean section.<sup>56</sup>

Isolation of HSV from the genital tract at the time of delivery is a major risk factor for neonatal herpes infection. One study found that cesarean section significantly reduced the rate of HSV infection in infants born to women from whom HSV was isolated at the time of delivery (1.2% versus 7.7%,  $P = .047$ ).<sup>57</sup> However, this effect of cesarean delivery was established by postdelivery analysis of data on viral shedding at delivery for a large cohort of pregnant women. In the absence of a reliable rapid test for HSV in the birth canal, it is difficult at this time to apply this information in clinical practice.

The benefit of cesarean section beyond 6 hours of ruptured membranes has not been evaluated. Although some protection may be expected, infection of the newborn has occurred despite delivery by cesarean section.<sup>49,58</sup>

Certain forms of medical intervention during labor and delivery may increase the risk of neonatal herpes if the mother has active shedding of the virus, although in most instances, viral shedding is not suspected clinically. For example, fetal scalp monitors can be a site of viral entry through skin.<sup>57,59,60</sup> The benefits and risks of these devices should be considered for women with a history of recurrent genital HSV infections. Because most women with genital infections caused by HSV are asymptomatic during labor and have no history of genital herpes, it is usually not possible to make this assessment.

### Incidence of Newborn Infection

A progressive increase in the number of cases of neonatal HSV infection to a rate of approximately 1 in 1500 deliveries was reported in King County, Washington, during the period from 1966 to 1983, when adult infection rates were also increasing.<sup>61</sup> Overall, the United States, with approximately 4 million deliveries each year, has an estimated 11 to 33 cases of neonatal infection per 100,000 livebirths. This estimate has been confirmed by a review of comprehensive hospital discharge data recorded in California for the years 1985, 1990, and 1995. The diagnosis of HSV infection in infants 6 weeks old or younger was made in 11.7, 11.3, and 11.4 infants, respectively, per 100,000 livebirths in each of these years.<sup>62</sup>

In studies where maternal serologic status during pregnancy and virologic status at the time of delivery are evaluated prospectively, the rate of transmission leading to neonatal HSV infection varies from 12 to 54 newborn infections per

100,000 livebirths. Higher rates of transmission are seen in babies born to seronegative mothers and those infected with HSV-1.<sup>57</sup>

Neonatal HSV infection occurs far less frequently than might be expected given the high prevalence of genital HSV infections in women of childbearing age in the United States. Some countries do not report a significant number of cases of neonatal HSV infection despite a similar high prevalence of antibodies to HSV-2 in women. In the United Kingdom, genital herpes infection is relatively common, but very few cases of neonatal HSV infection are recognized. Although serologic studies in central Africa indicate that women have a high frequency of antibodies to HSV-2, the first case of neonatal herpes was reported less than 25 years ago. Neonatal HSV infection in the Netherlands occurs in only 2.4 of 100,000 newborns.<sup>63</sup>

Although underreporting of cases may explain some differences between countries, there may be unidentified factors that account for these differences. The interpretation of incidence data must also include the potential for postnatal acquisition of HSV infection. Not all cases of neonatal herpes are the consequence of intrapartum contact with infected maternal genital secretions, which alters the overall estimate of delivery-associated infections.

### Times of Transmission of Infection

HSV infection of the newborn can be acquired in utero, intrapartum, or postnatally. The mother is the most common source of infection for the first two of these routes of transmission of infection. With regard to postnatal acquisition of HSV infection, the mother can be a source of infection from a genital or nongenital site, or other contacts or environmental sources of virus can lead to infection of the child. A maternal source is suspected when maternal herpetic lesions are discovered shortly after the birth of the child or when the infant's illness is caused by HSV-2. Although intrapartum transmission accounts for 85% to 90% of cases, in utero and postnatal infection must be recognized for public health and prognostic purposes.

Some infants acquire infection in utero, but this mode of transmission is rare.<sup>64-69</sup> Although it was originally presumed that in utero acquisition of infection resulted in a totally normal infant or premature termination of gestation,<sup>45</sup> it has become apparent that intrauterine acquisition of infection can lead to the clinical signs of congenital infection. By using stringent diagnostic criteria, more than 30 infants with symptomatic congenital disease have been described in the literature. These criteria include identification of infected infants with lesions present at birth, virologic confirmation of infection, and the exclusion of other infectious agents whose pathogenesis mimics the clinical findings of HSV infections, such as congenital cytomegalovirus infection, rubella, syphilis, or toxoplasmosis. Virologic diagnosis is a necessary criterion because no standard method for detection of IgM antibodies is available and infected infants often fail to produce IgM antibodies detectable by research methods.<sup>55,70</sup> The manifestations of disease in this group of children range from the presence of skin vesicles at the time of delivery to the most severe neurologic abnormalities.<sup>49,64</sup>

In utero infection can result from transplacental or ascending infection. The placenta can show evidence of

necrosis and inclusions in the trophoblasts, which suggests a transplacental route of infection.<sup>71</sup> This situation can result in an infant who has hydranencephaly at the time of birth, or it may be associated with spontaneous abortion and intrauterine HSV viremia. Virus has been isolated from the products of conception under such circumstances. Histopathologic evidence of chorioamnionitis suggests ascending infection as an alternative route for in utero infection.<sup>68</sup> Risk factors associated with intrauterine transmission are not known. Primary and recurrent maternal infections can result in infection of the fetus in utero.

HSV DNA has been detected in the amniotic fluid of two women experiencing a first-episode nonprimary infection and in one woman during a symptomatic recurrent infection. All three infants were healthy at birth and demonstrated no clinical or serologic evidence of HSV infection during follow-up.<sup>72</sup>

The second and most common route of infection is intrapartum contact of the fetus with infected maternal genital secretions. Intrapartum transmission is favored by delivery of the infant to a mother with newly acquired infection.

Postnatal acquisition is the third route of transmission. Postnatal transmission of HSV-1 has been suggested as an increasing risk. Data from the National Institute of Allergy and Infectious Diseases (NIAID) Collaborative Antiviral Study Group indicate that the frequency of infants with neonatal HSV-1 infection ranges from approximately 25% to 30%.<sup>49,73</sup> HSV-1 infections appear to account for only about 5% to 17% of all genital HSV infections in the United States,<sup>28</sup> creating greater concern about postnatal acquisition of HSV-1 infection from nonmaternal sources.

Relatives and hospital personnel with orolabial herpes may be a reservoir of virus for infection of the newborn. The documentation of postnatal transmission of HSV-1 has focused attention on such sources of virus.<sup>74-78</sup> Postpartum transmission from mother to child has been reported as a consequence of nursing on an infected breast.<sup>79</sup> Transmission from fathers and grandparents has also been documented.<sup>77</sup> When the infant's mother has not had HSV infection, the infant may be inoculated with the virus from a nonmaternal contact in the absence of any possible protection from maternally derived passive antibodies.

Because of the prevalence of HSV-1 infections in the general population, many individuals have intermittent episodes of asymptomatic excretion of the virus from the oropharynx and therefore can provide a source of infection for the newborn. The occurrence of herpes labialis, commonly referred to as fever blisters or cold sores, has ranged from 16% to 46% in various groups of adults.<sup>80</sup> Population studies conducted in two hospitals indicated that 15% to 34% of hospital personnel had a history of nongenital herpetic lesions.<sup>80,81</sup> In both hospitals surveyed, at least 1 in 100 individuals documented a recurrent cold sore each week. As is true of genital herpes, many individuals have HSV-1 infection with no clinical symptoms at the time of acquisition or during episodes of reactivation and shedding of infectious virus in oropharyngeal secretions. Prospective virologic monitoring of hospital staff increased the frequency with which infection was detected by twofold; however, no case of neonatal HSV infection was documented in these nurseries.

The risk of nosocomial infection in the hospital environment is a concern. The demonstration of identity by restriction

endonuclease analysis of virus recovered from an index case and a nursery contact leaves little doubt about the possibility of spread of virus in a high-risk nursery population.<sup>75,76</sup> The possible vectors for nosocomial transmission have not been defined. Whether personnel with herpes labialis should avoid working in the nursery while lesions are active remains a matter of debate. No cases of transmission of HSV from personnel to infants have been documented. Vigorous hand-washing procedures and continuing education of personnel in newborn nurseries can be expected to contribute to the low frequency of HSV transmission in this environment. Herpetic whitlow in a health care provider should preclude direct patient contact, regardless of the nursing unit. Because more infants are born to seronegative women now, our nursery practice is to exclude personnel with active herpes labialis from direct patient care activities until the lesion is crusted.

Because most mothers have antibodies to HSV and these antibodies are transferred to their infants, exposures to the virus in the newborn period may not often result in neonatal disease. However, if the mother was seronegative, nosocomial exposure may pose a more significant risk to the infant.

## IMMUNOLOGIC RESPONSE

The host response of the newborn to HSV is impaired compared with older children and adults.<sup>55,70,82-86</sup> There is no evidence for differences in virulence of particular HSV strains. The severity of the manifestations of HSV-1 and HSV-2 infections in the newborn, as described in "Neonatal Infection," can be attributed to immunologic factors. The relevant issues are protection of the fetus by transplacental antibodies, the innate immune response of the exposed infant and the acquisition of adaptive immunity by the infected newborn.

Passive antibodies to HSV influence the acquisition of infection and its severity and clinical signs.<sup>40,51,55,70</sup> Transplacentally acquired antibodies from the mother are not totally protective against newborn infection, but transplacentally acquired neutralizing antibodies correlate with a lower attack rate in exposed newborns.<sup>51,54,55</sup> Although the absence of any detectable antibodies has been associated with dissemination, the presence of antibodies at the time that clinical signs appear does not predict the subsequent outcome.<sup>49,70</sup> The most important example of the failure of passive antibodies to alter progression is the occurrence of encephalitis in untreated infants whose initial symptoms were limited to cutaneous lesions. Most infected newborns eventually produce IgM antibodies, but the interval to detection is prolonged, requiring at least 2 to 4 weeks.<sup>55</sup> This method cannot be used for diagnostic purposes to determine the need for antiviral therapy. These antibodies increase rapidly during the first 2 to 3 months, and they may be detectable for as long as 1 year after infection. The quantity of neutralizing antibodies and antibodies that mediate antibody-dependent cellular cytotoxicity in infants with disseminated infection is lower than that in those with more limited disease.<sup>55,82</sup> Humoral antibody responses to specific viral proteins, especially glycoproteins, have been evaluated by assays for antibodies to gG and by immunoblot.<sup>13,70</sup> Immunoblot studies indicate that the severity of infection correlates directly with

the number of antibody bands to defined polypeptides. Children with a more limited infection, such as infection of the skin, eye, or mouth, have fewer antibody bands compared with those children with disseminated disease. A vigorous antibody response to the ICP4 alpha gene product, which is responsible for initiating viral replication, has been correlated with poor long-term neurologic outcome, suggesting that these antibodies reflect the extent of viral replication. A regression analysis that compared neurologic impairment with the quantity of antibodies to ICP4 identified the child at risk for severe neurologic impairment.<sup>70</sup>

Adaptive cellular immunity is a critical component of the host response to primary herpetic infections. Newborns with HSV infections have a delayed T lymphocyte proliferative response compared with older individuals.<sup>55,84,85</sup> Most infants have no detectable T lymphocyte responses to HSV when evaluated 2 to 4 weeks after the onset of clinical symptoms.<sup>55</sup> The delayed T lymphocyte response to viral antigens in infants whose initial disease is localized to the skin, eye, or mouth may be an important determinant of the frequent progression to more severe disease in infants.<sup>55,85</sup> Lack of cell-mediated immunity is likely to permit viremia and dissemination in infants, which is otherwise controlled by the host response in older children and adults with new HSV infections.

Infected newborns have decreased interferon- $\alpha$  and interferon- $\gamma$  production in response to HSV antigen when compared with adults with primary HSV infection.<sup>55,85</sup> The importance of interferon- $\alpha$  may be related to its effect on the induction of innate immune mechanisms, such as natural killer cell responses.<sup>86</sup> Other mechanisms of the innate immune system of the newborn that may be deficient in controlling HSV include other nonspecific cytokine responses and complement-mediated effects. T lymphocytes from infected infants have decreased interferon- $\gamma$  production during the first month of life. This defect can be predicted to limit the clonal expansion of helper and cytotoxic T lymphocytes specific for herpes viral antigens, allowing more extensive and prolonged viral replication and failure to establish latency.

Antibody-dependent cell-mediated cytotoxicity has been demonstrated to be an important component of adaptive immunity to viral infection.<sup>82</sup> Antibodies and lymphocytes, monocytes, macrophages or polymorphonuclear leukocytes, as well as antibodies and complement, lyse HSV-infected cells *in vitro*.<sup>87</sup> However, newborns appear to have fewer effector lymphocytes than older individuals do. The immaturity of neonatal monocytes and macrophage function against HSV infection has been demonstrated *in vitro* and in animal models.<sup>88,89</sup> Adhesion defects may be responsible for suboptimal antibody-mediated target-cell binding of neonatal natural killer cells.<sup>90</sup> Additional information regarding the immune response to HSV is provided in Chapter 4.

## NEONATAL INFECTION

### Background

After direct exposure, replication of HSV is presumed to occur at the portal of entry, which is probably the mucous membranes of the mouth or eye, or at sites where the skin

has been damaged. Factors that determine whether the infection causes symptoms at the site of inoculation or disseminates to other organs are poorly understood. Sites of replication during the incubation period have not been defined, but the virus evades the host response during this early stage, probably by mechanisms such as blocking cell-mediated immune recognition of viral peptides by preventing major histocompatibility complex class I molecules from reaching the surface of infected cells. Intraneuronal transmission of viral particles may provide a privileged site that is inaccessible to circulating humoral and cell-mediated defense mechanisms, facilitating the pathogenesis of encephalitis. Transplacental maternal antibodies may be less effective under such circumstances. Disseminated infection appears to be the consequence of viremia. HSV DNA has been detected in peripheral blood mononuclear cells, even in infants who appear to have localized infection.<sup>91</sup> Extensive cell-to-cell spread could explain primary HSV pneumonia after aspiration of infected secretions.

After the virus has adsorbed to cell membranes and penetration has occurred, viral replication proceeds, leading to release of progeny virus and cell death. The synthesis of cellular DNA and protein ceases as large quantities of HSV are produced. Cell death in critical organs of the newborn, such as the brain, results in devastating consequences, as reflected by the long-term morbidity of herpes encephalitis. Cellular swelling, hemorrhagic necrosis, development of intranuclear inclusions, and cytolysis all result from the replicative process. Small, punctate, yellow-to-gray areas of focal necrosis are the most prominent gross lesions in infected organs. When infected tissue is examined by microscopy, there is extensive evidence of hemorrhagic necrosis, clumping of nuclear chromatin, dissolution of the nucleolus, cell fusion with formation of multinucleate giant cells, and ultimately, a lymphocytic inflammatory response.<sup>92</sup> Lymphocytic perivascular cuffing is particularly prominent in organs that exhibit extensive hemorrhagic necrosis, especially in the central nervous system.<sup>93</sup> Irreversible organ damage results from ischemia and direct viral destruction of cells.

## Clinical Presentations

Pediatricians must be prepared to consider the diagnosis of neonatal herpes in infants who have clinical signs consistent with the disease regardless of the maternal history of genital herpes. Only about 30% of mothers whose infants develop neonatal herpes have had symptomatic genital herpes or sexual contact with a partner who has recognized HSV infection during or before the pregnancy.

The clinical presentation of infants with neonatal HSV infection depends on the initial site and extent of viral replication. In contrast to human cytomegalovirus, neonatal infections caused by HSV-1 and HSV-2 are almost invariably symptomatic. Case reports of asymptomatic infection in the newborn exist, but they are uncommon, and long-term follow-up of these children to document absence of subtle disease or sequelae was not described.

Classification of newborns with HSV infection is used for prognostic and therapeutic considerations.<sup>94</sup> Historically, infants with neonatal HSV infection were classified as having localized or disseminated disease, with the former group being subdivided into those with skin, eye, or mouth disease

versus those with central nervous system infection. However, this classification system understates the significant differences in outcome within each category.<sup>95</sup> In a revised classification scheme, infants who are infected intrapartum or postnatally are divided into three groups, including those with disease localized to the skin, eye, or mouth; encephalitis, with or without skin, eye, or mouth involvement; and disseminated infection that involves multiple organs, including the central nervous system, lung, liver, adrenals, skin, eye, or mouth. A few infants with intrauterine infection constitute a fourth category.

Knowledge of the patterns of clinical disease caused by HSV-1 and HSV-2 in the newborn is based on prospectively acquired data obtained through the NIAID Collaborative Antiviral Study Group. These analyses have employed uniform case record forms from one study interval to the next. Of 186 infants enrolled in the NIAID Collaborative Antiviral Study Group studies of neonatal herpes virus infections between 1981 and 1997, 34% were classified with skin, eye, or mouth disease; 34% with central nervous system disease; and 32% with disseminated infection.<sup>73</sup> This analysis of the natural history of neonatal herpes infections likely underestimates the proportion of infants who present with skin, eye, or mouth disease. Patients with central nervous system or disseminated HSV infection were disproportionately enrolled in a high-dose acyclovir study conducted from 1989 to 1997.

The presentation and outcome of infection, including the effect of antiviral therapy on prognosis, varies significantly according to the clinical categories.<sup>96</sup> Table 26-1 summarizes disease classification and outcome of 291 infants with neonatal herpes simplex virus infections enrolled in NIAID Collaborative Antiviral Study Group protocols.

### *Intrauterine Infection*

Intrauterine infection is rare. The manifestations are seen in approximately 3 of every 100 infected infants.<sup>67</sup> When infection occurs in utero, severe disease follows acquisition of infection at virtually any time during gestation. In the most severely afflicted group of infants, evidence of infection is apparent at birth and is characterized by a triad of findings, including skin vesicles or scarring, eye damage, and the severe manifestations of microcephaly or hydranencephaly. Central nervous system damage is caused by intrauterine encephalitis. Infants do not have evidence of embryopathy. Often, chorioretinitis in combination with other eye findings, such as keratoconjunctivitis, is a component of the clinical presentation. Serial ultrasound examination of the mothers of infants infected in utero has demonstrated the presence of hydranencephaly, but cases are seldom diagnosed before delivery. Chorioretinitis alone should alert the pediatrician to the possibility of this diagnosis, although it is a common sign for other congenital infections. A few infants have been described who have signs of HSV infection at birth after prolonged rupture of membranes. The infants may have no other findings of invasive multiorgan involvement—no chorioretinitis, encephalitis, or evidence of other diseased organs—and can be expected to respond to antiviral therapy. Antiviral therapy is not effective for infants who are born with hydranencephaly. Intrauterine HSV infection has been reported as a cause of hydrops fetalis.<sup>97</sup>

**Table 26–1 Demographic and Clinical Characteristics of Infants Enrolled in the National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study**

Demographic Characteristics	Disease Classification		
	Disseminated	Central Nervous System	Skin, Eye, or Mouth

<sup>a</sup>Regardless of therapy.<sup>b</sup>Denominators vary according to number with follow-up available.

### Disseminated Infection

Infants whose initial diagnosis is disseminated herpes have the worst prognosis for mortality. Many of these infants are born to mothers who are experiencing a new HSV-1 or HSV-2 infection and may lack any passively acquired antibodies against the infecting virus type.<sup>13,51,98</sup> Infants with disseminated infection have signs of illness within the first week of life, although the diagnosis may be delayed until the second week. The onset of symptoms may occur less than 24 hours after birth, but most infants appear well at delivery. The short incubation period of disseminated herpes reflects an acute viremia, which allows transport of the virus to all organs; the principal organs involved are the adrenals and the liver, causing fulminant hepatitis in some cases.<sup>94,99-101</sup> Viremia is associated with infection of circulating mononuclear cells in these infants.<sup>91,100-103</sup> Infection can affect multiple organs, including the central nervous system, larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Initial signs and symptoms are irritability, seizures, respiratory distress, jaundice, coagulopathy, and shock. The characteristic vesicular exanthem is usually not present when the symptoms begin. Untreated infants may develop cutaneous lesions resulting from viremia. More than one third of children with disseminated infection do not develop skin vesicles during the course of their illness.<sup>49,73,100</sup> Disseminated infections caused by HSV-1 and HSV-2 are indistinguishable by clinical criteria.

The diagnosis of disseminated neonatal herpes is exceedingly difficult because the clinical signs are often vague and nonspecific, mimicking those of neonatal enteroviral disease or bacterial sepsis. The diagnosis of disseminated herpes should be pursued by obtaining specimens of oropharyngeal and respiratory secretions and a rectal swab to be tested by viral culture and by polymerase chain reaction (PCR) testing if a qualified reference laboratory is available. Direct immuno-

fluorescence methods are useful for rapid diagnosis of herpesvirus-infected cells in skin lesion specimens but must not be used to test oropharyngeal or other secretions. When discrete lesions are not available for obtaining infected cells, the virus can also be detected in the peripheral blood of some infants by viral culture or PCR, but confirmation of viremia is not necessary for clinical management.

Evaluation of the extent of dissemination is imperative to provide appropriate supportive interventions early in the clinical course. Infants should be assessed for hypoxemia, acidosis, hyponatremia, abnormal hepatic enzyme levels, direct hyperbilirubinemia, neutropenia, thrombocytopenia, and bleeding diathesis. Chest radiographs should be obtained, and depending on signs and whether the infant is stable enough, abdominal radiography, electroencephalography, and computed tomography or magnetic resonance imaging of the head should be used to further determine the extent of disease. The radiographic picture of HSV lung disease is characterized by a diffuse, interstitial pattern, which progresses to a hemorrhagic pneumonitis and on rare occasions, a significant pleural effusion.<sup>104</sup> Not infrequently, necrotizing enterocolitis with pneumatosis intestinalis can be detected when gastrointestinal disease is present. Meningoencephalitis appears to be a common component of disseminated infection, occurring in about 60% to 75% of children. Usual examinations of cerebrospinal fluid, including viral culture and PCR, should be performed along with noninvasive neurodiagnostic tests to assess the extent of brain disease.

The mortality rate for disseminated HSV in the absence of therapy exceeds 80%, and many survivors are impaired. The most common causes of death of infants with disseminated disease are intravascular coagulopathy or HSV pneumonitis. There is evidence that the long-term neurologic outcome is better for infants who survive disseminated HSV-1 involving the central nervous system than for those who are infected with HSV-2.<sup>96,105</sup>

### Encephalitis

Almost one third of all infants with neonatal HSV infection have encephalitis only as the initial manifestation of disease.<sup>96,106</sup> These infants have clinical manifestations distinct from those who have central nervous system infection associated with disseminated HSV. The pathogenesis of these two forms of brain infection is probably different. The virus is likely to reach brain parenchyma by a hematogenous route in infants with disseminated infection, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, neonates who present with only encephalitis are likely to develop brain disease because of retrograde axonal transport of the virus to the central nervous system. The evidence for this hypothesis is twofold. First, newborns with disseminated disease have documented viremia. Second, infants with encephalitis are more likely to have received transplacental neutralizing antibodies from their mothers, which may allow only intraneuronal transmission of virus to the brain.

Infants with localized HSV encephalitis as their initial manifestation of infection usually develop signs more than a week after birth, typically presenting in the second or third week but sometimes as late as 4 to 6 weeks. Clinical manifestations of encephalitis include seizures (focal and generalized), fever, lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Similar signs are observed when disseminated herpesvirus is associated with encephalitis. As in cases of disseminated herpesvirus, many infants with encephalitis do not have skin vesicles when signs of illness begin. Some infants have a history or residual signs of lesions of the skin or eye that were not recognized as herpetic. If untreated, infants with encephalitis may develop skin vesicles later in the disease course. Anticipated findings on cerebrospinal fluid examination include a mononuclear cell pleocytosis, moderately low glucose concentrations, and elevated protein. A few infants with central nervous system infection, proven by brain biopsy done immediately after the onset of seizures, have no abnormalities of their cerebrospinal fluid, but most infants have some pleocytosis and mild reduction of the glucose level. The hemorrhagic nature of the encephalitis may result in an apparent "bloody tap." Although initial protein concentrations may be normal or only slightly elevated, infants with localized brain disease usually demonstrate progressive increases in protein ( $\geq 1000$  mg/dL). The importance of cerebrospinal fluid examinations in all infants is underscored by the finding that even subtle abnormalities have been associated with significant developmental sequelae.<sup>94</sup>

Electroencephalography and computed tomography or magnetic resonance imaging can be very useful in defining the presence and extent of central nervous system abnormalities and should be done before discharge of all infants with this diagnosis.<sup>107,108</sup> These abnormalities may also be detected by ultrasound examination.<sup>108</sup> Typical abnormalities seen by neuroimaging include localized or multifocal areas of abnormal parenchymal attenuation, atrophy, edema, and hemorrhage involving the temporal, frontal, parietal, and subcortical regions of the brain<sup>109</sup> (Fig. 26-1).

Localized central nervous system disease is fatal in approximately 50% of infants who are not treated and is usually related to involvement of the brain stem. With rare exceptions, survivors are left with neurologic impairment.<sup>94</sup> The long-term

**Figure 26-1** Herpes simplex encephalitis. Computed tomographic scan of an infant with herpes simplex virus type 2 infection and severe sequelae.

prognosis is poor. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities.

Quantitative PCR methods show a greater amount of HSV-2 DNA in cerebrospinal fluid from patients with more extensive neurologic impairment.<sup>110</sup> There is evidence that progressive neurologic damage occurs after neonatal HSV encephalitis, although many infants have obvious severe sequelae within a few weeks after onset of HSV encephalitis.<sup>111,112</sup>

Despite the presumed differences in pathogenesis, clinical manifestations of disease in children with encephalitis alone are virtually identical to the findings for brain infection in disseminated cases. For infants with encephalitis, approximately 60% develop evidence of a vesicular rash characteristic of HSV infection. A newborn with pleocytosis and proteinosis of the cerebrospinal fluid but without a rash can easily be misdiagnosed as having another viral or bacterial infection unless HSV infection is considered.

### Skin, Eye, and Mouth Infections

Infection localized to the skin, eye, or mouth or some combination of these sites appears benign at the onset, but it is associated with a high risk of progression to serious disease. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease (Fig. 26-2). Vesicles occur in 90% of children with skin, eye, or mouth infection. The skin vesicles usually erupt from an erythematous base and are usually 1 to 2 mm in diameter. The formation of new lesions adjacent to the original vesicles is typical, creating a cluster that may coalesce into larger,

irregular vesicles. In some cases, the lesions progress to large bullae larger than 1 cm in diameter. Clusters of vesicles may appear initially on the presenting part of the body, presumably because of prolonged contact with infected secretions during birth, or at sites of trauma (e.g., scalp monitor sites). Nevertheless, first herpetic lesions in infants with localized cutaneous disease have been described on the trunk, extremities, and other sites. Children with disease localized to the skin, eye, or mouth or some combination of these sites typically have symptoms within the first 7 to 10 days of life.

Although discrete vesicles are usually encountered, crops and clusters of vesicles are described, particularly before antiviral treatment was available or when the cause of the first lesions is not recognized. In these cases, the rash can progress to involve other cutaneous sites, presumably by viremia and hematogenous spread. The scattered vesicles resemble varicella. Although progression is expected without treatment, a few infants have had infection of the skin limited to one or two vesicles, with no further evidence of cutaneous disease. These infants may be identified after the newborn period and should have a careful evaluation because many are likely to have had neurologic disease that was not detected. A zosteriform eruption is another manifestation of herpetic skin disease reported in infants.<sup>113</sup>

**Figure 26-2** Cutaneous herpes simplex virus infection. Initial vesicular lesion in a premature infant with herpes simplex type 2 infection.

Infections involving the eye may manifest as keratoconjunctivitis. Ocular infection may be the only site of involvement in the newborn. When localized eye infection is observed in infants who also have microphthalmos and retinal dysplasia, intrauterine acquisition should be suspected, and a thorough neurologic evaluation should be done. Before antiviral therapy was available, persistent ocular disease resulted in chorioretinitis caused by HSV-1 or HSV-2.<sup>114</sup> Keratoconjunctivitis can progress to chorioretinitis, cataracts, and retinal detachment despite therapy. Cataracts have been detected as a long-term consequence in infants with perinatally acquired HSV infections.

Localized infection of the oropharynx involving the mouth or tongue occurs, but newborns do not develop the classic herpetic gingivostomatitis caused by primary HSV-1 infection in older children. Overall, approximately 10% of patients have evidence of HSV infection of the oropharynx by viral culture. Unfortunately, many of these children did not undergo a thorough oral examination to determine whether the detection of infectious virus in oropharyngeal secretions was associated with lesions.

Long-term neurologic impairment has been encountered in children whose disease appeared to be localized to the skin, eye, or mouth during the newborn period.<sup>49,94,112</sup> The significant findings include spastic quadriplegia, microcephaly, and blindness. Important questions regarding the pathogenesis of delayed-onset neurologic debility are raised by these clinical observations. Despite normal clinical examinations in these children, neurologic impairment became apparent between 6 months and 1 year of life. At this stage of the disease, the clinical presentation may be similar to that associated with congenitally acquired toxoplasmosis or syphilis.

Newborns who have skin lesions invariably suffer from recurrences for months or years. Continued recurrences are common, particularly when the infecting virus is HSV-2, whether or not antiviral therapy was administered.

Historically, although death was not associated with disease localized to the skin, eye, or mouth, approximately 30% of these children eventually developed some evidence of neurologic impairment.<sup>49</sup> Table 26-2 shows morbidity and mortality 12 months after infection by HSV viral type and disease classification in patients enrolled in two studies

**Table 26-2 Morbidity and Mortality among Patients after 12 Months by Viral Type, 1981-1997**

Outcome	Number of Patients by Disease Classification (%) <sup>a</sup>					
	Skin, Eye, or Mouth		CNS		Disseminated	
	HSV-1	HSV-2	HSV-1	HSV-2	HSV-1	HSV-2
Normal	24 (100)	19 (95)	4 (75)	7 (17.5)	3 (23)	14 (41)
Mild impairment	0 (0)	0 (0)	0 (0)	7 (17.5)	0 (0)	1 (3)
Moderate impairment	0 (0)	1 (5)	1 (14)	7 (17.5)	0 (0)	0 (0)
Severe impairment	0 (0)	0 (0)	2 (29)	13 (32.5)	1 (8)	3 (9)
Death	0 (0)	0 (0)	0 (0)	6 (15)	9 (69)	16 (47)
Unknown	Total of 20		Total of 16		Total of 16	

<sup>a</sup>Survival rate (by Cox regression analysis) of patients infected with HSV-2 was higher compared with that of patients infected with HSV-1; however, the difference was not statistically significant. Patients infected with HSV-2 were more likely to have neurologic abnormalities compared with those infected with HSV-1 (borderline significance,  $P = .10$ ).

CNS, central nervous system; HSV, herpes simplex virus.

Data from Kimberlin DW, Lin CY, Jacobs RF, et al. Natural history of neonatal herpes simplex virus infections in the acyclovir era. *Pediatrics* 108:223-229, 2001.

conducted by the NIAID Collaborative Antiviral Study Group between 1981 and 1997. With parenteral acyclovir therapy, virtually all children with HSV-1 and most children with HSV-2 disease of the skin, eye, or mouth who enrolled and who were available for follow-up at 12 months had normal development.<sup>73</sup>

### Subclinical Infection

A few cases of apparent subclinical infection with HSV proven by culture isolation of virus in the absence of symptoms have been described.<sup>115</sup> It has been difficult to document such cases in the course of prospective evaluations of several thousand infants from many centers around the United States. Conversely, infants who were exposed to active maternal infection at the time of delivery and who did not develop symptoms have been followed for the first year of life and did not have immunologic evidence of subclinical infection.<sup>51</sup> HSV-1 or HSV-2 may be recovered from the infant's oropharyngeal secretions transiently, without representing true infection. Because of the propensity of the newborn to develop severe or life-threatening disease, laboratory evidence of neonatal HSV infection requires careful follow-up for clinical signs and the administration of antiviral therapy.

## DIAGNOSIS

### Clinical Evaluation

The clinical diagnosis of neonatal HSV infection is difficult because the appearance of skin vesicles cannot be relied on as an initial component of disease presentation. Enteroviral sepsis is a major differential diagnostic possibility in infants with signs suggesting neonatal HSV. Bacterial infections of newborns can mimic neonatal HSV infection. Skin lesions may resemble those seen with bullous or crusted impetigo. Some infants infected by HSV have been described who had concomitant bacterial infections, including group B *Streptococcus*, *Staphylococcus aureus*, *Listeria monocytogenes*, and gram-negative bacteria. A positive culture for one of these pathogens does not rule out HSV infection if the clinical suspicion for neonatal herpes infection is present. Many other disorders of the newborn can be indistinguishable from neonatal HSV infections, including acute respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and various ocular or cutaneous diseases.

When vesicles are present, alternative causes of exanthems should be excluded. Other diagnoses include enteroviral infection, varicella-zoster virus infection, and syphilis. Laboratory methods are available to differentiate these causes of cutaneous lesions in the newborn. Cutaneous disorders such as erythema toxicum, neonatal melanosis, acrodermatitis enteropathica, and incontinentia pigmenti often confuse physicians who suspect neonatal HSV infections. HSV lesions can be distinguished rapidly from those caused by these diseases using direct immunofluorescence stain of lesion scrapings or other methods for rapid detection of viral proteins and confirmed by viral culture.

HSV encephalitis is a difficult clinical diagnosis to make, particularly because many children with central nervous system infection do not have a vesicular rash at the time of clinical presentation. Infection of the central nervous system

is suspected in the child who has evidence of acute neurologic deterioration, often associated with the onset of seizures, and in the absence of intraventricular hemorrhage and metabolic causes. PCR to detect the viral DNA in cerebrospinal fluid has become an important diagnostic method, largely replacing the need for diagnosis by brain biopsy.<sup>116</sup> Infants with localized encephalitis usually have serial increases in cerebrospinal fluid cell counts and protein concentrations and negative bacterial cultures of the cerebrospinal fluid. Noninvasive neurodiagnostic studies can be used to define the sites of involvement.

### Laboratory Assessment

The appropriate use of laboratory methods is essential if a timely diagnosis of HSV infection is to be achieved.<sup>117</sup> Virus isolation remains the definitive diagnostic method. If skin lesions are present, a swab of skin vesicles, done vigorously enough to obtain cells from the base of the lesion, should be made and transferred in appropriate virus transport media to a diagnostic virology laboratory. Rapid diagnosis should be attempted by preparing material from skin lesion scrapings for direct immunofluorescence testing to detect the presence of virus-infected cells or for testing by enzyme immunoassays for viral proteins. Because of the possibility of false-positive results using immunofluorescence or other antigen detection methods, specimens should also be obtained for confirmation by viral isolation. Direct immunofluorescence staining for virus-infected cells is not reliable unless the specimen is obtained from a skin lesion. Cells from oropharyngeal swabs or from cerebrospinal fluid should not be tested using this method.

Clinical specimens should be transported to the diagnostic virology laboratory without being frozen and their processing expedited to permit the rapid confirmation of the clinical diagnosis. In addition to skin vesicles, other materials or sites from which virus may be isolated include the cerebrospinal fluid, stool, urine, throat, nasopharynx, and conjunctivae. The isolation of virus from swabs of superficial sites, such as the nasopharynx, may represent transient presence of the virus in secretions, when the culture is obtained within the first 24 hours after birth, and particularly when the specimen is taken immediately after birth. Typing of an HSV isolate may be done by one of several techniques. Because the outcome of antiviral treatment and risk of late sequelae may be related to the virus type, typing is of prognostic and epidemiologic importance.<sup>94</sup> Results of viral cultures of the cerebrospinal fluid may be positive for infants with disseminated HSV infections but are usually negative for those who have localized encephalitis.

Detection of HSV DNA in cerebrospinal fluid by PCR can allow a rapid presumptive diagnosis of HSV encephalitis in the newborn.<sup>116-120</sup> PCR was used in the retrospective analysis of materials collected from 34 infants enrolled in the NIAID Collaborative Antiviral Study Group antiviral studies.<sup>118</sup> HSV was detected by PCR assay of cerebrospinal fluid in 71% of infants before antiviral therapy was initiated. At least one specimen was positive in 76% of infants, and all samples that were positive by viral culture were positive by PCR. Similar findings were reported by Swedish investigators when stored cerebrospinal fluid specimens obtained from infants with neonatal HSV infection were tested for HSV by

PCR. HSV DNA was detected from cerebrospinal fluid in the acute phase of illness from 78% of patients with central nervous system disease.<sup>121</sup>

Use of HSV PCR methods on cerebrospinal fluid can potentially decrease the duration of time to diagnosis of some cases of HSV encephalitis; however, there are reports in older patients of initial negative HSV PCR results early in the course of illness. Cerebrospinal fluid obtained 4 to 7 days after the initial cerebrospinal fluid samples were obtained was subsequently positive for HSV DNA in a small number of patients.<sup>122</sup>

PCR tests of cerebrospinal fluid were positive in 7 (24%) of 29 infants enrolled in the NIAID Collaborative Antiviral Study Group antiviral studies whose clinical disease was limited to mucocutaneous lesions. Five of the six infants who were evaluated when 1 year old were developmentally normal.<sup>118</sup> The significance of this observation for disease classification and prognosis remains to be determined in prospective studies.

Most studies of PCR for the diagnosis of HSV central nervous system infections indicate the test is sensitive in approximately 75% to 100% of cases in small cohorts of infants.<sup>118-121</sup> Specificity of the test ranges from 71% to 100%. The broad range of values for sensitivity and specificity of HSV PCR probably results from different study methods and disease classifications.<sup>123</sup>

Some studies have shown that HSV PCR may be used to detect HSV DNA in peripheral blood mononuclear cells and plasma of infants with proven neonatal HSV infection. Using a sensitive and well-standardized PCR method, investigators found HSV DNA in peripheral blood mononuclear cells of 6 of 10 infants tested and in plasma of 4 of 6 infants tested.<sup>91</sup> Other investigators have reported the presence of HSV DNA in serum of 67% (20 of 30) infants with neonatal HSV infection.<sup>121</sup> Whether HSV PCR testing of peripheral blood mononuclear cells or plasma can be used to accurately diagnose neonatal HSV infection in the absence of positive cultures is unknown.

In clinical practice, there is considerable interlaboratory variability in HSV PCR test performance. Many clinical laboratories employ user-developed ("home-brew") protocols, further complicating interpretation of PCR results. Diagnostic laboratories that perform HSV PCR testing must be able to validate their test and participate in national and in-house proficiency testing programs.<sup>124</sup>

Until more information regarding the reliability of HSV PCR results obtained in clinical diagnostic laboratories has been determined, interpretation of negative or positive HSV PCR results must depend on clinical findings. A negative PCR result for HSV in cerebrospinal fluid in the setting of clinical, laboratory, or radiologic findings consistent with central nervous system infection does not rule out HSV infection. It is important to continue to use standard clinical and laboratory diagnostic methods for the evaluation of infants with possible neonatal HSV (Table 26-3).

Every effort should be made to confirm HSV infection by viral isolation. Cytologic examination of cells from the infant's lesions should not be used to diagnose HSV infection because reliable specific methods are available. Cytologic methods, such as Papanicolaou, Giemsa, or Tzanck staining, have a sensitivity of only approximately 60% to 70%. A negative result therefore must not be interpreted as excluding the

diagnosis of HSV, and a positive result should not be the sole diagnostic determinant for HSV infection in the newborn. Intracellular inclusions and multinucleated giant cells may be consistent with, but not diagnostic of, HSV infection.

In contrast to some other neonatal infections, serologic diagnosis of HSV infection has little clinical value. The interpretation of serologic assays is complicated by the fact that transplacentally acquired maternal IgG cannot be differentiated from endogenously produced antibodies, making it difficult to assess the neonate's antibody status during acute infection. Serial type-specific antibody testing may be useful for retrospective diagnosis if a mother without a prior history of HSV infection has a primary infection late in gestation and transfers little or no antibody to the fetus. Therapeutic decisions cannot await a diagnostic approach based on comparing acute-phase and convalescent-phase antibody titers. IgM production is delayed or does not occur in infected infants because of inherent immunodeficiencies in the response to systemic viral infections in the newborn, and commercially available assays for IgM antibodies to HSV have limited reliability.

The results of specific laboratory tests for HSV should be used in conjunction with clinical findings and general laboratory tests, such as platelet counts, cerebrospinal fluid analysis, and liver function tests, to establish a disease classification.

## TREATMENT

### Background

The cumulative experience of the past 2 decades demonstrates that perinatally acquired HSV infections are amenable to

<sup>a</sup>The diagnostic reliability of herpes simplex virus polymerase chain reaction (HSV PCR) results from blood or skin lesions performed outside of the research setting is unknown.

treatment with antiviral agents. Acyclovir is the drug of choice.<sup>96</sup> Because most infants acquire infection at the time of delivery or shortly thereafter, antiviral therapy has the potential to decrease mortality and improve long-term outcome. The benefits that antiviral therapy can provide are influenced substantially by early diagnosis. The likelihood of disease progression in infants who acquire HSV infections is an established fact. Without treatment, approximately 70% of those presenting with disease localized to the skin, eye, or mouth develop involvement of the central nervous system or disseminated infection. Treatment initiated after disease progression is not optimal because many of these children die or are left with significant neurologic impairment. Regardless of the apparently minor clinical findings in some cases, the possibility of HSV infection in the newborn requires aggressive diagnostic evaluation and likely or proved infection mandates the immediate initiation of acyclovir therapy, which must be given intravenously.

### Antiviral Drugs

Historically, four nucleoside analogues have been used to treat neonatal herpes: idoxuridine, cytosine arabinoside, vidarabine, and acyclovir. Of these compounds, the first three are nonspecific inhibitors of cellular and viral replication, and the fourth, acyclovir, is selectively activated by HSV thymidine kinase. Acyclovir acts as a competitive inhibitor of HSV DNA polymerase and terminates DNA chain elongation.<sup>125</sup> Idoxuridine and cytosine arabinoside have no value as systemic therapy for any viral infection because of toxicity and equivocal efficacy. Vidarabine was the first drug demonstrated to be efficacious; it decreased mortality and improved morbidity in cases of neonatal HSV infections.<sup>126</sup> A comparison of vidarabine with acyclovir suggests that these compounds have a similar level of activity for this disease; however, vidarabine is no longer available for clinical use.<sup>112</sup> Acyclovir is safe for use in newborns and is familiar to pediatricians from its other clinical uses.

Acyclovir has been established as efficacious for the treatment of primary genital HSV infection when administered by intravenous, oral, and topical routes.<sup>127,128</sup> Oral and intravenous administration of acyclovir to the immunocompromised host decreases the frequency of reactivation after immunosuppression and the duration of disease.<sup>129</sup> Acyclovir has been established to be superior to vidarabine for the treatment of HSV encephalitis in older children and adults.<sup>130</sup> Because this compound is a selective inhibitor of viral replication, it has a low frequency of side effects.

After pharmacokinetic and tolerance evaluations of acyclovir were done in infants,<sup>131,132</sup> the NIAID Collaborative Antiviral Study Group compared vidarabine and acyclovir for the treatment of neonatal HSV infection in a randomized trial.<sup>112</sup> The dose of vidarabine used was 30 mg/kg/day, and acyclovir was given at a dose of 10 mg/kg every 8 hours. The duration of therapy was 10 days. There were no significant differences in survival between the two treatment groups (Fig. 26-3). There were no differences in adverse effects or laboratory evidence of toxicity.

Survival with antiviral therapy depended on classification of the extent of disease at diagnosis (Fig. 26-4). Mortality and morbidity were also influenced by clinical status at the time of diagnosis and the virus type. Among infants with

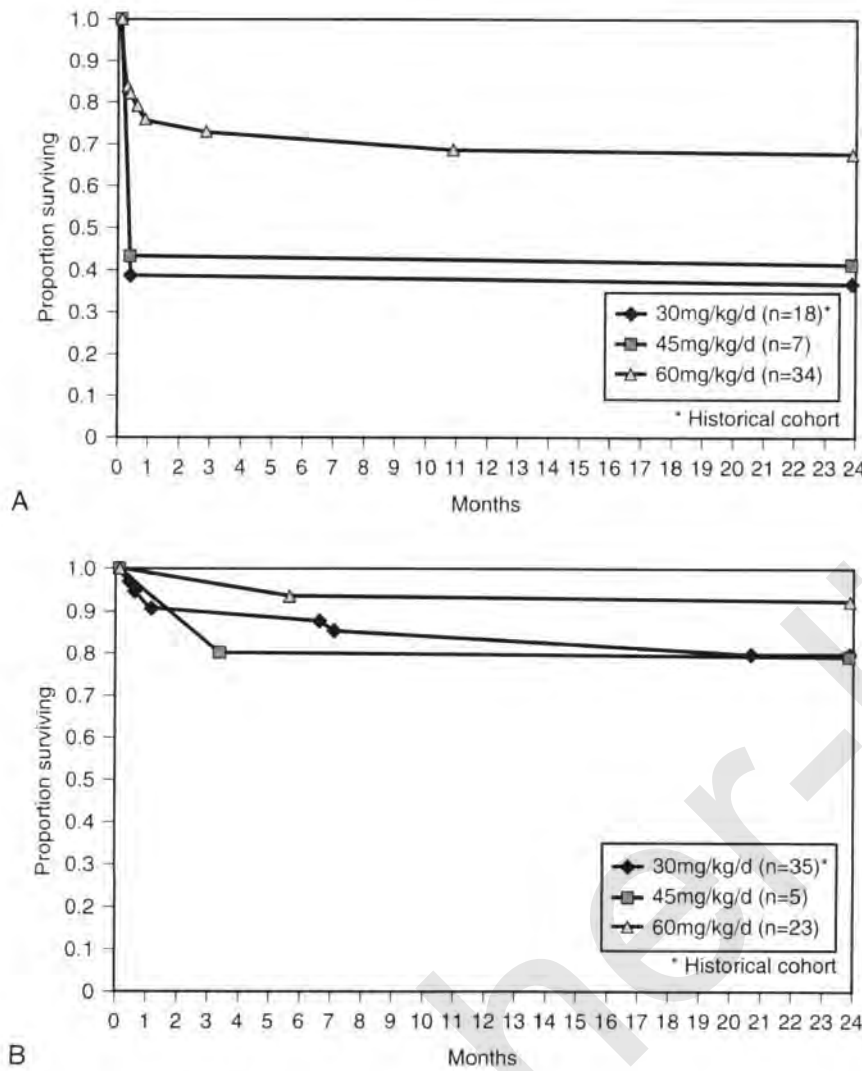

**Figure 26-3** Survival of babies with neonatal herpes simplex virus infection according to treatment and the extent of disease. The infection was classified as confined to the skin, eyes, or mouth; affecting the central nervous system (CNS); or producing disseminated disease. After adjustment for the extent of disease with the use of a stratified analysis, the overall comparison of vidarabine with acyclovir was not statistically significant ( $P = .27$ ) by a log-rank test. No comparison of treatments within disease categories was statistically significant. (From Whitley R, Arvin A, Prober C, et al. A controlled trial comparing vidarabine with acyclovir in neonatal herpes simplex virus infection. *N Engl J Med* 324:444, 1991.)

**Figure 26-4** Survival of babies with neonatal herpes simplex virus infection according to the extent of disease ( $P < .001$  for all comparisons). (From Whitley R, Arvin A, Prober C, et al. Predictors of morbidity and mortality in neonates with herpes simplex infections. *N Engl J Med* 324:450, 1991.)

skin, eye, or mouth disease, those with HSV-1 infections were all normal developmentally at 1 year compared with 86% of those with HSV-2 infections. Infants who were alert or lethargic when treatment was initiated had a survival rate of 91%, compared with 54% for those who were semi-comatose or comatose; similar differences in survival rates related to neurologic status were observed in infants with

**Figure 26-5** Mortality rates for patients with disseminated disease (A) and central nervous system disease (B) depending on the dose of acyclovir. (Data from Kimberlin DW, Chin-Yu L, Jacobs RF, et al. Safety and efficacy of high-dose intravenous acyclovir in the management of neonatal herpes simplex virus infections. *Pediatrics* 108:230-238, 2001.)

disseminated infection. Prematurity, pneumonitis, and disseminated intravascular coagulopathy were poor prognostic signs.<sup>94</sup>

The improved outcome compared with historical data probably reflects earlier diagnosis and institution of antiviral therapy, thereby preventing progression of disease from skin, eye, or mouth to more severe disease. The mean duration of symptoms before treatment for all participants, regardless of disease classification, was 4 to 5 days, indicating that therapy might have been instituted even sooner. These observations suggested that further advances in therapeutic outcome might be achieved by earlier intervention. Unfortunately, despite advances in laboratory diagnosis and treatment of neonatal HSV infection, the mean time between onset of disease symptoms and initiation of antiviral therapy has not changed.<sup>73</sup>

Despite the proven efficacy of antiviral therapy for neonatal HSV infection, the mortality rate remains high, and many infants who survive disseminated or central nervous system disease have serious sequelae. This circumstance dictated the need to evaluate high doses of acyclovir and longer treatment regimens. Infants were enrolled in an NIAID Collaborative Antiviral Study Group assessment of acyclovir given at an intermediate dose (45 mg/kg/day) or

high dose (60 mg/kg/day). Mortality rates for infants with disseminated or central nervous system disease were lower for infants given high-dose acyclovir than observed in the earlier studies (Fig. 26-5).<sup>133</sup> There was no significant difference in morbidity status at 12 months of follow-up between high-dose and standard-dose acyclovir recipients for each of the three disease categories. Transient and reversible neutropenia occurred more frequently during high-dose therapy but resolved during or after cessation of treatment. The dose of acyclovir used had no impact on the duration of viral shedding.<sup>133</sup>

The current recommendation for treatment of neonatal HSV infection is acyclovir, 60 mg/kg/day in three doses (20 mg/kg/dose) given intravenously. Disseminated and central nervous system infections are treated at least 21 days. Duration of treatment for skin, eye, and mucous membrane infection, after disseminated and central nervous system infection have been ruled out, is a minimum of 14 days.<sup>134</sup>

The use of oral acyclovir is contraindicated for the treatment of acute HSV infections in newborns. Its limited oral bioavailability results in plasma and cerebrospinal fluid concentrations of drug that are inadequate for therapeutic effects on viral replication. The high risk of progression from localized mucocutaneous infections requires the administration of

intravenous acyclovir to these infants, regardless of how well they appear at the time of diagnosis. In addition to intravenous therapy, infants with ocular involvement caused by HSV should receive one of the topical ophthalmic agents approved for this indication. Topical acyclovir is not necessary for treatment of mucocutaneous lesions caused by HSV because parenteral drug reaches these sites.

Acyclovir treatment is based on a laboratory diagnosis of neonatal HSV infection. Rapid methods, including direct antigen detection and PCR, should be used to facilitate early laboratory confirmation of suspected cases. Acyclovir prophylaxis is not recommended. Presumptive treatment may be a reasonable option when circumstances prevent rapid laboratory diagnosis and the clinical manifestations are those described for mucocutaneous infections, disseminated disease, or HSV encephalitis. In all cases, specimens should be obtained for laboratory testing to guide the decision to continue treatment. During the course of therapy, careful monitoring is important to assess the therapeutic response. Even in the absence of clinical evidence of encephalitis, evaluation of the central nervous system should be done for prognostic purposes. Serial evaluations of hepatic and hematologic parameters may indicate changes caused by the viral infection or by drug toxicity.

Intravenous acyclovir is tolerated well by infants. Adequate hydration is necessary to minimize the risk of nephrotoxicity, and dosage adjustments are necessary if renal clearance is impaired. As for all drugs, the possibility of acute toxicity should be considered in any child receiving parenteral antiviral therapy and should be assessed by serially evaluating bone marrow, renal, and hepatic functions. The potential for long-term harm from these drugs remains to be defined.

Acyclovir resistance has been reported in an infant with acute HSV infection of the larynx in the newborn period; in this case, the initial isolate was not inhibited by acyclovir, although the source of this infection could not be explained.<sup>135</sup> Acyclovir resistance has also been reported in a premature infant with cutaneous and central nervous system disease caused by an initially acyclovir-susceptible HSV. The infant developed recurrent disseminated HSV infection 8 days after a 21-day course of acyclovir. The virus isolated at the onset of recurrent symptoms was found to lack thymidine kinase activity on the basis of a frame-shift mutation in the thymidine kinase gene.<sup>136</sup> Another infant born to a mother with severe systemic primary HSV-2 infection developed an acyclovir resistant mutant during acyclovir therapy for disseminated HSV infection and eventually died. The use of steroids to treat blood pressure instability may further have hampered this baby's immune response to infection.<sup>137</sup>

Isolates of HSV recovered from infants who received intravenous acyclovir for cutaneous disease in the newborn period and had subsequent recurrent cutaneous lesions typically remain sensitive to acyclovir.<sup>138</sup> Emergence of viral resistance to acyclovir has been described in patients requiring prolonged or repeated treatment with this drug. One infant who was given long-term oral acyclovir for suppression of recurrences during the first 6 months of life had a resistant HSV isolated from a lesion after therapy was discontinued, but subsequent isolates were susceptible.<sup>139</sup>

Antiviral resistance does not generally explain the failure of infants with the disseminated or encephalitic form of the disease to respond well to antiviral therapy. Clinical deterio-

ration, despite appropriate therapy and supportive care, can be attributed to virus-induced destruction of cells comprising infected organs, such as liver or brain, or irreversible changes, such as disseminated intravascular coagulopathy.

The observation of an association between late sequelae and frequent recurrences of skin lesions in infants who were treated for localized HSV-2 infections during the newborn period has raised questions about the potential efficacy of suppressive therapy with oral acyclovir. The NIAID Collaborative Antiviral Study Group has undertaken an assessment of the safety and efficacy of suppression as an adjunct after the recommended treatment of mucocutaneous disease with intravenous acyclovir.<sup>139</sup> Infants were given 300 mg/m<sup>2</sup> twice or three times per day for 6 months. Of 16 infants given the three daily doses, 13 (81%) had no recurrences of lesions while receiving therapy, compared with 54% of infants from earlier studies who received intravenous acyclovir only. Forty-six percent of the 26 infants developed neutropenia. In one infant, suppressive therapy was associated with a transient recurrence of infection due to an acyclovir-resistant isolate of HSV-2; subsequent recurrences were caused by susceptible isolates. Whether this effect on cutaneous recurrences, which was limited to periods of active oral suppressive therapy, has any effect on late neurologic sequelae is unknown. Oral acyclovir prophylaxis is not recommended for routine use, pending results from a larger NIAID Collaborative Antiviral Study Group trial of efficacy against this end point.

### Other Issues in Acute Management

Isolation of the newborn with HSV infection is important to decrease the potential for nosocomial transmission. Many infants with this infection have life-threatening problems, including disseminated intravascular coagulation, shock, and respiratory failure, and they require supportive care that is available only at tertiary medical centers.

There is no indication that administration of immune globulin or hyperimmune globulin is of value for the treatment of neonatal HSV infection. Although a series of studies have suggested that the quantity of transplacental neutralizing antibodies affects the attack rate among exposed infants and may influence the initial disease manifestations, the presence of antibodies may or may not influence the subsequent course of infection.<sup>49,51,54,55,82</sup> The administration of standard preparations of intravenous immune globulin does not enhance the titers of functional antibodies against HSV in low-birth-weight infants.<sup>140</sup> The evaluation of virus-specific monoclonal antibodies in combination with antiviral therapy may become feasible as new technologies for deriving human or humanized antibody preparations are developed.<sup>141</sup>

No other forms of adjunctive therapy are useful for treating neonatal HSV infections. Various experimental modalities, including bacille Calmette-Guérin, interferon, immune modulators, and immunization, have been attempted, but none has produced demonstrable effects.

### Long-Term Management of Infected Infants

With the advent of antiviral therapy, an increasing number of newborns who suffered from HSV infection are surviving and require careful long-term follow-up. The most common complications of neonatal HSV infection include neurologic

and ocular sequelae that may be detected only on long-term follow-up. It is therefore necessary that these children receive serial long-term evaluation from qualified pediatric specialists in these areas, which should include neurodevelopmental, ophthalmologic, and hearing assessments.

Recurrent skin vesicles are present in many children, including those who did not have obvious mucocutaneous disease during the acute phase of the clinical illness. Skin vesicles provide a potential source for transmission of infection to other children or adults who have direct contact with these infants. The increasing use of daycare for children, including those surviving neonatal HSV infections, stimulates many questions from daycare providers about these children. There is some risk that children with recurrent HSV skin lesions will transmit the virus to other children in this environment. The most reasonable recommendation in this situation is to cover the lesions to prevent direct contact. It is much more likely that HSV-1 will be present in the daycare environment in the form of asymptomatic infection or gingivostomatitis. In both cases, virus is present in the mouth and pharynx, and the frequent exchange of saliva and other respiratory droplets that occurs among children in this setting makes this route of transmission more likely. Education of daycare workers and the general public about herpesvirus infections, their implications, and the frequency with which they occur in the population as a whole can calm fears and correct common misconceptions.

Parents of children with neonatal HSV infection often have significant guilt feelings. Parents often require support from psychologists, psychiatrists, or counselors. The family physician or pediatrician can provide a supportive role of great value to the family in this situation. Most parents and many physicians are unaware of the high prevalence of HSV-2 infection in the United States and of the lifelong persistence and subclinical nature of these infections. Concern about the risk of fetal and neonatal infection during subsequent pregnancies is often a major issue that can be addressed effectively based on the low risks as proved from large, prospective studies.

## PREVENTION

### Background

Despite the progress that has been made in antiviral treatment of neonatal HSV infection, the ideal approach is to prevent the exposure of infants to active maternal infection at the time of delivery. Unfortunately, genital infections caused by HSV are often clinically silent when they are acquired as new infections and when the virus reactivates. The high prevalence of HSV-2 infections in the U.S. population means that women are at risk for acquiring new genital infections during pregnancy and that at least one in five will become infected before pregnancy. The problem of asymptomatic genital HSV infection means that the transmission of HSV from mothers to infants cannot be eliminated even with the best obstetric management. It is futile to obtain sequential genital cultures during the last weeks of gestation in women with a history of genital herpes in an effort to identify those who will have asymptomatic infection at the onset of labor.<sup>48</sup> These cultures do not predict the

**Table 26-4 Projected Risk of Transmission of HSV-2 from Mothers to Infants at Delivery in a Cohort of 100,000 Pregnant Women**

25% with Past HSV-2 Infection	75% Susceptible to HSV-2 Infection
25,000 women	75,000 women
1.5% reactivation at delivery	0.02% seroconversion/wk
375 women with reactivation	30 women with infection <2 wk before delivery
<5% risk of transmission to infant	≈50% risk of transmission
19 infected infants	15 infected infants

Data from Arvin AM. The epidemiology of perinatal herpes simplex infections. In Stanberry L (ed). *Genital and Neonatal Herpes*. New York, John Wiley & Sons, 1996, pp 179-192.

infant's risk of exposure at delivery because of the usually brief duration of asymptomatic shedding and the time required for the culture to become positive. Because of the attention of the lay press to the devastating outcome of neonatal HSV infection, many women who know that they have genital herpes experience severe anxiety about the potential risks to the fetus and newborn. As a consequence, these women may have an unnecessarily high frequency of cesarean deliveries. The risk of neonatal HSV infection in the newborn is approximately equivalent for women who have no prior history of genital herpes or a partner with known infection (Table 26-4).

### Management of Pregnant Women with Known Genital Herpes

Women who have a history of recurrent genital herpes should be reassured that the risk of fetal or neonatal infection is very low. Intrauterine HSV infections are rare, with an estimated overall risk of 1 in 200,000 pregnancies.<sup>64</sup> Information about the risk of exposure to asymptomatic reactivation at delivery derived from six large-scale prospective studies is sufficient to conclude that the incidence of asymptomatic reactivation in these women is about 2% and that the attack rate for their exposed infants is approximately 3% or less; the risk of neonatal infection under these circumstances is less than 1 in 2000 deliveries.

Because laboratory methods cannot be used to detect asymptomatic infection in a timely manner, the current approach to management is to perform a careful vaginal examination at presentation and to elect cesarean delivery if the mother has signs or symptoms of recurrent genital herpes at the onset of labor. Given the low probability of neonatal infection, it is appropriate to deliver infants of women who have a history of recurrent genital herpes but who have no active clinical disease at delivery by the vaginal route.<sup>56</sup> An analysis of the occurrence of HSV infections in infants in California showed no change from 1985 to 1995, despite a documented decrease in deliveries by cesarean section and

an increase in the proportion of women with a previous diagnosis of genital herpes whose infants were delivered vaginally.<sup>62</sup>

A culture for HSV obtained at the time of delivery may be useful in establishing whether the virus was present at delivery to facilitate recognition of neonatal infection if it occurs. However, the value of this approach has not been established. Alternative diagnostic approaches, such as those based on PCR to detect virus, are being developed to expedite identification of women at risk for delivering infected infants.<sup>142,143</sup> Evidence indicates that detection of viral presence in genital samples by PCR is more sensitive than culture methods. However, the significance of a positive PCR result in predicting risk of transmission of HSV to the infant is unknown.<sup>144</sup> Viral DNA can persist for a longer interval than infectious virus.

The utility of suppressive therapy of genital herpes in women with a known history of recurrent infection remains a question for clinical investigation because of risk-benefit considerations. It has already been established from the trials of suppressive therapy with acyclovir in individuals with frequently recurrent genital herpes that reactivation of virus can occur despite the administration of 200 mg of acyclovir three times daily.<sup>145,146</sup> Results of one study evaluating the efficacy of 400 mg of oral acyclovir three times daily indicate that prophylactic acyclovir significantly reduces the number of genital lesions. Despite prophylaxis, a few women continue to have virus detectable by PCR.<sup>144</sup>

The pharmacokinetics and metabolism of acyclovir in the human fetus are unknown. The possibility of fetal nephrotoxicity related to acyclovir is a potential risk that must be considered. Whether acyclovir treatment of mothers with primary genital herpes late in gestation can reduce the neonatal risk of these infections is also a research issue. However, signs of disseminated herpes in the mother warrant the administration of intravenous acyclovir.

### Management of Infants of Mothers with Genital Herpes

Infants of mothers with histories of genital herpes delivered vaginally or by cesarean section and whose mothers have no evidence of active genital herpetic infection are at low risk for acquiring neonatal HSV infection. These children need no special evaluation during the newborn period.

Infants delivered vaginally to mothers with an active genital HSV infection or who have genital cultures done at delivery that are positive for HSV should be isolated from other infants for the duration of their hospitalization up to age 4 weeks. Parents and primary care physicians should be notified about the exposure of the infant so that the infant can be observed for the occurrence of nonspecific signs consistent with possible neonatal herpes. The parents and responsible family members should be educated about the low risk of transmission to relieve anxiety and to ensure prompt return for care in the unlikely event that signs of infection appear. Information regarding infection should include a description of the risks associated with transmission of infection to the newborn, the common signs and symptoms of neonatal herpes, the necessity for careful monitoring for the onset of illness as long as 4 weeks after birth, and the planned approach to treatment if symptoms occur.

It may be useful to obtain cultures from the exposed infant between 24 and 48 hours after delivery and at intervals during the first 4 weeks of life. Sites from which virus may be recovered include the eye, oropharynx, nasopharynx, and skin lesions that are suspected to be herpetic. Weekly viral cultures have been suggested for the surveillance of exposed infants; the utility of this approach has not been proved by prospective studies, and it should be considered an optional addition to clinical observation.

If cultures from any site in the infant are positive, a thorough diagnostic evaluation should be done, including obtaining additional specimens for viral culture from the site that was reported to be positive, the oropharynx, and the cerebrospinal fluid, and treatment with acyclovir should be initiated. Viral cultures of urine and viral culture and HSV PCR of peripheral blood mononuclear cells may also be considered to identify additional sites of viral infection. PCR testing must be performed by a laboratory with a validated HSV PCR assay and expertise in proper performance of PCR on specimens from various sources. A positive HSV PCR result in addition to the initial positive culture can provide additional evidence to support the diagnosis of HSV infection. A negative HSV PCR result does not in itself rule out infection.

No data are available to support the administration of acyclovir to exposed infants who have no clinical signs or laboratory evidence of infection. Parameters for duration of such prophylaxis cannot be defined. The experience from other clinical settings is that the virus is suppressed only for the period the drug is given and is not eradicated. Careful clinical follow-up of these infants, with immediate institution of antiviral therapy if symptoms occur, is an appropriate approach.

An issue of frequent concern is whether the mother with an active genital HSV infection at delivery should be isolated from her child after delivery. Women with recurrent orolabial HSV infection, as well as cutaneous HSV infections at other sites (e.g., breast lesions), are at similar risk for transmission of virus to their newborn. Because transmission occurs by direct contact with the virus, appropriate precautions by the mother, including careful hand washing before touching the infant, should prevent any need to separate mother and child. In some cases, it is possible to have the exposed infant room-in with the mother as a means of isolating the child from other newborns. Breast-feeding is contraindicated if the mother has vesicular lesions involving the breast.

### CONCLUSIONS

Neonatal HSV infection remains a life-threatening disease in the newborn. With an increasing prevalence of genital herpes and the recognition that many infections are completely asymptomatic in the mother, pediatricians, neonatologists, obstetricians, and family practitioners must continue to remain alert to infants whose symptoms may be compatible with HSV infections. Early identification leads to prompt treatment. It is hoped that during this decade, the development of safe and efficacious vaccines and a better understanding of factors associated with transmission of virus from mother to infant will enable prevention of neonatal HSV infection.<sup>147-149</sup>

## Acknowledgments

The databases on clinical presentations, diagnosis, and antiviral treatment of neonatal HSV infections have been generated through the efforts of the NIAID Collaborative Antiviral Study Group for more than 20 years, with support from the National Institute of Allergy and Infectious Diseases. The institute has also supported prognostic studies of HSV infection in pregnancy and the newborn in the United States.

# HUMAN PARVOVIRUS INFECTIONS

Stuart P. Adler • William C. Koch

## Microbiology 868

### Pathogenesis: General Aspects 869

### Epidemiology and Transmission 870

Global Distribution  
 Seasonality and Periodicity  
 Seroprevalence by Age  
 Seroprevalence by Gender  
 Seroprevalence by Race  
 Incidence  
 Risk Factors for Acquisition  
 Hospital Transmission  
 Routes of Viral Spread  
 Risk of B19 Acquisition for Women of Childbearing Age

### Clinical Manifestations Other than Intrauterine Infection 874

Erythema Infectiosum  
 Transient Aplastic Crisis  
 Arthropathy  
 Infection in the Immunocompromised Host  
 Other Dermatologic Syndromes  
 Central Nervous System Infection and Neurologic Disorders  
 Renal Disease

### Diagnosis: General Approach and Laboratory Methods 876

### Epidemiology of B19 Infections and Risk of Acquisition in the Pregnant Woman 877

Prevalence and Incidence in the United States  
 Prevalence and Incidence in Other Countries

### Clinical Manifestations of B19 Infections in the Pregnant Woman 878

### Intrauterine Transmission Rates, Clinical Manifestations, and Fetal Outcomes 879

Fetal Death  
 Asymptomatic Fetal Infection  
 Birth Defects  
 Meconium Ileus and Peritonitis  
 Fetal Hydrops  
 Fetal Outcome in Relation to Maternal Manifestations

### Pathogenesis of Infection in the Fetus 881

Fetal Immune Responses to B19

General Measures  
 Vaccine Development

The parvoviruses are a family of small, single-stranded DNA viruses that have a wide cellular tropism and broad host range, causing infection in invertebrate and vertebrate species from insects to mammals. Although many are important veterinary pathogens, there is only one proven human pathogen in the family, the human parvovirus B19. The virus is most commonly referred to as parvovirus B19, or simply B19. A new genus and name have been proposed for this virus: erythrovirus B19,<sup>1</sup> based on its cellular tropism for erythroid lineage cells and to distinguish it from the other mammalian parvoviruses.

Compared with most other common human viruses, B19 is a relatively new pathogen, but since its initial description, B19 has come to be associated with a variety of seemingly diverse clinical syndromes in a number of different patient populations (Table 27-1). Although the list of clinical manifestations caused by B19 infection is probably not yet complete, some proposed relationships such as to rheumatologic disease and neurologic disorders remain controversial.<sup>2,3</sup>

Parvovirus B19 was accidentally discovered by Cossart and associates<sup>4</sup> in 1975 as an anomalous band of precipitation while screening blood donor serum for hepatitis B antigen by counterimmunoelectrophoresis. The name *B19* refers to the donor unit from which it was originally isolated. Initial analysis of the new virus revealed it had physical features characteristic of the known parvoviruses,<sup>5</sup> allowing classification in this family. Because the donors from which it was originally isolated were asymptomatic, B19 infection was not initially associated with any illness, and for the next several years after its description, it was a virus in search of a disease. In 1981, Pattison<sup>6</sup> found a high prevalence of antibodies to this virus in the serum of children hospitalized with the transient aplastic crisis of sickle cell disease and proposed B19 as the viral cause of this clinically well-described event. Sergeant and colleagues<sup>7</sup> later confirmed this association in population studies of sickle cell patients in Jamaica. It was not until 1983, 8 years after its initial description, that Anderson proposed B19 as the cause of the common childhood exanthem known as erythema infectiosum (EI), or fifth disease, that the virus was linked to its most common clinical manifestation.<sup>8</sup> This benign rash illness of children had been clinically recognized and well described for many decades, but the cause was unknown. The name *fifth disease*

Table 27-1 Clinical Manifestations of Parvovirus B19 Infection

Diseases	Primary Patient Groups
<b>Diseases Associated with Acute Infection</b>	
Erythema infectiosum (fifth disease)	Normal children
Polyarthropathy	Normal adolescents and adults
Transient aplastic crisis	Patients with hemolytic anemia or accelerated erythropoiesis, or both
Papular-purpuric "gloves and socks" syndrome	Normal adolescents and adults
<b>Diseases Associated with Chronic Infection</b>	
Persistent anemia (red cell aplasia)	Immunodeficient or immunocompromised children and adults
Nonimmune fetal hydrops	Intrauterine infection
Congenital anemia	Intrauterine infection
Chronic arthropathy	Rare patients with B19-induced joint disease
Infection-associated hemophagocytosis	Normal or immunocompromised patients
Vasculitis or purpura	Normal adults and children
Myocarditis	Intrauterine infection, normal infants and children, immunocompromised patients

Data from Brown KE, Young NS. Parvovirus B19 infection and hematopoiesis. *Blood Rev* 9:176, 1995.

was derived from the 19th century practice of numbering the common exanthems of childhood, and EI was the fifth rash designated in this scheme and the only one for which this numeric designation has persisted in clinical practice.<sup>9</sup> The others in the series included measles, scarlet fever, rubella, and Filatov-Dukes disease (a mild variant of scarlet fever that is no longer recognized).

The possibility of fetal disease associated with EI was considered long before the viral origin was known, primarily because of comparison with rubella and the incidence of congenital rubella syndrome after community epidemics.<sup>10-12</sup> Advances in knowledge of the virology of other animal parvoviruses and their known propensity to cause disease in fetuses and newborn animals further fueled this concern.<sup>13</sup> This suspicion was confirmed in 1984, when two reports<sup>14,15</sup> of B19 infection in pregnant women associated with adverse fetal outcomes appeared and were later followed by a larger report of a series of cases of nonimmune hydrops fetalis caused by intrauterine infections with B19.<sup>16</sup> Over the ensuing decade, a variety of clinical manifestations associated with acute and chronic infections have been attributed to this virus in different patient groups (see Table 27-1).

Since the initial reports of fetal infection, knowledge of the epidemiology, pathophysiology, and short-term outcome of fetal and neonatal infection with B19 has increased immensely because of several large, population-based studies.<sup>17-21</sup> B19 infection during pregnancy has probably been the subject of more such studies than any of the other manifestations, with the possible exception of the transient aplastic crisis of sickle cell disease. However, there is still much to be learned regarding the long-term outcome of fetal infection, the unusual clinical manifestations of infection in neonates, and the immunologic response to infection. The potential for prevention through vaccine development is a topic of current interest and ongoing research.

## MICROBIOLOGY

Like other members of the family Parvoviridae, B19 is a small, nonenveloped, single-stranded DNA virus. The taxon-

omy for this family has been revised to include two subfamilies<sup>22,23</sup>: the Densovirinae, which are insect viruses; and the Parvovirinae, which infect vertebrates. The Parvovirinae subfamily is composed of three genera: Dependovirus, Parvovirus, and Erythrovirus. The dependoviruses require co-infection with another, unrelated helper virus (i.e., adenovirus or herpesvirus) to complete their life cycle. There are some dependoviruses that infect humans (e.g., adeno-associated viruses), but the infection is asymptomatic and without consequence. In contrast to the dependoviruses, members of the genera Parvovirus and Erythrovirus are able to replicate autonomously. Previously included in the genus Parvovirus, B19 is now classified as an Erythrovirus (i.e., Erythrovirus B19). The genus Erythrovirus consists of only two members, B19 and a simian parvovirus (SPV) that has a similar genomic organization as B19 and has a similar tropism for erythroid cells.<sup>24</sup> Although a number of parvoviruses are pathogenic to other mammals (e.g., canine parvovirus, feline panleukopenia virus), B19 is the only parvovirus that causes disease in humans.

There is only one recognized serotype of B19. Minor variations in the nucleotide sequence occur among different B19 viral isolates from different geographic areas, but they have not been definitely shown to affect clinical patterns of infection or pathogenicity.<sup>25-27</sup> Two isolates of human parvovirus, V9 and V6, whose nucleotide sequence differs significantly (>10%) from B19 have been described.<sup>28,29</sup> Both were isolated from patients with a transient red cell aplasia indistinguishable clinically from the typical B19-induced aplastic crisis. The clinical significance of these variants and whether they represent different genotypes or merely geographic variants of B19 remains a topic of debate.<sup>27,30</sup>

The B19 genome is very small ( $\approx 5.6$  kb) and contained within an icosahedral protein capsid. The capsid structure and lack of an envelope make the virus very resistant to heat and detergent inactivation, features that appear to be important in transmission. The genome appears to encode only three proteins. Two are capsid proteins, designated VP1 and VP2. VP2 is smaller but more abundant and makes up approximately 96% of the capsid protein. VP1 is larger and constitutes about 4% of the capsid but contains a unique

region that extends out from the capsid surface and serves as the attachment site for the cellular receptor.<sup>31</sup> VP2 has the unique ability to self-assemble into capsids that are morphologically and antigenically similar to B19 viruses when expressed in cell culture systems *in vitro*.<sup>32,33</sup> When present with VP1, the capsids incorporate both proteins, but VP1 alone does not self-assemble.<sup>32</sup>

The third gene product is a nonstructural protein designated NS1. The function of this protein is not entirely clear, but it is involved in regulation of the viral promoter and appears to have a role in DNA replication.<sup>23</sup> Studies of NS1 have been hampered by the observation that it appears to be toxic to cells by an unknown mechanism.<sup>34</sup> Studies have further suggested that production of NS1 can lead to programmed cell death (i.e., apoptosis) mediated by stimulation of cytokine production.<sup>35,36</sup>

Because of its limited genomic complement, B19 requires a mitotically active host cell for replication. It can replicate only in certain erythroid lineage cells stimulated by erythropoietin, such as erythroid precursors found in bone marrow, fetal liver, umbilical cord blood, and a few erythroleukemic cell lines.<sup>23,37-41</sup> B19 cannot be propagated in standard cell cultures,<sup>42</sup> a fact that previously limited the availability of viral products for development of diagnostic assays. Much of this limitation has been overcome by the development of molecular methods for the detection of viral nucleic acid, but reliable commercial serologic assays are still somewhat limited.

The cellular receptor for the virus has been identified as globoside, a neutral glycosphingolipid found on erythrocytes, where it represents the P blood group antigen.<sup>43</sup> This receptor is necessary for viral infection to occur, and individuals who lack this antigen (p phenotype) are naturally immune to B19 infection.<sup>44</sup> The P antigen is present on other cells such as endothelial cells, fetal myocardial cells, placenta, and megakaryocytes.<sup>43</sup> The tissue distribution of this receptor may explain some of the clinical manifestations of infection with this virus (discussed later).

Although the P antigen is necessary for B19 viral infection, it is not sufficient, because some cells, particularly nonerythroid tissues, that express the receptor are not capable of viral infection.<sup>45</sup> A co-receptor has been described on cells that are permissive for B19 infection.<sup>46</sup> The hypothesis is that the globoside receptor is necessary for viral attachment but that the co-receptor somehow allows for viral entry into the cell, where viral replication can occur. If confirmed, this may provide an alternative explanation of the pathogenesis of infection in nonerythroid tissues that express globoside without the co-receptor.

## **PATHOGENESIS: GENERAL ASPECTS**

Parvovirus B19 requires a mitotically active host cell to complete its full replicative life cycle. The primary target for B19 infection appears to be erythroid progenitor cells that are near the pronormoblast stage of development. The virus can be propagated only in human erythroid progenitor cells from bone marrow, umbilical cord blood, fetal liver, peripheral blood, and a few erythroid leukemic cell lines.<sup>47</sup> B19 lytically infects these cells, with progressive loss of targeted cells as infection proceeds. *In vitro* hematopoietic

assays demonstrate that B19 suppresses formation of erythroid colony-forming units and this effect can be reversed by addition of serum containing anti-B19 immunoglobulin G (IgG) antibodies.<sup>48</sup> The virus has little to no effect on the myeloid cell line *in vitro*, but it inhibits megakaryocytopoiesis *in vitro* without viral replication or cell lysis.<sup>49</sup>

Clinically, this situation is best illustrated in the transient aplastic crisis of sickle cell disease. Patients have fever, weakness, and pallor on presentation, with a sudden and severe drop in their reticulocyte counts. This cessation of red blood cell production, coupled with shortened red blood cell survival because of hemolysis, produces a profound anemia. Examination of the bone marrow typically reveals hypoplasia of the erythroid cell line and a maturational arrest; giant pronormoblasts are often seen with intranuclear viral inclusions.<sup>48</sup> With development of specific antibodies, viral infection is controlled, and reticulocyte counts begin to rise.

Evaluation of infection in normal volunteers has shown similar hematologic changes, but because of the longer life of red blood cells, these changes are clinically insignificant.<sup>50</sup> Adult volunteers inoculated intranasally with B19 developed viremia after 5 to 6 days with a mild illness. Their reticulocyte counts fell to undetectable levels, and this was accompanied by a modest fall in hemoglobin and hematocrit levels. Platelets and granulocyte counts also declined. Specific antibody production with immunoglobulin M (IgM) was followed by IgG, and viremia was cleared rapidly. A second-phase illness developed at 17 to 18 days with rash and arthralgias but without fever, and hematologic indices had returned to normal.

The tissue distribution of the cellular receptor for the virus (P antigen) may explain the predominance of hematologic findings associated with B19 infection. Its presence on other tissues may help to explain other clinical manifestations, such as myocardial disease, congenital infection, and vasculitis syndromes. Although the cellular receptor is present and the virus can attach, unlike erythroid cells, these cells are nonpermissive for viral replication; the virus is unable to undergo a complete life cycle with the resultant lysis of the host cells. Instead, interaction in these tissues leads to accumulation of the nonstructural protein NS1. This protein is essential for viral replication and has a variety of proposed functions<sup>23</sup> but appears to be toxic to most mammalian cell lines when present in excess.<sup>34</sup> NS1 has been associated with apoptosis.<sup>36,41</sup> NS1 also has been linked to production of tumor necrosis factor- $\alpha$  and interleukin-6, a potent proinflammatory cytokine.<sup>35,41,51</sup> This may lead to cellular injury through cytokine pathways and provide another mechanism aside from lytic infection for some of the clinical manifestations.

Chronic infections in immunocompromised patients develop when patients are unable to mount an adequate neutralizing antibody response. These infections are characterized by viral persistence in serum or bone marrow and lack of detectable circulating antibody. Clinical manifestations include chronic anemia or red cell aplasia and may include granulocytopenia and thrombocytopenia. The mechanism for the leukopenia and thrombocytopenia is not known, although it has been shown<sup>49</sup> that B19 causes disturbances in megakaryocytic replication when infected *in vitro*.

## EPIDEMIOLOGY AND TRANSMISSION

B19 is a highly contagious and common infection worldwide. In the United States, 60% or more of white adults are seropositive (i.e., have IgG antibodies to B19 in their sera). This indicates a previous infection, usually one acquired in childhood. Among African Americans, the rate of seropositivity is lower, about 30%.<sup>19</sup> Transmission of B19 from person to person probably occurs by droplets from oral or nasal secretions. This is suggested by the rapid transmission among those in close physical contact, such as schoolmates or family members, and from a study of healthy volunteers experimentally infected with B19, in whom virus was found in blood and nasopharyngeal secretions for several days beginning 1 or 2 days before symptoms appeared.<sup>50</sup> In the volunteer study, no virus was detected in urine or stool.

Given the highly contagious nature of B19 infections, it is not surprising that most outbreaks occur in elementary schools and occasionally child-care centers. Susceptible (seronegative) adult school personnel are at high risk for acquiring the infection from students.<sup>19</sup> Some outbreaks in schools may be seasonal (often late winter and spring) and epidemic, with many children and staff acquiring the infection and developing symptoms of EI. At other times, the infection is often endemic, with transmission occurring slowly and with only a few persons manifesting symptoms.

### Global Distribution

B19 infections occur worldwide. Serologic evidence of B19 infection has been found everywhere studied, including developed countries, undeveloped countries, urban and rural areas, and isolated island populations.<sup>52-55</sup> The diseases and associated signs and symptoms are the same worldwide. No important strain or antigenic differences have been detected, and serologic assays are independent of the source or location of patient serum. Disease caused by B19 appears to be unrelated to specific viral genotypes, although analysis of the antigenic variation or nucleotide sequences of widely dispersed B19 isolates shows some heterogeneity of unknown significance.<sup>25,26,56-61</sup>

### Seasonality and Periodicity

Transmission of B19 continues throughout the year, but there are seasonal variations in transmission rates. Outbreaks of EI most often occur in winter and spring in temperate climates and less frequently in fall and summer.<sup>62-64</sup> In schools or daycare centers, outbreaks of EI may persist for months, usually starting in late winter or early spring and ending with summer vacation. Figure 27-1 highlights multiyear outbreaks of B19 exposure among pregnant women and the associated seasonal variation in Pittsburgh, Pennsylvania. Most cases occurred in late spring and summer of each year.

In Jamaica, an island nation, careful studies of those with sickle cell disease show that epidemics of transient aplastic crises occurred about every 5 years, with little disease occurring inside this interval.<sup>65</sup> Epidemics of B19 infections at 5-year intervals were also observed in Rio de Janeiro, Brazil.<sup>66</sup> In Japan, age-related serologic evaluation of stored serum samples showed no evidence for B19 epidemics over a 10-year period.<sup>67</sup> The prevalence of IgG antibodies to B19 among three tribes of South American Indians living in remote regions of Brazil was very low (<11%), and was zero for those younger than 30 years in one tribe.<sup>55</sup> However, school nursing records in Iowa over 14 years identified cases of EI every year but one.<sup>68</sup>

### Seroprevalence by Age

In numerous studies of B19 infection based on serologic testing, the seroprevalence of B19 infection increases with age.<sup>4,65,69-74</sup> Figure 27-2 shows the age-dependent increase in seroprevalence in Richmond, Virginia.<sup>75</sup> Transplacentally acquired maternal antibodies are undetectable by 1 year of age. In children younger than 5 years, the prevalence of IgG antibodies to B19 is usually less than 5%. The greatest increase in seroprevalence and B19 infection occurs between 5 and 20 years of age. By age 20 years, the seroprevalence of B19 infection rises from about 5% to almost 40%. Afterward, without regard to risk factors, B19 seroprevalence increases slowly. In adult blood donors, the seroprevalence of IgG antibodies to B19 ranges from 29% to 79% with a median of 45%.<sup>76-82</sup> By age 50, the seroprevalence may be greater than

**Figure 27-1** Seasonal variation in reported parvovirus B19 exposures in pregnant women. Each month is indicated by its first letter. (Data from Harger J, Koch W, Harger GF. Prospective evaluation of 618 pregnant women exposed to parvovirus B19: risks and symptoms. *Obstet Gynecol* 91:413, 1998.)

**Figure 27-2** Percentage of family subjects positive for IgG antibody to B19 by age. The sample includes 283 subjects from 111 families. Subjects were one twin of each twin pair, nontwin parents, and the oldest child of each family. (Data from Adler SP, Koch W. Human parvovirus B19 infections in women of childbearing age and within families. *J Pediatr Infect Dis* 8:83, 1989.)

75%. Similar results on the age-related seroprevalence of B19 infections were observed in India.<sup>83</sup>

### Seroprevalence by Gender

In most studies, the prevalence of antibodies to B19 in sera obtained from men and women is similar.<sup>70</sup> At least four studies, however, have reported that women have a higher rate of B19 infection than men.<sup>19,75,77,84</sup> In one study of adult blood donors, the proportion of women who were seropositive, 47.5%, was 1.5 times higher than for men. The prevalence of IgG antibodies averaged 51% for women of all ages, compared with 38% for males in one of two family studies in Richmond, Virginia, and 64% for women and 50% for men in the other.<sup>19,75</sup> In Taiwan, the prevalence of IgG antibodies to B19 among females was significantly higher than among males (36.4% versus 29.4%,  $P < .001$ ).<sup>85</sup> The most likely explanation for the higher rates of B19 infection among women compared with men is that women are likely to have more frequent contact with children, especially school-aged children, who are the major sources of B19 transmission because of school attendance. For adults, contact with school-aged children is the major risk factor for B19 infection.<sup>19</sup>

### Seroprevalence by Race

In the United States, there are significant differences in the seroprevalence to B19 between blacks and whites. For example in Richmond, Virginia, approximately 60% of whites are seropositive, compared with 45% of blacks.<sup>19</sup> The reasons for the lower rate of infection among blacks are unknown, but may reflect the fact that students in Richmond schools are predominantly African American.

### Incidence

In tests of serum from random blood donors for evidence of recent B19 infection using detection of viral antigens or DNA, the rate using antigen detection of infection is 0 to 2.6 cases per 10,000 individuals tested, with a median of 1 per 10,000; using DNA detection, the rate is 0 to 14.5 per 10,000, with a median of 2 per 10,000.<sup>86-91</sup> When IgM antibodies to B19 are used to detect recent infection, the rate has been zero, but all studies included fewer than 1000 patients.<sup>76,92,93</sup> As for seroprevalence, women may have a greater risk for infection during outbreaks of EI. During an epidemic of EI in Port Angeles, Washington, the attack rate for women was 15.6%, more than twice the rate of 7.4% for men.<sup>10</sup>

In Spain and Chile, children have the highest rates of B19 infection, which is true for groups of children 0 to 4 years old and for those 5 to 9 years old.<sup>94,95</sup> A study of 633 children with sickle cell disease followed at the Children's Hospital in Philadelphia between 1996 and 2001 found that 70% were seronegative (i.e., susceptible), and during this period, 110 patients developed B19 infections, for an incidence of 11.3 per 100 patients per year.<sup>96</sup> Among the 110 patients infected, there were 68 episodes of transient aplastic crisis, characterized by an acute exacerbation of anemia, acute chest syndrome, pain, and fever. The high incidence of disease among these patients emphasizes the need for a vaccine against a parvovirus B19.

### Risk Factors for Acquisition

B19 is efficiently transmitted among those residing in the same home, with attack rates based on the development of signs and symptoms of EI ranging from 17% to 30%.<sup>10,97</sup> Using serologic testing to identify asymptomatic infection and to exclude immune individuals, the secondary attack rate for susceptible household contacts is 50%. Most secondary cases of EI or aplastic crisis in the home occur 6 to 12 days after the index case.<sup>10, 97-100</sup> A serologic study of pregnant Danish women indicated that seropositivity was significantly correlated with increasing number of siblings, having a sibling of the same age, number of own children, and occupational exposure of children.<sup>101</sup>

During epidemics, B19 transmission is widespread among school-aged children. Studies of school or classroom outbreaks of EI with at least one serologically confirmed case of acute B19 infection revealed student infection rates ranging from 1% to 62% based on the occurrence of a rash illness. The median rate for all studies was 23%.<sup>102-109</sup> Because asymptomatic infections are common and other signs and symptoms of EI may be mild and overlooked, these studies undoubtedly underestimate the true incidence of infection. Studies of students using serologic assays to identify B19 infection during outbreaks report infection rates of between 34% and 72%, with most not associated with a rash illness.<sup>103,108,109</sup> The higher rates of infection occur in elementary schools and daycare centers compared with secondary schools and in boarded school students compared with nonboarded students.<sup>107-109</sup>

During school epidemics, employees in contact with children have the highest rates of infection compared with community controls. The attack rate based on detection of rash illness or arthropathy may be relatively low (12% to

25%).<sup>103,107</sup> However, the seroprevalence of B19 IgG antibodies to B19 in school employees is greater than adult community controls and ranges between 50% and 75%.<sup>19,109,110</sup> When serologic testing is used to identify employees with asymptomatic infection and to exclude immune employees, the attack rate among the susceptibles is usually very high. In four school outbreaks where serologic testing was used, the attack rate varied from 19% to 84%, and the frequency of asymptomatic infection was greater than 50% in all but one outbreak.<sup>103,106,109,110</sup> The highest infection rates occurred among susceptible elementary school teachers compared with middle and high school teachers, and this may reflect exposure to more infected children or a greater likelihood of contact with respiratory secretions in younger children.<sup>109,110</sup> During a community-wide outbreak of EI in Connecticut in 1988, the infection rate among susceptible women was 16% for school teachers, 9% for daycare workers and homemakers, but only 4% for other women working outside the home.<sup>109</sup>

The risk of infection may be increased for school employees even in the absence of recognized epidemics of EI. In a study of 927 susceptible school employees conducted during a 3.5-year period when no community outbreaks were detected, the annual incidence of specific IgG seroconversion was 2.9%, compared with 0.4% for a control population of 198 hospital employees.<sup>19</sup> The rate of 3.4% was higher for school employees with jobs involving direct contact with children compared with only 0.6% observed for persons with other job classifications. Most of the individuals who seroconverted did not recall an illness characterized by rash or arthropathy.

Salivary antibodies can be used to detect IgG and IgM antibodies to B19 because serum antibodies passively diffuse into saliva. Testing saliva for antibodies to B19 was useful in documenting outbreaks in schools and households. In an outbreak in England, school attack rates varied from 8% to 50%, including an attack rate of 45% for the teaching staff.<sup>111</sup> The household transmission attack rate was 45% for 11 susceptible individuals. These rates are similar to what has been previously observed.<sup>111</sup>

Crowding and low socioeconomic status are not proven risk factors for B19 infection. However, these factors are suggested by the observation that in Rio de Janeiro, the seroprevalence of IgG antibodies to B19 is 35% in children age 5 years or younger, but in Niger, it was 90% by 2 years of age.<sup>54,70</sup>

### Hospital Transmission

B19 can be transmitted from infected patients to hospital workers.<sup>112</sup> Most investigations reveal that hospital transmission of B19 is common and includes direct patient-to-patient transmission and indirect transmission from materials or specimens known to contain B19 to laboratory personnel.<sup>112-115</sup> One patient with sickle cell anemia became ill with aplastic crisis 9 to 11 days after contact in the hospital with a patient with hereditary spherocytosis hospitalized for aplastic crisis; B19 infection was confirmed in both.<sup>116</sup> An outbreak of EI occurred on a pediatric ward where 13 (26%) of 50 children developed a rash illness.<sup>117</sup> B19 seroconversion occurred in 5 (71%) of 7 children with rash illness and in 9 (35%) of 26 children who were asymptomatic. Transmission from patient to health care worker occurred twice in one hospital after admission of patients with aplastic crisis.<sup>112</sup> In

the first case, 4 (36%) of 11 susceptible employees with close contact had IgM antibodies to B19, indicating recent infection; in the second case, 10 (48%) of 21 employees had specific IgM antibodies to B19 or seroconverted from IgG negative to positive. Eleven (79%) of 14 were symptomatic with rash or arthropathy. Another study of an outbreak of EI among health care workers on a pediatric ward found that 10 (33%) of 30 susceptible health care workers had serologic evidence of acute B19 infection, along with 2 (17%) of 12 immunocompromised patients being cared for on the ward.<sup>113,118</sup> The two infected patients were not symptomatic, but analysis of preexisting sera showed they acquired B19 while hospitalized. Onset of symptoms among the employees was temporally clustered, indicating a chronic source such as an immunocompromised patient or person-to-person transmission.

Studies in Hong Kong identified three immunocompromised patients who appeared to transmit genetically identical strains of B19 from patient to patient.<sup>119</sup> At least one of these three patients appeared to be able to transmit the virus over many months. Immunocompromised patients often have chronic infections and therefore may be infectious for long periods. DNA sequence analysis was also used in Japan to document B19 transmission between hospital staff members, including nursing staff, office workers, and a physiotherapist.<sup>120</sup>

Other investigations have observed little or no risk for hospital transmission. No evidence of patient-to-employee transmission was found among 10 susceptible health care workers with frequent contact with a chronically infected patient hospitalized for 24 days before institution of isolation precautions.<sup>121</sup> Transmission to hospital employees did not occur after exposure to a parvovirus B19-infected mother, her infected stillborn fetus, and contaminated objects in the hospital room.<sup>122</sup> During a community outbreak of B19, none of 17 susceptible pregnant health care workers with possible exposure had serologic evidence (IgM antibodies to B19) of a recent infection.<sup>123</sup> In a case-control study of hospital transmission, serologic testing was used to determine the infection rates among personnel exposed to patients with sickle cell disease and transient aplastic crisis before the subjects being placed in isolation.<sup>124</sup> Only 1 of 32 susceptible exposed hospital workers acquired a B19 infection, compared with 3 of 37 susceptible workers not exposed. Results of this study suggested that hospital workers who cared for patients with aplastic crisis were not at an increased risk for B19 acquisition.

Two prospective studies from one institution determined the incidence of infection in health care workers during endemic (nonepidemic) periods. The first study found the annual seroconversion rate to be 1.4% for 124 susceptible female health care workers followed for an average of 1.7 years. In a subsequent study of 198 susceptible hospital employees, the annual rate was 0.4%, compared with 2.9% for school employees.<sup>19</sup>

Taken as a whole, the evidence indicates that B19 may be highly contagious in the hospital, although perhaps not in every circumstance. Many potential variables may affect rates of transmission from patients to staff, including the type of patient (immunocompromised or not), the duration of B19 infection at the time of hospitalization, and potentially, the viral load of the infected patient. Patients with erythrocyte

aplasia or others with suspected EI or B19 infection should be presumed to have a B19 infection until proved otherwise. These patients should receive respiratory and contact isolation while hospitalized.

### Routes of Viral Spread

Person-to-person spread of B19 probably occurs through contact with respiratory secretions. Viral DNA is present in saliva<sup>50,108,124,125</sup> at levels similar to those in blood, and in a volunteer study, infection was initiated by intranasal inoculation of B19.<sup>50,126</sup> B19 cannot be detected in columnar epithelial cells of the large airways.<sup>127</sup> Indirect evidence suggests B19 is not transmitted by aerosols. Viruses such as measles and influenza that are transmitted by aerosols are rapidly spread during outbreaks, but new cases of EI are spread out over many months during school outbreaks, suggesting that B19 transmission is inefficient. B19 DNA may be found in the urine, but it is unlikely that this is associated with infectious virus.

The only well-documented routes of spread for B19 are vertically from mother to fetus and from parenteral transfusion with contaminated blood products or needles. Vertical transmission is discussed later. Transmission of B19 by transfusion occurs but is rare because of the low prevalence of B19 viremia among donors of blood and blood products; however, the risk increases for pooled blood products.<sup>128-131</sup> For example, B19 DNA is frequently found in clotting factor concentrates, including products treated with solvents and detergents, steam, or monoclonal antibodies, and even treated products may be infectious.<sup>91,129,131-134</sup> Seroprevalence of IgG antibodies to B19 is high among hemophiliacs compared with age-matched controls and is higher for those who received frequent infusions of clotting factors prepared from large donor pools compared with those prepared from small donor pools.<sup>130</sup>

Parvoviruses are resistant to chemical inactivation. In one hospital, B19 transmission occurred without recognized direct patient contact, suggesting possible transmission by fomites or environmental contamination.<sup>112</sup> That B19 is transmitted by fomites has not been directly established, but considering the stability of related animal parvoviruses, this possibility exists. B19 DNA, not infectious virus, was found in a study of a suspected nosocomial outbreak in a maternity ward.<sup>123</sup> B19 DNA was detected by polymerase chain reaction (PCR) on the hands of the mother of a stillborn fetus infected with B19 and on the sink handles in her hospital room. Samples from countertops, an intravenous pump, and telephone were also positive by a sensitive nested-PCR DNA technique. PCR is so sensitive that minute quantities of DNA can be detected by this technique, and the presence of B19 DNA on surfaces does not imply that these surfaces are sources of infection. Infected fetal tissues and placental or amniotic fluids are more likely sources of infection for health care workers than fomites.

### Risk of B19 Acquisition for Women of Childbearing Age

We completed a large epidemiologic study<sup>19</sup> to determine the relative risk of B19 acquisition for women of childbearing age in daily contact with children, including nurses, daycare

employees, and teachers at all levels. We identified risk factors for B19 infections for hospital and school employees during an endemic period. We monitored by serologic testing 2730 employees of 135 schools in three school systems and 751 employees of a hospital, all in Richmond, Virginia. Sixty percent were initially seropositive. After adjusting for age, race, and gender, risk factors for seropositivity were contact with children 5 to 18 years old at home or at work and employment in elementary schools. Over 42 months, only 1 of 198 susceptible hospital employees seroconverted (0.42% annual rate), compared with 62 of 927 (2.93% annual rate) school employees (relative risk = 6.9). Four factors associated with seroconversion were employment at elementary schools, contact with children 5 to 11 years of age at home, contact at work with children 5 to 18 years old; and age younger than 30 years. Those in daily contact with school-aged children had a fivefold increased annual occupational risk for B19 infection.<sup>19</sup>

Several observations indicate that B19 infections were endemic but not epidemic or pandemic in the Richmond area during the 42-month prospective evaluation.<sup>19</sup> First, few cases of B19 infection were reported by the school nurses, and no cluster of cases was observed at any single school or group of schools. Second, the seroconversion rates during each of three consecutive study periods were the same for all groups or subgroups. Third, for employees, B19 infections were not clustered at individual schools or groups of schools. Fourth, the infection rates we observed among employees, even for those teaching elementary school, were less than those observed for the 1988 Connecticut epidemic, in which 46 infections occurred among 236 susceptible individuals exposed in the schools, for a minimum annual infection rate of 19%.<sup>109</sup> In a study of secondary B19 infections among exposed household members, rates ranged from 30% to 50%.<sup>98</sup>

Persons with B19 infections are often asymptomatic or have no rash, and low-level endemics can go unnoticed. We observed that 28 of 60 infected employees were asymptomatic and that only 20 knew of a specific exposure. In a study of 52 household contacts of patients with B19 infections during an Ohio epidemic, infections without a rash occurred in 15 (94%) of 16 blacks and 17 of 35 (47%) whites, and completely asymptomatic infections occurred in 11 (69%) of 16 blacks and 6 (20%) of 30 whites.<sup>98</sup> During the Connecticut outbreak, 5 (8%) of 65 teachers who were never exposed to a child with a rash became infected.<sup>109</sup> Observations of high secondary attack rates during epidemics and the high rates of rashless or asymptomatic infections provide strong evidence that even during periods when EI is inapparent in the community, school or hospital personnel in contact with children have a significant occupational risk for B19 infections.

Contact with elementary school-aged children, whether at home or at work, may be the most important risk factor for B19 acquisition. When seropositivity for those with children at home was stratified by the child's age, the association between seropositivity and children at home was significant ( $P < .05$ ) when all children between 5 and 18 years old were included, and for seroconversion, the significant association was with elementary school-aged children at home.<sup>19</sup> The low seroprevalence and seroconversion rate among hospital employees without known contact with

children indicates that this group has a low occupational risk for acquiring B19 infections.

The major conclusions from these studies were that when EI is inapparent in the community, school or hospital personnel in contact with children still have a significant occupational risk for B19 infections and that school employees have an approximately twofold greater risk of acquiring B19 from children at work than from elementary school-aged children at home. We also found that hospital employees without contact with children have a low risk for acquiring B19.

Using the Richmond data and assuming that on average 50% of pregnant women are immune, we estimate that 1% to 4% of susceptible women will become infected during pregnancy during endemic periods. If the rate of fetal death after maternal infection is as high as 5% to 10% (discussed later), the occupational risk of fetal death for a pregnant woman with unknown serologic status will be between 1 in 500 and 1 in 4000. These rates are so low that during endemic periods, they do not justify intervention such as serologic testing for pregnant women, furloughing workers, or temporary transfer of pregnant seronegative employees to administrative or other positions without child contact.

Knowing B19 infection rates during endemic periods may be more important than knowing rates during epidemic periods. In the United States, B19 infections are endemic most of the time. Because more than 75% of B19 infections are inapparent, most women who acquire B19 infection during pregnancy do so during endemic periods, not during epidemics. For establishing public health policy and assessing the potential importance of immunizing against B19, knowing that for seronegative women the endemic rate is between 1% and 4% is more important than knowing epidemic rates.

## CLINICAL MANIFESTATIONS OTHER THAN INTRAUTERINE INFECTION

### Erythema Infectiosum

The most common clinical manifestation of infection with parvovirus B19 is EI, or fifth disease, a well-known rash illness of children. EI begins with a mild prodromal illness consisting of low-grade fever, headache, malaise, and upper respiratory tract symptoms. This prodrome may be so mild as to go unnoticed. The hallmark of the illness is the characteristic exanthem. The rash usually occurs in three phases, but these are not always distinguishable.<sup>10,102,135</sup> The initial stage consists of an erythematous facial flushing described as a slapped-cheek appearance. In the second stage, the rash spreads quickly to the trunk and proximal extremities as a diffuse macular erythema. Central clearing of macular lesions occurs promptly, giving the rash a lacy, reticulated appearance. Palms and soles are usually spared, and the rash tends to be more prominent on the extensor surfaces. Affected children at this point are afebrile and feel well. Adolescents and adult patients often complain of pruritus or arthralgias concurrent with the rash. The rash resolves spontaneously, but it typically may recur over the course of 1 to 3 weeks in response to a variety of environmental stimuli such as sunlight, heat, exercise, and stress.<sup>136</sup>

Lymphadenopathy is not a consistent feature but has been reported in association with EI<sup>97</sup> and as sole manifestations of infection.<sup>137-139</sup> A mononucleosis-like illness associated with confirmed B19 infections has occasionally been reported, but B19 does not typically cause a mono-like illness. Atypical rashes not recognizable as classic EI have also been associated with acute B19 infections; these include morbilliform, vesiculopustular, desquamative, petechial, and purpuric rashes.<sup>2</sup>

Asymptomatic infection with B19 also occurs commonly in children and adults. In studies of large outbreaks, asymptomatic infection is reported in approximately 20% to 30% of serologically proven cases.<sup>97,98</sup>

### Transient Aplastic Crisis

Transient aplastic crisis was the first clinical illness to be definitively linked to infection with B19. An infectious origin had been suspected for this condition because it usually occurred only once in a given patient, had a well-defined course and duration of illness, and tended to occur in clusters within families and communities.<sup>136</sup> Attempts to link it to infection with any particular agent had repeatedly failed until 1981, when Pattison and colleagues<sup>6</sup> reported six positive tests for B19 (seroconversion or antigenemia) among 600 admissions to a London hospital. All six were children with sickle cell anemia admitted with aplastic crisis. This association was confirmed by studies of an outbreak of aplastic crisis in the population with sickle cell disease in Jamaica.<sup>7</sup>

In contrast to EI, patients with a transient aplastic crisis are ill at presentation with fever, malaise, and signs and symptoms of profound anemia (e.g., pallor, tachypnea, tachycardia). These patients rarely have a rash.<sup>100,140</sup> The acute infection causes a transient arrest of erythropoiesis with a profound reticulocytopenia. Given the short half-life of these patients' red cells and their dependence on active erythropoiesis to counterbalance their increased red cell turnover, this leads to a sudden and potentially life-threatening decline in serum hemoglobin. Children with sickle hemoglobinopathies may also develop a concurrent vaso-occlusive pain crisis, which may further complicate the clinical picture.

Although such transient aplastic crises are most commonly associated with sickle cell anemia, any patient with a condition of increased red cell turnover and accelerated erythropoiesis can experience a similar transient red cell aplasia with B19 infection. B19-induced aplastic crises have been described in many hematologic disorders, including other hemoglobinopathies (e.g., thalassemia, sickle-C hemoglobin); red cell membrane defects (e.g., hereditary spherocytosis, stomatocytosis); enzyme deficiencies (e.g., pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency); antibody-mediated red cell destruction (e.g., autoimmune hemolytic anemia); and decreased red cell production (e.g., iron deficiency, blood loss).<sup>48,140</sup> B19 is not a significant cause of transient erythroblastopenia of childhood, another condition of transient red cell hypoplasia that usually occurs in younger, hematologically normal children and follows a more indolent course.<sup>47</sup>

Leukopenia and thrombocytopenia may occur during a transient aplastic crisis, but the incidence varies with the underlying condition. In a French study of 24 episodes of aplastic crisis (mostly in individuals with hereditary spherocytosis), 35% to 40% of patients were leukopenic or thrombo-

cytopenic, compared with 10% to 15% reported in a large U.S. study of mostly sickle cell patients.<sup>100,141</sup> These transient declines in leukocyte count or platelets follow a time course similar to that for reticulocytopenia, although they are not as severe and recovery occurs without clinical sequelae. The relative preservation of leukocyte and platelet counts in sickle cell anemia compared with other hereditary hemolytic anemias presumably is caused by the functional asplenia associated with sickle cell disease.<sup>48</sup>

As observed in experimental infection in human volunteers, B19 infection in normal subjects does result in a fall in the reticulocyte count, but because of the normal red cell half-life, this is not clinically significant or noticeable. Various degrees of leukopenia and thrombocytopenia also occur after natural B19 infection in hematologically normal patients.<sup>50</sup> Some cases of idiopathic thrombocytopenic purpura (ITP) and cases of childhood neutropenia have been reported in association with acute B19 infection.<sup>142,143</sup> Aside from these few anecdotal reports, larger studies have not confirmed B19 as a common cause of ITP or chronic neutropenia in children.<sup>47</sup>

## Arthropathy

Joint symptoms are reported by up to 80% of adolescents and adults with B19 infection, whereas joint symptoms are uncommon in children.<sup>10,102</sup> Arthritis or arthralgia may occur in association with the symptoms of typical EI or be the only manifestation of infection. Females are more frequently affected with joint symptoms than males.<sup>10,102</sup>

The joint symptoms of B19 infection usually manifest as the sudden onset of a symmetric peripheral polyarthropathy.<sup>144</sup> The joints most often affected are the hands, wrists, knees, and ankles, but the larger joints can also be involved.<sup>106,145</sup> The joint symptoms have a wide range of severity, from mild morning stiffness to frank arthritis with the classic combination of erythema, warmth, tenderness, and swelling. Like the rash of EI, the arthropathy has been presumed to be immunologically mediated because the onset of joint symptoms occurs after the peak of viremia and coincides with the development of specific IgM and IgG antibodies.<sup>50</sup> Rheumatoid factor may also be transiently positive, leading to some diagnostic confusion with rheumatoid arthritis (RA) in adult patients.<sup>146</sup> Fortunately, there is no joint destruction, and in most patients, joint symptoms resolve within 2 to 4 weeks. For some patients, joint discomfort may last for months or, in rare individuals, for years. The role of B19 in these more chronic arthropathies is not clear.

The arthritis associated with B19 infection may persist long enough to satisfy clinical diagnostic criteria for RA or juvenile rheumatoid arthritis (JRA).<sup>85,93,145,147,148</sup> This has led some to suggest that B19 might be the etiologic agent of these conditions.<sup>2</sup> This speculation has been supported by the detection of B19 DNA in synovial tissue from patients with RA and reports of increased seropositivity among patients with these conditions.<sup>94,149-151</sup> Later findings of DNA from other viruses in addition to B19 in synovial tissue from patients with arthritis and the finding of B19 DNA in synovium from persons without arthritis suggest that this may be a nonspecific effect of inflammation.<sup>152,153</sup> A review of the accumulated evidence on this topic has concluded that B19 is unlikely to be a primary cause in these rheumatic diseases

but may be one of several viral triggers capable of initiating joint disease in genetically predisposed individuals.<sup>154</sup>

## Infection in the Immunocompromised Host

Patients with impaired humoral immunity are at risk for developing chronic and recurrent infections with B19. Persistent anemia, sometimes profound, with reticulocytopenia is the most common manifestation of such infections, which may also be accompanied by neutropenia, thrombocytopenia, or complete marrow suppression. Chronic infections with B19 occur in children with cancer who receive cytotoxic chemotherapy,<sup>155,156</sup> children with congenital immunodeficiency states,<sup>157</sup> children and adults with acquired immunodeficiency syndrome (AIDS),<sup>158</sup> and transplant recipients,<sup>159</sup> and they may even occur in patients with more subtle defects in immunoglobulin production who are able to produce measurable antibodies to B19 but are unable to generate adequate neutralizing antibodies.<sup>160</sup>

B19 has also been linked to viral-associated hemophagocytic syndrome (VAHS),<sup>155,161</sup> more generally referred to as infection-associated hemophagocytic syndrome (IAHS). This condition of histiocytic infiltration of bone marrow and associated cytopenias usually occurs in immunocompromised patients. B19 is only one of several viruses that have been implicated as causing VAHS. IAHS is considered a nonspecific response to a variety of viral and bacterial insults rather than a specific manifestation of a single pathogen.

Infections in the immunocompromised host can lead to chronic infection. This is most often manifested as chronic anemia (i.e., red cell aplasia), but various degrees of cytopenia have been described, ranging from thrombocytopenia or neutropenia to complete bone marrow failure.<sup>140</sup> Patients with an inability to produce neutralizing antibodies are at greatest risk, and this complication of B19 infection has been described in children with congenital immunodeficiency syndromes, patients on cytoreductive chemotherapy, transplant recipients on immunosuppressive therapy, and adults and children with AIDS.<sup>140</sup>

Increased recognition of B19 infection in solid-organ transplant recipients led to several reports.<sup>162-164</sup> Although most such infections are manifested as the typical persistent anemia, an association of B19 viremia with acute graft rejection has been described.<sup>165</sup>

## Other Dermatologic Syndromes

### Vasculitis and Purpura

A variety of atypical skin eruptions has been associated with B19 infections. Most of these are petechial or purpuric in nature, often with evidence of vasculitis in those that report skin biopsy results, and the eruptions may resemble the rash of other connective tissue diseases.<sup>2,166</sup> There are reports of confirmed acute B19 infections associated with non-thrombocytopenic purpura and vasculitis, including several cases clinically diagnosed as Henoch-Schönlein purpura,<sup>86,167</sup> an acute leukocytoclastic vasculitis of unknown origin in children. Chronic B19 infection has also been associated with necrotizing vasculitis, including cases of polyarteritis nodosa and Wegener's granulomatosis.<sup>168</sup> These patients had no underlying hematologic disorder and were generally not

anemic at diagnosis. The pathogenesis is unknown, but these details may suggest an endothelial cell infection, as occurs with some other viruses such as rubella.

Information from biopsy of rashes temporally associated with B19 infection is limited, although several reports have appeared. B19 capsid antigens and DNA were found in a skin biopsy from a patient with EI, and this observation lends support to a role for B19 in these vascular disorders.<sup>169</sup> Rashes resembling those of systemic lupus erythematosus, Henoch-Schönlein purpura, and other connective tissue disorders have been described.<sup>166,170</sup> In a controlled study of 27 children with Henoch-Schönlein purpura, B19 was not a common cause.<sup>171</sup> Only 3 of 27 children had detectable B19 IgM antibodies indicating a recent infection. The role of B19 in these conditions remains speculative.

### **Papular-Purpuric "Gloves and Socks" Syndrome**

Papular-purpuric "gloves and socks" syndrome (PPGSS) is a distinctive, self-limited dermatosis first described in the dermatologic literature in 1990.<sup>172</sup> The syndrome is characterized by fever, pruritus, and painful edema and erythema localized to the distal extremities in a distinct glove and sock distribution. The distal erythema is usually followed by petechiae, and oral lesions often develop. Resolution of all symptoms usually occurs in 1 to 2 weeks. A search for serologic evidence of viral infection led to the discovery of an association with acute B19 infection in many of these patients, based on demonstration of specific IgM or seroconversion. This association has been further confirmed with subsequent reports and demonstration of B19 DNA in skin biopsy samples and sera from these patients.<sup>172,173</sup> Initially described in adults, a number of children with this condition were subsequently described.<sup>174</sup> There appears to be sufficient evidence to suggest that PPGSS is a rare but distinctive manifestation of primary, acute infection with parvovirus B19, occurring mainly in young adults but also affecting children.

### **Central Nervous System Infection and Neurologic Disorders**

Although a variety of neurologic symptoms and disorders have been described in patients clinically diagnosed as having EI or laboratory-confirmed B19 infection,<sup>2</sup> the issue of whether B19 causes central nervous system (CNS) infection or is etiologic for other neurologic conditions remains unresolved. Cases of meningitis,<sup>175,176</sup> encephalitis,<sup>177</sup> and encephalopathy<sup>178</sup> caused by B19 infection have been reported. Many of these cases were determined during outbreaks of EI from older reports based on clinical diagnosis only, before reliable laboratory tests for B19 were available. In one study, headache was reported in as many as 32% of children with rash illness.<sup>175</sup> However, there are no controlled comparative studies to evaluate the frequency of signs or symptoms suggestive of meningeal inflammation or CNS infection in B19 infection. Cerebrospinal fluid (CSF) abnormalities such as pleocytosis and increased levels of CSF protein have been reported in some patients with meningismus or altered level of consciousness associated with EI.<sup>2</sup> B19 DNA has been detected in CSF using PCR in several cases of serologically confirmed acute B19 infection with meningoencephalitis or encephalopathy.<sup>179-181</sup> However, most of these reported patients were also viremic at the time,

and the possibility that the CSF PCR was positive because of contamination from blood could not be completely excluded.

Disorders of the peripheral nervous system have included brachial plexus neuropathy,<sup>182</sup> extremity paresthesias and dysesthesias,<sup>183</sup> myasthenia-like weakness,<sup>184</sup> and carpal tunnel syndrome.<sup>185</sup> The onset of most of these peripheral nerve symptoms has been coincident with the onset of rash and or joint pain at a time when the patient should have a brisk immune response, suggesting that the neurologic abnormalities could be immunologically mediated.<sup>2</sup> In the course of one well-described outbreak of EI among intensive care nurses, numbness and tingling of the fingers were reported by 54% of the 13 B19-infected nurses.<sup>183</sup> The neurologic symptoms persisted for more than 1 year in three of the nurses, and one had low levels of B19 DNA in serum for more than 3 years in association with recurrent episodes of paresthesias. She was never anemic and had no demonstrable immunodeficiency.<sup>186</sup> Although these cases are suggestive, the role of B19 in neurologic disease and CNS infection will remain unresolved until the pathogenesis of the viral infection in these conditions can be elucidated.<sup>3,187</sup>

### **Renal Disease**

Reports of renal disease after B19 infection, previously rare, have increased within the past few years.<sup>188-190</sup> Most have been case reports of glomerulonephritis or focal glomerulosclerosis temporally related to an acute B19 infection. Immune complex deposition has been demonstrated in renal tissue, and B19 DNA occasionally can be found in renal tissue by PCR.<sup>191</sup> Renal failure is rarely reported. The virus is not known to infect kidney cells in vitro, and its presence in renal tissue may reflect filtration of the viremia of acute infection. B19 DNA has been detected in urine in studies of infants with evidence of intrauterine infections. B19 antigens may trigger an immune complex-mediated nephritis, but this may be a nonspecific effect, and further study is necessary to define the relationship between B19 infection and the potential for renal disease.

## **DIAGNOSIS: GENERAL APPROACH AND LABORATORY METHODS**

The diagnosis of EI is usually based on the clinical recognition of the typical exanthem, a benign course, and exclusion of similar conditions. Rarely is laboratory confirmation necessary. A presumptive diagnosis of a B19-induced transient aplastic crisis in a patient with known sickle cell disease (or other condition associated with chronic hemolysis) is based on an acute febrile illness, a sudden and severe decline in the serum hemoglobin level, and an absolute reticulocytopenia. Likewise, a clinical diagnosis of PPGSS can be based on the characteristic skin eruption in the distinct acral distribution.

Specific laboratory diagnosis depends on identification of B19 antibodies, viral antigens, or viral DNA. In the immunologically normal patient, determination of anti-B19 IgM is the best marker of recent or acute infection on a single serum sample. IgM antibodies develop rapidly after infection and are detectable for as long as 6 to 8 weeks.<sup>192</sup> Specific IgG antibodies become detectable a few days after IgM and

persist for years and probably for life. Seroconversion from an IgG-negative to IgG-positive status on paired sera confirms a recent infection. Anti-B19 IgG, however, primarily serves as a marker of past infection or immunity. Patients with EI or acute B19 arthropathy are usually IgM positive, and a diagnosis usually can be made from a single serum sample. Patients with B19-induced aplastic crisis may present before antibodies are detectable; however, IgM will be detectable within 1 to 2 days of presentation, and IgG will follow within days.<sup>100</sup>

The availability of serologic assays for B19 had previously been limited by the lack of a reliable and renewable source of antigen for diagnostic studies. The development of recombinant cell lines that express B19 capsid proteins have provided more reliable sources of antigen suitable for use in commercial test kits.<sup>193,194</sup> Several commercial kits are available for detection of B19 antibodies, but they employ a variety of different antigens (e.g., recombinant capsid proteins, fusion proteins, synthetic peptides), and their performance in large studies has varied.<sup>193</sup> Based on studies of the humoral immune response to the various B19 viral antigens, it appears to be important to have serologic assays based on intact capsids that provide conformational epitopes. Antibody responses to these antigens are more reliable and longer lasting than are responses to the linear epitopes used in some assays.<sup>195</sup> Only one commercial assay based on such capsids has received Food and Drug Administration approval in the United States<sup>196</sup>; other commercial assays for this purpose are considered research tests. Until serologic tests are more standardized and results more consistent, some knowledge of the assay and antigens used will be necessary for proper interpretation of B19 antibody test results.

In immunocompromised or immunodeficient patients, serologic diagnosis is unreliable because humoral responses are impaired, and methods to detect viral particles or viral DNA are necessary to make the diagnosis of a B19 infection. Because the virus cannot be isolated on routine cell cultures, viral culture is not useful. Detection of viral DNA by DNA hybridization techniques<sup>197</sup> or by PCR<sup>198,199</sup> is useful in these patients. Both techniques can be applied to a variety of clinical specimens, including serum, amniotic fluid, fresh tissues, bone marrow, and paraffin-embedded tissues.<sup>144</sup>

Histologic examination is also helpful in diagnosing B19 infection in certain situations. Examination of bone marrow aspirates in anemic patients typically reveals giant pronormoblasts or "lantern cells" against a background of general erythroid hypoplasia. However, the absence of such cells does not exclude B19 infection.<sup>200,201</sup> Electron microscopy has proved useful and may reveal viral particles in serum of some infected patients and cord blood or tissues of hydropic infants (discussed later).

## EPIDEMIOLOGY OF B19 INFECTIONS AND RISK OF ACQUISITION IN THE PREGNANT WOMAN

### Prevalence and Incidence in the United States

We have completed three studies<sup>19</sup> using complementary strategies to determine the incidence of human parvovirus B19 infection during pregnancy. First, using the data from a study of school personnel, we estimated the average B19

infection rate among pregnant school personnel. Of the 60 individuals who seroconverted during that study, 8 (13%) were pregnant. However, not all pregnant women in the school system participated in the study. Although we had data on the pregnancy rates for the female school personnel who participated, these volunteers may have been biased toward younger females, raising the possibility that their pregnancy rates may not have been representative of all school employees. Of approximately 11,637 total school employees in Richmond, Virginia, we enrolled 2730 (24%) in our study. To determine whether the sample enrolled was representative, we performed a random survey of 733 school employees at the schools studied. The results provided strong evidence that the seroprevalence and annual infection rates observed among study subjects were representative and applicable to the entire school employee population.<sup>19</sup> Assuming no seasonality to B19 infections (none was observed) and that pregnancy does not affect susceptibility, we predicted that without regard to risk factors, seronegative pregnant personnel have an average annual infection rate of 3%, for a rate of 2.25% per pregnancy.<sup>19</sup>

Second, in Richmond from 1989 to 1991, we collected sera from 1650 pregnant women from a lower socioeconomic group who attended a high-risk pregnancy clinic for patients without medical insurance. This group was 80% African American, with an average maternal age of 24 years. We randomly selected a subset of 395 women for serotesting and monitoring, 35% of whom were seropositive. Of the 256 seronegative women, 2 (0.8%) seroconverted, for an annual rate of 1.7%. This rate was similar to the rate observed among low-risk and African American school personnel in Richmond.<sup>19</sup>

We also obtained serial sera from a large number of private practice obstetric patients from Birmingham, Alabama.<sup>202</sup> From this serum bank, we randomly selected 200 patients per year over 4 years (1987 to 1990). No significant differences were observed by year among the 800 patients (average age was 27 years and 88% were white), and 46% were seropositive overall. Of 413 seronegative women serially tested over the 4 years, 5 seroconverted. Overall, the annual seroconversion rate was 2%. Combining data from the studies of pregnant women done in Richmond and Birmingham, we observed that 7 of 669 seronegative women seroconverted during pregnancy, for a rate of 1% per pregnancy (95% CI, 0.3% to 21%).

### Prevalence and Incidence in Other Countries

In numerous studies conducted worldwide, for pregnant women and women of reproductive age, the seroprevalence of IgG antibodies to B19 has varied from 16% to 72%, with most estimates falling between 35% and 55%.<sup>69,74,75,124</sup> In Denmark, a serologic survey of 31,000 pregnant Danish women found 65% had evidence of past infection<sup>101</sup>; the seroprevalence of IgG antibody among 1610 pregnant women in Barcelona was 35.03%<sup>203</sup>; 81% of pregnant Swedish women had parvovirus antibodies;<sup>20,204</sup> and in Japan, the seroprevalence of IgG antibodies to B19 was 26% for women between the ages of 21 and 30, and 44% for women between the ages of 31 and 40.<sup>74</sup> The prevalence of IgG antibodies to B19 in cord blood from normal newborns provides estimates of maternal immunity ranging from 50% to 75%.<sup>17,205,206</sup>

Without regard to maternal age or other potential risk factors, a South African study found that 64 (3.3%) of 1967 pregnant women acquired B19 infection during pregnancy, and another in Barcelona found that 60 (3.7%) of 1610 pregnant women became infected with B19 during pregnancy.<sup>20,203</sup> Seroconversion rates among susceptible pregnant Danish women during endemic and epidemic periods were 1.5% and 13%, respectively. In Denmark, risk of infection increased with the number of children in the household and having children 6 to 7 years old resulted in the highest rate of seroconversion, and nursery school teachers had a threefold increased risk of acute infection.<sup>101</sup> Extrapolating to a 40-week period places the infection rate during pregnancy among susceptible women at approximately 1.1%, with a range of 1% to 4%, depending on risk factors. The Danish and Barcelona data are similar to those obtained in Richmond, Virginia.<sup>19</sup>

A few studies have tried to estimate the infection rate based on the prevalence of IgM antibodies to B19 in pregnancy or in women of reproductive age. Although B19-specific IgM is an accurate diagnostic test for recent infection, it is a poor test for epidemiologic studies. B19-specific IgM persists for only a few months and therefore underestimates the maternal infection rate because women who have had a B19 infection 6 to 9 months before testing are not detected. Another problem with IgM surveys is that most studies have surveyed high-risk populations such as women with rash illness, possible exposure to cases of EI, or recent diagnosis of adverse reproductive outcomes. Sampling high-risk populations biases the results toward rates higher than would be observed in population-based studies. A few studies used B19-specific IgM to test pregnant women or women of reproductive age who did not have risk factors. The observed range in these studies was 0% to 2.6%.<sup>17,205,207</sup> For susceptible women with B19-specific IgM in populations known to be at increased risk, the prevalence of IgM has ranged from 0% to 12.5%.<sup>17,74,124,208,209</sup>

In countries other than the United States, the prevalence of IgG antibodies to B19 among pregnant women and women of reproductive age varies widely and probably reflects exposure during prior epidemics. Studies of infections during pregnancy are fraught with potentially confounding variables such as IgM testing, which lacks sensitivity, and biases introduced by selection criteria for the population studied. Despite these problems, it is likely that the risk for B19 infection during pregnancy in other countries is similar to the risk observed in the United States.

### CLINICAL MANIFESTATIONS OF B19 INFECTIONS IN THE PREGNANT WOMAN

The symptoms reported by pregnant women with a proven recent B19 infection are usually vague and nonspecific, and serologic confirmation is essential to establish the diagnosis. The signs and symptoms of classic EI in children are significantly different in adults; the sunburned or slapped-cheek facial rash common in children rarely occurs in adults. Malaise is a common feature of B19 infection in children and in adults, but it is nonspecific. In pregnant women and adolescents, the most characteristic symptom is symmetrical arthralgias, occasionally with signs of arthritis and usually involving the small (distal) joints of hands, wrists, and feet.

The proportion of pregnant women with serologically proven B19 infection who are asymptomatic varies with the inclusion criteria in the few studies that address symptoms. In a cohort of 1610 pregnant women studied in Barcelona, the sera of 30 women had IgM antibodies to B19 at the first prenatal visit, and another 30 seroconverted during pregnancy.<sup>20</sup> Of these 60 women, only 18 (30%) reported any combination of fever, rash, and arthralgias, and 70% were asymptomatic. The investigators did not report when questions about symptoms were asked in relation to the serologic results, and no comment was made about the distribution of symptoms nor about which joints were affected by the arthralgias.<sup>20</sup> Similarly, during an epidemic of EI in Connecticut, fully 69% of nonpregnant adults with serologically proven B19 infection were asymptomatic. In this study, symptoms were assessed by mailed questionnaires after the women were provided their serologic results.<sup>109,123</sup> In a British multicenter study, only 6 (3%) of 184 patients were asymptomatic, but the population was ascertained largely by recruiting women with typical symptoms, and this study therefore is not comparable to the others.<sup>18</sup>

We studied 618 pregnant women in Pittsburgh with known exposure to someone with a rash illness highly suggestive of EI.<sup>210</sup> Each exposed patient was questioned about symptoms before serologic testing. Only 33% of the 52 women with serologically proven B19 infection reported no symptoms, and the remaining 67% reported rash, fever, arthralgias, coryza, or malaise, or some combination of these symptoms.<sup>210</sup> Malaise, although a very vague and nonspecific finding, was reported by 27 (52%) of the 52 infected women.<sup>210</sup> In contrast, only 5.5% of 307 exposed but not susceptible (IgG-seropositive and IgM-seronegative) women reported this symptom. After malaise, symmetrical arthralgias were the second most common symptom reported. Of the 618 known exposures in pregnant women, 24 (46%) of the 52 infected pregnant women reported arthralgias, compared with 11 (3.6%) of 307 immune women and 12 (4.6%) of 259 susceptible but uninfected women ( $P < .0001$ ).<sup>210</sup> Of the 24 women with arthralgias in this study, 23 also reported malaise, 16 had rash, 7 had coryza, and 7 had fever. Among the 24 IgM-positive women with arthralgias, the symmetrical joints most commonly affected by pain, swelling, and erythema were the knees (75%), followed by wrists (71%), fingers (63%), ankles (42%), feet (29%), elbows (29%), shoulders (17%), hips (13%), and back and neck (8%). Only 2 of the 24 had only one set of joints involved, and very few other women reported monarticular pain or swelling. In most women, the arthralgias were easily controlled by anti-inflammatory drugs and lasted only 1 to 5 days. However, arthralgias occasionally lasted 10 to 14 days and, in some women, were so painful that they were incapacitated for 2 to 3 days.

The high frequency of arthralgia in pregnant women with B19 infection is consistent with reports that distal arthralgias and arthritis are the most frequent finding in adults with EI. The frequency of arthralgias among nonpregnant adults with proven B19 infection in the Torrington, Connecticut, epidemic was 24% (11 of 46 adults), compared with 12% (61 of 512 adults) in adults without B19 infection ( $P < .05$ ).<sup>109</sup> In another Connecticut study, arthralgias occurred significantly more often (26%) in 19 adults with IgM antibodies to B19 than in 460 adults (7%) who lacked IgM antibodies to B19

( $P < .01$ ).<sup>123</sup> Arthralgias were even more common during outbreaks in Ireland; they occurred in 79% of 47 recently infected women and men. Ninety-three percent of those with arthralgias reported that their knees were involved.<sup>211</sup>

Rash is less frequent in pregnant women than in children with EI, and the rash in pregnant women is not characteristic. In one report of the Connecticut epidemic, rashes occurred in 6 (13%) of 46 infected adults, compared with 49 (10%) of 512 individuals who were uninfected. In another report, rashes occurred in 3 (16%) of 19 infected adults, compared with 33 (7%) of 460 uninfected individuals. This difference is not significant ( $P = .16$ ) and may represent random variation.<sup>109</sup> In contrast to the classic curtain lace rash in children, pregnant women (80%) often have a maculopapular rash that rarely involves the face and may even be urticarial or morbilliform. In adults, these rashes are rarely pruritic and usually resolve within 1 to 5 days.

In the Pittsburgh series, coryza was reported by 23% of the 52 B19-infected pregnant women but was reported in only 6.8% of the 307 previously infected women and 5.8% of the 259 seronegative women.<sup>210</sup> This difference was significant ( $P < .0001$ ), but the nonspecific nature of coryza in pregnant women means this symptom alone is not diagnostically helpful.

In the Pittsburgh series, a temperature of 38.0°C or higher occurred in 19% of the 52 IgM B19-infected women, compared ( $P < .0001$ ) with 2.6% of 307 previously infected patients and 3.1% of 259 susceptible, noninfected patients.<sup>210</sup> In 9 of 10 women with fever, at least one other symptom was present. No woman's temperature exceeded 38.9°C. In 16 uninfected women with fever, all had at least one other symptom, and they had temperatures up to 40.0°C, suggesting that a temperature of more than 39.0°C in a pregnant woman indicates infections other than B19. In a London outbreak of B19 infection, 7 of 10 infected adults had an elevated temperature.<sup>113</sup> In the Connecticut epidemic, fever was reported in 15% of the 46 infected individuals and in 16% of the 512 uninfected individuals.<sup>109</sup> Pregnant women with fever are likely to seek medical attention.

Occasionally, pregnant women infected with B19 develop rapidly increasing fundal height, preterm labor, or even preeclampsia. Such symptoms are nonspecific and rarely indicate B19 infection.

### **INTRAUTERINE TRANSMISSION RATES, CLINICAL MANIFESTATIONS, AND FETAL OUTCOMES**

Primary maternal infection with B19 during gestation has been associated with adverse outcomes such as nonimmune hydrops fetalis, intrauterine fetal death, asymptomatic neonatal infection, and normal delivery at term.<sup>14,15</sup> Initial reports of fetal hydrops related to maternal B19 infection were anecdotal and retrospective, suggesting rates of adverse outcomes as high as 26% and generating concern that B19 may be more fetotropic than rubella or cytomegalovirus.<sup>212,213</sup> Subsequent reports of normal births after documented maternal B19 infection made clear the need for better estimates of the rate of intrauterine transmission and the risk of adverse outcomes.<sup>214,215</sup>

### **Fetal Death**

B19 was first linked to fetal death in 1984.<sup>15</sup> As anticipated based on the epidemiology of B19 transmission, the percentage of fetal deaths attributable to B19 varies, probably depending on the frequency of B19 infections in the population being studied.

Prospective studies report rates of intrauterine viral transmission ranging from 25% to 50%.<sup>18,216,217</sup> Initial studies indicated that the risk of an adverse fetal outcome after a recent maternal infection was less than 10% (probably much less) and greatest in the first 20 weeks of pregnancy.<sup>144</sup> A large, prospective study in the United Kingdom identified 186 pregnant women with confirmed B19 infections during an epidemic and followed them to term.<sup>18</sup> There were 30 (16%) fetal deaths, with as many as 17 (9%) estimated to be caused by B19 on the basis of DNA studies of a sample of the abortuses. Most of the fetal deaths occurred in the first 20 weeks, with an excess fetal loss occurring in the second trimester.<sup>18</sup> The intrauterine transmission rate was estimated at 33% based on analysis of the abortuses, fetal IgM in cord blood, and persistence of B19 IgG at a 1-year follow-up assessment of the infants. A smaller study of 39 pregnancies complicated by maternal B19 infection and followed to term found two fetal deaths (fetal loss rate of 5%), one (3%) of which was attributable to B19 and occurred at 10 weeks' gestation.<sup>216</sup> A prospective study conducted by the Centers for Disease Control and Prevention identified 187 pregnant women with B19 infection and compared their outcomes to 753 matched controls.<sup>217</sup> The overall fetal loss rate in the infected group was 5.9%, with 10 of 11 occurring before the 18th week of gestation, compared with a 3.5% fetal loss rate in the control group, suggesting a fetal loss rate of 2.5% attributable to B19 infection. In a prospective Spanish study during an endemic period, 1610 pregnant women were screened for B19 infection, and 60 (3.7%) were identified.<sup>20</sup> There were five abortions among this group, but only one (1.7%) was caused by B19 based on histologic and virologic analysis of fetal samples. The incidence of vertical transmission was estimated at 25% based on serologic evaluation of the infants at delivery and at 1 year of age. In a similar prospective study of an obstetric population, 1967 pregnant women were screened, and 64 (3.3%) identified as recently infected.<sup>203</sup> Among this group, no adverse effects were seen by serial ultrasound examinations, and no case of fetal hydrops was identified; one abortion occurred, but the fetus was not examined for evidence of B19 infection (maximal fetal loss attributable = 1.6%).

In a case-control study of 192 women with fetal deaths, with one half occurring before 20 weeks' gestation and one half after, there was serologic evidence of acute B19 infection in 1% of both case and control groups.<sup>17</sup> The prevalence of IgG antibodies was similar. In this study, the percentage of fetal deaths attributed to B19 infection was unlikely to exceed 3% in cases not selected for parvovirus exposure.

In another study, 5 (6.3%) of 80 women with spontaneous abortions between 4 and 17 weeks' gestation had IgM antibodies to B19 compared with 2 (2%) of 100 controls, but this difference was not statistically significant.<sup>209</sup> These investigators studied the aborted fetuses of the five seropositive cases and found B19 DNA in only two.

In a prospective study of 39 pregnant women infected with B19 during a community-wide outbreak in Connecticut, there were two fetal deaths, and only one (3%) was attributable to B19 infection.<sup>216</sup> Among women followed prospectively and who acquired B19 infection during pregnancy, there was no evidence of fetal damage in 43 in Virginia and 52 in Pittsburgh, and one fetal loss among 56 pregnancies in women from Barcelona.<sup>20,21,210</sup>

Two Chinese studies found fetal B19 infection frequently associated with fetal death.<sup>218,219</sup> The first study in China found that of 116 spontaneously aborted fetuses tested for B19 DNA, 27.3% were positive for parvovirus B19, but only 4% (1 of 25) of nonaborted fetal tissues in the control group tested positive.<sup>218</sup> This difference was significant. It was unknown when these samples were collected whether B19 was endemic or epidemic in the community.

Similarly a second Chinese study examined 175 biopsy tissues from spontaneous abortions from 1994 to 1995 and found that 25% were positive for B19 DNA in the fetal tissues.<sup>219</sup> A control group of 40 fetal tissues came from induced abortions, and only 2 (5%) were positive. This difference was not statistically significant but did support the observation that in China, B19 may be an important cause of fetal death, especially if B19 is epidemic in the community.

In contrast to the Chinese studies, a study from the Netherlands of fetal and placenta tissue from 273 cases of first and second trimester fetal loss were tested for serologic or virologic evidence of B19 infection.<sup>220</sup> Of the 273 cases, 149 were from seronegative women, and the fetal deaths for these women were considered unrelated to B19 infection. In only two of the remaining 124 cases (0.7% of all 273 cases) did the mothers have IgM antibodies to B19 at the time of abortion. This study indicates that B19 infection was a rare cause of fetal loss during the first and second trimesters. No congenital anomalies were observed among the fetal tissues examined.

A study of 1047 pregnant women in Kuwait obtained maternal blood samples in the first, second, and third trimesters and tested them for serologic evidence of the recent B19 infection.<sup>221</sup> Forty-seven percent of the mothers were seronegative, and among these, the incidence of seroconversion was 16.5%. Among the women who seroconverted to a B19-positive status, the rate of fetal loss was 5.4%. All the fetal deaths occurred in the first two trimesters, suggesting that fetal death after maternal B19 infection is common, particularly during the first and second trimesters.

A report from Toledo, Ohio, describes five unexpected fetal deaths that occurred in the second trimester.<sup>222</sup> Only one of the fetuses was hydropic, but all five had viral inclusions in the liver, and all five women were seropositive for B19.

Third trimester fetal deaths have also been reported. A Swedish study of fetal deaths among 33,759 pregnancies found 93 cases of third-trimester fetal deaths, and of these, 7 (7.5%) had detectable B19 DNA in frozen placental tissue.<sup>223</sup> None of the seven fetuses was hydropic. The investigators suggested B19 occasionally caused third-, second-, and first-trimester fetal death.

A study of 13 pregnant women who acquired B19 infection during pregnancy and in whom the time of acquisition was known was completed in Japan.<sup>224</sup> Nonimmune hydrops occurred in three fetuses whose mothers acquired B19 infection in the first half of pregnancy. Spontaneous abortion without hydrops and intrauterine growth retardation occurred in

two fetuses whose mothers also developed B19 infection during the first half of pregnancy. The remaining eight fetuses, whose mothers acquired infection in the first or second half of pregnancy, were asymptomatic, although human parvovirus B19 DNA was detected in the immune serum of all of the infants. These results suggest that B19 transmission to the fetus is common and that death may occur in almost one half of the fetuses of infected mothers.

A Swedish study of 92 pregnancies for which there was an unexpected fetal death occurring after 22 weeks' gestation found B19 DNA in 13 (14%) of the 92 fetuses.<sup>225</sup> Only 2 of the 13 were hydropic. The Swedish study suggests that B19 can infect the fetus in the third trimester and result in fetal death or hydrops, or both. This observation was confirmed in a larger study from Sweden, in which 47 cases of fetal deaths occurring after 22 weeks' gestation were identified and compared with 53 normal pregnancies.<sup>226</sup> Seven of the 43 intrauterine fetal deaths were positive for parvovirus B19 DNA, whereas B19 DNA was not detected in any of the normal pregnancies.

In summary, B19 is a likely cause of first-, second-, and third-trimester fetal death, and most infected infants are not hydropic. The estimates of fetal deaths attributable to B19 range from 0% to 27%, making it difficult to assess the precise increase in fetal mortality attributable to B19.

### Asymptomatic Fetal Infection

Although the published prospective studies of B19 infection in pregnancy have varied in their estimates of adverse fetal outcome and rates of vertical transmission, it is clear that most women infected during pregnancy deliver normal-appearing infants at term. Some of these infants have asymptomatic infections.<sup>227</sup> Results of a prospective study that combined serologic with virologic markers of infection suggest that the rate of intrauterine transmission is very high.<sup>21</sup> In this study, 43 pregnant women with a confirmed B19 infection were followed to delivery. The infants were tested at birth and at intervals throughout the first year of life for IgM and IgG to B19 and by PCR for viral DNA in serum, urine, or saliva. No fetal losses or cases of fetal hydrops were observed in this study, although the rate of intrauterine viral transmission was 51%.<sup>21</sup>

### Birth Defects

There is circumstantial evidence that intrauterine B19 infection may occasionally cause birth defects. The first case was reported in 1987.<sup>228</sup> A fetus aborted at 11 weeks' gestation was described with striking ocular abnormalities, including microphthalmia, aphakia, and dysplastic changes of the cornea, sclera, and choroid of one eye and retinal folds and degeneration of the lens in the other eye.<sup>229,230</sup> The mother had a history of a rash illness with arthropathy at 6 weeks that was serologically confirmed.

There have been few additional reports of malformations or developmental abnormalities in aborted fetuses or live-born infants after intrauterine infection, and most of these cases could not be unequivocally attributed to infection with B19.<sup>231-238</sup> However, three live-born infants had severe CNS abnormalities after serologically confirmed maternal B19 infection.<sup>239,240</sup> Subsequent case reports have also identified

CNS manifestations, including mild to moderate hydrocephalus with CNS scarring associated with fetal B19 infection.<sup>241</sup> These reports suggest possible long-term neurologic sequelae in surviving infants that may not be apparent at birth.

There are no other data suggesting that B19 is an important cause of birth defects in live-born infants. In an uncontrolled study of 243 infants younger than 4 months with birth defects, none had IgM antibodies to B19 detected.<sup>205</sup> In a controlled study of 57 infants with structural abnormalities or stigmata of congenital infection, specific IgM was not detected in cord blood of any of the affected infants or of the matched normal newborn controls.<sup>17</sup> There are no data suggesting that structural defects are common in newborns after maternal B19 infection. During a large community-wide outbreak of EI, there was no increase in congenital malformations compared with the periods before and after the epidemic.<sup>242</sup> In the British study of maternal infections during pregnancy, outcomes were available for 186 patients; anencephaly was reported in 1 of the 30 fatal cases but not attributed to B19 infection, and hypospadias was present in 2 of the 156 live-born infants.<sup>18</sup> No new anomalies or serious neurodevelopmental problems were detected in the 114 infants followed clinically for at least 1 year.<sup>242</sup> In another prospective, but uncontrolled study of 39 pregnancies with maternal B19 infection, hypospadias was reported in 1 of the 37 live-born infants, and no abnormalities were reported in the one fatal case for which tissues were available.<sup>216</sup>

### Meconium Ileus and Peritonitis

Meconium ileus and peritonitis have been associated with maternal B19 infection in a few reports.<sup>140,236</sup> Three infants with congenital anemia after maternal infection and intrauterine hydrops have been reported.<sup>14</sup> All three had abnormalities identified on bone marrow examination and B19 DNA detected in bone marrow by PCR.

### Fetal Hydrops

Although parvovirus B19 infection in utero may cause nonimmune hydrops fetalis, it is one of many causes of this syndrome and probably accounts for only 10% to 15% of fetal hydrops cases.<sup>140</sup> Hydrops fetalis is rare, occurring in only 1 of 3000 births; and in 50% of cases, the cause is unknown. In a study of 50 fetuses, B19 DNA was detected by *in situ* hybridization in the tissues of 4 fetuses, but most cases were caused by chromosomal or cardiovascular abnormalities.<sup>243</sup> In another study, B19 DNA was demonstrated in 4 of 42 cases of nonimmune hydrops fetalis.<sup>244</sup>

However, B19 infection is frequently associated with nonimmune fetal hydrops during local epidemics of EI. Ten cases of B19-associated hydrops, representing 8% of all cases of nonimmune hydrops and 27% of anatomically normal cases of nonimmune hydrops, occurred over 17 years in a hospital series from England.<sup>232</sup> In a consecutive series of 72 patients with nonimmune hydrops from Germany, 3 (4.2%) had B19 infection.<sup>245</sup> In a series of 673 fetal and neonatal autopsies conducted over 6 years in Rhode Island, 32 (0.7%) cases of hydrops were identified, and 5 (16%) of these had histologic and laboratory evidence of B19 infection.<sup>246,247</sup> In the British study, 1 of the 156 live-born infants had been

diagnosed with intrauterine hydrops and recovered after intrauterine transfusion; and of the six fatal cases that were positive for B19 DNA, hydrops was identified in one of three fatal cases with laboratory confirmed intrauterine infection.<sup>18,248</sup> Postmortem examination may not be able to identify hydrops in fetal death occurring in early pregnancy. In summary, published reports suggest that nonimmune hydrops is not a common manifestation of fetal infection with B19.

### Fetal Outcome in Relation to Maternal Manifestations

There are no data suggesting that the clinical manifestations of B19 infection in the mother influences the pregnancy outcome. There is evidence for an association between the B19-affected fetus and maternal hypertension. Pregnancy-induced hypertension, preeclampsia, and eclampsia have been reported for some women with B19-associated fetal hydrops, and there is a record of improvement with spontaneous resolution of hydrops in one case.<sup>16,232,245,260-262</sup> Hypertension of pregnancy may be caused by poor fetoplacental perfusion, and there is an increased risk in pregnancies complicated by hydrops. It is unknown whether there is an increased frequency of hypertensive disorders among B19-infected women compared with uninfected women or whether more careful monitoring of B19-infected women to detect findings of preeclampsia would be useful in identifying women at increased risk of B19-associated fetal hydrops. Long-term outcomes of live-born infants infected in utero with B19 are discussed in the "Prognosis" section of this chapter.

## **PATHOGENESIS OF INFECTION IN THE FETUS**

### Fetal Immune Responses to B19

When serologic and virologic markers of infection have been examined, fetal immune responses to B19 are variable.<sup>21,144,252</sup> B19-specific IgM in cord blood is a recognized marker of fetal infection, but sensitivity can be increased by adding other markers such as IgA, PCR positivity, and persistence of B19 IgG at 1 year of age.<sup>21,144,252</sup> Infants exposed to B19 earlier in gestation may be less likely to demonstrate a positive IgM response because of immaturity of the fetal immune system, whereas the IgM response of infants exposed late in gestation may be delayed because of interference by passively acquired maternal antibodies. In one study, only two of nine infected infants whose exposure occurred in the first 14 weeks of pregnancy were B19 IgM-positive at delivery, whereas all four infected infants exposed in the third trimester had B19-specific IgM in cord blood.<sup>21</sup> Serum IgA, like IgM, does not cross the placenta, and for some other congenital viral infections, such as rubella and human immunodeficiency virus (HIV), virus-specific IgA responses in cord blood has been used to provide evidence of intrauterine infection.<sup>253</sup> In the only study of B19 that examined this marker, B19 IgA in cord blood was associated with maternal infection with B19, and for a few infants, this was the only marker of intrauterine infection.<sup>21</sup>

The fetal immune response to B19 may be important for preventing B19-induced red cell aplasia in the fetus. This

effect is suggested by the apparently decreased rates of fetal death after 20 weeks' gestation in concert with the detection of IgM specific to B19 as early as 18 weeks' gestation<sup>254</sup> and the neutralization of B19 virus in vitro by fetal serum collected at 21 weeks' gestation.<sup>255</sup>

### Pathogenesis of B19 Hydrops

Nonimmune hydrops is the best-characterized complication of fetal B19 infection. Several mechanisms have been proposed, and more than one may contribute.<sup>232</sup> Severe fetal anemia affects most cases. Hemoglobin levels below 2 g/dL are detected by cordocentesis of hydropic fetuses.<sup>257,258</sup> Hypoxic injury to tissues may result in increased capillary permeability. Severe anemia may also increase cardiac output, as evidenced by increases in umbilical venous pressure, and subsequently result in high-output heart failure.<sup>259</sup> Alternatively, myocarditis may precipitate heart failure. Reduced fetal myocardial function as determined by echocardiography occurs in some cases of fetal hydrops.<sup>249</sup> Regardless of the cause, congestive heart failure can increase capillary hydrostatic pressure. Decreased venous return caused by massive ascites or organomegaly may lead to further cardiac decompensation. Hepatic function may be compromised by the extreme levels of extramedullary hematopoiesis, and lysis of B19-infected erythrocytes in the liver may cause hemosiderin deposition, fibrosis, and esophageal varices.<sup>250,251</sup> Impaired production of albumin may lead to a decrease in colloid osmotic pressure with transfer of fluid to the extravascular compartment. Placental hydrops may further compromise oxygen delivery to the fetus.

Considerable evidence demonstrates that non-red cells may be susceptible to B19 infection. Virus has been demonstrated in fetal myocytes, including myocardiocytes, along with inflammatory changes, and fetal myocarditis has occurred.<sup>127,234,256</sup> Histologic studies show vascular damage and perivascular infiltrates in some tissues. It is unknown whether this is caused by B19 infection in endothelial cells or a nonspecific effect related to hypoxic damage.

## **PATHOLOGY IN THE FETUS**

### **Anatomic and Histologic Features**

The hallmarks of fetal infection with B19 are edema, anemia, and myocarditis, and these conditions are reflected in the pathologic finding at autopsy. Otherwise, reports of gross and histopathologic pathology postmortem reveal few features specific for intrauterine B19 infection.<sup>16,232, 235,246,251,260-265</sup> At postmortem examination, B19-infected fetuses are often described as pale with subcutaneous edema. Rashes typically are absent, but a blueberry muffin rash caused by extramedullary hematopoiesis in the skin may occur.<sup>266</sup>

Fetal anemia is common in fetal deaths due to B19, although not in all cases.<sup>234,237,250,251,257,258,263,267</sup> Histologic findings suggesting B19 infection include erythroid hypoplasia and, occasionally, hyperplasia characteristic of recovery. Extramedullary hematopoiesis is common in many organs, especially the liver and spleen. Nucleated red cells with amphophilic intranuclear inclusions (Figs. 27-3 and 27-4) are highly suggestive of B19 infection. These nucleated red

**Figure 27-3** Placenta from a case of B19-associated nonimmune hydrops shows fetal capillaries filled with erythroblasts, most with margined chromatin and typical amphophilic intranuclear inclusions (hematoxylin & eosin stain).

**Figure 27-4** Fetal liver from a case of B19-associated nonimmune hydrops shows extramedullary hematopoiesis, intranuclear inclusions in erythroblasts, and focal areas with hemosiderin and fibrosis (hematoxylin & eosin stain).

cells are often found in the lumen of vessels and at sites of extramedullary hematopoiesis.<sup>127</sup> When stained with hematoxylin and eosin stain, the nuclei have an irregular band of dark chromatin. The center of the nucleus is lighter and has a smooth texture. The specificity of intranuclear inclusions for fetal B19 infection is unknown, but it is probably high when associated with anemia and hydrops. Viral DNA or inclusions may also be seen in macrophages and myocytes.<sup>127,256,268</sup>

PCR used for detecting B19 DNA is the best method to diagnose B19 infection in a dead fetus. In one study, 6 of 34 cases of idiopathic nonimmune hydrops contained B19 DNA in fetal or placental tissues, compared with no PCR-positive findings among 23 cases of hydrops that were noninfectious.<sup>269</sup> Histologic examination of these cases found no nucleated red cells with intranuclear inclusions.

## Placenta

B19 infection of the placenta probably precedes fetal infection. The placenta is usually abnormal when associated with fetal death due to B19. Grossly the placenta is often enlarged and edematous. Histologically, the placenta also contains nucleated red blood cells with typical intranuclear inclusions (see Fig. 27-4). Foci of red cell production also occur in the placenta, as does vascular inflammation.<sup>232,249,264</sup> In one study,<sup>232</sup> vasculitis of villous capillaries or stem arteries occurred in 9 of 10 placentas. The tissues demonstrated swelling of endothelial cells, fragmentation of endothelial cell nuclei, and fibrin thrombi. B19 DNA occurs in endothelial cells of patients with myocarditis and in patients with cutaneous lesions but has not been sought in placental endothelial cells. The human placenta contains a B19 receptor, the neutral glycosphingolipid (globoside), on the villous trophoblast layer of the placenta, and the concentration of the globoside decreases with advancing pregnancy.<sup>270</sup> The highest concentration occurs in the first trimester, with diminished reactivity occurring in the second trimester. The presence of this globoside in the placenta provides a mechanism by which the virus infects the placenta and fetus. It also may explain why there is a difference in fetal outcome associated with gestational age. Maternal infections in late pregnancy have a better prognosis than those occurring early in pregnancy. In addition to B19 receptors, there is a B19-induced inflammatory response in the placenta, characterized by a significant number of CD3<sup>+</sup> T cells and the inflammatory cytokine interleukin-2.<sup>271</sup>

## Heart

The anemia associated with B19 infection is caused by a specific viral tropism for progenitor erythroid cells, specifically P antigen, which is found on these cells.<sup>272</sup> However, clinical and laboratory evidence suggests that B19 has a wider tropism than for erythroblasts.<sup>273</sup> Fetal myocardial cells contain P antigen.<sup>273</sup> Direct infection of myocardial cells after fetal B19 infection of extramedullary erythroid progenitor cells has been demonstrated by *in situ* DNA hybridization or electron microscopy.<sup>57,68,127,274,275</sup> B19 myocarditis is also associated with acute lymphocytic infiltration. Case reports have described at least eight fetuses, five children, and four adults with myocarditis associated with a concurrent B19 infection.<sup>274,276-278</sup>

B19 causes acute and chronic myocarditis in infants. Myocarditis and the cardiac enlargement found in some B19-infected fetuses with hydrops suggest that B19 is pathogenic for the myocardium.<sup>127,232-235,246,254,256,276,279</sup> In infected fetuses, the heart may be normal or symmetrically enlarged, suggesting congestive heart failure. Pericardial effusions are common. Myocytes with intranuclear inclusions occur infrequently. Mononuclear cell infiltrates occur occasionally, and B19 DNA, not associated with cells, can be found in the lumen of large vessels. Focal areas with dystrophic calcification or fibroelastosis have occurred as a response to injury.

One case-control study<sup>280</sup> examined the relationship between congenital heart disease and B19 infection. Five of 29 cases of congenital heart disease had parvovirus B19 DNA detected in cardiac tissue using PCR, compared with none

of 30 matched controls. This difference was significant ( $P < .02$ ). Other infections, including herpes simplex virus, cytomegalovirus, rubella, and toxoplasmosis, were excluded. Additional studies testing for B19 infection of congenital heart disease are appropriate.

## Other Organs

Numerous other anatomic abnormalities have been associated with B19 infection of the fetus. Their occurrences, however, are so infrequent that it is unlikely that they are related to B19 infection. These associated abnormalities include dystrophic calcification of the brain and adrenal glands; anencephaly and ventriculomegaly; pulmonary hypoplasia; hypospadias; cleft lip; meconium peritonitis; corneal opacification and angioedema; and thymic abnormalities.<sup>16,18,127,231-233, 235-239,264,281-283</sup>

## DIAGNOSTIC EVALUATION AND MANAGEMENT OF THE WOMAN AND FETUS EXPOSED TO OR INFECTED BY B19 DURING PREGNANCY

Management of a pregnant woman exposed to B19 requires knowledge of the prevailing status of EI in the community, a detailed history of the exposure, knowledge of characteristic symptoms and signs of maternal EI and B19 infection in the fetus, appropriate laboratory tests needed to confirm maternal and fetal infection, knowledge of the methods for monitoring the fetus at risk for nonimmune hydrops, knowledge of therapeutic approaches for treating the hydropic fetus, and information about the prognosis of maternal and fetal infection and the expected outcomes for the therapeutic intervention.

### Prevalence of Erythema Infectiosum

The community health or school health departments may know whether EI is epidemic in the community, increasing the probability of primary infection in susceptible pregnant women.

### History of Exposure

Pregnant women who are potentially exposed to someone with EI should be asked about the type of exposure, including duration (brief or prolonged) and location (household or workplace, indoor or outdoor), and contact with respiratory secretions. Exposure to a child within the household constitutes the highest risk.

Did the contact have symptoms typical of EI, including a low-grade fever and a slapped-cheek rash that soon spread to the trunk or limbs in a lacy pattern? Did the rash disappear and then reappear when the child was warm from exercise or bathing? Had the child been exposed to any known source of EI, such as an outbreak in school, preschool, a daycare center, a family gathering, a play group, or church nursery? Was the child evaluated by a physician familiar with viral exanthems?

## Clinical Features Suggesting B19 Infection in the Pregnant Woman

The examiner should consider whether the mother's signs and symptoms are compatible with B19 infection in adults, including at least one or more of the following: malaise, arthralgia, rash, coryza, or fever higher than 38°C. Pregnant women with such symptoms, especially malaise with symmetrical arthralgias in the hands, wrists, knees, or feet, should be considered at high risk and tested for recent B19 infection. In Barcelona, however, Gratecos and colleagues<sup>20</sup> found that only 30% of 60 IgM-positive women recalled any such symptoms.

Pregnant women without such systemic symptoms but with a rapidly enlarging uterus (i.e., fundal height exceeding dates by more than 3 cm), an elevated serum  $\alpha$ -fetoprotein level, preterm labor, or decreased fetal movement should be asked about B19 exposure. If ultrasonography reveals evidence of hydrops fetalis or the fetus has ascites, pleural or pericardial effusion, skin thickening, polyhydramnios, or placentomegaly, maternal B19 testing is appropriate.

## Laboratory Diagnosis in the Pregnant Woman

With evidence of maternal B19 exposure or maternal disease, maternal serum should be tested for IgG and IgM antibodies to B19. If there is probable or possible exposure, the first serum sample should be drawn at least 10 days after the exposure. Because fetal morbidity is unlikely to occur within 2 weeks of exposure, immediate serologic testing is appropriate for a woman or fetus with symptoms or signs of B19 infection.

An initial serum sample that is IgG positive but IgM negative indicates a previous maternal infection, and additional testing is unnecessary. The IgM assay is sensitive, with few false-negative reactions. An initial serum sample that is negative for IgM and IgG indicates no previous maternal infection, and B19 infection is not responsible for maternal symptoms and signs or for hydrops fetalis.

If the IgM result is positive, a recent B19 infection is established regardless of the IgG titer. A concomitant negative IgG titer means an early B19 infection without time for IgG to be detectable. Detection of maternal viremia by PCR for B19 DNA is also diagnostic of B19 infection. Viremia may precede the development of IgM antibodies by 7 to 14 days and may persist for several months after a primary infection.

With a positive maternal IgM result, the fetus must be examined for signs of hydrops fetalis by ultrasonography within 24 to 48 hours. If the gestational age is less than 18 weeks, the absence of hydrops may not be reassuring, because hydrops can appear later. Because several cases of severe hydrops fetalis spontaneously reverting to normal over 3 to 6 weeks have been reported, advice about pregnancy termination is difficult.<sup>249,281,284</sup>

## Fetal Monitoring

For a fetal gestational age of more than 20 weeks, initial negative ultrasound results demand sonograms to be repeated weekly to detect hydrops. The number of weekly sonograms that should be performed is controversial. Rodis and associates<sup>233</sup> originally suggested continuing weekly scans for

Table 27-2 Fetal Deaths from B19 Infection

<sup>a</sup>Numbers in parentheses refer to intervals between exposure or onset of symptoms and the diagnosis of hydrops fetalis.

<sup>b</sup>Numbers in parentheses refer to gestational age at the time of diagnosis of hydrops fetalis.

NR, not reported.

6 to 8 weeks after exposure, and they reported a fetal death as late as 23 weeks' gestation after maternal fever and arthralgias in the first trimester.<sup>128</sup> The interval between maternal B19 infection and fetal morbidity is uncertain. Based on this report, others recommended weekly sonograms for 14 weeks after maternal B19 infection.<sup>284</sup> This approach often appeals to pregnant women fearful about fetal death, but it is time consuming and expensive.

The duration of monitoring for hydrops fetalis may be best determined by examination of the interval between maternal exposure or symptoms of B19 infection and the appearance of hydrops fetalis or fetal death. Table 27-2 summarizes reports with adequate information to evaluate the interval, which include 14 intervals between maternal B19 exposure or infection and fetal death and 7 intervals between maternal exposure or infection and the first diagnosis of hydrops fetalis. The intervals range from 1 to 19 weeks, with a median of 6 weeks. Seventeen (81%) of 21 cases developed between 3 and 11 weeks. Because 11 of the 21 cases developed between 4 and 8 weeks after maternal exposure or infection, this is the most common interval between infection and the detection of fetal hydrops. Based on these observations, weekly ultrasound monitoring of the fetus for 12 weeks after maternal exposure is optimal but cannot detect all delayed cases and may be expensive. Such frequent scanning may not be considered cost-effective because the incidence of hydrops after maternal B19 infection is low in many studies. In our study, none of the 52 fetuses born to B19-IgM-positive pregnant women developed hydrops fetalis; however, the 95% confidence interval based on our sample size ranged from 0% to 8.6% for the risk of hydrops fetalis.<sup>210</sup> Other studies using maternal symptoms as

criteria for maternal B19 infection have suggested a 9% incidence of fetal death due to B19 in B19-IgM-positive women.<sup>18</sup>

Serial maternal serum  $\alpha$ -fetoprotein (MSAFP) measurements may monitor the fetus in B19-infected women.<sup>285</sup> One report found elevated MSAFP levels in five B19-IgM-positive pregnancies associated with fetal death, but no fetal deaths in 11 IgM-positive women with B19 infection but normal MSAFP values.<sup>286</sup> A fatal case of B19-associated fetal death, discovered because of an elevated MSAFP level at 16 weeks in a routine test in an asymptomatic woman, has been described.<sup>16</sup> In adding a seventh case of fetal death associated with elevated MSAFP levels in B19-IgM-positive women, Bernstein and Capeless<sup>285</sup> suggested using the MSAFP values to indicate a good fetal prognosis.

A German study<sup>287</sup> found that neither MSAFP nor human gonadotropin levels were markers of B19-infected pregnancies, although both were frequently elevated when complications occurred. The study included 35 pregnant women with fetal complications associated with B19; significant elevations of MSAFP levels occurred in 13 of 35 women, and elevations of human gonadotropin concentrations occurred in 25 of 35. The investigators tested 137 sera from 65 pregnant women without acute parvovirus infection and no fetal complications. Of the 30 women without fetal complications, there were significant elevations of MSAFP levels in only 2 women, and elevations of human gonadotropin levels occurred in only 5 women. Neither protein was a marker for a poor pregnancy outcome early on, but levels were frequently elevated when complications developed. Despite these results, there is insufficient experience using MSAFP concentrations, and MSAFP measurements at any gestational age are relatively nonspecific indicators of fetal well-being.

Electronic fetal monitoring is ineffective in detecting hydrops fetalis and predicting the outcome of pregnancy in B19-IgM-positive women. Contraction stress tests and "non-stress" tests are not accurate predictors of fetal well-being in cases of fetal anemia or hydrops fetalis. Similarly, fetal assessment with estriol measurements or other biochemical markers have no documented role in cases of hydrops fetalis. Because fetal sonograms are as readily available and provide rapid specific information about hydrops fetalis, ultrasound is the best method to monitor the fetus after maternal B19 infection.

### Fetal Therapy

If hydrops fetalis is detected before 18 weeks, there is no effective intervention. Other causes of hydrops, such as chromosomal disorders or anatomic abnormalities, should be assessed. If at 18 weeks' gestation the fetus is still viable as determined by ultrasound examination, consideration can be given to percutaneous umbilical blood sampling (PUBS), also called cordocentesis. At 18 weeks' gestation, the umbilical vein diameter is about 4 mm, which is the minimum size required for successful PUBS. Fetal blood should be obtained for the hematocrit, reticulocyte count, platelet count, leukocyte count, antiparvovirus B19 IgM, karyotype, and tests for B19 DNA by PCR. The hematocrit must be determined immediately, and if fetal anemia exists, intrauterine intravascular fetal transfusion is performed with the same needle puncture.

If the fetus is between 18 and 32 weeks' gestation when hydrops fetalis is detected, fetal transfusion should be considered. Many successful cases of fetal transfusion for B19-induced hydrops fetalis have been reported, and some have long-term follow-up, but the success rate of the procedure remains unknown.<sup>288-294</sup>

Two or three separate transfusions are usually required before resolution of the fetal anemia and hydrops fetalis, increasing the 1% to 2% risk of each single PUBS procedure. Resolution of the hydrops usually occurs 3 to 6 weeks after the first transfusion. Although spontaneous resolution has been reported, it seems appropriate not to risk an uncertain outcome, because the longer the fetal transfusion is delayed, the less likely it is to be successful and the worse the potential harm to the fetus caused by continued fetal hypoxia.<sup>231, 249, 284, 289-291</sup>

For fetuses of 32 weeks' gestation or older when hydrops is discovered, immediate delivery with neonatal exchange transfusion, thoracentesis, and paracentesis as indicated usually is the safest management.

### DIFFERENTIAL DIAGNOSIS

Recalling that the hallmarks of fetal infection with B19 are anemia, hydrops, and myocarditis helps in compiling a differential diagnosis. For infants with anemia, the differential diagnosis includes all the known causes, including fetal-maternal transfusion, intracranial bleeding, blood group incompatibilities, congenital anemias such as Diamond-Blackfan syndrome, nutritional deficiencies, and inborn metabolic errors. Fetal hydrops and fetal and placental edema may be associated with other congenital infections, particularly congenital syphilis, chromosomal abnormalities, immune hydrops associated with blood group incompatibilities, hypothyroidism, and heart or renal failure, or both.

### PROGNOSIS

Pregnant women can be reassured about the relatively low risk of fetal morbidity resulting from exposure to B19. About one half of women already are seropositive. The seronegative maternal B19 infection rate ranges from about 29% for exposures by the woman's own children to about 10% to 18% for other exposures. The expected fetal morbidity and mortality risk is about 2% (1 of 50). The overall risk of fetal death varies from 0.3% ( $\frac{1}{2} \times \frac{3}{10} \times \frac{1}{50} = \frac{3}{1000}$ ) to a mere 0.1% ( $\frac{1}{2} \times \frac{1}{10} \times \frac{1}{50} = \frac{1}{1000}$ ).<sup>210</sup>

Live-born infants infected in utero may die shortly after birth. Two infants born prematurely at 24 and 35 weeks' gestation developed an illness characteristic of congenital viral infection, including placentomegaly, petechial rash, edema, hepatomegaly, anemia, thrombocytopenia, and respiratory insufficiency, and both died postnatally.<sup>295</sup> Both infants had nuclear inclusions in erythroid precursor cells, and PCR confirmed the presence of parvoviral DNA in one of the infants.

Data regarding the long-term outcomes of live-born children infected in utero or born of mothers infected during pregnancy are very limited. In one study, 113 pregnant women with B19 infection during pregnancy and a control

group of immune women were questioned about the health and development of their children when the median age of the children was 4 years for both groups.<sup>242</sup> The incidence of developmental delays in speech, language, information processing, and attention was similar between the study group and the controls (7.3% versus 7.5%). Two cases of cerebral palsy were found in the study group, compared with none in the controls. Although not statistically significant, this 2% incidence of cerebral palsy in the infected group is 10-fold higher than the reported national incidence.<sup>242</sup>

In a British study of 427 pregnant women with B19 infection and 367 of their surviving infants, 129 surviving infants were reassessed when 7 to 10 years old.<sup>296</sup> The follow-up included questionnaires to obstetricians and general practitioners about the outcome of pregnancy and health of surviving infants. Maternal infection was confirmed by B19-specific IgM assay or IgG seroconversion. An excess rate of fetal loss was confined to the first 20 weeks' gestation and averaged 9%. There were seven cases of fetal hydrops with maternal infections between 9 and 20 weeks' gestation. There were no abnormalities attributable to B19 infection found at birth in surviving infants. No late effects were observed when the children were 7 to 10 years old. This study concluded that approximately 1 in 10 women infected before 20 weeks' gestation would have a fetal loss due to B19, that the risk of an adverse outcome of pregnancy beyond this stage was unlikely, and that infected women could be reassured that the risk of congenital abnormality due to B19 is less than 1% and that long-term development would be normal.

One study used IQ testing and standard neurodevelopmental tests to assess 20 children who had parvovirus-induced fetal hydrops and intrauterine transfusion of packed red cells.<sup>288</sup> Testing of the 20 children when they were between 13 months and 9 years old revealed that all of their results ranged within two standard deviations of a population norm. There was no significant developmental delay. This study concluded that children who survived successful intrauterine transfusion from B19 anemia and hydrops had a good neurodevelopmental prognosis.

## PREVENTION

### General Measures

Because B19 is usually endemic in most communities, what is appropriate management for pregnant women with daily contact with children? The prevalence of seropositivity (immunity) to B19 among pregnant women varies according to geographic location, sex, age, and race. Assuming that on average 50% of pregnant women are immune; that during endemic periods, between 1% and 4% of susceptible women become infected during pregnancy; and that the rate of fetal death after maternal infection is 2%, the occupational risk of fetal death for a pregnant woman with unknown serologic status is between 1 in 1000 and 1 in 2500. These low rates do not justify intervention such as serologic testing for pregnant women, furloughing pregnant workers, or temporarily transferring pregnant seronegative employees to administrative or other positions without child contact. During epidemic periods in specific schools, when the infection rates may be 5- to 20-fold higher, serologic testing or temporary transfer

of pregnant employees may occasionally be appropriate, and some very anxious women may choose to leave the workplace.

Given the low risk for individual pregnant women, seronegative women should not send their own children away, and schools and daycare centers cannot stop B19 outbreaks by excluding children with rash illnesses because B19 is transmissible before the rash appears. Whether B19 can be transmitted by breast-feeding is unknown.

### Vaccine Development

For most women, fetal B19 infections during pregnancy occur from exposure to school-aged children at home rather than from occupational exposure. Given the highly communicable and endemic nature of the infection, the broad spectrum of illness that B19 causes, and the large portion of population (30% to 50%) who are susceptible, an effective B19 vaccine, preferably administered in infancy, is appropriate, and at least one vaccine is being developed.<sup>297</sup> This vaccine is composed of the major B19 capsid proteins VP1 and VP2 and administered with a squalene adjuvant, MF59. After testing in a limited number of subjects, the vaccine appears to be safe and induces neutralizing antibodies. Studies using volunteers challenged with wild-type B19 should be able to assess efficacy. A vaccine that induces sustained neutralizing antibody IgG levels to B19 should be effective given that prior immunity to B19 protects against reinfection.

### Acknowledgments

 Prospects for the Future

The impact of rubella virus infection and the progress made toward controlling congenital rubella infection have been well chronicled.<sup>1-9</sup> Rubella was first recognized in the mid-18th century as a clinical entity by German researchers, who called it *Rötheln*. However, they considered it to be a modified form of measles or scarlet fever.<sup>1</sup> Manton<sup>10</sup> first described it as a separate disease in the English literature in 1815. In 1866, Veale<sup>11</sup> gave it a “short and euphonious” name, *rubella*. The disease was considered mild and self-limited.

Rubella became a focus of major interest in 1941, only after Gregg,<sup>12</sup> an Australian ophthalmologist, associated intrauterine acquisition of infection with production of

cataracts and heart disease. Although his findings were initially doubted, numerous reports of infants with congenital defects after maternal rubella infection soon appeared in the literature.<sup>1</sup> Subsequent investigations showed that the major defects associated with congenital rubella infection included congenital heart disease, cataracts, and deafness. Mental retardation and many defects involving almost every organ have also been reported.<sup>2-4,7,13,14</sup> Before the availability of specific viral diagnostic studies, the frequency of fetal damage after maternal infection in the first trimester was estimated to be in excess of 20%, a figure now known to be much too low.

Recognition of the teratogenic potential of rubella infection led to increased efforts to isolate the etiologic agent. The viral cause of rubella was suggested by experimental infections in humans and monkeys as early as 1938 but was not confirmed until reports of the isolation of the viral agent in cell cultures were made independently in 1962 by Weller and Neva at Harvard University School of Public Health and by Parkman, Buescher, and Artenstein at Walter Reed Army Institute for Research.<sup>15-20</sup> This accomplishment paved the way for the development of serologic tests and a vaccine.<sup>2-4,21-23</sup> Efforts to develop a vaccine were hastened by the tragic events associated with a worldwide rubella pandemic from 1962 through 1964, which in the United States resulted in approximately 12.5 million cases of clinically acquired rubella, 11,000 fetal deaths, and 20,000 infants born with defects collectively referred to as the congenital rubella syndrome; 2100 infants with congenital rubella syndrome died in the neonatal period.<sup>24</sup> The estimated cost to the U.S. economy was approximately \$2 billion. Routine use of rubella vaccine, in a two-dose schedule as measles-mumps-rubella vaccine (MMR) has not prevented importation-related infection, but it has eliminated indigenous rubella in the United States (personal communication from the CDC, 2004). However, congenital rubella syndrome remains a problem in many countries, with current estimates of 100,000 new cases annually.<sup>25</sup>

In 1969, three strains of live-attenuated rubella vaccine were licensed in various countries: HPV-77 (high-passage virus, 77 times), grown in duck embryo for five passages (DE-5) or dog kidney for 12 passages (DK-12); Cendehill, grown in primary rabbit cells; and RA 27/3 (rubella abortus, 27th specimen, third explant), grown in human diploid fibroblast culture.<sup>26-28</sup> Although these and other strains of vaccine are now used globally, the RA 27/3 vaccine has been used exclusively in the United States since 1979.<sup>2-4,7,29</sup>

In addition to providing the impetus for vaccine research and development, the rubella pandemic provided the scientific community with a unique opportunity to gain knowledge about the nature of intrauterine and extrauterine infections and the immunity stimulated by both. The quest for more knowledge using the tools of molecular biology has

continued since vaccine licensure and serves as a tribute to Gregg's historic contribution to our understanding of intra-uterine infection.

Much interest has focused on the epidemiology of rubella and congenital rubella syndrome in countries with immunization programs, the desirability of introducing vaccine in countries without a program, and the optimal strategy to control congenital rubella (i.e., universal immunization versus selective immunization of females).<sup>3,5-7,30-35</sup> Vaccination of all children and of susceptible adolescents and young adults, particularly females, has had such a dramatic impact on the occurrence of rubella and congenital rubella in the United States that efforts are now in progress to eliminate congenital rubella syndrome from the United States.<sup>5,24,31,36</sup> Given the magnitude of international travel, this goal will remain elusive until similar goals are adopted by other countries. The Pan American Health Organization (PAHO) has adopted a resolution calling on all countries of the Western Hemisphere to eliminate rubella by 2010.<sup>37</sup> However, among developing countries, rubella immunization has not yet been given priority.

Duration and quality of vaccine-induced immunity<sup>5,8,38-57</sup> and adverse events associated with immunization, particularly arthritis and the risk of the vaccine to the fetus,<sup>5,8,58-65</sup> have been a concern, but the vaccine continues to confer long-lasting immunity while placing the vaccinated person at minimal risk of adverse events. Success in eliminating indigenous disease in the United States and the absence of teratogenicity observed after massive immunization programs (2001-2002) in Latin America offer considerable assurance about the long-term efficacy and safety of rubella vaccine. In Brazil, where 28 million women were immunized in mass campaigns, and in Costa Rica, more than 2400 susceptible pregnant women were immunized. Although infants were infected, none had evidence of congenital rubella syndrome.

Research on the characteristics of the rubella virus, its effect on the developing fetus, the host's immune response, and diagnostic methodology has yielded new information about the structural proteins of the virus and about the difference in the immune response to these proteins after congenital and acquired infections.<sup>66-86</sup> Differences in antibody profile may be useful in diagnosing congenital infection retrospectively and may provide further information on the pathogenesis of congenital infection.<sup>64,85,87</sup> Techniques that detect rubella-specific antibodies within minutes have been developed by using latex agglutination and passive hemagglutination.<sup>88-94</sup> Studies to examine the subclass distribution of immunoglobulin G (IgG) and the kinetics of rubella-specific immunoglobulins (including IgA, IgD, and IgE) after acquired rubella, congenital infection, and vaccination may eventually lead to the development of additional diagnostic tools.<sup>95-99</sup> In particular, rubella IgG avidity testing can be helpful in distinguishing between recently acquired and remote infection.<sup>100-102</sup>

Improved laboratory methods defined the risk of fetal infection and congenital damage in all stages of pregnancy.<sup>103-110</sup> The risk of fetal infection after first-trimester maternal infection and subsequent congenital anomalies after fetal infection may be higher than previously reported (81% and 85%, respectively, in one study).<sup>105</sup> The fetus may be at risk of infection throughout pregnancy, even near term, although the occurrence of defects after infection beyond 16

to 18 weeks' gestation is small. Sensitive laboratory assays have shown that subclinical reinfection after previous natural infection, as after vaccination, may be accompanied by an IgM response, making differentiation between subclinical reinfection and asymptomatic primary infection at times difficult.<sup>41,51,53,55</sup> IgG avidity testing may be helpful also in this situation. Although reinfection usually poses no threat to the fetus, rare instances of congenital infection after maternal reinfection have been reported.<sup>41,43,45,47,51-53,55,111-116</sup>

Follow-up of patients with congenital rubella has provided information about the pathogenesis, immune status, interplay between congenital infection, and human leukocyte antigen (HLA) haplotypes and the long-term outcome associated with congenital infection.<sup>117-134</sup> These studies have documented that congenital infection is persistent, that virtually every organ may be affected, and that autoimmunity and immune complex formation are probably involved in many of the disease processes, particularly in the delayed and persistent clinical manifestations. They also confirm earlier studies, noting an increased risk of diabetes mellitus and other endocrinopathies in patients with congenital rubella syndrome compared with rates for the general population.

## THE VIRUS

### Morphology and Physical and Chemical Composition

Rubella virus is a generally spherical particle, 50 to 70 nm in diameter, with a dense central nucleoid measuring 30 nm in diameter. The central nucleoid is surrounded by a 10-nm-thick, single-layered envelope acquired during budding of the virus into cytoplasmic vesicles or through the plasma membrane.<sup>135-149</sup> Surface projections or spikes with knobbed ends that are 5 to 6 nm long have been reported. The specific gravity of the complete viral particle is  $1.184 \pm 0.004$  g/mL, corresponding to a sedimentation constant of  $360 \pm 50$  Svedberg units.<sup>135</sup>

The wild-type virus contains infectious RNA (molecular weight of 3 to  $4 \times 10^6$ ) within its core.<sup>120</sup> The rubella virus envelope contains lipids that differ quantitatively from those of the plasma membrane and are essential for infectivity.<sup>150,151</sup> Rubella virus is heat labile and has a half-life of 1 hour at 57° C.<sup>152</sup> However, in the presence of protein (e.g., 2% serum albumin), infectivity is maintained for a week or more at 4° C and indefinitely at -60° C. Storage at freezer temperatures of -10° C to -20° C should be avoided because infectivity is rapidly lost.<sup>152,153</sup> Rubella virus can also be stabilized against heat inactivation by the addition of magnesium sulfate to virus suspensions.<sup>154</sup> Specimens to be examined virologically should be transported to distant laboratories packed in ice rather than frozen, with the addition of stabilizer if possible. Infectivity is rapidly lost at pH levels below 6.8 or above 8.1 and exhausted in the presence of ultraviolet light, lipid-active solvents, or other chemicals such as formalin, ethylene oxide, and  $\beta$ -propiolactone.<sup>152,155-157</sup> Infectivity of rubella in cell culture is inhibited by amantadine, but the drug appears to have no therapeutic effect.<sup>158-161</sup>

Several laboratories have described the structural proteins of rubella virus and determined the nucleotide sequence of the genes coding for these proteins.<sup>66,81,135,162-165</sup> Originally,

three structural proteins were identified and designated as VP-1, VP-2, and VP-3.<sup>162</sup> These three major structural proteins now are designated E1, E2, and C, with relative molecular weights of 58,000, 42,000 to 47,000, and 33,000, respectively.<sup>67-69</sup> E1 and E2 are envelope glycoproteins and make up the characteristic spikelike projections that are located on the viral membrane. Structural protein C, which is not glycosylated, is associated with the infectious 40S genomic RNA to form the nucleocapsid.<sup>71</sup> The E2 glycopeptide has been shown on polyacrylamide gels to be heterogeneous with two bands, which are designated E2a (relative molecular weight of 42,000) and E2b (relative molecular weight of 47,000).<sup>67</sup>

Monoclonal antibody studies have begun to delineate the functional activities of these structural proteins. E1 appears to be the viral hemagglutinin and binds hemagglutination-inhibiting and hemolysis-inhibiting antibody; E2 does not appear to be involved in hemagglutination.<sup>66,68,70,72-75</sup> Monoclonal antibodies specific for E1 and E2 have neutralizing activity.<sup>66,70,76,85,86</sup> Studies also indicate that there are multiple epitopes on the structural proteins that are involved in hemagglutination inhibition (HI) and neutralizing activities.<sup>75,78</sup> Molecular analyses of rubella viruses isolated during the period of 1961 to 1997 from specimens obtained in North America, Europe, and Asia have documented the remarkable antigenic stability of the E1 envelope glycoprotein.<sup>80</sup> E1 amino acid sequences have differed by no more than 3%, indicating no major antigenic variation over the 36-year period that spanned the major worldwide pandemic of 1962 to 1964 and the 30 years since introduction of rubella vaccine. However, two genotypes were evident: genotype I isolated before 1970 grouped into a single diffuse clade, indicating intercontinental circulation, whereas most of the post-1975 viruses segregated into geographic clades from each continent, indicating evolution in response to vaccination programs. The availability of molecular analysis and the minor variations in amino acid sequences have provided an additional tool for monitoring the sources of infection in areas where indigenous rubella has been greatly reduced by high levels of immunization. As discussed in more detail later, the complexity of the antigenic nature of the rubella virion affects the ability of the host to respond to the full complement of antigens and affects the various antibody assays required to detect all the corresponding antibody responses (see "Natural History").

## Classification

Rubella has been classified as a member of the togavirus family (from the Latin word *toga*, meaning "cloak"), genus Rubivirus.<sup>166,167</sup> No serologic relationship exists between rubella and other known viruses. Minor biologic differences identified in different passaged strains of rubella virus are not reflected in the antigenic differences assessed by comparing protein composition or serologic reactions.<sup>135,165,168,169</sup> Differences in the immune response after immunization with the various vaccines now in use are not caused by inherent differences in the viral strain but rather by modification of the viruses during their attenuation in cell culture.<sup>29</sup> The reported variation in the virulence of rubella epidemics does not appear to be explained by the molecular analyses described earlier, but it may result from differences in population susceptibility and underreporting of cases of congenital rubella.<sup>170-177</sup>

## Antigen and Serologic Testing

Purified rubella virus has a number of antigenic components associated with the viral envelope and the ribonucleoprotein core.<sup>157,163</sup> These antigens and the ability of specific antiserum to neutralize virus form the basis for the wide variety of serologic methods available to measure humoral immunity after natural and vaccine-induced infection.

The ability of antibodies to inhibit agglutination of erythrocytes by the surface hemagglutinin (HA antigen) forms the basis for the HI test, which at one time was the most popular rubella serologic test. The HA antigen was originally prepared from BHK tissue culture fluids and then from alkaline extracts of infected BHK-21 cells.<sup>23,178</sup> This antigen can agglutinate a variety of red blood cells, including newborn chick, adult goose, pigeon, and human group O erythrocytes.<sup>179</sup> Rubella hemagglutinin is unique in its dependency on calcium ions to attach to red blood cell receptors.<sup>179,180</sup> After extraction from infected cells, rubella hemagglutinin is stable for months at  $-20^{\circ}\text{C}$ , several weeks at  $4^{\circ}\text{C}$ , and overnight at  $37^{\circ}\text{C}$  but is destroyed within minutes after heating to  $56^{\circ}\text{C}$ .<sup>178,180</sup> The HA antigen can be protected from ether inactivation by pretreatment with Tween 80. Cells and serum contain heat-stable beta-lipoproteins that can inhibit rubella hemagglutination and give rise to false-positive results.<sup>23,157</sup> Although it has been reported that nonspecific inhibitors do not interfere in the HI test if the HA antigen and erythrocytes are mixed before addition of serum, the recommended method is to pretreat the sera to remove these inhibitors.<sup>157,181</sup> Earlier test procedures used kaolin adsorption for removal of these nonspecific inhibitors; however, a number of faster and more specific methods are now used, such as treatment with heparin-MnCl<sub>2</sub> or dextran sulfate-CaCl.<sup>182,183</sup>

Cell-associated complement fixation antigen was first derived from infected rabbit kidney (RK-13) and African green monkey kidney cell cultures and later prepared from alkaline extracts of infected BHK-21 cells.<sup>22,184</sup> There are two complement fixation antigens—one is similar in size and weight to the hemagglutinin and infectious virus, and the other is smaller and "soluble."<sup>185-187</sup> The antibody response as measured by the soluble antigen develops more slowly than that to the larger antigen, which parallels the HI response. In contrast to the HA antigen, complement fixation antigens do not lose their antigenicity after either treatment.<sup>184,186</sup>

A variety of precipitin antigens have been serologically demonstrated; two of these, the theta and iota antigens, are associated with the viral envelope and core, respectively.<sup>188-190</sup> The antibody response to these two antigens is of interest. Antibodies to the theta antigen rise promptly and persist. Antibodies to the iota antigen are detectable later and for a shorter time.<sup>191</sup> The RA 27/3 vaccine appears to be unique among vaccine strains in its ability to elicit a response to the iota antigen, making its immune response more like natural infection. The significance of this observation remains unclear.<sup>192</sup>

Rubella virus antigen-antibody complexes (involving the envelope and the core antigens) cause aggregation of platelets.<sup>193,194</sup> However, the main platelet aggregation activity appears to reside with the viral envelope.

Antibody directed against the rubella virus can also be measured by virus neutralization in tissue culture.<sup>2-4,21,195-197</sup>

Whereas the presence of neutralizing antibodies correlates best with protective immunity, neutralization assays are time consuming, expensive, and relatively difficult to perform. Laboratories have traditionally performed the complement fixation and HI tests. Because the complement fixation test is insensitive for screening purposes and cannot detect an early rise in antibody in acute acquired infection, the HI test has been the most widely used assay.<sup>2-4,157,191,195,198,199</sup>

However, a number of more rapid, easily performed, reliable, and sensitive tests have replaced the HI test for routine use.<sup>88,199,200</sup> These include passive (or indirect) hemagglutination; single radial hemolysis (also known as hemolysis in gel), which is used widely abroad; radio-immunoassay; immunofluorescence; and enzyme immunoassay tests, also referred to as enzyme-linked immunosorbent assays.<sup>195,198-229</sup> Rapid latex agglutination and passive hemagglutination assays can provide results in minutes for screening and diagnostic purposes.<sup>88-94</sup> The large number of assays now available and their greater sensitivity compared with the HI test have led to some confusion about the level of antibody that should be considered indicative of immunity (see "Update on Vaccine Characteristics").<sup>44,54,57,199,227</sup> However, the HI test still remains the reference test against which other assays are compared.

Immunoglobulin class-specific antibody can be measured in most of the serologic systems.<sup>157,206-210,213,215,224-227,230-238</sup> This most frequently involves detection of IgM in whole or fractionated sera. A number of techniques are used to fractionate and then test the serum. An important consideration in any IgM assay is the possibility of false-positive results because of the presence of rheumatoid factor. Solid-phase IgM capture assays, however, appear to be unaffected by rheumatoid factor.<sup>99-102,210,225,236</sup>

### Growth in Cell Culture

Rubella replicates in a wide variety of cell culture systems, primary cell strains and cell lines.<sup>153,157,239</sup> The time required for virus recovery varies markedly, depending in part on the culture system being employed.

As a generalization, rubella growing in primary cell cultures (i.e., human, simian, bovine, rabbit, canine, or duck) produces interference to superinfection by a wide variety of viruses (especially enteroviruses, but also myxoviruses, papovaviruses, arboviruses, and to some extent, herpesviruses) but no cytopathic effect.<sup>19,20,152</sup> In contrast, a cytopathic effect of widely varying natures results from infection of continuous cell lines (i.e., hamster, rabbit, simian, and human). Generally, primary cells, especially African green monkey kidney, have proved superior for isolation of virus from human material by the interference technique. However, the continuous RK-13 and Vero (vervet kidney) cell lines are also used because cytopathic effect is produced and there is no problem with adventitious simian agents.<sup>153</sup> Continuous cell lines, such as BHK-21 and Vero, are best suited for antigen production because of the higher levels of virus produced.

All cell lines support chronic infection with serial propagation, but some are limited by the occurrence of cytopathic effect. These cells grow slowly and can be subcultivated fewer times than when not infected.<sup>153</sup> The mechanisms of rubella-induced interference and persistent infection in cell cultures are not completely understood. Although interferon

production has been described after rubella infection of cell cultures, interference appears to be an intrinsic phenomenon.<sup>153,157,240-242</sup> As with other viruses, generation of defective interfering particles can be found in tissue culture.<sup>243</sup> However, these particles are thought to be non-essential for persistence.

Rubella virus can be plaqued in RK-13, BHK-21, SIRC (i.e., rabbit cornea), and Vero cells.<sup>157</sup> Plaquing forms the basis of neutralization assays, and differences in plaquing characteristics can be used as markers to differentiate strains.<sup>21,157,169,195-197</sup>

### Pathogenicity for Animals

Rubella virus grows in primates and in various small laboratory animals. However, in no animal has the acquired or congenital disease been completely reproduced.

Vervet and particularly rhesus monkeys are susceptible to infection by the intranasal, intravenous, or intramuscular routes.<sup>244-246</sup> Although no rash develops, there is nasopharyngeal excretion of viruses in all of the inoculated monkeys and demonstrable viremia in 50%. Attempts to produce transplacental infection in pregnant monkeys have been partially successful. Rubella virus has been recovered from the amnion and the placenta, but the embryo itself has not been shown to be consistently infected.<sup>247,248</sup>

The ferret is by far the most useful of the small laboratory animals in rubella studies. Ferret kits are highly sensitive to subcutaneous and particularly to intracerebral inoculations. Virus has been recovered from the heart, liver, spleen, lung, brain, eye, blood, and urine for a month or longer after inoculation, and neutralizing and complement fixation antibodies have developed.<sup>249</sup> Ferret kits inoculated at birth develop corneal clouding. Virus appears in fetal ferrets after inoculation of pregnant animals.<sup>250</sup>

Rabbits, hamsters, guinea pigs, rats, and suckling mice have all been infected with rubella virus, but none has proved to be a consistent and reliable animal model system for study of rubella infection.<sup>170,171,251-254</sup> Studies indicating that Japanese strains of rubella virus were less teratogenic to offspring of infected rabbits than U.S. strains have not been confirmed.<sup>170,171</sup> These experiments were conducted to examine further the hypothesis referred to earlier that there is a difference in the virulence among rubella virus strains circulating in Japan and other parts of the world.<sup>168,170-174,176</sup>

### EPIDEMIOLOGY

Humans are the only known host for rubella virus. Continuous cycling in humans is the only apparent means for the virus to be maintained in nature. Because rubella is predominantly a self-limited infection seen in late winter and spring, questions have arisen about how the virus persists throughout the remainder of the year. Person-to-person transmission probably occurs at very low levels in the general population throughout summer and winter and probably at much higher levels in closed populations of susceptible individuals.<sup>255-276</sup> Congenitally infected infants can shed virus from multiple sites and can serve as reservoirs of virus during periods of low transmission.<sup>161,277-282</sup> This is of particular concern in the hospital setting.<sup>161,274</sup> Efficiency of

transmission may also vary among individuals, with some being better “spreaders” than others. This phenomenon may contribute to continued circulation of the virus.<sup>283</sup>

Rubella remains worldwide in distribution.<sup>284-290</sup> The virus circulates almost continually, at least in continental populations. In the Northern Hemisphere’s continental temperate zones, rubella is consistently more prevalent in the spring, with peak attack rates in March, April, and May; infection is much less prevalent during the remainder of the year, increasing or decreasing during the 2 months before or after the peak period.<sup>287,289</sup> Before widespread rubella immunization, sizable epidemics occurred every 6 to 9 years in most of the world, with major ones occurring at intervals ranging from 10 to 30 years. Epidemics usually built up and receded gradually over a 3- to 4-year interval, peaking at the midpoint.<sup>9,284,287,289</sup> The apparent increased infectivity and virulence of rubella as exemplified in the major epidemics have been the subject of considerable speculation. One popular thesis has been the unproven emergence of a more virulent strain of virus at widely separated intervals.<sup>168,170-174,176</sup> However, no convincing evidence exists concerning clinically different strains of rubella, and molecular analysis of the E1 envelope glycoprotein does not support the hypothesis of an epidemic versus endemic strain difference.<sup>80</sup> The apparent severity of the epidemic appears to be related to the number of susceptible adults, especially pregnant women, in any given population at the outset of an epidemic.<sup>175,177,289,291</sup> Host factors, such as the differences in the ability to transmit rubella, and still unknown factors may also be involved.<sup>283,291</sup>

Attack rates in open populations have not been defined precisely for a number of reasons. Because rubella is such a mild disease, it is underreported, even in areas where reporting has been mandatory for years. Mandatory reporting did not begin in the United States until 1966 (Fig. 28-1).<sup>287,292</sup> The high and variable rate of inapparent infection poses a major problem when attempting to interpret the recorded data, which are based usually on clinical findings.<sup>260,293-298</sup>

In childhood, the most common time of infection, 50% or more of serologically confirmed infections result in inapparent illness. The ratio may rise as high as 6:1 or 7:1 in adults, perhaps as a result of silent reinfection in naturally immune individuals who have lost detectable antibody.<sup>260,296</sup> The frequent occurrence of infections that clinically mimic rubella makes it even more difficult to determine attack rates in open populations.<sup>299</sup> Attack rates undoubtedly depend on the number of susceptible individuals, which varies widely in different locations.

Serologic assessments of rubella attack rates have been performed in closed populations, such as military recruits, isolated island groups with small populations, boarding home residents, and household members.<sup>260-262,283,295,298,299-306</sup> In such situations, individual exposure to the virus is more intense than that encountered in open populations. Under these circumstances, 90% to 100% of children and adults who are susceptible may become infected. Attack rates in susceptible persons on college and university campuses and in other community settings range from 50% to 90%.<sup>9,291</sup> Like primary infection, reinfection probably is increased as exposure becomes more intense.<sup>260,296,304,305</sup>

In most of the world, including the United States before the introduction of mass immunization of children in 1969, rubella was typically a childhood disease that was most prevalent in the 5- to 14-year-old age group.<sup>2,3,7,285-292</sup> It was rare in infants younger than 1 year of age. The incidence increased slowly for the first 4 years, rose steeply between 5 and 14 years, peaked around 20 to 24 years, and then leveled off. In developed countries before mass immunization, the incidence of infection did not reach 100% before the ages of 35 to 40 years; 5% to 20% of women of childbearing age remain susceptible to infection.

In the era before a rubella vaccine, in isolated or island populations, such as in Trinidad, some areas of Japan, Panama, rural Peru, and Hawaii, a relatively high rate of susceptibility

**Figure 28-1** Incidence rates for reported cases of rubella and congenital rubella syndrome in the United States from 1966 to 2003. (Data from Centers for Disease Control and Prevention, courtesy of S. Reef, March 1, 2004.)

was found among young adults.<sup>285,286,288,289,302</sup> Between 26% and 70% of women of childbearing age remained susceptible. This situation existed even though rubella was endemic with ample opportunity for multiple introductions of virus from the outside. Low population density, tropical climate, low concentration of effective spreaders, and genetic factors have all been invoked to explain these low attack rates, but none can adequately account for this peculiar epidemiologic phenomenon by itself.<sup>283,288,289,291</sup> Later studies from 45 developing nations where rubella immunization efforts have been minimal have revealed a wide range of susceptibility ( $\leq 10\%$  to  $\geq 25\%$ ).<sup>303</sup>

In other areas, particularly in South America, infection began earlier in life and peak incidence occurs before puberty.<sup>288</sup> However, infection rates in most South American countries reach a plateau at approximately the same level as that seen in Europe and North America, leaving 10% or more of young women who are susceptible, based on serologic tests. Chile appeared to be an exception, with almost all persons being infected before puberty.<sup>288</sup> The impact of major immunization programs in the PAHO countries to reach a goal of eliminating rubella by 2010 will change these data.

Initial mass vaccination of children, followed by routine vaccination of 1-year-old children and vaccination of susceptible adolescents and adults, has been extremely successful in controlling rubella and congenital rubella syndrome in the United States.<sup>5,24,31,36,258,292</sup> The characteristic 6- to 9-year epidemic cycle has been interrupted, and the reported incidence of rubella that ranged from approximately 200 to 400 cases annually during the period 1992 through 2000 dropped to less than 25 between 2001 and 2004. For comparison, there were approximately 58,000 cases reported in 1969, the year of vaccine licensure in the United States (see Fig. 28-1). Age-specific declines in the occurrence of rubella have been greatest in children, who, because they were the major reservoir of the virus, have been the primary target of the U.S. immunization program. However, the risk of rubella decreased by 99% in all age groups after efforts to increase vaccination levels in older, susceptible persons, especially childbearing-aged females (see "Prevention of Congenital Rubella").<sup>255,257</sup> Nonetheless, serologic surveys continue to document a 10% to 20% susceptibility rate in this population because of less-than-optimal immunization coverage rates.<sup>264,292,307-313</sup>

Adolescents and young adults now account for most reported cases, with more cases reported among those older than age 15 years than in children. Outbreaks are still reported in colleges, hospitals, cruise ships, and other settings in which persons live or work in proximity.<sup>266-268,271-276</sup> Outbreaks no longer occur among military recruits because they receive rubella vaccine as soon as they arrive for basic training.<sup>263</sup> Whereas the reported incidence of cases of congenital rubella syndrome has decreased dramatically, the number of cases of rubella and congenital rubella reported in the United States increased in 1989 to 1991, documenting that the potential for cases will continue as long as children and women of childbearing age remain underimmunized.<sup>36</sup> The outbreak of rubella and congenital rubella among the Amish in Pennsylvania in 1991 and 1992 was a tragic reminder that there are still pockets of susceptible individuals in the United States.<sup>270</sup>

## TRANSMISSION IN UTERO

In pregnant women with clinical or inapparent primary rubella, virus infects the placenta during the period of viremia and subsequently infects the fetus.<sup>2,6,284,299,314-329</sup> Intrauterine transmission of virus associated with maternal reinfection is rare. It is presumed that this difference is a reflection that viremia is absent or greatly reduced because of immunity induced by the primary infection (natural or vaccine induced).<sup>\*</sup> Maternal infection may result in no infection of the conceptus, resorption of the embryo (seen only with infections occurring in the earliest stages of gestation), spontaneous abortion, stillbirth, infection of the placenta without fetal involvement, or infection of the placenta and fetus.<sup>6</sup> Infected infants can have obvious multiorgan system involvement or, as is frequently observed, no immediately evident disease.<sup>6,13,107,330-337</sup> However, after long-term follow-up, many of these seemingly unaffected infants have evidence of hearing loss or central nervous system or other defects.<sup>6,13,14,112,131,132,330,331,333-336</sup>

Gestational age at the time of maternal infection is the most important determinant of intrauterine transmission and fetal damage.<sup>2-4,6,284,299,317</sup> The risk of fetal infection and congenital anomalies decreases with increasing gestational age. Fetal damage is rare much beyond the first trimester of pregnancy.

Availability of more sensitive antibody assays has led to refinement of our understanding of the risk of fetal infection and subsequent congenital defects throughout all stages of pregnancy.<sup>103,110</sup> Although the risk of defects does decrease with increasing gestational age, fetal infection can occur at any time during pregnancy. Data on the risk of fetal infection are inconsistent when maternal rubella occurs before conception.<sup>1,12,108,110,338-341</sup> If some risk exists, the risk is small.

### Risk of Fetal Infection

Early attempts to define the risk of fetal infection relied on isolation of virus from products of conception.<sup>314-320</sup> Between 40% and 90% of products of conception obtained from women with clinical rubella during the first trimester were found to be infected. The higher rates were observed in serologically confirmed cases of maternal rubella and when improved isolation techniques were employed.<sup>319,320</sup> Attempts were made to refine the risk estimates by evaluating placental and fetal tissue separately. In some of these studies, equal rates of persistent placental and fetal infection were observed, ranging from 80% to 90%.<sup>319,320</sup> In others, persistent placental infection was found to be twice as frequent as fetal infection: 50% to 70% versus 20% to 30%.<sup>314,317</sup> However, high rates of fetal infection accompanied placental infection when specimens obtained during the first 8 weeks of gestation were examined. For example, of 14 cases in which virus was cultured from placental tissue, six of seven fetuses were culture positive when maternal rubella occurred during the first 8 weeks of pregnancy. In contrast, only one of seven fetal specimens was positive when infection occurred between 9 and 14 weeks of gestation.<sup>314</sup> In another similar study, fetal infection rates decreased sharply after the eighth week of

Total	258 <sup>d</sup>	45 (117)	102	20	

<sup>a</sup>Defects in seropositive patients only.

<sup>b</sup>Overall risk of defects = rate of infection × rate of defects.

<sup>c</sup>Numbers in parentheses are number of children infected.

<sup>d</sup>None of 11 infants whose mothers had subclinical rubella were infected.

Adapted from Miller E, Cradock-Watson JE, Pollock TM. Consequences of confirmed maternal rubella at successive stages of pregnancy. *Lancet* 2:781, 1982, with permission.

gestation, whereas placental infection rates decreased but less rapidly.<sup>317</sup> After the eighth week, placental infection occurred in 36% (8 of 22) and fetal infection occurred in 10% (2 of 20) of cases. Although fetal infection was not documented beyond the 10th week of gestation, placental infections were identified up to the 16th week.

Further data on the risk of fetal infection have been obtained from studies using sensitive laboratory tests to detect congenital infection in children born to mothers with serologically confirmed rubella.<sup>103,110</sup> Because congenital rubella is often subclinical in infants and young children, use of such tests is necessary to assess accurately the risk of congenital infection.<sup>6,103-108,331,333-336</sup> In investigations in which this approach was used, with detection of rubella-specific IgM antibody in sera to document congenital infection, the discrepancy between rates of placental and fetal infection seen in viral isolation studies is less apparent. These studies have provided new information on the events after maternal infection in the second and third trimesters.

In a study involving a total of 273 children (269 of whom had IgM antibody assessment), Miller and colleagues<sup>105</sup> reported that fetal infection after serologically documented symptomatic maternal rubella in the first trimester was, as expected, quite high: 81% (13 of 16), with rates of 90% and 67% for those exposed before 11 weeks and at 11 to 12 weeks, respectively (Table 28-1). Of greater interest is that the infection rate was 39% (70 of 178) after exposure in the second trimester (decreasing steadily from 67% at 13 to 14 weeks to 25% at 23 to 26 weeks) but rose to 53% (34 of 64) with third-trimester infection (with infection rates of 35%, 60%, and 100% during the last 3 months of pregnancy, respectively).

In another investigation of fetal infection after first-trimester maternal rubella infection based on IgM determination, Cradock-Watson and associates<sup>103</sup> found that 32% of 166 children were infected after second-trimester exposure and that a comparable proportion (24% of 100) were infected after infection in the third trimester. The rate of infection increased during the latter stages of gestation

after initially decreasing to a low of 12% by the 28th week and was 58% (11 of 19) when maternal infection occurred near term. Even higher rates were observed when persistence of IgG antibody was used as the criterion for congenital infection. The true fetal infection rate probably lies between the rates calculated by using the IgM and persistent IgG data.

In both studies, the fetal infection rate declined between 12 and 28 weeks, suggesting that the placenta may prevent transfer of virus, although not completely.<sup>103</sup> Some of the infections recorded during the last weeks of pregnancy could have been perinatally or postnatally acquired (e.g., by means of exposure to virus in the birth canal or from breast milk), but the available evidence indicates that the placental barrier to infection may be relatively ineffective during the last month, perhaps to the same degree as that seen during the first trimester, and that the fetus is susceptible to infection throughout pregnancy, albeit to various degrees.<sup>342-344</sup>

### Risk of Congenital Defects

Estimates of the risk of congenital anomalies in live-born children after fetal infection have been affected by a number of factors. Early retrospective and hospital-based studies led to overestimates of the risk of congenital defects after first-trimester infection (up to 90%).<sup>6,107,291</sup> The risk of abnormalities as determined by prospective studies relying on a clinical diagnosis of maternal rubella varied considerably (10% to 54% overall, with a 10% to 20% risk for major defects recognizable in children up to 3 years old) and tended to underestimate the risk because serologic evaluation of infants was not performed.<sup>107,338,345-349</sup> The proportion of pregnancies electively terminated can affect observed malformation rates. The fact that fetal infection can occur during all stages of pregnancy also influences assessments of the risk of congenital defects.

Because most infants born with congenital rubella who were exposed after the 12th week of gestation do not have grossly apparent defects, long-term follow-up is necessary to

detect subtle, late-appearing abnormalities, such as deafness and mental impairment.<sup>6,13,14,112,131,132,330,331,333-336</sup> This is especially true for infants infected beyond the 16th to 29th week of gestation, who appear to be at little, if any, risk of congenital anomalies.<sup>103,109</sup> Studies by Peckham and associates<sup>107,335</sup> demonstrate that estimates of the risk of defects are affected by the serologic status and age at evaluation of the child. The overall incidence of defects in 218 children studied when they were about 2 years old was 23%; it was 52% if maternal infection occurred before 8 weeks' gestation, 36% at 9 to 12 weeks, and 10% at 13 to 20 weeks. No defects were observed when maternal infection occurred after 20 weeks. When considering only seropositive children, the overall risk of defects increased to 38%, with increased risks of 75%, 52%, and 18%, respectively, for the three gestational periods previously cited. At follow-up when the children were 6 to 8 years old, the overall risk of abnormalities in infected children who were seropositive when 2 years old increased from 38% to 59%; the risk after first-trimester infection increased from 58% to 82%.

Miller and co-workers<sup>105</sup> observed higher rates of defects in infected children observed for only 2 years (see Table 28-1). Defects were seen in 9 of 9 seropositive children exposed during the first 11 weeks, 2 of 4 exposed at 11 to 12 weeks, 2 of 12 exposed at 13 to 14 weeks, and 7 of 14 exposed at 15 to 16 weeks. Congenital heart disease and deafness were observed after infection before the 11th week; deafness was the sole defect identified after infection at 11 to 16 weeks' gestation. No defects were observed in 63 children infected after 16 weeks. However, some children infected in the third trimester had growth retardation.

Although the number of subjects is small, results of the study of Miller and co-workers<sup>105</sup> indicate that the risk of damage in seropositive infants is 85% if fetal infection occurs in the first trimester and 35% after infection during weeks 13 to 16. These rates of defects are higher than previously reported, but they may be an accurate reflection of intra-uterine events because all maternal cases were serologically confirmed and sensitive antibody assays were used to detect congenital infection. With further follow-up, higher rates of defects may be observed.

These rates pertain to offspring known to be infected and are useful in evaluating the risk of defects given fetal infection. For counseling purposes, it is essential to know the risk of congenital defects after confirmed maternal infection. This can be derived by multiplying the rates of defects in infected fetuses by the rates of fetal infection. Based on the reported experience of Miller and colleagues,<sup>105</sup> the risks are 90% for maternal infection before the 11th week, 33% for infection during weeks 11 to 12, 11% for weeks 13 to 14, and 24% for weeks 15 to 16 (see Table 28-1). The risk after maternal infection in the first trimester is 69%.

## NATURAL HISTORY

### Postnatal Infection

#### *Virologic Findings*

The pertinent virologic findings of postnatal infection are depicted in Figure 28-2. The portal of entry for rubella virus is believed to be the upper respiratory tract. Virus then spreads

**Figure 28-2** Relation of viral excretion and clinical findings in postnatally acquired rubella. (Data from Alford CA. Chronic congenital and perinatal infections. In Avery GB [ed]. Neonatology. Philadelphia, JB Lippincott, 1987.)

through the lymphatic system, or by a transient viremia to regional lymph nodes, where replication first occurs. Between 7 and 9 days after exposure, virus is released into the blood and may seed multiple tissues, including the placenta. By the 9th to 11th day, viral excretion begins from the nasopharynx, as well as from the kidneys, cervix, gastrointestinal tract, and various other sites.<sup>9,278,294,301,342-344,350</sup>

The viremia peaks at 10 to 17 days, just before rash onset, which usually occurs 16 to 18 days after exposure. Virus disappears from the serum in the next few days, as antibody becomes detectable.<sup>278,294,301,350</sup> However, infection may persist in peripheral blood lymphocytes and monocytes for 1 to 4 weeks.<sup>59,64,351,352</sup> Virus is excreted in high titers from nasopharyngeal secretions. Nasopharyngeal shedding rarely may be detected for up to 3 to 5 weeks. Although virus can usually be cultured from the nasopharynx from 7 days before to 14 days after rash onset, the highest risk of virus transmission is believed to be from 5 days before to 6 days after the appearance of rash. Viral shedding from other sites is not as consistent, intense, or prolonged.<sup>294,350</sup> Rubella virus has been cultured from skin at sites where rash was present and where it was absent.<sup>353,354</sup>

#### *Humoral Immune Response*

In challenge studies conducted in the early 1960s, Green and co-workers<sup>294</sup> demonstrated that neutralizing antibody was first detected in serum 14 to 18 days after exposure (usually 2 to 3 days after rash onset), peaked within a month, and persisted for the duration of the follow-up period of 6 to 12 months. The HI test soon became the standard method for detecting rubella antibodies after acute postnatal rubella infection because of its reliability and ease compared with the neutralization test. Several other methods for measuring rubella antibody responses have supplanted the HI test in popularity (see "The Virus").<sup>88,199,200</sup> The kinetics of the immune response to acute infection detected by these various serologic assays, which have been exhaustively compared with the HI technique, is depicted in Figure 28-3.<sup>88-92,191,195-205,207,214-224,226,229</sup>

In general, there are three distinct patterns of antibody kinetics. Antibodies of the IgG class measured by HI, latex agglutination, neutralization, immunofluorescence, single radial hemolysis (or hemolysis in gel) (not shown in Fig. 28-3), radioimmunoassay, and enzyme-linked immunoassay theta

**Figure 28-3** Schematic diagram of the immune response in acute rubella infection. CF, complement fixation; EIA, enzyme immunoassay; FIA/FIAX and IFA, immunofluorescence assays; HI, hemagglutination inhibition; IgM, immunoglobulin M; LA, latex agglutination; NI, neutralization; PHA, passive agglutination; RIA, radioimmunoassay. (Data from Herrmann KL. Rubella virus. In Lennette EH, Schmidt NJ. [eds]. *Diagnostic Procedures for Viral, Rickettsial and Chlamydial Infections*. Washington, DC, American Public Health Association, 1979, p 725, and from Herrmann KL. Available rubella serologic tests. *Rev Infect Dis* 7[Suppl 1]:S108, 1985.)

precipitation (not shown) follow the first pattern. Such antibodies usually become detectable 5 to 15 days after rash onset, although they may appear earlier and may even be detected 1 or 2 days before the rash appears. The antibody titers rapidly increase to reach peak values at 15 to 30 days and then gradually decline over a period of years to a constant titer that varies from person to person. In some patients with low levels of residual antibody, a second exposure to rubella virus may lead to low-grade reinfection of the pharynx. A booster antibody response can then be detected with any of the assays. This rapidly terminates the new infection, which is most often subclinical, and little or no viremia occurs.<sup>38,44,47,50,54,56,260,305,329</sup>

A second pattern of immune response to rubella infection is seen when IgG antibodies are measured by passive hemagglutination. The peak titer of these antibodies is similar to that measured by HI, but the passive hemagglutination antibodies are relatively delayed in appearance, and levels rise only slowly to their maximal titers. They first become detectable 15 to 50 days after the onset of the rash and often take 200 days to reach peak titers. The antibodies probably persist for life. Booster responses may be seen with reinfections.

Studies indicate that the predominant IgG subclass detected by all these various assays is probably IgG1.<sup>95,97</sup> Failure to detect IgG3 may be indicative of reinfection.<sup>98</sup>

A third distinct pattern of antibody production is represented in Figure 28-3 by the IgM antibody class immune response. Rubella-specific IgM antibody can be measured by HI, immunofluorescence, radioimmunoassay, or enzyme immunoassay.<sup>99,157,206-210,213,215,224,225,230-228</sup> IgM antibodies are most consistently detectable 5 to 10 days after the onset of the rash, rise rapidly to peak values at around 20 days, and then decline so rapidly that they usually disappear by 50 to 70 days. In a few patients, however, low levels may persist for up to 1 year.<sup>355-357</sup> The booster IgG antibody response to re-

infection described earlier does not usually involve the IgM class of antibody, and the presence of high-titer IgM antibodies usually indicates recent primary infection with rubella. However, more sensitive techniques, such as radioimmunoassay or enzyme immunoassay, may occasionally detect low levels of specific IgM antibodies in some patients with reinfections, which may cause some difficulty in differentiating subclinical reinfection, which is almost always of no consequence, from acute primary subclinical infection.<sup>41,51,53,55</sup> Determination of avidity of rubella-specific IgG may help resolve this problem.<sup>358-360</sup> Primary infection appears to be associated with low-avidity IgG, and reinfection seems to be associated with high-avidity IgG.

The kinetics of the immune response to rubella infection detected by other serologic assays is not as distinct as the three patterns just described, and marked variability between patients has been observed. Complement fixation antibodies or iota precipitins (not shown in Fig. 28-3) are lacking in the first 10 days after the rash and rise slowly to peak at 30 to 90 days.<sup>191</sup> These antibodies persist for several years in one third of patients and may reappear during reinfections. Iota precipitins do not persist for more than a few months and do not usually reappear with reinfections.

Antibodies of the IgA class appear within 10 days but may disappear within another 20 days or persist for several years.<sup>96,99,206,231</sup> IgD and IgE antibodies appear rapidly (6 to 9 days) after infection, remain high for at least 2 months, and then decline slightly at 6 months.<sup>96</sup> IgE antibodies reach an early peak similar to that seen for IgM and IgA. In contrast, the IgD response is somewhat delayed, like that of IgG.

The antibody response after infection is generally considered to confer complete and permanent immunity. Clinical reinfection is rare, and reinfections usually pose little risk to the fetus because placental exposure to the virus is minimal.<sup>38,41,44,47,50,51,53-56,329</sup> Some of the rare instances of fetal infection after maternal reinfection may be caused by an incomplete immune response to the various antigenic domains on each structural protein of the virus (see "The Virus").<sup>74-76,111,115,321,326-330</sup> For example, three cases after natural infection have been reported involving women who had positive HI results but who had no detectable levels of neutralizing antibody.<sup>321,326,328</sup> The sensitivity of the neutralizing assay itself is an important determinant in interpreting these results.<sup>111,196</sup> This phenomenon also may account for the four reported cases of congenital infection that followed reinfection of women who had presumably been immunized previously.<sup>42,45,52,116</sup> Some of the reported instances of maternal reinfection probably, and in at least one case definitely, represent cases of primary acute infection.<sup>5,6,113,323-325</sup>

### Cellular Immune Response

Cellular immunity to rubella virus has been measured by lymphocyte transformation response, secretion of interferon, secretion of macrophage migration-inhibitory factor, induction of delayed hypersensitivity to skin testing, and release of lymphokines by cultured lymphocytes.<sup>361-372</sup> Peripheral blood lymphocytes from seropositive individuals respond better in each of these tests than do lymphocytes from uninfected persons, suggesting that these assays measure parameters of the cellular immune response to rubella virus. The results from other studies in which chromium 51 microcyto-

toxicity assays have been used are difficult to interpret because syngeneic cell lines have not been used to control for HLA-restricted responses.<sup>362,365</sup>

In the first weeks after natural rubella infection, some degree of transient lymphocyte suppression may occur.<sup>366,368</sup> Generally, cell-mediated immune responses precede the appearance of humoral immunity by 1 week, reach a peak value at the same time as the antibody response, and subsequently persist for many years, probably for life.<sup>331</sup> Acute infection may suppress skin reactivity to tuberculin testing for approximately 30 days.<sup>373</sup>

### Local Immune Response

The local antibody response at the portal of entry in the nasopharynx is essentially IgA in character; low levels of short-lived IgG antibody are rarely detectable in nasopharyngeal secretions. The nasopharyngeal IgA antibody persists at detectable levels for at least 1 year after infection. Its persistence apparently minimizes the tendency for reinfection after natural rubella infection. The lack of local IgA nasopharyngeal response after parenteral administration of live rubella vaccines (less so with the RA 27/3 strain than with other strains) probably plays a key role in the increased incidence of subclinical reinfection after vaccination.<sup>38,40,44,50,54,56,374-377</sup>

Local antibody levels tend to be higher in individuals resistant to challenge with live virus, but no specific titer of antibody has been associated with complete protection.

A cell-mediated immune response in tonsillar cells has been detected by lymphocyte transformation and secretion of migration-inhibitory factor after natural rubella and after intranasal challenge with live RA 27/3 vaccine.<sup>378</sup> In guinea pigs, the response first becomes detectable 1 to 2 weeks after intranasal vaccination, peaks at 4 weeks, and then disappears at about 6 weeks.<sup>379</sup>

## Congenital Infection

### Virologic Findings

An important feature that distinguishes congenital infection from postnatal infection is that the former is chronic.<sup>2,13,284,310,317,380,381</sup> During the period of maternal viremia, the placenta may become infected and transmit virus to the fetus (see "Transmission In Utero").<sup>2,6,284,299,314-320</sup> Although virus may persist for months in the placenta, recovery of virus from the placenta at birth occurs infrequently.<sup>382</sup> In contrast, after the fetus is infected, the virus persists typically throughout gestation and for months postnatally. It can infect many fetal organs or only a few.<sup>317</sup> In infected infants, virus can be recovered from multiple sites (e.g., pharyngeal secretions, urine, conjunctival fluid, feces) and is detectable in cerebrospinal fluid, bone marrow, and circulating white blood cells.<sup>†</sup> Pharyngeal shedding of virus is more common, prolonged, and intense during the early months after delivery (Fig. 28-4). By 1 year of age, only 2% to 20% of infants shed virus.<sup>277-279</sup> In rare instances, shedding may continue beyond the age of 2 years.<sup>280-282</sup> Virus can be isolated from the eye and cerebrospinal fluid, particularly when disease is evident in the corresponding organs and can persist for more than a year in the eye and central nervous

**Figure 28-4** Rate of virus excretion by age in infants and children with congenital rubella infection. (Data from Cooper LZ, Krugman S. Clinical manifestations of postnatal and congenital rubella. Arch Ophthalmol 77:434, 1967.)

system.<sup>384-387</sup> Virus has been isolated from the brain of a 12-year-old boy with later-appearing subacute panencephalitis occurring after congenital rubella infection.<sup>388,389</sup>

### Humoral Immune Response

Studies have shown that placental infection does not prevent passive transfer of maternal antibody and that the infected fetus can mount an immune response.<sup>284,314-320,390-392</sup> Although the development and function of the other components of the immune response of the fetus may be important, critical factors that allow fetal infection to occur in the presence of antibody may be the timing when antibody is present in the fetal circulation or the quality of the antibody that the fetus produces, or both.

Although placental transfer of antibody occurs despite persistent infection, levels of antibody in fetal blood during the first half of gestation are only 5% to 10% of those in maternal serum.<sup>392-396</sup> As the placental transfer mechanisms mature by mid-gestation (16 to 20 weeks), increasing levels of maternal IgG antibody are transferred to the fetus (Fig. 28-5).<sup>395</sup>

The development of the fetal humoral immune system appears to be too late to limit the effects of the virus. Cells with membrane-bound immunoglobulins of all three major classes—IgM, IgG, and IgA—appear in the fetus as early as 9 to 11 weeks' gestation.<sup>396</sup> However, circulating fetal antibody levels remain low until mid-gestation, despite the presence of high titers of virus and the development of antigen receptors on the cell surface (see Fig. 28-5). At this time, levels of fetal antibody increase, with IgM antibody predominating.<sup>392,397-401</sup> Fetal IgA, IgD, and IgG also are made, although in lesser amounts.<sup>96,398,401</sup> As in the case with other chronic intra-uterine infections, congenital rubella infection may lead to an increase in total IgM antibody levels.<sup>390,392,393,401</sup> Total IgA levels are also occasionally raised, but IgG levels seldom exceed those of uninfected infants.<sup>390,392,401,402</sup> At the time of delivery of infected infants, levels of IgG rubella antibodies in cord sera are equal to or greater than those in maternal

<sup>†</sup>See references 2, 13, 161, 277-282, 284, 314, 315, 317, 319, 380-384.

**Figure 28-5** Schematic diagram of the immune response in the mother, fetus, and infant after maternal and fetal rubella infections in the first trimester of pregnancy. (Data from Alford CA. Immunology of rubella. In Friedman H, Prier JE [eds]. Rubella. Springfield, Ill, Charles C Thomas, 1972.)

sera, even if the infant is born prematurely.<sup>392</sup> IgG is the dominant antibody present at delivery in rubella-infected infants and is mainly maternal in origin. In contrast, the IgM levels are lower but are totally fetus derived.

In the first 3 to 5 months after birth, the levels of maternally derived IgG decrease as maternal antibody is catabolized (see Fig. 28-5).<sup>392</sup> In contrast, IgM antibodies increase in titer and can predominate. Later, as viral excretion wanes and disappears, the IgM antibody levels diminish, and IgG becomes the dominant and persistent antibody type. Cradock-Watson and colleagues<sup>401</sup> found that total IgM was elevated in nearly all sera obtained from infected infants during the first 3 months of life and in one half of sera from infected infants 3 to 6 months old. Rubella-specific IgM has been shown consistently to persist for 6 months, frequently for a year, and rarely longer when assayed by sensitive serologic procedures, such as radioimmunoassay and immunofluorescence.<sup>212,401</sup> For example, Cradock-Watson and colleagues<sup>401</sup> also reported that IgM was detectable in 48 (96%) of 50 sera during the first 6 months of life and in 11 (29%) of 38 sera from children between 6.5 months and 2 years old. The total level of antibody, as measured by a variety of serologic tests, remains virtually unchanged throughout the first year of life, despite the fluctuations in immunoglobulin composition.<sup>392,401</sup>

High levels of IgG antibody are usually maintained for several years after detectable virus excretion ends, suggesting that there may be continued antigenic stimulation. During the first few years of life, some patients have a relative hypergammaglobulinemia, particularly of the IgM and IgG classes of antibody, which results from the increased antigenic stimulus accompanying the chronic infection.<sup>401,403</sup> With increasing time, however, antibody levels may decrease and even become undetectable in 10% to 20% of patients.<sup>335,404-406</sup> Cooper and co-workers<sup>406</sup> found that the geometric mean HI titer decreased by a factor of 16 by age 5 years in 223 children

with congenital rubella syndrome. No HI antibodies were detected in 8 of 29 5-year-old children. In a study from Japan, only 3% of 381 children with congenital infection observed for more than 17 years had undetectable HI titers.<sup>407</sup> There was an initial rapid decline from a geometric mean titer of 1:416 ( $2^{8.7}$ ) to 1:84 ( $2^{6.4}$ ) over the first 2 years of follow-up. After this, there was a modest continuing decline, and the final geometric mean titer was 1:42 ( $2^{5.4}$ ).

Cooper and co-workers<sup>406</sup> reported that congenitally infected children who have lost detectable rubella-specific antibody did not develop a boost in antibody titer after rubella vaccination. This finding may reflect some sort of immunologic tolerance that follows intrauterine exposure to rubella virus. None of the children with congenital rubella in Japan had evidence of significant boosts in antibody or a history of clinical disease when exposed during recent outbreaks of rubella.<sup>407,408</sup>

Hypogammaglobulinemia with low levels of all three major classes of immunoglobulins has been reported in a few instances of congenital rubella.<sup>133,161,409,410</sup> Usually, only IgA is affected. There may also be instances when IgG levels are low, whereas levels of IgM are two or three times the upper limit of normal for adults. These IgG and IgM abnormalities may occur with or without IgA abnormalities.<sup>409</sup> Over time, immunoglobulin development may become normal, and this can occur despite continued viral excretion but is more likely if viral titers are decreasing.<sup>280</sup>

In addition to defects in the immune globulin levels, defects in specific antibody production have been observed. One such defect is a complete lack of antibody response to any antigen, including the rubella virus itself. Response only to the virus, in the absence of a response to most other antigens, has also been reported.<sup>280</sup> This state of immunologic unresponsiveness resolves in many patients. Antibody production becomes normal as the patient's general condition improves and as immune globulin levels normalize.

Immunoprecipitation studies of sera from patients with congenital rubella syndrome provide further information on defective antibody production. They indicate that the antibody profile to the three structural proteins of the rubella virus is qualitatively different from that observed in sera from persons with postnatally acquired infection (see "The Virus").<sup>84,85,87</sup> Little or no antibody to the core structural protein (C) is found, and the absolute and relative amounts of antibody to structural proteins E1 and E2 appear to vary with age.<sup>84,85</sup> These findings further suggest that the immune response of the infected fetus may be incomplete and may explain why detectable antibodies are not present in some sera.<sup>87,335,404-407</sup> If a serum contains relatively little antibody to structural protein E1 (i.e., hemagglutinin), assays that detect antibody to the whole virion will be more likely to be positive than those that detect antibody only to E1 (e.g., the HI assay). It is not clear whether these abnormal antibody patterns persist for life.

### Cellular Immune Response

Like the cells responsible for the humoral immune response (i.e., B cells), the cells involved in cellular immunity (i.e., T cells and macrophages) develop some of their functions early in gestation.<sup>411-413</sup> However, little is known about their response in utero because appropriate specimens have not been obtainable for study. The cellular immune response of

the infected fetus has been inferred from studies of infected infants and children. Available evidence indicates that some infants with congenital rubella have impaired cellular immune responses.

Retarded development of the thymus and lymphocyte depletion have been reported, but these abnormalities may result from the stress of infection rather than the virus itself.<sup>414</sup> Abnormal delayed hypersensitivity skin reactions to a number of antigens (e.g., diphtheria toxoid, *Candida*, dinitrofluorobenzene) have also been reported.<sup>280,415</sup> This defect has been associated with abnormalities in the humoral system and resolves as antibody production returns to normal.

Results of studies of in vitro lymphocyte blastogenesis in congenitally infected infants and children have been confusing. Early studies demonstrated a poor response to phytohemagglutinin, vaccinia, and diphtheria toxoid.<sup>415-418</sup> However, because rubella virus can depress the lymphocyte blastogenic response and the virus can be isolated from lymphocytes of chronically infected infants, the abnormality may be a result of viral infection of the circulating blood cells rather than an inherent defect in cell-mediated immunity.<sup>416-419</sup> This diminished cellular response may normalize over time because elevated lymphocyte responses have been detected in some older infected children.<sup>411,420</sup>

Buimovici-Klein and colleagues<sup>372,421</sup> showed that lymphocytes from older children and adolescents with congenital rubella had no or very poor lymphocyte proliferative responses to rubella virus antigens and had markedly reduced interferon and migration-inhibition factor production. These studies indicated that these defects were greater in children exposed early in gestation than those exposed later, with the greatest degree of abnormality in those whose mothers had been infected during the first 8 weeks of pregnancy. They also pointed out that these defects could persist long after viral excretion had ceased. It remains unclear if these cellular immune defects are responsible for viral persistence or are yet another manifestation of intrauterine infection.<sup>421</sup>

Other investigators have confirmed that patients with congenital rubella have defects in cell-mediated immunity.<sup>120,133,134</sup> Verder and colleagues<sup>134</sup> reported a decreased proportion of suppressor or cytotoxic (CD8<sup>+</sup>) T cells in an infant with congenital rubella. Rabinow and co-workers<sup>133</sup> documented persistent T cell abnormalities in patients with congenital infection who were 9 to 21 years old. Compared with normal subjects, the congenitally infected patients had depressed ratios of T4 cells (helper or inducer) to T8 cells (from a decreased proportion of T4 and an increased percentage of T8 cells). Such findings persist for only 1 month after acute postnatal rubella infection.<sup>422</sup>

Lymphocytes of infected children were unable to kill rubella-infected cells in a cytotoxicity assay.<sup>423</sup> These results were questioned because syngeneic target cells were not used, and these responses are known to be HLA restricted. However, similar results have been found by Verder and associates,<sup>134</sup> who observed abnormal killer and natural killer cell activities.

### Interferon Response

It has long been suggested that the fetus has a deficient interferon response to viral infections, including rubella, but this evidence has been derived from indirect studies with in vitro cell systems or animal models.<sup>173,174,319,424,425</sup> Technical

difficulties have hampered direct studies of humans. However, interferon that appeared to be specifically stimulated by the presence of rubella virus in rubella-infected human embryos has been demonstrated.<sup>426</sup> The interferon was found as early as 7 weeks' gestation and persisted as long as 12 weeks after symptoms ceased in the mothers. Direct study of fetal blood and amniotic fluid has also shown that the fetus can produce interferon in response to the virus.<sup>427</sup>

Children with congenital infection do have the capacity to make interferon on challenge. For example, Desmyter and co-workers<sup>428</sup> reported that interferon could not be detected from the serum or urine of nine such children 11 to 18 months old who were excreting virus. However, after vaccination with live measles vaccine (i.e., Edmonton B or Schwarz strains), all the children seroconverted and produced detectable levels of interferon.

## PATHOGENESIS

### Postnatal Infection

The events leading to acute postnatal infection are relatively well known and have been detailed in "Natural History." Available information indicates that viral replication and postinfection immune phenomena are involved in the clinical manifestations of the illness.

Viremia may lead to seeding of multiple organs, but few are clinically affected.<sup>6</sup> Speculation that the rash may be an immune phenomenon caused by circulating immune complexes has not been documented. Few persons with uncomplicated illness have immune complexes containing rubella virus, and virus has been isolated from involved and uninvolved skin.<sup>123,128,353,354</sup> Virus has been isolated from lymph nodes and conjunctiva, accounting for the lymph node enlargement and conjunctivitis observed in many patients.<sup>350,429</sup> Virus has been isolated from synovial fluid, but immune mechanisms may play a role in some cases of arthralgia and arthritis, particularly if symptoms are persistent.<sup>123,429-433</sup> Encephalitis is probably a manifestation of the immune response, but direct viral invasion may be involved, particularly in the rare case of progressive panencephalitis that has been reported to follow postnatal infection.<sup>121,434-436</sup> It has been suggested that pregnant women are at increased risk of serious complications because of the impaired immune response associated with pregnancy, but there are few data to support this claim.<sup>436-438</sup> There has also been interest, especially in Japan, in the influence of HLA type and other genetic factors on the incidence and severity of postnatal infection.<sup>118,119,122,124,127,439</sup> No consistent pattern has been reported.

### Congenital Infection

The outcome of maternal rubella infection follows a logical sequence of events, beginning with maternal infection, followed by viremia, placental seeding, and dissemination of infection to the fetus (see "Transmission In Utero" and "Natural History").<sup>2,6,284,299,314-320</sup> The fetus may escape infection entirely, succumb in utero, be born with multiple obvious defects, or appear to be normal at birth, only to develop abnormalities later in life.<sup>6,13,107,278,330-337</sup> The vari-

ability in outcome is highlighted by the observation that one identical twin may be infected and the other spared.<sup>6,440,441</sup>

The most important determinant of fetal outcome is gestational age at the time of infection.<sup>2,3,6,103,110,284,299,314,317</sup> The disease is more severe and has a greater tendency to involve multiple organs when acquired during the first 8 weeks' gestation. However, the factors that govern the influence of gestation are unknown. It is possible that immature cells are more easily infected and support the growth of virus better than older, more differentiated cells. It is also possible that the placenta becomes increasingly resistant to infection (or at least more able to limit infection) as it rapidly matures during the first trimester. A third possibility is that maturing fetal defense mechanisms become capable of confining and clearing the infection. This last explanation is probably important after 18 or 20 weeks' gestation but seems unlikely in the latter half of the first trimester, when attenuation of fetal infection begins. It is likely that a combination of these and other factors are responsible for the decrease in virulence of fetal infection with increasing gestational age.

The hallmark of fetal infection is its chronicity, with the tendency for virus to persist throughout fetal life and after birth.<sup>2,13,161,277-282,284,299,314-320,372-389</sup> The fact that virus can be isolated long after birth also raises the possibility of reactivation, at least in brain tissue.<sup>388,389</sup> It is not clear why the virus has these properties, because the fetus is not truly immunologically tolerant and appears to be able to produce interferon.<sup>212,284,331,391,392,401,424-428</sup> In any case, chronic or reactivated infection can lead to ongoing pathologic processes.<sup>6,13,14,107,131,132,330,331,333-336</sup>

The causes of cellular and tissue damage from congenital rubella infection are poorly defined.<sup>424,425</sup> Only a variable, small number of cells are infected (1 per 1000 to 250,000).<sup>320</sup> In tissue culture, infection with rubella virus has diverse effects, ranging from no obvious effect to cell destruction (see "The Virus"); this is also likely to be the case in vivo,<sup>157</sup> but cytolysis is uncommon (see "Pathology").<sup>2,3,6,9,442-446</sup> Inflammation is minimal and consists mainly of infiltration of small lymphocytes. Polymorphonuclear leukocytes and plasma cells are lacking, particularly compared with other viral infections of the human fetus, in which inflammation and general necrosis are quite extensive. In contrast, vascular insufficiency appears to be more important than cell destruction or secondary inflammatory damage in the genesis of congenital defects.<sup>2,3,6,9,442-446</sup> This suggestion is supported by the observation that rubella virus has low destructive potential for cells growing in vitro, including those of human origin. A number of investigators have maintained multiple types of rubella-infected human fetal cells in culture for years without loss of viability or evidence of cytopathic effect.<sup>447-449</sup>

Other defects have been reported in chronically infected cells that might help explain the mechanism of congenital defects. These include chromosomal breaks, reduced cellular multiplication time, and increased production of a protein inhibitor that causes mitotic arrest of certain cell types.<sup>380,447,450-455</sup>

A report by Bowden and associates<sup>456</sup> indicates that rubella virus may interfere with mitosis by having an adverse effect on actin microfilaments. Observations of Yoneda and co-workers<sup>457</sup> show that rubella virus may alter cell receptors to specific growth factors. All of these abnormalities, if occurring in vivo, may result in decreased cell multiplication

because of slow growth rates and limited doubling potential during the period of embryogenesis, when cell division and turnover are normally very rapid. Naeye and Blanc<sup>458</sup> found histopathologic evidence for mitotic arrest and reduced cell numbers in infants who died of congenital rubella syndrome. These observations have been offered to explain the increased incidence of intrauterine growth retardation seen in infants with congenital rubella, but this explanation probably represents an oversimplification of the actual mechanisms involved.

Immunologic responses also have been proposed as causes of cellular damage. Although cellular immune defects may be a result of chronic infection, it is possible that these defects contribute to ongoing tissue damage.<sup>372,421,459</sup> Excessive serum immunoglobulin development, persistent antibody production in the face of viral replication for prolonged periods, and production of rheumatoid factor, all indicative of overstimulation of the immune system, also may have a role in the pathogenesis of congenital rubella syndrome.<sup>460,461</sup> The presence of immune complexes and autoantibodies and the influence of certain HLA types may contribute to the delayed expression of some signs of congenital rubella, such as pneumonitis, diabetes mellitus, thyroid dysfunction, and progressive rubella panencephalitis (see "Clinical Manifestations").<sup>†</sup> Some of these immunologic events may be directly involved in tissue damage (e.g., immune complexes, autoantibodies), whereas others may allow the virus to persist or reactivate.

## **PATHOLOGY**

### **Postnatal Infection**

Little is known about the pathology of postnatally acquired rubella because patients seldom die of this mild disease. As observed by Cherry,<sup>9</sup> the histologic findings of tissues that have been examined (i.e., lymph nodes and autopsy specimens from patients dying with encephalitis) are unremarkable. Changes in lymphoreticular tissue have been limited to mild edema, nonspecific follicular hyperplasia, and some loss of normal follicular morphology. Examination of brain tissue has revealed diffuse swelling, nonspecific degeneration, and little meningeal and perivascular infiltrate.

### **Congenital Infection**

In contrast to the situation with postnatal rubella, much is known about the pathology of congenital rubella infection.<sup>2,3,6,9,442-446,462</sup> In general, small foci of infected cells are seen in apparently normal tissue. Cellular necrosis and secondary inflammation are seldom obvious, although a generalized vasculitis predominates (see "Pathogenesis").

The pathologic findings of the placenta include hypoplasia, inflammatory foci in chorionic villi, granulomatous changes, mild edema, focal hyalinization, and necrosis.<sup>442,443,462,463</sup> Disease usually causes extensive damage to the endothelium of the capillaries and smaller blood vessels of the chorion. The vessel lesions consist mainly of endothelial necrosis,

<sup>†</sup>See references 13, 14, 117, 120, 121, 123, 125, 126, 129-134, 388, 389.

with fragmentation of intraluminal blood cells. Töndury and Smith<sup>442</sup> postulated that emboli of infected endothelial cells originating from the chorion might seed target organs in the fetus. These emboli may also contribute to organ damage by obstructing the fetal blood supply. Petechiae and the presence of hemosiderin-laden phagocytes in surrounding tissue are evidence of functional vascular damage.<sup>443</sup>

Although not nearly as common as vascular lesions, specific cytolysis, presumably caused by direct viral effect on the cell, is also present in the placenta. This is characterized by cytoplasmic eosinophilia, nuclear pyknosis or karyorrhexis, and cellular necrosis. Specific cellular inclusion bodies, both nuclear and cytoplasmic, are rare but have been observed.<sup>463</sup> Whereas placentitis would be expected to be present in all affected placentas, regardless of when fetal infection occurred, Garcia and colleagues<sup>463</sup> found that placental lesions appeared to be more intense when infection occurred in the last trimester of pregnancy. This finding is consistent with the observation that the placenta is not a barrier to fetal infection in the latter stages of pregnancy.<sup>103,109,333,335</sup>

Autopsies show that virtually every organ may be involved, with hypoplasia being a common finding. The necrotizing angiopathy of small blood vessels seen in the placenta is the most characteristic lesion in fetal organs. Cytolysis with tissue necrosis and accompanying inflammatory changes are also far less common but have been found in the myocardium, brain, spinal cord, skeletal muscle, viscera, and epithelial cells of the developing lens, inner ear (organ of Corti), and teeth.

The overall pathologic process of congenital rubella, in keeping with its chronic nature, is progressive. Both healing and new lesions can be found in specimens obtained in the later stages of gestation.<sup>442,443</sup> The pathologic changes vary among embryos in quantity and in organ distribution, and the location and nature of organ lesions depend somewhat on the gestational age at the time of infection.<sup>442</sup> The pathologic findings parallel the enormous variability of the clinical disease seen in infected newborns.

## CLINICAL MANIFESTATIONS

### Postnatal Infection

Rubella is usually a mild disease with few complications. Clinical illness may be more severe in adults.<sup>6,9,291,294,360,464</sup> Measles, varicella, and some enteroviruses acquired close to delivery may be associated with serious illness in the newborn, probably because of fetal exposure to transplacental viremia in the absence of protective levels of maternal antibody. One case report suggests that the same may be true in rubella. Sheinis and associates<sup>465</sup> reported the death of a neonate with rash onset when 12 days old; the mother developed rash on the day of delivery. This single observation needs to be confirmed. There are no conclusive data to indicate that infection in the immunocompromised host is associated with an increased risk of complications.

The first symptoms of rubella occur after an incubation period of 16 to 18 days, with a range of 14 to 21 days. In the child, rash is often the first sign detected. In adolescents and adults, however, the eruption is commonly preceded by a 1- to 5-day prodromal period characterized by low-grade

fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, cough, and lymphadenopathy usually involving suboccipital, postauricular, and cervical nodes.

The constitutional symptoms often subside rapidly with the appearance of the rash. The rash can last 1 to 5 days or longer and can be pruritic in adults. Infection without a rash is quite common. The ratio of subclinical to clinical infections has varied from 1:9 to 7:1.<sup>260,296</sup> Subclinical infection can lead to fetal infection, although it is not clear whether the risk is as great as that associated with clinically apparent infection.<sup>2,3,6,105,108,335,341</sup>

Arthralgia and frank arthritis with recrudescence of low-grade fever and other constitutional symptoms may appear after the rash fades. Joint involvement typically lasts 5 to 10 days but may be more persistent. The frequency of these symptoms is variable, but it is more common in adults, particularly women.<sup>9</sup> In some studies of adult patients, the frequency has been as high as 70%.<sup>466</sup> Thrombocytopenia (occurring in approximately 1 of 3000 patients) and acute postinfection encephalitis (occurring in 1 of 5000 to 6000 patients) are rare complications that usually occur 2 to 4 days after rash onset.<sup>9</sup> Rare complications associated with postnatal rubella include myocarditis, Guillain-Barré syndrome, relapsing encephalitis, optic neuritis, and bone marrow aplasia.<sup>9,467-471</sup> Two cases of a progressive panencephalitis, similar to measles-associated subacute sclerosing panencephalitis, have been reported.<sup>434,435</sup> This central nervous system disturbance is more likely to manifest in patients with congenital rubella syndrome, although it still occurs infrequently.<sup>389,472,473</sup> Testalgia has also been reported in patients with rubella, but this may have been a coincidental finding.<sup>474,475</sup>

### Congenital Infection

Gregg's original report<sup>12</sup> in 1941 defined the rubella syndrome as a constellation of defects, usually involving some combination of congenital heart, eye, and hearing abnormalities, with or without mental retardation and microcephaly. After the extensive studies in the mid-1960s, in which virologic and serologic methods of assessment were used, the pathologic potential associated with intrauterine rubella had to be greatly expanded.<sup>2,3</sup> The recognition of various new defects associated with congenital rubella infection led to speculation that they had not existed before the 1962 to 1964 pandemic. However, a review of the abnormalities in infants born during previous non-epidemic periods indicated that they were not new but had not been appreciated previously because of the small number of affected infants studied.<sup>476</sup>

The virus can infect one or virtually all fetal organs and, once established, can persist for long periods (see "Transmission In Utero," "Natural History," "Pathogenesis," and "Pathology").<sup>5</sup> Congenital rubella, a chronic infection, may kill the fetus in utero, causing miscarriage or stillbirth. At the other extreme, the infection may have no apparent effect clinically detectable at the delivery of normal-appearing infants. Alternatively, severe multiple birth defects may be

<sup>9</sup>See references 6, 13, 14, 107, 131, 132, 161, 277-282, 284, 299, 314-320, 330-337, 380-389.

obvious in the newborn period. The wide spectrum of disease is summarized later in the chapter (see Tables 28-3 and 28-4).

Silent infections in the infant are much more common than symptomatic ones. Schiff and colleagues<sup>334</sup> prospectively examined 4005 infants born after the 1964 rubella epidemic. Based on virologic and serologic techniques to detect infection in the newborns, the overall rate of congenital rubella was in excess of 2%, compared with only approximately 0.1% in endemic years.<sup>334,341</sup> Sixty-eight percent of the infected newborns had subclinical infection during the neonatal period. Among those who were followed, 71% developed manifestations of infection at various times in the first 5 years of life. Many important rubella defects can be undetectable or overlooked in the early months of life. Existing manifestations of infection can progress, and new manifestations may appear throughout life.<sup>6,13,14,107,131,132,330-337</sup> Some abnormalities of congenital rubella syndrome usually are not detected until the second year of life or later (see Table 28-3). The silent and progressive nature of congenital rubella infection has important implications for accurate, timely diagnosis and appropriate short-term and long-term management.

It is useful to group the clinical features of congenital rubella into three categories: transient manifestations in newborns and infants; permanent manifestations, which may be present at birth or become apparent during the first year of life; and developmental and late-onset manifestations, which usually appear and progress during childhood, adolescence, and early adult life.<sup>13,441,477</sup> These groupings overlap.

### **Transient Manifestations**

Transient manifestations appear to reflect ongoing heavy viral infection, perhaps abetted by the newborn's emerging, often abnormal immune function.<sup>6,120,134</sup> Examples of these manifestations include hepatosplenomegaly, hepatitis, jaundice, thrombocytopenia with petechiae and purpura, discrete bluish red ("blueberry muffin") lesions of dermal erythroplasia, hemolytic anemia, chronic rash, adenopathy, meningoencephalitis (in some cases), large anterior fontanelle, interstitial pneumonia, myositis, myocarditis, diarrhea, cloudy cornea, and disturbances in bone growth that appear as striated radiolucencies in the long bones. More than 50% of infants with these transient findings usually have evidence of intrauterine growth retardation and may continue to fail to thrive during infancy.<sup>278</sup> These transient abnormalities were referred to as the *expanded rubella syndrome* when widely reported after the pandemic of 1962 to 1964. Careful review of the early observations during the 1940s and 1950s revealed that these were not new manifestations of congenital rubella.

These conditions usually are self-limiting and clear spontaneously over days or weeks.<sup>2</sup> These lesions are important from a diagnostic and prognostic standpoint. They may be associated with other, more severe defects. This applies especially to thrombocytopenia and bone lesions.<sup>13,477</sup> The mortality rate was approximately 35% in one group of infants who presented with neonatal thrombocytopenia. Extreme prematurity, gross cardiac lesions or myocarditis with early heart failure, rapidly progressive hepatitis, extensive meningoencephalitis, and fulminant interstitial pneumonitis contributed to the mortality during infancy.<sup>441</sup>

### **Permanent Manifestations**

Permanent manifestations include heart and other blood vessel defects, eye lesions, central nervous system abnormalities, deafness, and a variety of other congenital anomalies. These structural defects result from defective organogenesis (i.e., some cardiac, eye, and other organ defects) and from tissue destruction and scarring (i.e., hearing loss, brain damage, cataracts, chorioretinopathy, and vascular stenosis). Relatively few defects result from gross anatomic abnormalities. It is not certain that all of the malformations given in Table 28-2 are associated with congenital rubella.<sup>13,315,381,454,476-504</sup> Because many of them occur in the absence of intrauterine rubella infection, their presence in affected infants may be coincidental.<sup>9</sup>

Congenital heart disease is present in more than one half of children infected during the first 2 months of gestation. The most common lesions, in descending order, are patent ductus arteriosus, pulmonary artery stenosis, and pulmonary valvular stenosis. Aortic valvular stenosis and tetralogy of Fallot have also been recorded. A patent ductus arteriosus occurs alone in approximately one third of cases; otherwise, it is frequently associated with pulmonary artery or valvular stenosis.<sup>13,477,489</sup> Stenosis of other vessels plays an important role in the spectrum of congenital rubella syndrome.<sup>445,498,499</sup> These lesions may be related to coronary, cerebral, renal, and peripheral vascular disease seen in adults.<sup>131,529</sup>

A "salt and pepper" retinopathy caused by disturbed growth of the pigmentary layer of the retina is the most common of all ocular findings.<sup>6,13,441,477</sup> Cataracts, often accompanied by microphthalmia, occur in approximately one third of all cases of congenital rubella. Bilateral cataracts are found in one half of affected children. Primary glaucoma is relatively uncommon; it does not affect a cataractous eye. Cataracts and infantile glaucoma may not be present or detectable at birth but usually become apparent during the early weeks of life. Other ocular abnormalities occur later in life (see "Developmental and Late-Onset Manifestations").

Children with congenital rubella syndrome exhibit a number of central nervous system abnormalities that follow widespread insult to the brain. Microcephaly can be a feature of this syndrome. Mental retardation and motor retardation are common and are directly related to the acute meningoencephalitis in 10% to 20% of affected children at birth.<sup>9</sup> Behavioral and psychiatric disorders have been confirmed in many patients.<sup>13,441</sup> Of particular interest is autism, which has been reported to occur with a frequency of approximately 6%.<sup>441</sup> Chronic encephalitis has been reported in young children.<sup>6</sup> A late-onset progressive panencephalitis may occur in the second decade of life.<sup>389,472,473</sup> This is discussed later with other developmental manifestations.

The incidence of deafness has been underestimated because many cases had been missed in infancy and early childhood. However, follow-up studies showed that deafness was the most common manifestation of congenital rubella, occurring in 80% or more of those infected.\* In contrast to other serious defects, hearing impairment often is the only significant consequence of congenital rubella. Rubella-related defects of organogenesis (i.e., cataracts and some

heart lesions) are uncommon after infection beyond 8 weeks' gestation. However, the organ of Corti is vulnerable to the effects of the virus up to the first 16 weeks and perhaps up to the first 18 to 20 weeks. The deafness, ranging from mild to profound and from unilateral or bilateral, is usually peripheral (sensorineural) and is more commonly bilateral. Central auditory impairment and language delay may lead to a misdiagnosis of mental retardation.<sup>13,505-509</sup>

### Developmental and Late-Onset Manifestations

Developmental and late-onset manifestations have been reviewed by Sever and Shaver and their colleagues.<sup>131,132</sup> They include endocrinopathies, deafness, ocular damage, vascular effects, and progression of central nervous system disease (Table 28-3).<sup>5</sup> A number of mechanisms may be responsible for the continuing disease process that leads to these abnormalities: persistent viral infection, viral reactivation, vascular insufficiency, and immunologic insult. The last problem may be mediated by circulating immune complexes and autoantibodies. Abnormalities in cellular immunity and genetic factors have also been studied.

Insulin-dependent diabetes mellitus is the most frequent of all these manifestations, occurring in approximately 20% of patients by adulthood.<sup>13,117,125,130-132,512</sup> This reported prevalence is 100 to 200 times that observed for the general

population. Studies of HLA type indicate that congenital rubella syndrome patients with diabetes have the same frequencies of selected HLA haplotypes as diabetic patients without the syndrome (e.g., increased HLA-DR3 and decreased HLA-DR2). The presence of pancreatic islet cell and cytotoxic surface antibodies in children with congenital rubella syndrome does not appear to be related to any specific HLA type. It has been postulated that congenital infection increases the penetrance of a preexisting susceptibility to diabetes in these patients.<sup>130</sup> Rabinowe and associates<sup>133</sup> also reported an elevation in the number of Ia-positive ("activated") T cells in patients with congenital rubella syndrome. They suggested that this T cell abnormality may be related in these patients to the increased incidence of diabetes mellitus and other diseases associated with autoantibodies.

Thyroid dysfunction affects about 5% of patients and manifests as hyperthyroidism, hypothyroidism, and thyroiditis.<sup>117,129,513-518</sup> Autoimmune mechanisms appear to be responsible for these abnormalities. For example, Clarke and colleagues<sup>129</sup> reported that 23% of 201 deaf teenagers with congenital infection had autoantibodies to the microsomal or globulin fraction, or both fractions, of the thyroid and that 20% of those with autoantibodies had thyroid gland dysfunction. Coexistence of diabetes and thyroid dysfunction has been reported, but the significance of the association is unknown.<sup>117,133</sup>

Two cases of growth hormone deficiency have been reported.<sup>519</sup> The defect appears to be hypothalamic in origin. However, among eight growth-retarded older children with congenital rubella syndrome, Oberfield<sup>520</sup> found no evidence of functional abnormality in the hypothalamic-pituitary axis and normal or elevated levels of somatomedin C. Growth patterns in a group of 105 late adolescents revealed three patterns: growth consistently below the fifth percentile; growth in the normal range but early cessation of growth, usually with a final height below the fifth percentile; and normal growth. The magnitude of the cognitive deficits was closely correlated with growth failure.<sup>521</sup> Ziring<sup>14</sup> has commented on a case with Addison's disease, and precocious puberty has been observed.<sup>13,14</sup>

The delayed diagnosis of preexisting deafness has already been referred to. However, the hearing deficit can increase over time, and sudden onset of sensorineural deafness may occur after years of normal auditory acuity.<sup>346,510,530</sup> As reported by Sever and co-workers,<sup>131</sup> the latter has been observed in a child 10 years old.

A number of late-onset ocular defects can occur. Glaucoma has been reported in patients between 3 and 22 years old who did not previously have the congenital or infantile variety of glaucoma associated with congenital rubella syndrome.<sup>522</sup> Other reported manifestations are keratic precipitates, keratoconus, corneal hydrops, and spontaneous lens absorption.<sup>525,526</sup>

The retinopathy of congenital rubella, which was previously believed to be completely benign, has more recently been associated with the delayed occurrence of visual difficulties caused by subretinal neovascularization.<sup>523,524,531</sup> Another delayed manifestation associated with vascular changes is hypertension resulting from renal artery and aortic stenosis.<sup>529</sup>

Mental retardation, autism, and other behavioral problems may be delayed in appearance and can be progressive.<sup>13,441</sup> However, the most interesting and serious delayed central

<sup>5</sup>See references 13, 14, 117, 125, 130, 131, 133, 330, 335, 389, 441, 473, 474, 486, 499, 505-519, 522-529.

nervous system manifestation is the occurrence of a progressive and fatal panencephalitis resembling subacute sclerosing panencephalitis that manifests during the second decade of life. The first cases were reported by Weil and Townsend and their co-workers.<sup>389,472</sup> At the time of their review, Waxham and Wolinsky<sup>473</sup> found that 10 cases of progressive rubella panencephalitis had been identified among patients with congenital rubella syndrome. Two cases have been reported after postnatally acquired rubella.<sup>434,435</sup> Patients with this condition present with increasing loss of mental function, seizures, and ataxia. These symptoms continue to progress until the patient is in a vegetative state and ultimately dies. Rubella virus has been recovered from the brain of one congenitally infected patient.<sup>388,389</sup> Elevated serum and cerebrospinal fluid antibodies and increased amounts of cerebrospinal fluid protein and gamma globulin have been detected. Virus has also been isolated from lymphocytes, and rubella-specific immune complexes have been identified.<sup>121,532</sup> Although rare, this syndrome focuses attention on the ability of the virus to persist and to become reactivated after years of latency.

### Long-Term Prognosis

Fifty survivors of the congenital rubella epidemic of 1939 to 1943 in Australia were seen at age 25, and their status was reviewed again in 1991.<sup>579</sup> Seven subjects had died in the interval—three with malignancies, three with cardiovascular disease, and one with the acquired immunodeficiency syndrome. Among the 1991 survivors, 5 were diabetic, all 40 examined were deaf, 23 had eye defects, and 16 had cardiovascular defects. Despite these conditions, the group was characterized by remarkably good social adjustment. Most (29) were married, and they had 51 children—only 1 with a congenital defect (deafness presumed to be hereditary from his deaf father, who did not have congenital rubella). Most were of normal stature, although 6 of the 40 were less than the third percentile for height. This group of survivors is quite different from the approximately 300 survivors followed in New York since the rubella epidemic of 1963 to 1965.<sup>580</sup> In their late 20s, approximately one third of these survivors were leading relatively normal lives in the community, one third live with their parents and may have “non-competitive” employment, and one third reside in facilities with 24-hour care. Neither the Australian nor the New York group is a representative sample of all survivors of maternal rubella infection, but these groups do offer insight on long-term prognosis. The differences in outcome between the Australian group (survivors of Norman Gregg’s original patients) and the New York group probably reflect the different methods by which the groups were collected and the significant differences in the medical technology of the 1940s compared with the 1960s.

## LABORATORY DIAGNOSIS

Timely, accurate diagnosis of acute primary rubella infection in the pregnant woman and congenital rubella infection in the infant is imperative if appropriate management is to be undertaken (see “Management Issues”). The diagnosis must be confirmed serologically or virologically because clinical diagnosis of postnatal and congenital rubella is unreliable. In

any suspected exposure of a pregnant woman, every effort should be made to confirm rubella infection so that accurate counseling can be offered about the risks to the fetus. Laboratory proof of congenital infection facilitates proper treatment, follow-up, and long-term management.

## Maternal Infection

Because of inapparent infection, the variable clinical manifestations of rubella, and the mimicking of rubella by other viral exanthems, laboratory diagnosis is essential in managing potential rubella infection during pregnancy (see “Natural History” and “Clinical Manifestations”).<sup>157,199,226,227,308</sup> Although virus can be cultured from the nose and throat, isolation techniques are impractical. Although reverse transcriptase–polymerase chain reaction (RT-PCR) offers another reliable tool for confirming the diagnosis during acute rubella, laboratory confirmation usually is limited to serologic testing (see “The Virus”). Acute primary infection can usually be documented by demonstrating a significant rise in antibody level between acute and convalescent sera or the presence of rubella-specific IgM antibody. Appropriate timing of specimen collection with regard to rash onset (or exposure in the case of subclinical infection) is critical for accurate interpretation of results. Diagnosis is greatly facilitated if the immune status is known before disease onset or exposure.<sup>259</sup> Women with laboratory evidence of immunity are not at risk. From a practical point of view, women with a history of vaccination on or after the first birthday should also be considered immune.<sup>256,257</sup> However, because seroconversion is not 100% (see “Prevention of Congenital Rubella”), serologic testing may be indicated on an individual basis in vaccinated women who have a known exposure or a rash and illness consistent with rubella to rule out acute primary infection.

Traditionally, a fourfold or greater rise in antibody titer (i.e., HI, complement fixation, or latex agglutination tests) has been considered a significant rise in antibody. However, with the advent of enzyme immunoassay, the diagnosis may be based on significant changes in optical density expressed as an index rather than a titer. The acute-phase specimen should be taken as soon as possible after onset of the rash, ideally within 7 days. If a positive titer is obtained for a specimen taken on the day of rash onset or 1 to 2 days later, the risk of acute infection is low but cannot be excluded. The convalescent-phase serum sample should be taken 10 to 14 days later. If the first serum sample is obtained more than 7 days after rash onset, some assays (e.g., HI) may not be able to detect a significant antibody rise because titers may have already peaked. In this situation, measurement of antibodies that appear later in the course of infection may be useful. A significant rise in complement fixation titer or, for example, a high HI, latex agglutination, or enzyme immunoassay titer and little or no antibody as measured by passive hemagglutination suggests recent infection.

When multiple serum samples are obtained in the course of the diagnostic workup, all should be tested simultaneously in the same laboratory to avoid misinterpretation of laboratory-related variations in titer. Although a single high titer is consistent with recent infection, it is not specific enough to conclude that recent infection has occurred.<sup>259</sup>

Detection of rubella-specific IgM (RIgM) is a very useful method for confirming acute, recent infection. Although RIgM testing is valuable, a number of factors can affect test results. Results must be interpreted with careful attention to the timing of the specimens. Samples taken within the first several days after onset of rash may have low or even undetectable levels of RIgM, but a specimen taken 7 to 14 days later invariably shows higher titers of antibody. The levels of RIgM may decline promptly thereafter. Many of the methods previously described for detecting IgM have some limitations (see "The Virus"). IgM antibody testing may involve pretreatment of the serum by a variety of techniques to separate IgM from IgG, such as column chromatography, sucrose gradient centrifugation, or adsorption of IgG with staphylococcal protein A. The serum IgM fraction can then be assayed by HI, immunofluorescence, radioimmunoassay, or enzyme immunoassay.<sup>157,206-210,213,215,224-228,230-238</sup> A false-positive result may occur if the serum was pretreated with protein A, because about 5% of IgG is not removed. The radioimmunoassay and enzyme immunoassay techniques can directly detect specific IgM antibodies in unfractionated sera, but false-positive results may be produced by the presence of rheumatoid factor.<sup>157,207,209</sup> A solid-phase, immunosorbent (i.e., capture) technique appears to be unaffected by rheumatoid factor.<sup>99,210,225,236</sup> A warning is necessary. Whereas high or moderate titers provide very good evidence of recent infection, low rubella-specific IgM titers detected by sensitive assays must be interpreted cautiously. Low titers have been shown to persist for many months in a few patients after natural infection and can be detected in some immune patients with subclinical reinfection.<sup>41,51,53,55,355-360</sup> Diagnosis of subclinical infection is relatively straightforward if the woman is known to be susceptible, the exposure is recognized, and a serum sample is obtained approximately 28 days after exposure. The diagnosis is more difficult if the immune status of the woman is unknown. However, it can be facilitated if the acute-phase serum specimen is obtained as soon as possible after a recognized exposure that did not occur more than 5 weeks earlier.<sup>259</sup> The convalescent serum sample, if necessary, should then be obtained approximately 3 weeks later. If the first specimen lacks detectable antibody, continued close clinical observance and serologic follow-up are necessary. If the first specimen has detectable antibody and was obtained within 7 to 10 days of exposure, there is no risk of infection, and further evaluation is unnecessary. A positive titer in a specimen obtained after this period indicates a need for further serologic investigation. If test results of paired serum specimens are inconclusive, RIgM testing may be helpful, but a negative test result may be difficult to interpret.

More significant diagnostic difficulties arise when women of unknown immune status are exposed at an unknown time, were exposed more than 5 weeks earlier, or had rash onset more than 3 weeks earlier.<sup>259</sup> In these situations, expert consultation may be necessary if positive titers are obtained. Where available, avidity testing of rubella IgG may be used to help clarify the timing of infection. Recent rubella infection is characterized by antibody of low avidity. When such low-avidity antibody is found in the presence of rubella IgM, it supports a diagnosis of recent rubella infection.<sup>358-360</sup>

Unfortunately, conclusive information about the timing of past infection and risk to the fetus is often not available, even when a combination of antibody assays is used. These

situations can be minimized if prenatal rubella testing is carried out routinely. Laboratories performing prenatal screening should store these specimens until delivery in case retesting is necessary.<sup>256,533</sup>

## Congenital Infection

A presumptive diagnosis of congenital rubella infection should be entertained for any infant born to a mother who had documented or suspected rubella infection at any time during pregnancy (see "Transmission In Utero").<sup>103,109</sup> The diagnosis should also be considered in any infant with evidence of intrauterine growth retardation and other stigmata consistent with congenital infection, regardless of maternal history (see "Clinical Manifestations"). Although such findings are sensitive for clinically apparent disease, they are nonspecific because many of them can be associated with other intrauterine infections, such as cytomegalovirus infection, syphilis, and toxoplasmosis. Many affected infants are asymptomatic. As with maternal rubella, congenital infection must be confirmed by laboratory tests.

In contrast to maternal rubella, attempting to isolate rubella virus in tissue culture is a valuable tool for diagnosing congenital rubella in newborns. The virus is most readily isolated from the posterior pharynx and less consistently so from the conjunctivae, cerebrospinal fluid, or urine.\*\* Virus isolation should be attempted as soon as congenital rubella is suspected clinically because viral excretion wanes during infancy (see Fig. 28-2). In older children in whom virus shedding has ceased from other sites, virus may be isolated from cataractous lens tissue.<sup>387</sup> In children with encephalitis, virus may persist in the cerebrospinal fluid for several years.<sup>360-362,361,362,486</sup>
