Respiratory diphtheria has been well controlled in the United States since the introduction of diphtheria toxoid in the 1920s, although it remained endemic in some states through the 1970s.<sup>30</sup> The results of a survey of cases of diphtheria reported to the Centers for Disease Control [and Prevention] (CDC) of the U.S. Public Health Service, Atlanta, Georgia, for the period 1971 to October 1975 showed that no cases involved children younger than 1 month of age and that only six cases occurred in children younger than 1 year of age (the youngest was 5 months old) (G Filice, personal communication, 1981). During the period 1980 through 1995, 41 cases of respiratory diphtheria were reported to the CDC; 4 (10%) were fatal, all of which occurred in unvaccinated children.<sup>31</sup> Importation of diphtheria from countries where diphtheria remains endemic, including areas of the world experiencing a resurgence of disease such as in the former Soviet Union, account for a majority of the cases in industrialized nations.<sup>32</sup> Reemergence of diphtheria in these newly independent states of the former Soviet Union underscores the need to maintain control measures in the United States, including universal childhood immunization, adult boosters, and maintenance of surveillance activities.<sup>33</sup> Maternal immunization may provide some protection to infants in the neonatal period before diphtheria vaccine is given.<sup>34</sup>

The newborn receives antibodies to *Corynebacterium diphtheriae* from the mother if she is immune, and the titers of mother and child at birth are approximately equivalent.<sup>35</sup> Protection of some degree results in the neonate from this passively transferred antibody. Serologic surveys performed in the United States in the 1970s and 1980s suggested that 20% to 60% of adults older than 20 years of age may be susceptible to diphtheria.<sup>36,37</sup> Additional data from Europe confirmed that many adults remain susceptible to diphtheria.<sup>38,39</sup> As is the case in general with passively transferred immunity, protection depends on the level of maternal antibody at the time of the infant’s birth, and protection decreases during the months after birth unless the infant is immunized.<sup>40,41</sup>

Neonatal diphtheria usually is localized to the nares. Diphtheria of the fauces is less common. The skin and mucous membranes may be affected; the two infants in Los Angeles included an 8-day-old neonate with diphtheritic conjunctivitis.<sup>28</sup> Because isolation of *C. diphtheriae* requires inoculation of special culture media, notification of the

laboratory about the possibility of diphtheria is important. Specimens of both nasal and pharyngeal secretions may improve yield of positive cultures.<sup>42</sup> Infants with suspected diphtheria should be isolated and receive penicillin or erythromycin to eradicate the organism from the respiratory tract or other foci of infection to terminate toxin production and decrease likelihood of transmission. The mainstay of therapy, however, is diphtheria antitoxin, which should be administered as soon as the diagnosis of diphtheria is considered. This product is available in the United States from the CDC.<sup>43</sup>

## Pertussis

Infants and young children in the United States are at the highest risk for pertussis and its complications.<sup>44</sup> Although the incidence of pertussis has declined markedly since 1934, when more than 250,000 cases were recorded, resurgence of disease since the early 1980s underscores the need for continued awareness of this disease.<sup>45</sup> There were 29,134 cases of pertussis in the US in the years 1997 to 2000; 29% occurred in infants younger than 1 year of age, representing an 11% increase from surveillance data for 1994 to 1996.<sup>46</sup> The number of deaths in infants younger than 4 months of age increased from 49 (64% of deaths from pertussis) in 1980 to 1989 to 84 (82% of deaths) in 1990 to 1999.<sup>47</sup> There were 17 deaths due to pertussis in the United States in 2000; in all cases, onset of symptoms was before 4 months of age.<sup>48</sup>

Pertussis occurs in exposed and unprotected newborns.<sup>49</sup> Between 1959 and 1977, pertussis was diagnosed in 400 children in Dallas hospitals; 69 patients (17%) were younger than 12 weeks of age. An adult in the household with undiagnosed mild disease was the usual source of infection for these neonates and young infants.<sup>50</sup> A report of a nursery outbreak in Cincinnati highlights the persistent threat of pertussis in the young infant and in hospital personnel.<sup>51</sup> Between February and May 1974, pertussis developed in six newborns, eight physicians, and five nurses (documented by isolation of *Bordetella pertussis* from the nasopharynx). Four additional infants had clinical illness, but the organism was not isolated from the upper respiratory tract. Two mothers of uninfected infants became ill. The initial case was that of a 1-month-old infant managed in a ward whose infection spread to the nursery when house officers became infected and transmitted the organism to other newborns.

In the United States in the early 1990s, cases of pertussis were reported from every state, and large outbreaks occurred in Cincinnati and Chicago.<sup>52</sup> In the Chicago outbreak, the highest attack rate was in infants younger than 6 months of age; factors associated with transmission of pertussis in this age group included young maternal age and cough lasting 7 days or longer in their mothers.<sup>53</sup> Another risk factor for pertussis may be low birth weight. A study of cases of pertussis in Wisconsin infants and young children concluded that children of low birth weight were more likely than their normal-birth-weight counterparts to contract pertussis and to be hospitalized with the disease.<sup>54</sup> Fatal pertussis was identified through a pediatric hospital-based active surveillance system in 16 infants in Canada from 1991 to 2001; 15 of 16 infants were 2 months of age or younger. When fatal cases were matched with 32 nonfatal cases by age, date, and geography, pneumonia and leukocytosis were

identified as independent predictors of a fatal outcome in hospitalized infants.<sup>55</sup>

Antibody to *B. pertussis* crosses the placenta, and titers in immune mothers and their newborns are approximately equal.<sup>35,56</sup> If high titers of the passively transferred antibody are present, the antibody is protective for the newborn. This was demonstrated by Cohen and Scadron, who observed protection of 6 months' duration in the offspring of recently immunized women.<sup>56</sup> Three cases of clinical pertussis occurred among six infants who were exposed to infection and whose mothers had not been immunized, whereas no cases occurred among eight similarly exposed infants of immunized mothers. In the group of infants aged 7 to 12 months, there were two cases of clinical pertussis in offspring of immunized and unimmunized mothers, which suggests that passively transferred immunity was no longer present in the infants whose mothers had been immunized during pregnancy. Many women who were vaccinated during infancy have low levels of antibody when they reach childbearing age, and this concentration of antibody may be insufficient to protect offspring if the infants are exposed to pertussis during the first few months of life (before they are immunized). Older children and adults are important sources of infection for infants.<sup>57</sup> These findings suggest that maternal immunization would provide sufficient antibody to protect infants before durable immunity could be provided by infant immunization. In addition, adolescent and adult immunization could reduce the number of individuals able to contract pertussis and infect infants.<sup>58</sup>

Clinical presentation of pertussis in newborns is similar to that in older children but may lack some features typical of disease in older children. The incubation period may vary, ranging from 5 to 10 days. The initial sign usually is mild coughing, which may progress over a period of several days to severe paroxysms with regurgitation and vomiting of food. The characteristic "whoop" may be absent in infants. The clinical picture of the most severely affected infants may be dominated by marked respiratory distress, cyanosis, and apnea, rather than significant cough. Fever is usually absent. Lymphocyte counts are frequently in excess of 30,000/mm<sup>3</sup>. Cockayne described a case of clinical pertussis in a neonate whose mother and brother were infectious at the time of birth.<sup>59</sup> The infant began to cough on the fifth day of life and had a high white blood cell count (36,000/mm<sup>3</sup>), with a majority of lymphocytes. Phillips reported two cases of pertussis in newborns who were infected by an obstetric nurse.<sup>60</sup> The infants began to cough on the eighth and tenth days of life, respectively. Clinical signs of respiratory infection caused by *Chlamydia trachomatis* are similar to those of pertussis (see Chapter 11).

Complications of pertussis in young infants include convulsions, bronchopneumonia, and hemorrhage. Bacterial and viral superinfection may occur. In a study of 182 infants and children younger than age 2 hospitalized with pertussis from 1967 to 1986 in Dallas, apnea and convulsions occurred significantly more frequently in infants younger than 3 months of age; the three deaths all were in 1-month-old infants with secondary bacterial infection.<sup>61</sup> Mortality among infants younger than 3 months is high; in the earlier Dallas series, 5 of 69 infants (7%) with onset of signs at between 2 and 6 weeks died.<sup>50</sup> *B. pertussis* pneumonia may progress rapidly; pulmonary hypertension resulting from difficulty perfusing

the congested lung may result in right-sided heart failure or fatal cardiac arrhythmias.<sup>62</sup> Long-term sequelae of whooping cough in infancy and early childhood were studied by Johnston and co-workers; there was a significant reduction in forced vital capacity in adulthood in persons who had pertussis before age 7 compared with those who did not have pertussis.<sup>63</sup> A case of hemolytic uremic syndrome in a neonate has been reported following pertussis.<sup>64</sup>

Diagnostic methods for pertussis depend on the age of the patient and the duration of cough. In children younger than 11 years of age and older patients with cough lasting less than 14 days, nasopharyngeal specimens should be obtained for bacterial culture using Dacron or calcium alginate swabs. Best results will be obtained if specimens are inoculated at the bedside or taken immediately to the laboratory in appropriate transport media. It is helpful to inform the laboratory of suspicion of pertussis because specialized agar (Regan-Lowe or Bordet-Gengou) is required. The organism is isolated most easily during the catarrhal or early paroxysmal stage of illness and rarely is found after the fourth week of illness. Direct fluorescent antibody testing of nasopharyngeal secretions has low sensitivity and variable specificity and cannot be relied on to diagnose pertussis. Polymerase chain reaction (PCR) assay shows promise as a diagnostic tool,<sup>65,65a</sup> but it is not yet widely available or standardized between laboratories.

Serologic testing is the diagnostic method of choice for patients 11 years of age or older and has excellent sensitivity and specificity when done in an experienced laboratory on paired specimens, the first having been collected as early as possible during the course of illness. No single serologic marker has been identified as diagnostic for pertussis; efforts to standardize serologic studies are under way.

Antimicrobial therapy may lessen severity of the disease if it is given in the catarrhal stage, but it has no clinical effect once paroxysms occur. Antibiotic therapy does eliminate carriage of the organisms from the upper respiratory tract and is of value in limiting communicability of infection, even if given late in the clinical course. The antibiotic of choice for treatment of pertussis is erythromycin estolate, 40 to 50 mg/kg per day orally in four divided doses, with a maximum daily dose of 2 g. Resistance of *B. pertussis* to erythromycin has been reported<sup>66</sup> but does not appear to be widespread. The newer macrolide antibiotics—azithromycin (10 to 12 mg/kg per day orally, in one dose for 5 days; maximum daily dose of 600 mg) and clarithromycin (15 to 20 mg/kg per day orally, in two divided doses, for 7 days; maximum daily dose of 1 g)—may be as effective as erythromycin and have the advantage of fewer side effects and better adherence but are not approved for use in neonates.<sup>66a</sup> Penicillins and first- and second-generation cephalosporins are ineffective against *B. pertussis*. One study demonstrated clinical efficacy in treating pertussis with high-dose specific pertussis globulin from donors immunized with acellular pertussis vaccine,<sup>67</sup> although efficacy of this regimen on a larger scale has not been proved. One investigator has proposed a role for inhaled corticosteroids in the treatment of pertussis.<sup>68</sup> There are no data available to evaluate the role of albuterol or other beta-adrenergic agents in the treatment of pertussis.

Erythromycin also is of value in prevention of pertussis in exposed infants. Granstrom and colleagues described its use

in 28 newborns of mothers with pertussis.<sup>69</sup> The women had serologic or culture-confirmed pertussis at the time of labor. Mothers and their newborns received a 10-day course of erythromycin. The infected and treated mothers were allowed to nurse their infants. None of the infants developed signs or serologic evidence of pertussis. Erythromycin has also been shown to be effective in preventing secondary spread within households in which infants resided.<sup>70</sup>

Erythromycin (40 to 50 mg/kg per day, orally in four doses, maximum 2 g per day) for 14 days is recommended for household<sup>70</sup> and other close contacts, such as those in the hospital, including medical and surgical personnel.<sup>71</sup> Although their efficacies have not been established, clarithromycin, azithromycin, and trimethoprim-sulfamethoxazole may be alternatives for patients who cannot tolerate erythromycin.<sup>71a</sup> Azithromycin (10-12 mg/kg per day orally in one dose for 5 days) or clarithromycin (15-20 mg/kg per day orally in two divided doses for 7 days) may have fewer adverse effects and better compliance than erythromycin for treatment of the infected infant.<sup>71</sup>

Reports of clusters of cases of pyloric stenosis among infants given erythromycin for prophylaxis after exposure to pertussis have raised concern about using erythromycin in this setting.<sup>72,73</sup> A study of 469 infants given erythromycin during the first 3 months of life confirmed an association between systemic (but not ophthalmic) erythromycin and pyloric stenosis and identified that risk was highest in the first 2 weeks of life.<sup>74</sup> Because erythromycin remains the only medication proven effective for this purpose, and pertussis can be life-threatening in the neonate, the drug remains the recommended agent until alternative regimens can be shown to be safe and effective. Health care professionals who prescribe erythromycin to newborns should inform parents of the risk of pyloric stenosis and counsel them about signs and symptoms of pyloric stenosis.

## OTITIS MEDIA

Otitis media in the newborn may be an isolated infection, or it may be associated with sepsis, pneumonia, or meningitis. Acute otitis media is defined as the presence of fluid in the middle ear (middle ear effusion) accompanied by an acute sign of illness. Middle ear effusion may be present without other signs of acute illness. Diagnostic criteria for otitis media in the newborn are the same as in the older child, but the vulnerability of the newborn infant and potential differences in the microbiology of otitis media in the neonate, especially in the first 2 weeks of life, make it necessary to exercise special considerations in choosing antimicrobial therapy.

## Pathogenesis and Pathology

During fetal life, amniotic fluid bathes the entire respiratory tree, including the lungs, paranasal sinuses, and middle ear cleft. Amniotic fluid and cellular debris usually are cleared from the middle ear in most infants within a few days after birth.<sup>75</sup> In term infants, the middle ear usually is well aerated, with normal middle ear pressure and normal tympanic membrane compliance, within the first 24 hours.<sup>76</sup> A study of 68 full-term infants examined by otoscopy, tympanometry, and acoustic reflectometry within the first 3 hours of life

revealed the presence of middle ear effusion in all neonates; fluid was absent at 72 hours of life in almost all infants.<sup>77</sup>

Studies of the middle ear at autopsy provide important information about the development of otitis media in the neonate. Inflammation in the lungs or paranasal sinuses usually was accompanied by inflammation in the middle ear.<sup>75-80</sup> DeSa examined 130 infants, including 36 stillborn infants, 74 neonates who died within 7 days of life, and 20 infants who died between 8 and 28 days. In 56 cases, the middle ear was aerated or contained a small amount of clear fluid. In 55 cases, amniotic debris was present; in 2 additional cases, cellular material was mixed with mucus. A purulent exudate was present in the middle ear of 17 infants; these exudates were cultured, and a bacterial pathogen was isolated from 13. Amniotic material was present in specimens obtained from most of the stillborn infants. Purulent exudate was not seen in the stillborns; the frequency of its presence increased with postnatal age at time of death. Of the 20 infants who lived for 7 or more days, 11 had purulent exudate in the middle ear. Each of the 17 infants with otitis media had one or more significant infections elsewhere; 12 had pneumonia, and 6 had meningitis.<sup>75</sup> The author subsequently identified mucosal metaplasia and chronic inflammation in the middle ears of newborns receiving ventilatory support.<sup>81</sup>

Factors that may affect the development of otitis media in the neonate include the nature of the amniotic fluid, the presence of other infectious processes, the need for resuscitative efforts (especially positive-pressure ventilation), the presence of anatomic defects such as cleft palate, the immunologic status of the infant, and the general state of health of the infant. Aspiration of infected amniotic fluid through the eustachian tube may be one factor in the development of otitis media in the neonate; dysfunction of the eustachian tube, which is shorter, wider, and more horizontal than in the older child,<sup>82</sup> and failure to clear aspirated material from the middle ear probably have etiologic roles as well. Piza and associates<sup>83</sup> speculate that infants born through thick meconium fluid may be at greater risk for otitis media because of the inflammatory nature of this fluid. DeSa noted that many infants in whom otitis media developed had required assistance in respiration and speculated that the pressure of ventilation efforts was responsible for propelling infected material into the middle ear.<sup>75</sup> In infants, as in older children, middle ear effusion appears to be frequent in patients with nasotracheal tubes, and the effusion occurs first on the side of intubation.<sup>84</sup> Berman and colleagues<sup>85</sup> described an association between nasotracheal intubation for more than 7 days and the presence of middle ear effusion.

Infants with cleft palate are at high risk for recurrent otitis media and conductive hearing loss due to the persistence of middle ear effusion. Attempts to reduce the incidence of permanent hearing impairment have included intensive monitoring of children with cleft palate for middle ear effusion and repair of these defects earlier in infancy. One study, however, found that early cleft palate repair did not reduce significantly the subsequent need for ventilating tubes in these children.<sup>86</sup>

Breast-fed infants are at lower risk than bottle-fed infants for acute otitis media. Results of studies of Canadian Eskimo infants<sup>87</sup> and of infants in India,<sup>88</sup> Finland,<sup>89</sup> Denmark,<sup>90</sup> and the United States<sup>91</sup> indicate a significant decrease in the incidence of infection of the middle ear in breast-fed compared

with bottle-fed infants. A study from Cooperstown, New York, identified a significantly lower incidence of acute lower respiratory tract infection in infants who were breast-fed compared with infants who were bottle-fed; the incidence of otitis media was lower in the breast-fed infants, but this difference was not statistically significant.<sup>92</sup> Boston infants who were breast-fed had a lower risk for either having had one or more episodes of acute otitis media or having had recurrent acute otitis media (three or more episodes) during the first year of life. Of interest was the fact that the protective association of breast-feeding did not increase with increased duration of breast-feeding; infants who were breast-fed for 3 months had an incidence of otitis media in the first year of life that was as low as infants who were breast-fed for 12 months.<sup>93</sup>

The beneficial effects of breast-feeding may be due to immunologic factors in breast milk or to development of musculature in the breast-fed infant that may affect eustachian tube function and assist in promoting drainage of middle ear fluid. Alternatively, the findings could indicate harmful effects of bottle-feeding, including the reclining or horizontal position of the bottle-fed infant that allows fluid to move readily into the middle ear,<sup>94,95</sup> allergy to one or more components in cow's milk or formula, or aspiration of fluids into the middle ear during feeding. The hypothesis that breast milk is protective is substantiated by the results of studies of a special feeding bottle for infants with cleft palate. Among infants who were fed by this bottle containing breast milk, the number of days with middle ear effusion was less than in infants fed by this device containing formula, which suggests that protection was more likely to be a quality of the milk rather than of the mode of feeding.<sup>96</sup> Adherence of *S. pneumoniae* and *Haemophilus influenzae* to buccal epithelial cells was inhibited by human breast milk.<sup>97</sup>

Early onset of pneumococcal otitis media has been associated with low levels of cord blood pneumococcal immunoglobulin G (IgG) antibodies. Among a group of infants who had siblings with middle ear disease, low concentrations of cord blood antibody to pneumococcal serotype 14 or 19F were associated with earlier onset of otitis media.<sup>98</sup> Low cord blood antibody concentrations to serotype 19F predicted more episodes of otitis media over the first year of life in a cohort of 415 infants whose mothers enrolled in the study during pregnancy.<sup>99</sup> In these infants, early otitis media was associated significantly with type 14 IgG1 in the lowest quartile, but not with type 19F IgG1 antibody or with either IgG2 antibody.<sup>100</sup> These findings prompted study of maternal immunization to prevent pneumococcal disease in neonates. Immunization of pregnant chinchillas with heptavalent pneumococcal vaccine resulted in reduced incidence and severity of experimental otitis in their infants.<sup>101</sup> Immunization of pregnant women in Bangladesh, the Gambia, and the United States with pneumococcal polysaccharide vaccine resulted in pneumococcal antibody concentrations that were higher at birth in infants of immunized mothers than in controls.<sup>102-104</sup> In addition, pneumococcal IgG antibody acquired by infants of immunized mothers had greater opsonophagocytic activity than that in control infants.<sup>104</sup> A trial is under way to assess the role of maternal pneumococcal immunization in prevention of early infant otitis media.<sup>105</sup>

Antibody to pneumococci in breast milk has been proposed to have a role in prevention of early otitis media.

Early colonization with pneumococci or other bacteria is associated with early otitis media.<sup>106</sup> The role of antibodies to pneumococci in human milk in prevention of nasopharyngeal colonization of infants with pneumococci remains controversial. A study in Sweden involving 448 mother-infant pairs failed to demonstrate reduction in carriage of pneumococci in neonates fed milk with anticapsular and antiphosphorylcholine activity and showed an increase in colonization when infants were fed milk with anti-cell wall polysaccharide antibody activity.<sup>107</sup> Maternal immunization with pneumococcal polysaccharide vaccine resulted in higher breast milk IgA antibodies to serotype 19F, but not type 6B.<sup>102</sup>

## Epidemiology

The incidence of acute otitis media or middle ear effusion in the newborn is uncertain because of the paucity of definitive studies. Warren and Stool examined 127 consecutive infants whose birth weights were less than 2300 g and found 3 with middle ear effusions (at 2, 7, and 26 days of life).<sup>108</sup> Jaffe and co-workers examined 101 Navajo infants within 48 hours of birth and identified 18 with impaired mobility of the tympanic membrane.<sup>109</sup> Berman and co-workers identified effusion in the middle ear of 30% of 125 consecutively examined infants who were admitted to a neonatal intensive care unit (NICU).<sup>85</sup> The clinical diagnosis was corroborated by aspiration of middle ear fluid. The basis for the differences in incidence in the various studies is uncertain, but there may be an association with procedures used in the nurseries.

Acute otitis media is common in early infancy. In the prospective study of Boston children, 9% of children had an episode of middle ear infection by 3 months of age.<sup>93</sup> Age at the time of first episode of acute otitis media appears to be an important predictor for recurrent otitis media.<sup>93,109,110</sup> Children who experience a first episode during the first months of life are more likely to experience repeated infection than children whose first episode occurs after the first birthday. Additional risk factors include parental smoking and low socioeconomic status.<sup>111,112</sup>

Some host factors that also are present in infants with neonatal sepsis have been identified in infants with middle ear infection. The incidence of infection is higher in premature infants than in those delivered at term in some studies,<sup>113,114</sup> but not in the prospective study of Boston children.<sup>93</sup> Male infants are more frequently infected than female infants.<sup>113</sup> Otitis media also is associated with a prolonged interval after rupture of maternal membranes and with other obstetric difficulties.<sup>75,115</sup> Middle ear infection is more severe in Native Americans and Canadian Eskimos than in the general population, and it is likely that this is true in neonates and older infants as well.<sup>87,109</sup> Children with cleft palate have a high incidence of otitis media, which may begin soon after birth.<sup>116</sup> Prenatal, innate, and early environmental exposures were assessed in relation to early otitis media in a cohort of 596 infants followed prospectively from birth. In multivariable analysis, prenatal factors were not associated with early onset of otitis media, but environmental (day care, upper respiratory infection, birth in the fall) and innate factors (parental and sibling history of otitis media) were associated with early and/or recurrent otitis media.<sup>117</sup>

## Microbiology

The bacteriology of otitis media in infants has been studied by investigators in Honolulu,<sup>113</sup> Dallas,<sup>114</sup> Huntsville,<sup>118</sup> Boston,<sup>118</sup> Denver,<sup>85,85a</sup> Milwaukee,<sup>119</sup> Tampere Hospital in Finland,<sup>120</sup> and Beer-Sheva, Israel (see Table 7-1).<sup>121</sup> *S. pneumoniae* and *H. influenzae* are isolated frequently from fluid aspirated from the middle ear in the very young, as is the case in older infants and children. Although it has been suggested that otitis media in the youngest neonates (younger than 2 weeks of age) is caused more frequently by organisms associated with neonatal sepsis, such as group B streptococci, *S. aureus*, and gram-negative enteric bacilli, this pattern does not emerge consistently when multiple studies are examined. Pneumococci were isolated from middle ear fluid in the first 2 weeks of life, and otitis associated with gram-negative enteric organisms and group B streptococci occurred in older infants. Microbiology of middle ear disease in infants who are in neonatal intensive care nurseries may be an exception to the pattern associated with otitis media in previously healthy infants and may reflect pathogens present in the NICU setting. In a small series of 13 such infants, only gram-negative enteric organisms and staphylococcal species were identified in the 10 samples of middle ear fluid from which bacteria were identified.<sup>85</sup> Table 7-1 shows the microbiology of middle ear isolates from 8 studies of otitis media in infants; when possible, data from the youngest neonates have been separated from data from older infants.

Susceptibility patterns of organisms causing otitis media in newborns reflect local patterns. In general, trends toward increasing resistance of pneumococci to antibacterial agents, and colonization and disease due to pneumococcal serotypes not present in the pneumococcal conjugate vaccine used routinely in the United States and other countries, have been observed.

Gram-negative enteric bacilli have been the predominant organisms isolated at autopsy from purulent effusions of the middle ear. Of 17 infants studied by deSa, 7 were found to have *E. coli* and 6 had *P. aeruginosa*.<sup>75</sup> Beta-hemolytic streptococci (not further identified) were isolated from one infant, and no organism was recovered from the remaining three. Because pneumonia and meningitis accompanied the otitis in all of these cases, the predominance of gram-negative pathogens in this series is not unexpected.

Congenital tuberculosis of the ear<sup>122</sup> and of the ear and parotid gland<sup>123</sup> has been reported in preterm infants from Hong Kong and Turkey. Both cases were notable for significant regional lymphadenopathy, lack of response to antibacterial therapy, and presence of active pulmonary tuberculosis in the mother. Authors of both reports suggest that there is continued need for a high index of suspicion for this disease in appropriate circumstances. Otitis media and bacteremia due to *P. aeruginosa* occurring at 19 days of life was thought to occur following inoculation of the organism during a water birth.<sup>124</sup> *B. pertussis* was isolated from middle ear fluid in a 1-month-old infant hospitalized with pertussis; intubation of the child's airway may have facilitated spread of the organism from the nasopharynx to the middle ear.<sup>125</sup>

## Diagnosis

During the first few weeks of life, examination of the ear requires patience and careful appraisal of all of the

structures of the external canal and the middle ear.<sup>126</sup> The diagnostic criteria for acute otitis media in the neonate are the same as those in the older child: presence of fluid in the middle ear accompanied by signs of acute illness. Middle ear effusion and its effect on tympanic membrane mobility are best measured with a pneumatic otoscope. The normal tympanic membrane moves inward with positive pressure and outward with negative pressure. The presence of fluid in the middle ear dampens tympanic membrane mobility.

In the first few days of life, the ear canal is filled with vernix caseosa; this material is readily removed with a small curette or suction tube. The canal walls of the young infant are pliable and tend to expand and collapse with insufflation during pneumatic otoscopy. Continuing pneumatic insufflation as the speculum is advanced is helpful because the positive pressure expands the pliable canal walls. The tympanic membrane often appears thickened and opaque, and mobility may be limited during the first few days of life.<sup>127</sup> In many infants, the membrane is in an extreme oblique position, with the superior aspect proximal to the observer (Fig. 7-1). The tympanic membrane and the superior canal wall may appear to lie almost in the same plane, so it is often difficult to distinguish the point where the canal ends and the pars flaccida of the membrane begins. The inferior canal wall may bulge loosely over the inferior position of the tympanic membrane and move with positive pressure, simulating movement of the tympanic membrane. The examiner must distinguish between the movement of the canal walls and the movement of the membrane. The following considerations are helpful in recognition of these structures: Vessels are seen within the tympanic membrane but are less apparent in the skin of the ear canal; and the tympanic membrane moves during crying or respiration when the middle ear is aerated. The ear canals of most neonates permit entry of only a 2-mm-diameter speculum. Because the entire eardrum cannot be examined at one time, owing to the small diameter of the speculum, quadrants must be examined sequentially. By 1 month of age, the infant's tympanic membrane has assumed an oblique position that is less marked than in the first few weeks of life and is similar to the position in the older child.

Tympanometry is of limited value in diagnosis of middle ear effusion in the neonate. The flat tympanogram indicative of effusion in children 6 months of age or older often is not present in the younger infant, even when fluid is documented by aspiration.<sup>128</sup> Acoustic reflectometry may be advantageous compared with tympanometry in the neonate because it does not require insertion into the ear canal or the achievement of a seal within the canal, but there are insufficient data to identify sensitivity and specificity.<sup>129</sup>

Culture of the throat or nasopharynx is an imperfect method of identifying the bacterial pathogens responsible for otitis media. Many studies have demonstrated the diagnostic value of needle aspiration of middle ear effusions (tympanocentesis) in acute otitis media. The specific microbiologic diagnosis defines the appropriate antimicrobial therapy and is sufficiently important in the sick neonate to warrant consideration of aspiration of the middle ear fluid. Aspiration of middle ear fluid is more difficult in the neonate than in the older child, and usually the assistance of an otolaryngologist (using an otoscope with a surgical head or an otomicroscope) is required.

Table 7-1 Microbiology of Otitis Media in Newborn Infants

Author(s)	Site (year[s])	Patients		Causative Organism: No. of Cases (%)						Comment
		Age Range	No. in Series	<i>S. pneumoniae</i>	<i>H. influenzae</i>	Staphylococcal Species	Enteric Gram-Negative Species	Other

<sup>a</sup>In some infants, more than one organism was identified, or cultures of middle ear fluid yielded no growth.

<sup>b</sup>Nonpathogen in this study.

<sup>c</sup>Includes group A and group B streptococci, *Staphylococcus* species, *Neisseria* species, diphtheroids, and hemolytic streptococci.

*H. influenzae*, *Haemophilus influenzae*; NA, not applicable; NICU, neonatal intensive care unit; *S. pneumoniae*, *Streptococcus pneumoniae*.

**Figure 7-1** Lateral section of the middle ear and otoscopic view of the tympanic membrane in the neonate and older infant and child. (Courtesy of Charles D. Bluestone, MD.)

When spontaneous perforation has occurred, the fluid exuding into the external canal from the middle ear is contaminated by the microflora from the canal. Appropriate cultures may be obtained by carefully cleaning the canal with 70% alcohol and obtaining cultures from the area of perforation as the fluid emerges or by needle aspiration through the intact membrane.

### Treatment

Initial therapy for febrile or ill-appearing infants with otitis media during the first 2 weeks of life is similar to that for children with neonatal sepsis. Both a penicillin and an aminoglycoside or third-generation cephalosporin should be used. Specific therapy can be provided if needle aspiration is performed and the pathogen is identified. Infants who remain in the nursery because of prematurity, low birth weight, or illness require similar management during the first 4 to 6 weeks of life. If the infant was born at term, had a normal delivery and course in the nursery, has been in good health since discharge from the nursery, is not ill-appearing, and is 2 weeks of age or older, the middle ear infection probably is due to *S. pneumoniae* or *H. influenzae* and may be treated with an appropriate oral antimicrobial agent such as amoxicillin or amoxicillin-clavulanate.<sup>130</sup> The infant may be managed outside the hospital if he or she does not appear to have a toxic condition. For infants born at term who have acute otitis media and are in a toxic condition, the physician must consider hospitalization, cultures of blood and cerebrospinal fluid, and use of parenterally administered antimicrobial agents because of possible systemic infection, a focus of infection elsewhere, or presence of a resistant organism.

### Prognosis

Infants who have infections of the middle ear in the neonatal period appear to be susceptible to recurrent episodes of

otitis media.<sup>93,109,110</sup> The earlier in life the child has an episode of otitis media, the more likely the child is to have recurrent infections. It is uncertain whether this means that an early episode of otitis media damages the mucosa of the middle ear and makes the child more prone to subsequent infection, or whether early infection merely identifies children with dysfunction of the eustachian tube or subtle or undefined immune system abnormalities who have a propensity to infection of the middle ear because of these abnormalities.

### MASTOIDITIS

The mastoid air cells are not developed at birth and usually consist of only a single space each. Therefore, mastoiditis rarely occurs in the neonate. One report, however, cited a case of meningitis and mastoiditis caused by *H. influenzae* in a newborn.<sup>131</sup> Roentgenograms of the mastoid area demonstrated a cloudy right antrum. At operation, the middle ear was normal but the antrum was filled with infected mesenchymal tissue.

### PNEUMONIA

Pneumonia, inflammation of the lungs, in the fetus and newborn can be classified into four categories according to the time and mode of acquisition of inflammation:

1. *Congenital pneumonia acquired by the transplacental route:* The pneumonia is one component of generalized congenital disease.
2. *Intrauterine pneumonia:* This is an inflammatory disease of the lungs found at autopsy in stillborn or live-born infants who die within the first few days of life, usually associated with fetal asphyxia or intra-uterine infection and thus includes infectious and noninfectious causes.
3. *Pneumonia acquired during birth:* The signs of pneumonia occur within the first few days of life, and infection is due to microorganisms that colonize the maternal birth canal.
4. *Pneumonia acquired after birth:* The illness manifests itself during the first month of life, either in the nursery or at home; sources of infection include human contacts and contaminated equipment.

Although helpful as a general framework for understanding neonatal pneumonia, these four categories have clinical features and pathologic characteristics that overlap. Thus, management of pneumonia is essentially the same for all four categories, requiring aggressive supportive measures for the respiratory and circulatory systems along with treatment for the specific underlying infectious disorder.

Pneumonia in the neonate may be caused by viruses, bacteria, or parasitic organisms. Detailed information about causative organisms mentioned in this chapter other than bacteria is found in the appropriate chapters in this book; bacterial disease is covered in detail here.

Pneumonia acquired by the transplacental route may be caused by rubella, cytomegalovirus, herpes simplex virus, adenoviruses,<sup>132</sup> mumps virus,<sup>133</sup> *Toxoplasma gondii*, *L. monocytogenes*, or *T. pallidum*. Some of these organisms

and the enteroviruses, genital mycoplasmas, *C. trachomatis*, and *Mycobacterium tuberculosis* are also responsible for intrauterine pneumonia resulting from aspiration of infected amniotic fluid. Fatal pneumonitis due to echovirus has also been reported in newborns (see Chapter 24).<sup>134</sup> Isolation of *Trichomonas vaginalis* from the tracheal aspirates of infants with pneumonia suggests a possible association of this organism with respiratory tract disease in the neonate.<sup>135,136</sup>

Group B streptococci constitute the most frequent cause of bacterial pneumonia acquired at delivery. Pneumonia due to group B streptococci and to other bacteria such as *E. coli* or *L. monocytogenes* may resemble hyaline membrane disease.

Pneumonias acquired after birth, either in the nursery or at home, include those caused by respiratory viruses such as respiratory syncytial virus, influenza virus, or adenoviruses; gram-positive bacteria such as pneumococci and *S. aureus*; gram-negative enteric bacilli; *C. trachomatis*; *Mycoplasma*; and *Pneumocystis carinii*.<sup>137</sup> Pneumonia caused by non-bacterial microorganisms is discussed in the appropriate chapters. Bacterial pneumonia and neonatal sepsis acquired during or soon after birth share many features of pathogenesis, epidemiology, and management, and these aspects are discussed in Chapter 6. This section consists of a discussion of pneumonia in the fetus and newborn not presented elsewhere in the text.

## Pathogenesis and Pathology

### **Congenital or Intrauterine Pneumonia**

Histologic features of congenital or intrauterine pneumonia have been described from autopsy findings in infants who are stillborn or who die shortly after birth (usually within 24 hours). An inflammatory reaction is found in histologic sections of lung. Polymorphonuclear leukocytes are present in the alveoli and often are mixed with vernix and squamous cells. Infiltrates of round cells may be present in interstitial tissue of small bronchioles and interalveolar septa.<sup>138-143</sup> Alveolar macrophages may be present and have been associated with both duration of postnatal life and inflammatory pulmonary lesions.<sup>144</sup> The inflammation is diffuse and usually is uniform throughout the lung. Bacteria are seen infrequently, and cultures for bacteria are often negative. Davies and Aherne<sup>141</sup> noted that the usual characteristics of bacterial pneumonia are missing in congenital pneumonia; among these characteristics are pleural reaction, infiltration or destruction of bronchopulmonary tissue, and fibrinous exudate in the alveoli.

The pathogenesis of congenital pneumonia is not well understood.<sup>145</sup> Asphyxia and intrauterine infection, acting alone or together, appear to be the most important factors.<sup>141</sup> It is thought that microorganisms of the birth canal contaminate the amniotic fluid by ascending infection after early rupture of maternal membranes or through minimal and often unrecognized defects in the membranes. Evidence of aspiration of amniotic fluid is frequent.<sup>141</sup> Naeye and colleagues proposed that microbial invasion of the fetal membranes and aspiration of infected amniotic fluid constitute a frequent cause of chorioamnionitis and congenital pneumonia.<sup>146-148</sup> Bacteriologic studies, however, have given equivocal results. Many infants with congenital pneumonia do not have bacteria in their lungs, yet cultures

of the lung of some infants without pneumonia do yield bacteria.<sup>149</sup> Fetal asphyxia or hypoxia appears to be a factor in most cases of congenital pneumonia. The asphyxia may cause death directly or by eliciting a pulmonary response consisting of hemorrhage, edema, and inflammatory cells. From his studies of congenital pneumonia, Barter concluded that hypoxia or infection may produce similar inflammation in the lungs.<sup>150</sup> In addition, Bernstein and Wang found that evidence of fetal asphyxia was frequently present at autopsy in infants with congenital pneumonia who also had generalized petechial hemorrhage, subarachnoid and intracerebral hemorrhage, liver cell necrosis, or ulceration of the gastrointestinal mucosa.<sup>151</sup>

Although it is likely that asphyxia and infection can produce similar inflammatory patterns in lungs of the fetus, available information is insufficient to determine which is more important or more frequent. In a review of fetal and perinatal pneumonia, Finland concluded that "pulmonary lesions certainly play a major role in the deaths of the stillborn and of infants in the early neonatal period. Infection, on the other hand, appears to play only a minor role in what has been called 'congenital pneumonia,' that is, the inflammatory lesion seen in the stillborn or in those dying within the first few hours, or possibly the first day or two; it assumes greater importance in pneumonias that cause death later in the neonatal period."<sup>152</sup> Davies noted that the histologic presentation of congenital pneumonia appears to represent aspiration of materials in amniotic fluid, including maternal leukocytes and amniotic debris, rather than infection originating in the pulmonary airspaces. Evidence of infiltration of alveoli or destruction of bronchopulmonary tissue is rarely present.<sup>153</sup>

### **Pneumonia Acquired during the Birth Process and in the First Month of Life**

The pathology of pneumonia acquired during or after birth is similar to that in older children or adults. The lung contains areas of densely cellular exudate with vascular congestion, hemorrhage, and pulmonary necrosis.<sup>141,151,154</sup> Bacteria often are seen in sections of the lung. *S. aureus* (see Chapter 17) and *Klebsiella pneumoniae*<sup>155,156</sup> may produce extensive tissue damage, microabscesses, and empyema. Pneumatocoles are a common manifestation of staphylococcal pneumonia but also may occur in infections with *K. pneumoniae*<sup>155,156</sup> and *E. coli*.<sup>157</sup> Hyaline membranes similar to those seen in respiratory distress syndrome have been observed in the lungs of infants who died with pneumonia caused by group B streptococci. Cocci were present within the membranes, and in some cases, exuberant growth that included masses of organisms was apparent. Although most thoroughly documented in cases of pneumonia caused by group B streptococci, similar membranes have been seen in histologic sections of the lungs of infants who died with pneumonia caused by *H. influenzae* and gram-negative enteric bacilli.<sup>158</sup>

The pathogenesis of pneumonia acquired at or immediately after birth is similar to that of neonatal sepsis and is discussed in Chapter 6. Presumably, aspiration of infected amniotic fluid or secretions of the birth canal are responsible for most cases of pneumonia acquired during delivery. After birth, the infant may become infected through human contact or contaminated equipment. Infants who receive

assisted ventilation are at risk because of the disruption of the normal barriers to infection due to the presence of the endotracheal tube and possible irritation of tissues near the tube. Bacteria or other organisms may invade the damaged tissue, which may result in tracheitis or tracheobronchitis.<sup>159</sup> Ventilator-associated pneumonia may be prevented by reducing bacterial colonization of the aerodigestive tract and decreasing the incidence of aspiration. A recent review highlighted strategies for prevention of pneumonia in patients receiving mechanical ventilation, including nonpharmacologic strategies such as attention to hand washing and standard precautions, positioning of patients, avoiding abdominal distention, avoiding nasal intubation, and maintaining ventilator circuits and suction catheters and tubing, as well as pharmacologic strategies such as appropriate use of antimicrobial agents.<sup>160</sup> Newborns with congenital anomalies such as tracheoesophageal fistula, choanal atresia, and diaphragmatic hernia have an increased risk of developing pneumonia.

Lung abscess and empyema are uncommon in neonates and usually occur as complications of severe pneumonia. Abscesses also may occur as a result of infection of congenital cysts of the lung.

## Microbiology

Most information about the bacteriology of fetal and neonatal pneumonia has been derived from studies done at autopsy of stillborn infants and of infants who die during the first month of life. A study reviewing causes of death of very low birth weight infants concluded, on the basis of histologic studies done at autopsy, that pneumonia was an underrecognized cause of death in these infants.<sup>161</sup> Bacteriologic studies at autopsy of infants with and without pneumonia were reported by Barter and Hudson.<sup>149</sup> The incidence of bacteria in the lungs increased with age in infants dying with and without pneumonia; among those infants with pneumonia, bacteria were cultured from the lungs of 55% of stillborn infants and infants who died during the first day of life, 70% of infants who died between 24 hours and 7 days of age, and 100% of infants who died between 7 and 28 days of age. Among those infants without pneumonia, bacteria were cultured from the lungs of 36% of stillborn infants and infants who died within the first 24 hours, 53% of infants who died between 24 hours and 7 days of age, and 75% of infants who died between 7 and 28 days of age. The bacterial species were similar in the infants with and without pneumonia, with the exception of group B streptococci, which was found only in infants with pneumonia.

These results were corroborated by Penner and McInnis: Bacteria were cultured from 92% of the lungs of fetuses and neonates with pneumonia and from 40% of the lungs of fetuses and neonates without pneumonia.<sup>143</sup> Davies did lung punctures in stillborn and live-born infants immediately after death, and bacteria were cultured from the lungs of 74% of 93 infants, although pneumonia was diagnosed in only 9 cases.<sup>162</sup> Barson identified bacteria in lung cultures at autopsy of 252 infants dying with bronchopneumonia; positive cultures were obtained in 60% of infants dying on the first day of life and in 78% of infants dying between 8 and 28 days of age.<sup>163</sup> Thus, bacteria were cultured at

autopsy from the lungs of many infants with and without pneumonia.

Information about bacterial etiology of pneumonia also can be obtained by culturing blood, tracheal aspirates and pleural fluid and by needle aspiration of the lungs of living children with pneumonia.

The bacterial species responsible for fetal and neonatal pneumonia are those present in the maternal birth canal; included in this flora are gram-positive cocci such as group A, group B, and group F<sup>164</sup> streptococci and gram-negative enteric bacilli, predominantly *E. coli* and, to a lesser extent, *Proteus*, *Klebsiella*, and *Enterobacter* species. Microorganisms acquired postnatally may, for those infants who remain hospitalized, reflect the microbial environment of the inpatient setting. For those infants who develop pneumonia in the community, typical organisms causing community-acquired pneumonia predominate. In the 1950s and 1960s, *S. aureus* was a common cause of neonatal pneumonia; this is uncommon now. Few data exist about relative frequency of specific etiologic agents of neonatal pneumonia or incidence of pneumonia due to specific organisms. One review of invasive pneumococcal disease monitored prospectively by the U.S. Pediatric Multicenter Pneumococcal Surveillance Group identified 29 cases of pneumococcal infection in infants younger than 30 days of age among 4428 cases in children; 4 of these were bacteremic pneumonia.<sup>165</sup> In addition to *S. pneumoniae*,<sup>166-168</sup> *H. influenzae*<sup>158,169</sup> and *Moraxella catarrhalis*<sup>170</sup> also are infrequent causes of pneumonia in the newborn. Pneumonia caused by these organisms is frequently associated with bacteremia, and sometimes with meningitis.<sup>141,166,168,169</sup> Many other organisms have been reported in association with pneumonia in neonates, including a fatal case of congenital pneumonia caused by *Pasteurella multocida* in a full-term neonate associated with maternal infection and colonization of the family cat with the same organism.<sup>171</sup> A case of pneumonia and sepsis due to ampicillin-resistant *Morganella morganii* was reported from Texas<sup>172</sup>; the authors speculate about the role of increased use of intrapartum antibiotics in predisposing to colonization and infection with ampicillin-resistant organisms.

Certain bacteria are associated with a predilection for developing lung abscess or empyema. During the 1950s and 1960s, outbreaks of staphylococcal pneumonia occurred; many times these infections were accompanied by empyemas and pneumatoceles. This is now seen infrequently. Although rare in newborns, *H. influenzae* was associated with pneumonia and empyema<sup>173</sup> until its virtual disappearance after initiation of universal immunization in the early 1990s. Single or multiple abscesses may also be caused by group B streptococci, *E. coli*, and *K. pneumoniae*.<sup>174,175</sup> Cavitory lesions may develop in pneumonia due to *Legionella pneumophila*.<sup>176</sup> Lung abscess and meningitis caused by *Citrobacter koseri* was reported recently in a previously healthy 1-month-old infant.<sup>177</sup> Nosocomial infection due to *L. pneumophila* has been reported, including cases of fatal necrotizing pneumonia and cavitory pneumonia.<sup>178</sup> Reports have identified *Citrobacter diversus* as a cause of lung abscess<sup>179</sup> and *Bacillus cereus* as a cause of a necrotizing pneumonia in premature infants.<sup>180</sup>

Empyema can also be associated with extensive pneumonia. Empyema due to *E. coli* and *Klebsiella* has been reported in 6- and 8-day-old infants,<sup>181</sup> and *Serratia marcescens* was isolated from blood, tracheal aspirate, and empyema fluid in

a premature neonate.<sup>182</sup> The past decade was characterized by emergence of increased incidence of invasive disease due to group A streptococci. Cases of pleural empyema due to group A streptococci have been reported from the United Kingdom and Sweden<sup>183,184</sup>; it remains to be seen whether these reports represent isolated cases or are part of a generalized increase in this disease.

## Epidemiology

### INCIDENCE

The incidence of pneumonia at autopsy of stillborn and live-born infants is given in Table 7-2. Pneumonia remains a significant cause of death in the neonatal period,<sup>185</sup> and infection of amniotic fluid leading to pneumonia may be the most common cause of death in extremely premature infants.<sup>186</sup> The definition of pneumonia in the autopsy studies usually was based on the presence of polymorphonuclear leukocytes in the pulmonary alveoli or interstitium or both. The presence or absence of bacteria was not important in the definition of pneumonia. The incidence rates for congenital and neonatal pneumonia at autopsy are similar despite the different times of study (1922 to 1999) and different locations<sup>138-140,142,151,184-189</sup> (with the single exception of a report from Helsinki<sup>154</sup>): 15% to 38% of stillborn infants and 20% to 32% of live-born infants had evidence of pneumonia. The incidence rates for pneumonia were similar in premature and in term infants. Rates of pneumonia derived from epidemiologic studies are scarce. Sinha and colleagues report an attack rate of 0.4 per 100 infants diagnosed during a nursery stay, and 0.03 and 0.01 per 100 infants diagnosed at pediatric office visits and in hospital or emergency department visits, respectively. They

acknowledged a paucity of data with which to compare their rates, which they derived from retrospective review of data from a large health maintenance organization.<sup>190</sup>

### RACE AND SOCIOECONOMIC STATUS

In two studies, black infants had pneumonia at autopsy significantly more often than did white infants. The Collaborative Study of the National Institutes of Health<sup>189</sup> considered the incidence of pneumonia in live-born infants who died within the first 48 hours of life: 27.7% of black infants had evidence of pneumonia, whereas only 11.3% of white infants showed signs of this disease, and this difference was present in every weight group. In New York City, Naeye and co-workers studied 1044 consecutive autopsies of newborn and stillborn infants; black infants had significantly more pneumonia (38%) than did Puerto Rican infants (22%) or white infants (20%).<sup>146</sup> The same study showed that the incidence of pneumonia in the infant was inversely related to the level of household income. Infants from the families with the lowest income had significantly more pneumonia than infants from the families with the highest income. At comparable levels of household income, black infants had a higher incidence of neonatal pneumonia than that seen in Puerto Rican or white infants. These racial and economic differences were not readily explained by the authors or by other investigators.

### EPIDEMIC DISEASE

Pneumonia may be epidemic in a nursery because of a single source of infection, such as a suppurative lesion caused by *S. aureus* in a nursery employee or contamination of a common solution or piece of equipment, usually caused by *Pseudomonas*, *Flavobacterium*, or *S. marcescens*. Infection may also spread by droplet nuclei among infants or between

personnel and infants. Epidemics of respiratory infection related to viruses also have been reported (see Chapters 34 and 35).

#### DEVELOPING COUNTRIES

Pneumonia is a particular threat to neonates in developing countries. A survey of a rural area in central India revealed that the mortality rate for pneumonia in the first 29 days of life was 29 per 1000 live-born children (the rate during the first year was 49.6 per 1000 live-born children).<sup>191</sup> The aerobic bacteria grown from the vagina of rural women were used as a surrogate for likely pathogens of pneumonia in neonates.<sup>192</sup> Vaginal flora included *E. coli* and other gram-negative enteric bacilli and staphylococcal species in expected proportions but a relatively low rate of  $\beta$ -hemolytic streptococci (3.2%). Management of pneumonia cases (those that did not necessitate immediate referral to a hospital) included continued breast-feeding and trimethoprim-sulfamethoxazole. Because of the lack of microbiologic information, syndrome-based management of infectious diseases is encouraged in the developing world. A meta-analysis of this approach found a reduction of pneumonia mortality of 42% in neonates managed in this fashion.<sup>193</sup>

Singhi and Singhi studied the clinical signs of illness in Chandigarh infants younger than 1 month of age with radiologically confirmed pneumonia to determine how to increase accuracy of diagnosis of pneumonia by health care workers.<sup>194</sup> Rural health care workers (most were illiterate) used revised World Health Organization (WHO) criteria for pneumonia in infants, including respiratory rate greater than 60 breaths per minute, presence of severe chest indrawing (retraction), or both.<sup>195</sup> Cough and respiratory rate greater than 50 breaths per minute missed 25% of cases; decreasing the threshold respiratory rate to 40 breaths per minute increased the sensitivity. In the absence of cough, chest retraction and/or respiratory rate greater than 50 breaths per minute had maximum accuracy.

### Clinical Manifestations

Onset of respiratory distress at or soon after birth is characteristic of intrauterine or congenital pneumonia. Before delivery, fetal distress may be evident: The infant may be tachycardic, and the fetal tracing may demonstrate poor beat-to-beat variability or evidence of deep decelerations. Meconium aspiration may have occurred before delivery, suggesting fetal asphyxia and gasping. The infant may have episodes of apnea or may have difficulty establishing regular respiration. In some cases, severe respiratory distress is delayed, but it may be preceded by increasing tachypnea, apneic episodes, and requirement for increasing amounts of oxygen. The infant may have difficulty feeding, temperature instability, and other signs of generalized sepsis, including poor peripheral perfusion, disseminated intravascular coagulation, and lethargy.

Infants who acquire pneumonia during the birth process or postnatally may have signs of systemic illness such as lethargy, anorexia, and fever. Signs of respiratory distress may be present at the onset of the illness or may develop later; these signs include tachypnea, dyspnea, grunting, coughing, flaring of the alae nasi, irregular respirations, cyanosis, intercostal and supraclavicular retractions, rales,

and decreased breath sounds. Severe disease may progress to apnea, shock, and respiratory failure. Signs of pleural effusion or empyema may be present in suppurative pneumonias associated with staphylococcal infections, group A<sup>196</sup> and group B streptococcal infections, and *E. coli* infections.<sup>197</sup>

An outpatient study demonstrated the rarity of pneumonia in infants younger than 60 days of age. Infants with the following characteristics did not have pneumonia: illness in the summer; absence of cough, dyspnea, and respiratory distress (grunting, flaring, retracting); respiratory rate lower than 60 breaths per minute; absence of rales and decreased breath sounds; presence of normal color; and white blood cell count lower than 19,000/mm<sup>3</sup>.<sup>198</sup>

### Diagnosis

#### CLINICAL DIAGNOSIS

A history of premature delivery, prolonged interval between rupture of maternal membranes and delivery, prolonged labor, excessive obstetric manipulation, and presence of foul-smelling amniotic fluid frequently are associated with neonatal infection, including sepsis and pneumonia. The clinical manifestations of pneumonia may be subtle and nonspecific at the onset, and specific signs of respiratory infection may not be evident until late in the course of illness. Most commonly, pneumonia is associated with evidence of respiratory distress, including tachypnea, retractions, flaring of nasal alae, and increasing requirement for oxygen.

#### RADIOLOGIC DIAGNOSIS

A chest roentgenogram is the most helpful tool for making the diagnosis of pneumonia. The roentgenogram of the infant with intrauterine pneumonia, however, may contribute no information or show only the coarse mottling of aspiration. If the radiologic examination is done early in the course of meconium or other aspiration pneumonias, typical radiologic features may not yet have developed. The roentgenogram of the child with pneumonia acquired during or after birth may show streaky densities or confluent opacities. Peribronchial thickening, indicating bronchopneumonia, may be present. Pleural effusion, abscess cavities, and pneumatoceles are frequent in infants with staphylococcal infections but also may occur in pneumonia caused by group A streptococci, *E. coli*,<sup>157</sup> or *K. pneumoniae*.<sup>156</sup> Diffuse pulmonary granularity or air bronchograms similar to that seen in respiratory distress syndrome have been observed in infants with pneumonia related to group B streptococci.<sup>199</sup> Computed tomography with contrast medium enhancement is of benefit in localizing pulmonary lesions such as lung abscess and distinguishing abscess from empyema, pneumatoceles, or bronchopleural fistulas.<sup>175</sup> Ultrasound examination was used to diagnose hydrothorax in utero at 32 weeks of gestation.<sup>200</sup>

Although it is not possible to distinguish bacterial from viral pneumonia on the basis of a chest radiograph alone, several features may help distinguish between the two. Findings that are more characteristic of viral pneumonias include hyperexpansion, atelectasis, parahilar peribronchial infiltrates, and hilar adenopathy, which is associated almost exclusively with adenovirus infection. Alveolar disease, consolidation, air bronchograms, pleural effusions, pneumatoceles,

and necrotizing pneumonias are more characteristic of bacterial processes.<sup>201</sup>

#### MICROBIOLOGIC DIAGNOSIS

Because of the difficulty in accessing material from a suppurative focus in the lower respiratory tree, microbiologic diagnosis of pneumonia is problematic. Although cultures of material obtained from lung aspiration have been shown to yield bacterial pathogens in about one third of a group of seriously ill infants with lung lesions accessible to needle aspiration,<sup>202</sup> this rate of positive results is unlikely to be obtained in an unselected group of infants with pneumonia. Diagnosis may be based on isolating pathogens from other sites. When generalized systemic infection is present, cultures of blood, urine, or cerebrospinal fluid may yield a pathogen. Bacteremia may be identified in about 10% of febrile children with pneumonia.<sup>203</sup> If a pleural effusion is present and the bacterial diagnosis is not yet evident, pleural fluid biopsy and/or culture may be helpful. Bacterial cultures of the throat and nasopharynx are unrevealing or misleading because of the high numbers of respiratory pathogens present.

Tracheal aspiration through a catheter is frequently valuable when performed by direct laryngoscopy, but the aspirate may be contaminated when the catheter is passed through the nose or mouth. Sherman and colleagues performed a careful study of the use of tracheal aspiration in diagnosis of pneumonia in the first 8 hours of life.<sup>204</sup> Tracheal aspirates were obtained from 320 infants with signs of cardiorespiratory disease and abnormalities on the chest radiograph; 25 infants had bacteria present in the smear of the aspirate, and the same organisms were isolated from cultures of 14 of 25 aspirates. Thureen and colleagues found that tracheal aspirate cultures failed to define an infectious cause of deterioration in ventilated infants. Positive tracheal aspirates were found with equal frequency among infants with clinically suspected lower respiratory tract infection and in "well" controls.<sup>205</sup> Tracheal aspirate cultures may provide useful information about potential pathogens in pneumonia or bacteremia but rarely indicate the risk or timing of such complications.<sup>206</sup> Often, surveillance cultures of tracheal aspirate material are used to guide empirical therapy when a new illness develops in an infant with a prolonged course on a ventilator.

Bronchoscopy can provide visual, cytologic, and microbiologic evidence of bacterial pneumonia.<sup>207</sup> Aspiration of pulmonary exudate (lung puncture or "lung tap") can be used to provide direct, immediate, and unequivocal information about the causative agent of pneumonia.<sup>208</sup> This procedure is now performed rarely; most reports of its use in infants and young children precede the introduction of antimicrobial agents.<sup>209,210</sup>

Open lung biopsy has been used to identify the etiology of lung disease in critically ill infants and appears to have been most helpful at a time when corticosteroids for bronchopulmonary dysplasia were withheld if there was concern about pulmonary infection. Cheu and colleagues identified three infections in 17 infants who had open lung biopsies: respiratory syncytial virus in 1 infant and *Ureaplasma urealyticum* in 2 infants.<sup>211</sup> Although the optimal indications for use of corticosteroids in bronchopulmonary dysplasia remain a topic of controversy,<sup>212,212a</sup> generally

corticosteroids are not withheld if indicated because of low likelihood of an infectious process.<sup>212b</sup>

#### HISTOLOGIC AND CYTOLOGIC DIAGNOSIS

The data of Naeye and co-workers indicate that congenital pneumonia or pneumonia acquired during birth is almost always accompanied by chorioamnionitis, although chorioamnionitis may be present in the absence of pneumonia or other neonatal infections.<sup>146</sup> These and other studies<sup>213</sup> suggest that the presence of leukocytes in sections of placental membranes and of umbilical vessels or in Wharton's jelly is valuable in diagnosing fetal and neonatal infections, including pneumonia and sepsis. Other investigators are less certain and believe that the presence of inflammation in the placenta or umbilical cord does not distinguish changes caused by hypoxia from those caused by infection.<sup>150,151</sup>

Culture of material obtained by aspiration of stomach contents usually is not helpful in diagnosing pneumonia because this material is contaminated by the flora of the upper respiratory tract. In addition, infants with pneumonia may have no evidence of the organism in the gastric aspirate.<sup>199,214</sup> There is some evidence, however, that microscopic examination of gastric contents may be useful in defining the presence of an inflammatory process in the lung after the first day of life. Because infants so afflicted are unable to expectorate, they swallow bronchial secretions. During the first few hours of life, inflammatory cells present in the gastric aspirate are of maternal origin; however, after the first day, any polymorphonuclear leukocytes present are those of the infant. Tam and Yeung demonstrated that if more than 75% of the cells in the gastric aspirate obtained from infants after the first day of life were polymorphonuclear leukocytes, pneumonia was usually present.<sup>214</sup> However, a study by Pole and McAllister did not confirm the value of gastric aspirate cytology in the diagnosis of pneumonia.<sup>215</sup>

Primary ciliary dyskinesia is congenital and may manifest in the newborn period as respiratory distress. Infants with situs inversus are at risk for this condition. Consultation with a geneticist may be warranted; a biopsy of nasal epithelium may be needed to identify the characteristic abnormal morphology of cilia of the immotile cilia syndrome.<sup>216-218</sup>

#### IMMUNOLOGIC DIAGNOSIS

Immunologic response to various microorganisms responsible for pneumonia is used extensively as an aid to diagnosis, including infections related to group B streptococci, *S. aureus* (see Chapters 13 and 17) and organisms that cause congenital infection (rubella virus, *T. gondii*, herpes simplex virus, cytomegalovirus, and *T. pallidum*). Giacoia and colleagues prepared antigens from microorganisms isolated from bronchial aspirates and correlated specific antibodies and nonspecific IgM antibody with clinical and radiologic evidence of pneumonia.<sup>219</sup> A significant immune response was identified in approximately one fourth of the patients studied. These data are of interest but remain of uncertain significance because of the difficulty of distinguishing immune response to organisms responsible for lower respiratory tract disease from the response to organisms colonizing the respiratory tree.<sup>220</sup>

Though controversial, testing of blood, urine, and cerebrospinal fluid for antigens to group B streptococci, pneumococci, *H. influenzae*, and *Neisseria meningitidis* may provide helpful information for selected infants with generalized sepsis and pneumonia.<sup>220a</sup> Interpretation of results must take into account possible contamination by organisms colonizing the area around the urethra (in the case of a bag specimen of urine) and possible interference with the test result caused by recent immunization against *H. influenzae* type b or pneumococci or recent infection due to these organisms. Bedside cold agglutination testing may be helpful in the case of *Mycoplasma* infection, but the test has low sensitivity, so a negative result remains undiagnostic. Although PCR testing has provided diagnostic information for many conditions, it does not at present offer any specific advantages in the diagnosis of pneumonia.

### Differential Diagnosis

A variety of noninfectious diseases and conditions may simulate infectious pneumonia. Respiratory distress syndrome (hyaline membrane disease), atelectasis, aspiration pneumonia, pneumothorax or pneumomediastinum, pulmonary edema

and hemorrhage, pleural effusions of the lung (e.g., chylothorax), cystic lung disease, hypoplasia or agenesis, pulmonary infarct, and cystic fibrosis all have some signs and symptoms similar to those of pneumonia. Meconium aspirated into the distal air passages may produce chemical pneumonitis or segmental atelectasis.<sup>221</sup> Multifocal pulmonary infiltrates have been associated with feeding supplements containing medium-chain triglycerides.<sup>222</sup> Infants with immotile cilia syndrome may present within the first 24 hours of life with tachypnea, chest retraction, and rales. Results of prospective epidemiologic studies of neonatal respiratory diseases from Sweden<sup>223</sup> for the period 1976 to 1977 and from Lebanon<sup>224</sup> for the period 1976 to 1984 indicate that infection was second in frequency to hyaline membrane disease in both surveys. Clues to the diagnosis of diseases and conditions producing respiratory distress based on information from the maternal history and signs in the infant were presented in a convenient table by Avery and co-workers (Table 7-3).<sup>225</sup>

Pneumonia may be superimposed on hyaline membrane disease. One survey showed that histologic evidence of pneumonia was present at autopsy in 16% of 1535 infants with hyaline membrane disease.<sup>226</sup> Foote and Stewart

Table 7-3 Clues to Diagnosis of Types of Respiratory Distress

Information from Maternal History	Most Probable Condition in Infant
Peripartum fever	Pneumonia
Foul-smelling amniotic fluid	Pneumonia
Excessive obstetric manipulation at delivery	Pneumonia
Infection	Pneumonia
Premature rupture of membranes	Pneumonia
Prolonged labor	Pneumonia
Prematurity	Hyaline membrane disease
Diabetes	Hyaline membrane disease
Hemorrhage in days before premature delivery	Hyaline membrane disease
Meconium-stained amniotic fluid	Meconium aspiration
Hydramnios	Tracheoesophageal fistula
Excessive medications	Central nervous system depression
Reserpine	Stuffy nose
Traumatic or breech delivery	Central nervous system hemorrhage; phrenic nerve paralysis
Fetal tachycardia or bradycardia	Asphyxia
Prolapsed cord or cord entanglements	Asphyxia
Postmaturity	Aspiration
Amnion fluid loss	Hypoplastic lungs
Signs in the Infant	Most Probable Associated Condition
Single umbilical artery	Congenital anomalies
Other congenital anomalies	Associated cardiopulmonary anomalies
Situs inversus	Kartagener's syndrome
Scaphoid abdomen	Diaphragmatic hernia
Erb's palsy	Phrenic nerve palsy
Inability to breathe with mouth closed	Choanal atresia; stuffy nose
Gasping with little air exchange	Upper airway obstruction
Overdistention of lungs	Aspiration; lobar emphysema or pneumothorax
Shift of apical pulse	Pneumothorax, chylothorax, hypoplastic lung
Fever or rise in body temperature in a constant-temperature environment	Pneumonia
Shrill cry, hypertonia or flaccidity	Central nervous system disorder
Atonia	Trauma, myasthenia, poliomyelitis, amyotonia
Frothy blood from larynx	Pulmonary hemorrhage
Head extended in the absence of neurologic findings	Laryngeal obstruction or vascular rings
Choking after feedings	Tracheoesophageal fistula or pharyngeal incoordination
Plethora	Transient tachypnea

From Avery ME, Fletcher BD, Williams RG. The Lung and Its Disorders in the Newborn Infant. Philadelphia, WB Saunders, 1981.

demonstrated, by chest roentgenography, that pneumonia modifies the reticulogranular pattern of hyaline membrane disease by replacing the air in the alveoli with inflammatory exudate.<sup>227</sup> Therefore, any modification of the radiographic pattern typical of hyaline membrane disease should lead the physician to consider superinfection.

Ablow and colleagues reported that infants with pneumonia caused by group B streptococci who also demonstrated clinical and radiologic signs of respiratory distress syndrome were easier to ventilate than were infants who had hyaline membrane disease with a clinical picture suggestive of respiratory distress syndrome unassociated with infection.<sup>228</sup> These findings are of limited value in identifying infection in individual infants and were not confirmed in a subsequent study by Menke and colleagues.<sup>229</sup>

Pleural fluid, usually limited to the lung fissures, occurs in many infants and may be related to slow resorption of fetal lung fluid, to transient tachypnea of the newborn, or to respiratory distress syndrome of noninfectious etiology. Large collections of fluid in the pleural space may represent bacterial empyema; noninfectious causes include chylothorax, hydrothorax (associated with hydrops fetalis, congestive heart failure, or transient tachypnea), meconium aspiration pneumonitis, or hemothorax related to hemorrhagic disease of the newborn.

The symptoms of cystic fibrosis may begin in early infancy. Thirty percent of patients with newly diagnosed cases seen in a 5-year period at Children's Hospital Medical Center in Boston were younger than 1 year of age.<sup>230</sup> The authors described the histories of four children whose respiratory symptoms began before the infants were 1 month of age. The clinical course of the disease in young infants is characterized by a bronchiolitis-like syndrome with secondary chronic obstructive pulmonary disease and respiratory distress, coughing, wheezing, poor exchange of gases, cyanosis, hypoxia, and failure to thrive.

## Management

Infants with bacterial pneumonia must receive prompt treatment with appropriate antimicrobial agents. Culture of blood and urine may identify a bacterial pathogen, especially in patients with generalized sepsis. Cerebrospinal fluid culture may be helpful if the infant is not too unstable for lumbar puncture. In intubated infants, tracheal aspirate smears may indicate presence of inflammatory cells and cultures may provide information about organisms colonizing the trachea.

Because the microbiology of pneumonia in the newborn is the same as that of sepsis, the guidelines for management discussed in Chapter 6 are applicable. Initial antimicrobial therapy should include a penicillin (penicillin G or ampicillin) or a penicillinase-resistant penicillin (if staphylococcal infection is a possibility) and an aminoglycoside or a third-generation cephalosporin. In situations in which resistant pneumococci or methicillin-resistant *Staphylococcus aureus* may be the cause of the pneumonia, vancomycin may be used for initial therapy until microbiologic data are available. The oxazolidinone antibiotic linezolid, an agent with a unique mechanism of action with activity against gram-positive organisms, has been studied in neonates. Sixty-three neonates with known or suspected resistant gram-positive infections were randomized to receive linezolid or

vancomycin. No difference in efficacy of the two agents was noted, and the authors concluded that linezolid is a safe and effective alternative to vancomycin in treatment of resistant gram-positive infections.<sup>231</sup> Other agents available for treatment of resistant gram-positive pathogens include linezolid, quinupristin-dalfopristin (Synercid), and daptomycin (Cubicin), although data on use of these agents in neonates are unavailable.

Duration of therapy depends on the causative agent: pneumonia caused by gram-negative enteric bacilli or group B streptococci is treated for 10 days; disease caused by *S. aureus* may require 3 to 6 weeks of antimicrobial therapy according to the severity of the pneumonia and the initial response to therapy. Empyema or lung abscesses may also require longer courses of therapy.

When clinical and radiologic signs of hyaline membrane disease are present, infection caused by group B streptococci or gram-negative organisms, including *H. influenzae*, is not readily distinguished from the respiratory distress syndrome of noninfectious etiology. Until techniques are developed that can distinguish infectious from noninfectious causes of respiratory distress syndrome, it is reasonable to treat all infants who present with clinical and radiologic signs of the syndrome. Therapy is instituted for sepsis, as outlined earlier, after appropriate cultures have been taken. If the results of cultures are negative and the clinical course subsequently indicates that the illness was not infectious, the antimicrobial regimen is stopped. Because of concern over respiratory signs as a part of the initial presentation of sepsis and the rapid progression of bacterial pneumonia in the neonate with associated high mortality rate, particularly that due to group B streptococci, early and aggressive therapy is warranted in infants with respiratory distress syndrome.

Antibiotics are only part of the management of the newborn with pneumonia; supportive measures such as maintaining fluid and electrolyte balance, providing oxygen or support of respiration with continuous positive airway pressure, or intubation and ventilation are equally important. Drainage of pleural effusions may be necessary when the accumulation of fluid results in respiratory embarrassment. Single or multiple thoracenteses may be adequate when the volumes of fluid are small. If larger amounts are present, a closed drainage system with a chest tube may be needed. The tube should be removed as soon as its drainage function is completed because delay may result in injury to local tissues, secondary infection, and sinus formation. Empyema and abscess formation are uncommon but serious complications of pneumonia. They may occur in association with pneumonia due to *S. aureus* and are discussed in detail in Chapter 17.

## Prognosis

Available data on the significance of pneumonia during early life have been obtained in large measure from autopsy studies. There is information about the natural course of pneumonia caused by *S. aureus* in infants (see Chapter 17), but few studies of the sequelae of pneumonia caused by other agents exist. Even autopsy studies are equivocal in determining the importance of pneumonia because respiratory disease may have been the cause of death, a contributing factor in death, or incidental to and apart from the main

cause of death.<sup>232,233</sup> Pneumonia was said to be the sole cause of death in about 15% of neonatal deaths studied by Ahvenainen.<sup>154</sup> In the British Perinatal Mortality Study,<sup>234</sup> pulmonary infections were considered to be the cause of death in 5.5% of stillborn infants and those dying in the neonatal period.

Ahvenainen<sup>154</sup> noted that pneumonia often is a fatal complicating factor in infants with certain underlying conditions; these children include those with central nervous system malformations or disease, congenital heart disease, and anomalies of the gastrointestinal tract such as intestinal atresia. Ventilator-associated pneumonia is a known complication of critical illness. A prospective study of premature newborns found ventilator-associated pneumonia to occur frequently and to be significantly associated with death in extremely premature infants who remained in an NICU for more than 30 days.<sup>235</sup>

Presence of pneumonia in the neonatal period has been implicated as a cause of chronic pulmonary disease in infancy and childhood. Pacifico and associates found that isolation of *U. urealyticum* from the respiratory tract of premature low-birth-weight infants in the first 7 days of life was associated with early development of bronchopulmonary dysplasia and severe pulmonary outcome.<sup>236</sup> Brasfield and colleagues studied a group of 205 infants hospitalized with pneumonitis during the first 3 months of life and identified radiographic and pulmonary function abnormalities that persisted for more than a year.<sup>237</sup>

## OSTEOMYELITIS

### Introduction

Osteomyelitis occurring in the first 2 months of life is uncommon. During the worldwide pandemic of staphylococcal disease from the early 1950s to the early 1960s, pediatric centers in Europe,<sup>1-5</sup> Australia,<sup>6</sup> and North America<sup>7-11</sup> reported the infrequent occurrence of neonatal osteomyelitis, accounting for only one or two admissions per year at each institution.

With the introduction of invasive neonatal supportive care and the increased use of diagnostic and therapeutic procedures, there was concern that osteomyelitis and septic arthritis secondary to bacteremia might occur more frequently in the newborn.<sup>12</sup> Yet subsequent experience in Europe,<sup>13-15</sup> Canada,<sup>16,17</sup> and the United States<sup>11,18,19</sup> (JD Nelson, personal communication, 1987) during the decade 1970 to 1979 indicated little or no change in the incidence of this condition. Even in intensive care nurseries, despite an increasing problem with fungal (*Candida*) osteoarthritis,<sup>20-24</sup> the overall rate of occurrence of nosocomial bone and joint infections remained low at 2.6 or fewer per 1000 admissions.<sup>22,25,26</sup> However, infections associated with invasive procedures, such as placement of intravascular catheters, may not appear or be recognized until days or weeks after the perinatal period.<sup>12,22</sup>

Little has been published on the relative incidence of neonatal osteomyelitis during the 1980s and 1990s. An ongoing review of nursery infections at a Kaiser Permanente hospital in southern California revealed only three cases of osteomyelitis among 67,000 consecutive live births between 1963 and 1993, and none occurred in the final years (A Miller, personal communication, 1993). A similar survey performed at two pediatric referral centers in Texas showed no significant variation in the number of annual admissions for this

condition from 1964 to 1986<sup>27</sup> (JD Nelson, personal communication, 1987). Physicians working in intensive care nurseries in Great Britain,<sup>28</sup> France,<sup>29</sup> Spain,<sup>30</sup> and various parts of the United States<sup>31</sup> (J Pomerance [Los Angeles, Calif], JS Bradley [Portland, Or], RT Hall [Kansas City, Mo], WJ Cashore [Providence, RI], personal communications, 1987) observe, on the average, one to three cases of bone or joint infection per 1000 admissions, an incidence almost identical to that noted 15 years ago.<sup>22,25,26</sup>

In a review of more than 300 cases of neonatal osteomyelitis, male infants predominated over females (1.6:1). Premature infants acquire osteomyelitis with relatively greater frequency than has been noted for term infants.<sup>11,13,16,32-41</sup> In a series of patients with osteomyelitis, 17 of 30 proven cases were in premature infants, 4 occurred in term infants receiving intensive care, and *Staphylococcus aureus* was responsible for 23 of the proven cases of osteomyelitis (methicillin-sensitive strains in 16 cases and methicillin-resistant in 7).<sup>42</sup> *Escherichia coli* and group B streptococci caused three and two cases, respectively. Risk factors for osteomyelitis and septic arthritis in premature infants have been mostly iatrogenic and include use of intravenous or intra-arterial catheters, ventilatory support, and bacteremia with nosocomial pathogens.

Although osteomyelitis was rare in the past, some recent series have suggested that its frequency may be increasing in the neonate. The spectrum of bacterial and fungal infections in Finland from 1985 to 1989 was studied in 2836 infections in children.<sup>43</sup> The incidence of osteomyelitis and septic arthritis in children 28 days of age or younger was 67.7 per 100,000 person years, compared with rates of 262.2 and 2013.1 per 100,000 for meningitis and bacteremia, respectively; both pneumonia (80.4 per 100,000) and pyelonephritis (143.8 per 100,000), however, also were more frequent than bone or joint infections. Studies from other countries have also suggested an increase in osteomyelitis; among 241 bone infections in Panamanian children, 9 occurred in neonates (3 cases were due to gram-negative bacilli, 3 cases to *S. aureus*, 1 case to group B streptococci, and 2 to other organisms).<sup>44</sup>

### Microbiology

Because most cases of neonatal osteomyelitis arise as a consequence of bacteremia, it is not surprising that the organisms responsible for causing osteomyelitis reflect the changing trends in the etiology of neonatal sepsis. Before 1940, hemolytic streptococci were the predominant organisms responsible for sepsis in the newborn<sup>45</sup> and also frequently caused osteomyelitis.<sup>46,47</sup> Streptococci were implicated in a majority of the cases of osteomyelitis in neonates and infants younger than 6 months of age.<sup>48</sup>

After 1950, the incidence of *S. aureus* osteomyelitis rose. A review of reports between 1952 and 1972 showed that 85% of the infections were caused by *S. aureus*, 6% were caused by hemolytic streptococci (no groups specified), and 2% were due to *Streptococcus pneumoniae*; either no organisms or miscellaneous organisms (particularly gram-negative bacilli) were isolated in 7% of the cases.<sup>2-6,11,35,38,49-56</sup>

Recognition of group B streptococcal sepsis in the 1970s was associated with a concomitant rise in reported frequency of bone infections caused by this organism.<sup>20,57</sup> This change in spectrum was reflected in U.S. reviews of osteomyelitis in infants hospitalized between 1965 and 1978 showing that group B streptococci had become the single most frequent agent.<sup>11,19,58</sup> However, this experience was not universal: newborn centers in Canada,<sup>16</sup> Sweden,<sup>13</sup> Spain,<sup>30</sup> Switzerland,<sup>14</sup> Nigeria,<sup>59</sup> and even sections of the United States<sup>27</sup> continued to find *S. aureus* as the predominant cause of osteomyelitis, with group B streptococci accounting for only a small number of cases. Although their relative importance may vary by region or institution, these two organisms have remained the most common cause of neonatal osteomyelitis.<sup>31-33,40</sup> A review of cases of occult bacteremia due to group B streptococci identified 147 children.<sup>60</sup> Eleven of these children had non-meningeal foci, including two with septic arthritis and two with osteomyelitis. More recent cases of unusual sites of group B streptococcal osteomyelitis in the iliac wing<sup>61</sup> and the vertebrae<sup>62</sup> emphasize the renewed importance and frequency of this infection.

Osteomyelitis caused by gram-negative enteric bacilli is relatively uncommon despite the frequency of neonatal bacteremia.<sup>32,45,63,64</sup> In Stockholm during 1969 to 1979, *E. coli* and *Klebsiella-Enterobacter* were responsible for about 30% of cases of neonatal septicemia<sup>15</sup> but only 5% of bone infections.<sup>13</sup> *S. aureus*, on the other hand, although also causing about 30% of neonatal bacteremia cases, was responsible for 75% of cases of osteomyelitis. Several other surveys performed within the past 20 years show about 10% of cases of neonatal osteomyelitis to be due to gram-negative enteric bacilli,<sup>11,14,16,27,31,38</sup> although rates as high as 19%<sup>59</sup> and 45%<sup>30,39,40</sup> have been observed. A review of the literature has revealed isolated instances of hematogenous osteomyelitis in newborns caused by *E. coli*,\* *Proteus* species,<sup>13,19,28,53,71-75</sup> *Klebsiella pneumoniae*,<sup>13,30,40,41,70,76-78</sup> *Enterobacter*,<sup>30,72,79,80</sup> *Serratia marcescens*,<sup>19,30</sup> *Pseudomonas* species,<sup>19,30,35,38,40,47,69,82</sup> and *Salmonella*.<sup>16,27,39,81-85</sup>

Presumptively, bacteremia from infected invasive devices is the usual cause of enteric osteomyelitis, infection, but infection may occur directly by translocation from the gut or from urinary tract infection. Studies of neonatal rats have suggested that formula feeding enhances translocation of enteric organisms with subsequent infection of the bone,<sup>86</sup> although other organs were infected as well. Although translocation of bacteria occurred in 23% of breast-fed rats, compared with 100% of formula-fed rats, positive bone cultures developed in 77% of the formula-fed rats, whereas none of the breast-fed rats had positive cultures. A single case of a 4-week-old boy with urinary tract infection with *K. pneumoniae* and vesicoureteral reflux suggests that this site also may be a source of gram-negative enteric bone and joint infections.<sup>87</sup>

Although suppurative arthritis is the most common manifestation of gonococcal sepsis involving the skeletal system,<sup>88</sup> osteomyelitis rarely is associated with sepsis as well and probably represents the site of primary infection in many cases.<sup>38,89,90</sup> Syphilitic osteitis and osteochondritis, although frequent in former years,<sup>91</sup> have been largely eliminated through serologic detection of disease during routine antenatal testing and institution of appropriate therapy for infected mothers. Unfortunately, an increase in the incidence of syphilis among women of childbearing age has been reflected in a parallel increase in the frequency of neonatal syphilis and attendant problems of treponemal bone infection.<sup>92,93</sup>

*Mycoplasma* and *Ureaplasma* have been reported as rare causes of osteomyelitis in infants. In one infant, bone infection due to *Mycoplasma hominis* developed in a sternotomy wound after cardiac surgery<sup>65</sup>; in another, 900-g infant with osteomyelitis of the hip and femur, the infection was caused by *Ureaplasma urealyticum*.<sup>66</sup>

Tuberculous osteomyelitis is extremely rare in the neonate, even in the presence of disseminated congenital tuberculosis.<sup>94,95</sup> Among a group of infants with widespread disease acquired in the perinatal or neonatal period, the youngest with skeletal involvement was 3 months of age.<sup>90</sup>

## Pathogenesis

Complications of pregnancy, labor, or delivery precede the occurrence of neonatal osteomyelitis in one third to one half of patients.<sup>11,13,16,19,30,38-40</sup> In the modern era of the neonatal intensive care unit, it is likely that the great majority of bone and joint infections occur in the small or premature infant as a result of prolonged nosocomial exposures and multiple invasive procedures. Although anoxia (as from placenta previa, breech extraction, or fetal distress) or exposure to microorganisms (from premature rupture of membranes) can explain this association in some cases, the means whereby maternal or obstetric problems influence the likelihood of acquiring bone infection is generally unknown.

Microorganisms may reach the skeletal tissues of the fetus and newborn in one of four ways: (1) by direct inoculation, (2) by extension from infection in surrounding soft tissues, (3) as a consequence of maternal bacteremia with transplacental infection and fetal sepsis, and (4) by blood-borne dissemination in the course of neonatal septicemia. Although hematogenous dissemination is responsible for most cases, examples of other routes of infection have appeared occasionally in the literature. As noted previously (see under "Microbiology"), other factors, such as preceding urinary tract infection or direct translocation of bacteria across the bowel wall, may explain bone or joint infection in some neonates.

Direct inoculation of bacteria resulting in osteomyelitis has followed femoral venipuncture,<sup>36,59,75,96-98</sup> radial artery puncture,<sup>30</sup> use of a fetal scalp monitor,<sup>14,99-102</sup> great toe<sup>88</sup> or heel<sup>14,30,31,104-108</sup> capillary blood sampling,<sup>103</sup> and serial lumbar punctures.<sup>109</sup> Infection after surgical invasion of bony structures (e.g., median sternotomy for cardiac surgery) is uncommon.<sup>110</sup> Nevertheless, trauma has been associated with osteomyelitis of the neonate (an association that has been noted for osteomyelitis in older children); *S. aureus* osteomyelitis has occurred in a neonate at 3 weeks of age at the site of a perinatal fracture of the clavicle.<sup>111</sup>

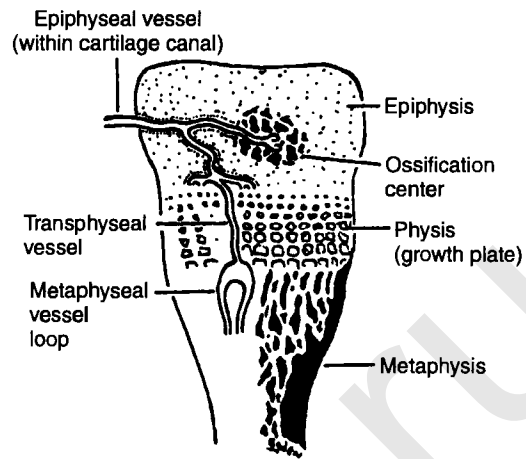

\*See references 2, 8, 11, 13, 14, 19, 30, 34, 38-40, 47, 53, 65-70.

Osteomyelitis caused by extension of infection from surrounding soft tissues usually is associated with organisms from an infected cephalhematoma involving the adjacent parietal bone.<sup>112-115</sup> A series of patients with *S. aureus* osteomyelitis of the skull associated with overlying scalp abscesses was reported nearly 50 years ago.<sup>116</sup> Predisposing factors in these patients were thought to be prolonged, excessive pressure on the fetal head when it lay against the sacral promontory or symphysis pubis, secondary ischemic necrosis, and localization of infection. Paronychia during the newborn period, although most frequently a source of sepsis and hematogenous dissemination of organisms, may extend into bony structures and cause phalangeal infection.<sup>47</sup>

Transplacental bacterial bone infection is most characteristic of syphilis (see Chapter 18). A rare exception, published as a case report in 1933, described a premature infant who died at 19 hours of age with evidence of subacute parietal bone osteomyelitis, meningitis, and cerebritis. Rupture of the amniotic sac immediately before delivery, histopathologic evidence of the prolonged course (at least 2 weeks) of the infection, and the lack of involvement of the overlying scalp epidermis indicate that despite apparent absence of maternal illness, this child was infected transplacentally. The authors postulated that a primary infection occurred in the parietal bone, with secondary extension to the meninges and brain. Although organisms were not isolated, gram-positive diplococci were identified in infected tissues.<sup>117</sup>

Blood-borne dissemination of organisms, with metastatic seeding of the skeletal system through nutrient arteries, represents the major cause of neonatal osteomyelitis.<sup>48,118</sup> Before the advent of antibiotics, the long bones reportedly became infected in as many as 10% of infants with bacteremia.<sup>47,119</sup> Since that time, early recognition and effective empirical therapy for bacterial sepsis led to a marked decrease in the incidence of this complication. Candidal invasion of the bloodstream has become a more frequent cause of bone and joint infections in small infants (see Chapter 33).<sup>20,22,23,33,120,121</sup>

The use of intravascular catheters, mostly central and occasionally peripheral, frequently has been associated with bacterial and fungal osteomyelitis in neonates.\* It is probable that septic embolization occurs from infected catheter-tip thrombi, producing relatively high-grade bacteremias; local hypoxia from partial occlusion of vessels by the catheter may also contribute to bone infections.<sup>123,124</sup> The most common etiologic agent has been *S. aureus*, but other microorganisms, such as *Klebsiella*,<sup>78</sup> *Proteus*,<sup>64</sup> *Enterobacter*,<sup>79,80</sup> and *Candida*,<sup>20,22,72,120</sup> have also been implicated. Because the iliac arteries are the most likely pathway for an arterial embolus originating in an aortic catheter tip, the hips or knees or both are involved in more than three fourths of patients.<sup>11,78,80,123-125</sup> There is a very close correlation between the site of the catheter and localization of osteomyelitis in the ipsilateral leg.<sup>124</sup> The distribution of infection originating in umbilical vein catheters is less predictable.<sup>22,79,120,126-128</sup> Although the incidence of osteoarthritis varies greatly, ranging from 1 in 30<sup>123</sup> to less than 1 in 600<sup>124</sup> infants with umbilical artery catheters, it can be reduced significantly by proper attention to aseptic technique and careful monitoring of catheter placement, combined with prompt catheter removal whenever possible.<sup>124</sup>

**Figure 8-1** Schematic depiction of blood supply in the neonatal epiphysis. Normally in children there are two separate circulatory systems: (1) the metaphyseal loops, derived from the diaphyseal nutrient artery, and (2) the epiphyseal vessels, which course through the epiphyseal cartilage within structures termed *cartilage canals*. In the neonatal period, sinusoidal vessels termed the *transphyseal vessels* connect these two systems. With ensuing skeletal maturation, these vessels disappear, and the epiphyseal and metaphyseal systems become totally separated. (From Ogden JA, Lister G. The pathology of neonatal osteomyelitis. *Pediatrics* 55:474, 1975.)

The disseminating focus of a bacteremia-producing metastatic abscess in bones is often unknown. Common primary sources include an omphalitis,\* pustular dermatitis,<sup>4,11,19,30,33,39,49,53,75</sup> purulent rhinitis,<sup>5,55,132</sup> paronychia,<sup>4,5,37,52,55,75,132</sup> and mastitis.<sup>4,49</sup> In a few infants, sepsis with subsequent osteomyelitis has arisen from infected circumcisions,<sup>8,36</sup> operative sites,<sup>8,31,75</sup> intramuscular injections,<sup>49,75</sup> or varicella lesions.<sup>11</sup> Although gonococcal osteoarthritis originates most commonly from a purulent conjunctivitis, virtually any orifice may provide a portal of entry.<sup>88</sup>

Hematogenous infection of long bones is initiated in dilated capillary loops of the metaphysis, adjacent to the cartilaginous growth plate (physis), where blood flow slows, providing pathogenic bacteria with an ideal environment to multiply, resulting in abscess formation (Fig. 8-1).<sup>118,133,134</sup> Once the infectious process localizes at this site, the following sequence may occur: (1) direct invasion and lysis of the cartilaginous growth plate; (2) spread from metaphyseal vessel loops into transphyseal vessels coursing through the growth plate and into epiphyseal vessels; or (3) rupture occurring laterally, through the cortex into the joint, subperiosteal space, or surrounding soft tissues.<sup>133,134</sup> Green and Shannon,<sup>48</sup> Blanche,<sup>56</sup> and others have pointed out that the large vascular spaces and thin spongy structure of metaphyseal cortex in infants permit early decompression of this primary abscess into the subperiosteal space. For this reason, the bone marrow compartment is seldom involved in neonates, and the term *osteitis* is probably more accurate than *osteomyelitis*.

After rupture into the subperiosteal space, the abscess dissects rapidly beneath loosely attached periosteum, often involving the entire length and circumference of the bone. As pressure increases from accumulating pus, there may be

\*See references 11, 13, 16, 20, 22, 23, 40, 78-80, 120, 122-129.

\*See references 4, 5, 11, 32, 39, 40, 49, 71, 75, 119, 130-132.

decompression through the thin, periosteal tissue into surrounding soft tissues, and a subcutaneous abscess may form. In the absence of surgical intervention, collected pus will “point” and drain spontaneously through the skin, forming a sinus tract. Once adequate decompression and drainage have been established, general supportive care often is sufficient to permit complete healing and resolution of osseous and soft tissue foci of infection.<sup>46,48,135,136</sup> Free communication between the original site of osteomyelitis and the subperiosteal space prevents the necrosis and extensive spread of infection through the bone shaft that occurs frequently in older children and adults. Cortical sequestra are therefore less common in infants, and because of the extreme richness of the newborn bone blood supply, sequestra often are completely absorbed if they do form.<sup>48</sup> In addition, the efficient vasculature and fertility of the inner layer of the periosteum encourage early development of profuse new bone formation (involucrum), permitting remodeling of bone within a very short period of time after the infectious process has been controlled.<sup>48,118</sup>

The same characteristics of neonatal bone that serve to prevent many of the features of chronic osteomyelitis seen in older children are also responsible for complications occurring in neonates and young infants, namely, epiphysitis and pyarthrosis. A consequence of the excellent bone blood supply in newborns is persistent fetal vessels that penetrate the cartilaginous epiphyseal plate and end in large venous lakes within the epiphysis.<sup>118,133,134</sup> Thus, localization of organisms at these sites early in the course of osteomyelitis leads to an epiphysitis, with resultant severe damage of the cartilage cells on the epiphyseal side of the growth plate. Once such damage occurs, it is generally irreparable<sup>70,118</sup> and ultimately results in arrest or disorganization of growth at the ends of the bone. By the age of 8 to 18 months, the vascular connections between metaphysis and epiphysis are obliterated, and the cartilaginous growth plate provides a barrier against the spread of infection that persists throughout childhood and adult life.<sup>118,133,134</sup>

Rapid decompression of the primary metaphyseal abscess through the adjacent cortex also permits ready entrance of pus into the articular space of those bones whose metaphyses lie within the articular capsule of the joint. Therefore, suppurative arthritis of the hips, shoulders, elbows, and knees is frequently associated with osteomyelitis of the humerus or femur in infants.\* When the infection originates in the epiphysis, pyarthrosis also may occur by direct extension of the primary abscess through the articular cartilage and into the joint space. Once pus enters the joint, it causes distention of the joint capsule, and the increasing pressure may eventually produce a pathologic dislocation, particularly of the shoulder or hip joint. The lytic action of pyogenic exudate within the joint<sup>140,141</sup> and ischemia produced by the high intra-articular tension often are sufficient to cause dissolution or separation of the entire head of the femur or humerus, both of which are composed almost completely of cartilage during the neonatal period.<sup>3,34,35,142-144</sup> Although serious growth disturbances and deformities may result from septic arthritis at other sites, complete destruction of the joint is rare.

## Clinical Manifestations

Greengard,<sup>145</sup> Thomson and Lewis,<sup>37</sup> and Dennison<sup>3</sup> have described two distinct clinical syndromes that may be associated with suppurative bone involvement in the newborn period: (1) a “benign form,” with little or no evidence of infection (other than local swelling) or disability, related to an osteomyelitis involving one or more skeletal sites, and (2) a “severe form,” with systemic manifestations of sepsis predominating until multiple sites of bone and visceral involvement are noted as manifestations of the infant’s underlying condition. The most likely cause of the benign form of neonatal osteomyelitis is a mild, transient bacteremia that arises at a peripheral site and causes only minimal inflammation and suppuration. The experience of most investigators indicates that this form of illness represents a majority of the cases.\* The few series in which high fever and evidence of sepsis were noted as common presenting signs probably represent instances in which diagnosis was delayed, resulting in more advanced disease at presentation.<sup>2,3,39,49</sup>

Infants with mild illness generally feed well, gain weight, and develop normally. Systemic manifestations are minimal, and the temperature is usually normal or only slightly elevated.<sup>4,14,31,32,56,137,142</sup> Thus, the diagnosis may be missed until 2 to 4 weeks have elapsed, by which time bone destruction may be severe and widespread.<sup>47,54,56,146</sup> Even in intensive care nurseries, where infants are under continuous professional observation, osteomyelitis may be missed for days or weeks. Bone involvement may be discovered during a skeletal survey or a generalized computed tomography (CT) or magnetic resonance imaging (MRI) scan as an unsuspected site or sites of infection in an infant without known bone involvement; osteomyelitis also has been diagnosed as an incidental finding on chest or abdominal radiographs.<sup>16,22,147</sup>

The first signs that may be noted by parents or physicians are diffuse edema and swelling of an extremity or joint, usually without discoloration, accompanied by excessive irritability of the infant. Handling the infant causes increased discomfort, and prolonged episodes of crying may be noted during after a diaper change or other physical manipulations of routine care. Examination reveals diminished spontaneous and reflex movement of the affected extremity, either as a result of pain (pseudoparalysis)<sup>19,31,32,40,74,77,134</sup> or because of weakness caused by an associated neuropathy.<sup>148-151</sup> Pyarthrosis of the hip joint is characterized by maintenance of the hip in a flexed, abducted, and externally rotated (“frog-leg”) position.<sup>148</sup> Because the slightest degree of passive motion of an extremity may cause severe pain and prolonged crying, attempts to elicit a point of maximal bone tenderness are often unsuccessful.

As the suppurative process extends through the metaphyseal cortex into the surrounding subperiosteal and subcutaneous tissues, external signs of inflammation become more intense, and points of maximal swelling, redness, and heat are more readily discernible. In most cases, an inflammatory mass is directly adjacent to the involved metaphysis or joint, although when deeper skeletal structures (e.g., vertebrae or pelvis) are involved, the abscess may point in

\*See references 3, 4, 6, 11, 13, 16, 19, 20, 35, 58, 134, 137-141.

\*See references 4, 6, 11, 13, 14, 16, 19, 31, 32, 38, 40, 51, 56, 135, 136.

distant sites. Thus, three infants have been described in whom vertebral osteomyelitis was not discovered, or even suspected, until after a large retroperitoneal abscess had developed.<sup>6</sup> An abscess arising from the proximal femur, ilium, or hip joint appears usually in the upper thigh, on the buttocks, or in the groin, but occasionally also in the iliac fossa, where it can be palpated through the abdominal wall or rectum.<sup>51</sup> Even when infection is localized in the distal extremities, it is difficult to determine solely on clinical grounds whether the bone or adjacent joint, or both, are involved. Radiologic examinations and diagnostic aspiration of suspected joints are generally necessary to establish a diagnosis.

The striking feature of the benign form of neonatal osteomyelitis is the satisfactory general condition of the infant, despite the intensity of the local process; feeding and weight gain are undisturbed, and there is no evidence of involvement of visceral structures. Although deformity and disability may follow such infections, the fatality rate is exceedingly low, and healing is prompt.

By contrast, signs and symptoms of the severe form of neonatal osteomyelitis are predominantly those of a septic process with prolonged and intense bacteremia. Infants with this condition usually demonstrate failure to thrive, with associated lethargy, refusal or vomiting of feedings, abdominal distention, jaundice, and other signs characteristic of sepsis in the newborn. Infection of the bones and joints may be noted almost simultaneously with onset of septicemia, or it may appear later, despite administration of antibiotics. The clinical evolution of the osteomyelitic process is identical to that in patients with the benign form of the disease. Early localizing signs and symptoms are frequently overshadowed by the systemic manifestations occurring in the infant. Evidence of a suppurative process in the bone may be discovered accidentally in the course of routine radiographic examinations, or it may not be apparent until formation of a local subcutaneous abscess directs attention to the underlying bone. The prognosis for these infants is guarded; death is generally caused by sepsis, with widespread and multiple foci of infection in the nervous system or viscera. The prognosis for the skeletal lesions among survivors is, however, not different from that described for the benign form.

As group B streptococcal infections have become increasingly prevalent, a distinctive clinical picture associated with osteomyelitis has emerged for this agent.<sup>19,31,58,152-156</sup> Most cases are caused by the type III serotype of streptococci and present as a late-onset illness during the third and fourth weeks of life (mean age at diagnosis, 25 days). Predisposing factors commonly seen with osteomyelitis caused by other agents, such as maternal obstetric complications, difficulties in the early neonatal period, use of vascular catheters, or other manipulative procedures, are unusual with group B streptococcal disease. The male preponderance usually identified with neonatal osteomyelitis is reversed, with a 1.5:1 excess of females. In almost 90% of the infants described with this condition, only a single bone has been involved, most commonly the humerus (50%) or femur (33%), affecting the shoulder or knee. In most cases, infants manifest the benign form of osteomyelitis without signs of systemic toxicity or involvement of other organ systems. Nevertheless, most are ill no more than 3 or 4 days before the diagnosis is established. Although affected joints are typically

neither warm nor erythematous, local swelling, tenderness, and diminished movement of the affected extremity are usually severe enough for parents to seek early medical attention.

The distribution of bone involvement reported in the literature is represented in Table 8-1, with 734 infected sites among 485 patients. A single bone was involved in 324 patients and multiple foci in 161 patients (33%).<sup>157,158</sup> Because radiographic or radionuclide skeletal surveys, which often identify unsuspected foci of osteomyelitis,<sup>13,16,22,32,129,147</sup> were generally not performed, the number of infants reported to have infection in multiple sites is probably falsely low. The high incidence of infections of the femur, humerus, and tibia in the neonate has also been noted in adults<sup>159</sup> and older infants and children.<sup>8,10,137,160</sup> The relatively large number of cases of maxillary osteomyelitis is, however, unique to the newborn period; therefore, this entity is discussed separately later on.

The exuberant new bone formation associated with osteomyelitis in the newborn period makes it difficult to determine the original foci of infection when radiographs are obtained late in the clinical course. For this reason, either the site of primary metaphyseal abscess was unspecified, or the infection was referred to as a "panosteitis" in many instances. In the femur, there are an equal distribution of

proximal, distal, and uncertain sites of early infection, whereas localization in the tibia and humerus occurs most often at proximal ends of bones; in the radius, distal osteomyelitis predominates. The major consequence of these patterns of infection is the high incidence of secondary purulent arthritis of the hips, shoulders, knees, and wrists; this secondary arthritis has been noted in virtually every large series of newborns with bone infection.

### Prognosis

From 1920 to 1940, reports of with neonatal osteomyelitis cited mortality rates of up to 40% in neonates and young infants<sup>48</sup> but stressed an overall benign nature of the disease and the good prognosis for life and function if sepsis was not present.<sup>46,48,135,136</sup> The introduction of antimicrobial agents effective against the common infecting organisms was associated with a considerable reduction in mortality rates. For example, only 24 deaths (mortality rate, 4.2%) were reported among approximately 575 newborns with osteomyelitis acquired between 1945 and 1990.\*

The improved survival rate directed greater attention to a high incidence of residual joint deformities following neonatal osteomyelitis, particularly with hip and knee involvement or delayed diagnosis for more than 3 or 4 days.<sup>34-36,38,39,56,70,75,161-163</sup> Destruction or separation of the capital femoral epiphysis may result in serious disturbances of growth, usually combined with a marked coxa vara, valga, or magna; an unstable hip joint; flexion contractures; and abnormalities of gait.<sup>†</sup> Damage to the cartilaginous growth plate in the knees also is often followed by disturbances in longitudinal growth and angulation at the site of infection, leading to genu varum or valgum, restricted motion, and instability of the joint.<sup>11,33,56,70,132,139</sup> Although the consequences of shortening of bone and angular deformities are more serious in lower extremities, analogous growth disturbances may follow osteomyelitis of the humerus, radius, or ulna.<sup>3,14,37,56,70,164</sup> Most of these data have been collected from infants with staphylococcal bone or joint infection, whereas, in contrast, the prognosis for full recovery is excellent after group B streptococcal infection<sup>19,58</sup> (J Pomerance [Los Angeles, Calif], JS Bradley [Portland, Or], RT Hall [Kansas City, Mo], WJ Cashore [Providence, RI], personal communications, 1987).

Although vertebral osteomyelitis in the newborn is unusual, the consequences can be grave. Collapse or complete destruction of one or more vertebral bodies may occur,<sup>13,22,164-168</sup> with severe kyphosis or paralysis caused by spinal cord compression appearing as late complications.<sup>13,164,165</sup> In most cases, vertebral involvement is not recognized until after paraspinal abscesses appear.<sup>6,169-171</sup>

The full clinical consequences of osteomyelitis in the newborn period may not be apparent for months to years. Thus, despite a seemingly favorable outcome, even infants with minor bone or joint involvement should be followed to skeletal maturity to observe for the appearance of late deformity, dysfunction, or growth arrest.<sup>70,75</sup> Early evidence of skeletal destruction frequently requires multiple orthopedic procedures to stabilize a joint or to straighten a limb or

equalize its length with that of the contralateral arm or leg. However, descriptions of late regeneration of femoral epiphyses despite severe injury emphasize the remarkable healing potential and unpredictability of this illness.<sup>172-178</sup>

Chronic osteomyelitis and sequestration of necrotic bone have been thought to be uncommon complications both before and after the availability of antibiotic therapy.<sup>6,37,39,48,56,135,136</sup> The apparent rarity of these complications in former years should be questioned, however, because approximately in 10% of infants with osteomyelitis who were studied by several groups of investigators, formation of sequestra occurred, and in many cases, sequestrectomy was required for complete cure.\* A rare complication of neonatal osteomyelitis is osteochondroma (or exostosis) at the distal ulna, following *S. aureus* osteomyelitis.<sup>178</sup>

### Diagnosis

Plain film radiographs remain the most useful means of establishing the diagnosis of neonatal osteomyelitis. Experience with CT and MRI in the evaluation of neonatal disease bone infection is limited. Often, transport of a small or sick neonate to MRI or CT diagnostic centers, and the need for monitoring of an anesthetized infant, preclude their use. Thus, these techniques are diagnostic methods that may be used if plain radiographs, ultrasonography (of joints), and bone scans have not yielded a diagnosis.<sup>179</sup>

The earliest radiographic sign is swelling of soft tissue around the site of primary infection. Although this finding reflects spreading edema and inflammation that occur as pus breaks through metaphyseal cortex, it is nonspecific and serves only to define an area of inflammation. The first distinct evidence of bone involvement appears as small foci of necrosis and rarefaction, most commonly located in the metaphysis adjoining the epiphyseal growth plate. This may be accompanied by capsular distention or widening of the joint space if inflammatory exudate or pus has entered the articular capsule. Unlike older children, in whom radiographic changes are commonly delayed for up to 3 weeks,<sup>10,160</sup> neonates almost always show definite signs of bone destruction after only 7 to 10 days.<sup>5,11,19,38,53,55,124,129,177</sup>

Extension of the suppurative process often produces widespread areas of cortical rarefaction, which, despite their appearance, infrequently result in significant bone sequestration. The presence of pus in the hip and shoulder joints may cause progressive lateral and upward displacement of the head of the femur<sup>32,143,144,180</sup> or humerus through stages of subluxation to pathologic dislocation. The absence in the newborn period of ossification centers, with the exception of those at the distal femur and proximal tibia, makes it very difficult to diagnose neonatal epiphysitis in any area but the knees.<sup>139</sup> For similar reasons, epiphyseal separation or destruction of the head of the femur or humerus is difficult to distinguish radiologically from simple dislocation.<sup>143,144</sup>

In most infants, the reparative phase begins within 2 weeks after onset of infection. The first sign of healing is the formation of a thin layer of subperiosteal bone, which rapidly

\*See references 2, 4-6, 11, 13, 14, 16, 19, 30, 31, 38-40, 54, 56, 74, 129, 132.

†See references 35, 56, 75, 90, 97, 132, 143, 144, 164, 165.

\*See references 2, 5, 16, 50, 51, 74, 116, 139, 176, 177.

enlarges to form a thick involucrum between the raised periosteum and the cortex. Although bone destruction may continue at the same time, necrotic foci are rapidly absorbed and filled in as new bone is deposited. The entire process from the first signs of rarefaction to restoration of the cortical structure may last no longer than 2 months; however, several months usually elapse before minimal deformities disappear and remodeling of the shaft is complete. In some cases, well-circumscribed defects involving the metaphysis and epiphysis may persist for years.<sup>139</sup>

The frequent benefit of utilizing radiologic skeletal surveys in newborns with osteomyelitis should be emphasized, particularly because the occurrence of multiple sites of osteomyelitis is much more common in the neonatal period. Thus, clinically unsuspected sites of infection can be discovered in a significant proportion of infants.<sup>13,16,22,33,129,181</sup> Demonstration of such lesions may provide therapeutic benefits: In one series,<sup>16</sup> four of seven areas of occult infection required aspiration or drainage, whereas in another study,<sup>13</sup> 3 of 17 hip joint infections were discovered on routine radiographs taken because the infant had osteomyelitis elsewhere. Therefore, plain film skeletal surveys for occult bone and joint infection are recommended in any infant with osteomyelitis.

As mentioned, experience with CT and MRI in the diagnosis of neonatal musculoskeletal infection is limited.<sup>182,183</sup> Although both procedures can be helpful adjuncts to clinical diagnosis and conventional radiography, they are slow and require heavy sedation—usually undesirable in a febrile septic infant—to prevent movement artifact and loss of resolution. CT provides good definition of cortical bone and is sensitive for early detection of bone destruction, periosteal reaction, and formation of sequestra. It has been used to particular advantage in diagnosis of osteomyelitis of the skull associated with infected cephalhematoma.<sup>112,113</sup> Plain radiographs of uninfected cephalhematomas can show soft tissue swelling, periosteal elevation, calcification, and even underlying radiolucency caused by bone resorption<sup>184</sup>—findings also consistent with bone infection. In such cases, CT has been able to define foci of bone destruction more accurately, helping confirm the presence of osteomyelitis.

MRI, on the other hand, is of limited value in defining structural changes in cortical bone but provides excellent anatomic detail of muscle and soft tissue, superior to that of any other imaging technique.<sup>185</sup> It is therefore particularly useful in disclosing the early soft tissue edema seen adjacent to areas of bone involvement before the appearance of any osseous changes. It is also helpful in determining the presence of a periosteal abscess and assessing the need for surgical drainage. The major advantage of MRI over CT is the ability to detect inflammatory or destructive intramedullary disease. However, it is of greater advantage in older children and adults than in neonates, because involvement of the marrow compartment is uncommon in neonates.

Both modalities provide excellent spatial resolution and anatomic detail; however, CT is best suited to cross-sectional views, whereas MRI can display anatomy with equal clarity in coronal and sagittal planes, permitting visualization in the plane most advantageous for accurate diagnosis. Absence of ionizing radiation is another distinct advantage of MRI over CT.

In recent years, there has been increasing interest in the use of ultrasonography for the detection of bone infection and joint effusions.<sup>185-189</sup> Diagnosis of osteomyelitis is based on demonstration of periosteal thickening or the presence of abscess formation as indicated by periosteal elevation and separation from bone. The exact role of ultrasonography in diagnosis of neonatal osteoarthritis has continued to be defined. It currently appears most useful as a tool for defining the presence of fluid collections in joints or adjacent to bone and as a guide for needle aspiration or surgical drainage of these collections. The occurrence of false-positive or false-negative examinations, although infrequent, requires that infants with conflicting clinical findings be evaluated further by other techniques. Reports of successful diagnosis of osteomyelitis in neonates with ultrasonography include the diagnosis of rib infection in a 650-g infant with staphylococcal osteomyelitis.<sup>190</sup> Other series have included 2- to 6-week-old infants with osteomyelitis of the costochondral junction and ribs as well.<sup>191,192</sup>

Despite reports emphasizing the reliability of technetium-99m bone imaging in older infants and children,<sup>193</sup> experience with the use of this technique in neonates has been far less favorable.<sup>16,33,40,129,194-198</sup> In one study, among 10 newborns subsequently proved to have osteomyelitis involving 20 sites in all, only 8 of these sites were found to be abnormal or equivocal by technetium scan.<sup>194</sup> Of the 12 sites that were normal by scan at 1 to 33 days (mean, 8 days) after onset of symptoms, 9 showed destructive changes in the corresponding radiograph. The increased radioactivity in areas of inflammatory hyperemia surrounding an osteomyelitic lesion, usually present in the early “blood-pool” images in children,<sup>195</sup> also was not seen, even in those infants with ultimately positive delayed bone scans. Although false-negative bone scans also have been described in older infants,<sup>199,200</sup> the reason for the excessively high incidence among neonates is not known. It has been suggested that the discrepancy is due either to differences in the pathophysiology of neonatal disease or to the inability of earlier gamma cameras to separate the increased activity of the growth plate in the first weeks of life from that of infection.<sup>147,193</sup>

As indicated by clinical studies, use of newer high-resolution cameras combined with electronic magnification may provide greater diagnostic accuracy.<sup>147</sup> However, in these studies, the investigators also used significantly (four- to sixfold) larger doses of technetium, and almost all sites of involvement had radiographically detectable lesions at the time of diagnosis. At present, it appears reasonable to limit the use of technetium radionuclide scans to evaluation of infants with normal or equivocal radiographs in whom there is a strong clinical suspicion of osteomyelitis.

Among older patients, gallium-67 bone imaging has been shown to be of value when results of the technetium scan and appearance on plain films are normal and osteomyelitis is strongly suspected.<sup>200</sup> Studies performed in small infants and neonates have shown similar results.<sup>199,201</sup> Unfortunately, the radiation burden of this isotope is high, and the probability that the results of a scan will, by themselves, influence therapy is low. Thus, the role of gallium bone imaging in the diagnosis of neonatal bone and joint infections is very limited.

Needle aspiration of an inflammatory area may provide a rapid diagnosis.<sup>19,31,38,40</sup> Differentiation of subcutaneous

from subperiosteal infection often is difficult; however, significant accumulations of pus aspirated from a periarticular abscess almost invariably are found to originate in bone rather than in the soft tissues.<sup>2,134</sup> Clinical or radiologic evidence of joint space infection, particularly in the hip and shoulder, requires immediate confirmation by needle aspiration. If no effusion is found and clinical signs persist, aspiration should be repeated within 8 to 12 hours. If there is doubt about whether the joint was actually entered, limited arthrography with small amounts of dye can readily be performed with an aspirating needle.<sup>143,144</sup> Most iodinated contrast materials will not interfere with bacterial growth from aspirated specimens.<sup>202</sup> Inserting a needle into the metaphyseal region or joint up to 24 hours before scanning does not interfere with the scintigraphic detection of osteomyelitis.<sup>196-198</sup>

The total peripheral white blood cell count is of little value in diagnosing neonatal osteomyelitis. In more than 150 cases in which these values were recorded, the median peripheral leukocyte count was approximately 17,000 cells per mm<sup>3</sup> (mean, 20,000; range, 4000 to 75,100). Polymorphonuclear leukocytes usually represented about 60% of the white blood cells counted; frequently, the number of immature forms was higher than normal. Neonates with osteomyelitis usually have a sedimentation rate higher than 20 mm per hour.<sup>11,31,32,58,123,154</sup> Like the leukocyte count, the sedimentation rate is helpful for diagnosis and follow-up evaluation when elevated but cannot be used to rule out osteomyelitis when normal.<sup>11,13,14,203</sup> Alternatively, the C-reactive protein is more useful than the erythrocyte sedimentation rate as an acute-phase reactant in neonate, and most methods for C-reactive protein determination require only 0.1 mL of blood, as opposed to the erythrocyte sedimentation rate, which may require 1 to 2 mL of blood.

## Differential Diagnosis

The early descriptions of pyogenic neonatal osteomyelitis emphasized difficulties in distinguishing the pseudoparalysis and irritability that are characteristic of this condition from the symptoms of congenital syphilis and from true paralysis of congenital poliomyelitis.<sup>204-206</sup> The clinical course and radiologic examinations are generally sufficient to rule out polio; however, the periostitis and metaphyseal bone destruction that accompany congenital syphilis are frequently indistinguishable from bone alterations observed in infants with multicentric pyogenic osteomyelitis (see Chapter 18).<sup>163,164</sup> Similar osseous changes have been noted at birth in infants with congenital tumors or leukemia.<sup>204,207</sup>

Serial radiologic examinations may be necessary to distinguish a superficial cellulitis, subcutaneous abscess, or bursitis<sup>208,209</sup> from a primary bone infection, particularly when these conditions arise in a periarticular location. Similarly, a suppurative arthritis arising in the joint space rather than in the adjacent metaphysis can be defined as such only by determining that no destruction has occurred in bones contiguous to that joint.

The relative lack of any inflammatory sign other than edema is the only clinical feature that helps to differentiate between candidal and bacterial osteomyelitis.<sup>20,22</sup> The former condition has been observed more frequently in recent years, particularly in premature infants, in whom antibiotic therapy,

placement of umbilical catheters, and use of parenteral hyperalimentation, together with immature host defense mechanisms, predispose to candidal infection and dissemination.<sup>20,22-24,34-37,80,120,210,211</sup> The lesions of *Candida albicans* infection typically are seen as well-defined ("punched-out") metaphyseal lucencies on radiographs but are less aggressive in appearance than those of staphylococcal osteitis, and often are surrounded by a slightly sclerotic margin.<sup>20,22,34,37,38,80,211,212</sup> Even when characteristic clinical circumstances and radiographic features are present, the diagnosis in almost all cases rests on identification of the organism by Gram stain or culture.

Several congenital viral lesions have also been associated with bone changes. Lesions caused by congenital rubella, although generally seen in the metaphyseal ends of the long bones, are distinct from those of bacterial osteomyelitis during the early stages of pathogenesis and show no evidence of periosteal reaction during the reparative phase.<sup>213</sup> There is little likelihood of confusion of the radiographic features of bone pathology resulting from congenital cytomegalic inclusion disease,<sup>214,215</sup> or from herpes simplex virus type 2 infections,<sup>216</sup> with those of hematogenous osteomyelitis, particularly when roentgenographic findings are considered in context with the characteristic clinical signs and symptoms of these infections.

A number of noninfectious conditions causing bone destruction or periosteal reaction may be confused with osteomyelitis on clinical and radiographic grounds as well as on the basis of radionuclide scan findings. These conditions include skeletal trauma caused by the birth process or caregiver abuse<sup>147,217-219</sup> or associated with osteogenesis imperfecta; congenital infantile cortical hyperostosis (Caffey's disease)<sup>147,218,220</sup>; congenital bone tumors, metastases, and leukemia<sup>145,205</sup>; extravasation of calcium gluconate at an infusion site<sup>221</sup>; and prostaglandin E<sub>1</sub> infusion.<sup>222</sup> The periosteal bone growth sometimes seen in normal infants, particularly the premature infant, may produce a "double-contour" effect in long bones that appears to be similar to the early involucrum of healing osteomyelitis but is unassociated with evidence of bone destruction and metaphyseal changes and is never progressive.<sup>223</sup>

## Therapy

Successful treatment of osteomyelitis or septic arthritis depends on prompt clinical diagnosis and identification of the infectious agent. Every effort should be made to isolate responsible organism(s) before therapy is initiated. Pus localized in skin, soft tissues, joint, or bone should be aspirated under strict aseptic conditions and sent to the laboratory for Gram stain, culture, and antibiotic susceptibility testing. Blood specimens for culture should be obtained; such cultures may be the only source of the pathogen<sup>16,27,35,38,52,55,224</sup> (JD Nelson, personal communication, 1987). Because osteomyelitis generally is the consequence of a systemic bacteremia, a lumbar puncture should be considered. Any potential source of infection should be examined, including the tip of intravascular catheters.<sup>225</sup> Bacterial antigen testing of urine, blood, or cerebrospinal fluid can occasionally be helpful when direct examination of suppurative material fails to provide an etiologic diagnosis (see Chapter 6). Choice of therapy should be guided by results of Gram stain, culture,

and antibiotic susceptibilities which in most cases should be available within 24 to 48 hours.

When the cause of infection cannot be immediately determined, the initial choice of antimicrobial agents must be based on the presumptive bacteriologic diagnosis. The penicillinase-resistant penicillins (e.g., nafcillin, oxacillin) and vancomycin are active against *S. aureus*, group A and group B streptococci, and *S. pneumoniae*, which together account for more than 90% of cases of osteoarthritis in neonates. Osteomyelitis caused by enteric organisms is sufficiently common to justify additional therapy with an aminoglycoside such as gentamicin, tobramycin, or amikacin or an extended-spectrum agent (cefotaxime). Both methicillin-resistant *S. aureus* (MRSA) and most strains of coagulase-negative staphylococci are increasingly frequent causes of sepsis and other focal infections in neonates. Numerous outbreaks of both nosocomial and community-acquired MRSA infections have been reported. Thus, infants who acquire infection in nurseries where MRSA is prevalent, or where community-acquired MRSA infections have occurred, should be started on vancomycin, rather than a penicillin antibiotic.<sup>129</sup> Alternative antibiotics recently approved and licensed for treatment of MRSA infections in older children and adults, including daptomycin, linezolid, and quinupristin-dalfopristin, have not been fully evaluated or approved for use in neonates in the first 2 months of life.

Once bacterial culture and sensitivity data are available, treatment should be changed to the single safest and most effective drug. If group B streptococcal infection is confirmed, combination therapy with penicillin G (or ampicillin) and gentamicin should be given for 2 to 5 days, after which time penicillin G (or ampicillin) alone is adequate.<sup>226</sup> Standard disk susceptibility tests may falsely indicate sensitivity of MRSA to cephalosporins.<sup>227</sup> Use of  $\beta$ -lactam antibiotics is inappropriate for MRSA infections and vancomycin should be continued for the full course of therapy. It is controversial whether the synergistic addition of an active aminoglycoside (e.g., gentamicin) to a penicillin antibiotic or vancomycin for a limited period of time (e.g., 5 days) enhances the clinical outcomes of infants with neonatal osteomyelitis caused by *S. aureus*.

All antibiotics should be given by the parenteral route, usually intravenously. There is no significant clinical advantage to intravenous over intramuscular administration, but the limited number of injection sites available in the newborn makes the intramuscular route impractical for use during prolonged periods. Intra-articular administration of antibiotics is unnecessary in the treatment of suppurative arthritis because adequate levels of activity have been demonstrated in joint fluid after parenteral doses of most drugs that would be used for therapy.<sup>224</sup> Antibiotic therapy for either osteomyelitis or suppurative arthritis should be continued for at least 4 or 6 weeks after defervescence. Monitoring serum acute-phase proteins (particularly C-reactive protein) has been proposed as a useful way to determine resolution of infection and duration of therapy.<sup>112,228,229</sup>

There are insufficient data on the absorption and efficacy of orally administered antibiotics in the neonate to routinely recommend their use in this age group for treatment of osteoarthritis. Nevertheless, after an initial course of intravenous therapy, newborns have been treated successfully

with oral dicloxacillin,<sup>203,230,231</sup> flucloxacillin,<sup>32</sup> fusidic acid,<sup>32,33</sup> and penicillin V<sup>32,181</sup> for additional periods varying from 14 to 42 days. If sequential parenteral-oral therapy is used, adequacy of antibiotic absorption and efficacy must be closely monitored with regular clinical evaluation and, possibly, serum bactericidal titers against the infecting organism.<sup>181,231,232</sup> It is likely, but unproved in the neonate, that the traditional antibiotics used for hematogenous osteomyelitis in older children (e.g., amoxicillin or cephalexin, in divided doses totally 100 to 150 mg/kg per day) would be tolerated and effective, but these agents should be used only after successful parenteral therapy has been established and only under the supervision of physicians with adequate training.

To overcome the uncertainties of oral absorption while still allowing discharge of the patient from the hospital, home intravenous antibiotic therapy has been advocated as an alternative form of treatment.<sup>235</sup> Although home management for older children and adults is now widely accepted, experience with newborns is still limited; however, with proper family and medical support, it can be a successful alternative to inpatient treatment.

Incision and drainage are indicated whenever there is a significant collection of pus in soft tissues. The need for drilling or "windowing" the cortex to drain intramedullary collections of pus is controversial.<sup>11,13,14,32</sup> There is no evidence, based on controlled studies, that these procedures are of any value in either limiting systemic manifestations or decreasing the extent of bone destruction. Open surgical drainage for relief of intra-articular pressure is, however, a critical measure for preserving the viability of the head of the femur or humerus in infants with suppurative arthritis of hip or shoulder joints.<sup>6,35,35,161</sup> Intermittent needle aspiration with saline irrigation usually is adequate for drainage of other, more readily accessible joints. Lack of improvement after 3 days, rapid reaccumulation of fluid, or loculation of pus and necrotic debris in the joint may indicate the need for open drainage of these joints as well.<sup>234</sup>

The affected extremity should be immobilized until inflammation has subsided and there is radiologic evidence of healing. Prolonged splinting in a brace or cast is necessary when pathologic dislocation of the head of the femur accompanies pyarthrosis of the hip joint. Maintenance of adequate nutrition and fluid requirements is critical in determining the ultimate course of the illness. Before the advent of antibiotics, attention to these factors alone often was adequate to ensure prompt healing of osseous lesions in those infants who survived the initial septic process.<sup>48</sup>

## PRIMARY SEPTIC ARTHRITIS

Although septic arthritis often is a complication of neonatal osteomyelitis, it also can occur in the absence of demonstrable radiologic changes in adjacent bone. Infection usually is the result of synovial implantation of organisms in the course of a septicemia. Infrequently, traumatic inoculation of organisms into the articular capsule may occur as a consequence of femoral venipuncture.<sup>36,59,96-98</sup> As in osteomyelitis, there is a strong association between septic arthritis and placement of an umbilical catheter.<sup>235</sup> Whatever the source of infection, the presence of a concurrent osteomyelitis

**Table 8-2 Organisms Isolated from Blood or Joints of Neonates with Primary Bacterial Arthritis (1972-1986)**

Bacteria	No. of Infants
<i>Staphylococcus aureus</i>	9
Group B streptococci	4
Streptococci, unspecified	2
<i>Staphylococcus epidermidis</i>	1
<i>Haemophilus influenzae</i> type b	
<i>Escherichia coli</i>	
<i>Klebsiella pneumoniae</i>	1
<i>Pseudomonas aeruginosa</i>	1
<i>Neisseria gonorrhoeae</i>	1

Data from JD Nelson, personal communication, 1987; Pittard WB III, Thullen JD, Fanaroff AA. Neonatal septic arthritis. *J Pediatr* 88:621, 1976; and Jackson MA, Nelson JD. Etiology and medical management of acute suppurative bone and joint infections in pediatric patients. *J Pediatr Orthop* 2:313, 1982.

can never be ruled out completely because of the possibility that the original suppurative focus lay in the radiolucent cartilaginous portion of the bone, permitting entry of organisms to the joint by direct extension.

The spectrum of agents responsible for primary septic arthritis is similar to that of organisms causing arthritis secondary to a contiguous osteomyelitis. Bacteria that have been isolated from blood or joints of newborns in two series are listed in Table 8-2.

Signs and symptoms of purulent arthritis are virtually identical to those seen in newborns with osteomyelitis.<sup>236,237</sup> Limitation in use of an extremity progressing to pseudo-paralysis is characteristic of both conditions, and although external signs of inflammation tend to be somewhat more localized to the periarticular area, recognition of this feature is of little diagnostic value in individual cases. Data are insufficient to provide any meaningful comparison between the skeletal distribution of septic arthritis and that of osteomyelitis. However, multiple joint involvement is common to both conditions. In one series of 16 consecutive newborns with pyarthrosis, 22 joints were involved; 4 (25%) infants had multifocal infections<sup>27</sup> (JD Nelson, personal communication, 1987). A migratory polyarthritides, which may precede localization in a single joint by several days, is particularly characteristic of gonococcal arthritis, as is an extremely high frequency of knee and ankle involvement.<sup>88</sup> A series from Malaysia emphasizes the frequency with which septic arthritis occurs within medical settings of newborn intensive care.<sup>238</sup> In this series, the knee, hip, and ankle were involved in 10 cases of septic arthritis, and 9 of the 10 cases were caused by MRSA, demonstrating the frequent occurrence of septic arthritis caused by nosocomial pathogens in premature infants in neonatal intensive care units.

The radiologic features, differential diagnosis, and therapy for septic arthritis are discussed under "Osteomyelitis." Studies of long-term evaluations are rare, precluding an accurate assessment of the prognosis for this condition.

## OSTEOMYELITIS OF THE MAXILLA

Although most series of neonatal osteomyelitis have emphasized clinical features of infections of tubular bones, substantial literature is available concerning neonatal osteomyelitis of the maxilla as a distinct clinical entity. Early reports of neonatal osteomyelitis frequently focused exclusively on this entity, and the specific aspects of infection in the extremities have received serious attention only within the past 50 years. In terms of total numbers, maxillary osteomyelitis is a rare condition (there are fewer than 200 reported cases); yet in several surveys of neonatal bone infections, maxillary involvement was noted in approximately 25% of infants.<sup>3,6,11,48,55,239</sup> The far lower incidence in children<sup>8,10</sup> and adults<sup>159</sup> is probably explained by earlier recognition and treatment of sinusitis in these age groups and by the lack of predisposing factors unique to the newborn.

The causative organism is most frequently *S. aureus*,<sup>240-242</sup> although hemolytic streptococci have been isolated on rare occasions from drainage sites.<sup>242</sup> More than 85% of all maxillary infections in infants occur in the first 3 months of life; the incidence is highest during the second to fourth weeks.<sup>241-244</sup>

In most cases, the predisposing cause remains obscure. Infants with sources of infection, such as skin abscesses or omphalitis, constitute a small minority.<sup>242,243</sup> It has been postulated that there is a relationship between breast abscess in the nursing mother and maxillary osteomyelitis<sup>242,243,245</sup>; however, it is unclear whether the maternal infection is a source or a result of the infant's condition.<sup>246</sup> The pathogenesis of bone infection after colonization of the infant by staphylococci is equally uncertain. In some cases, osteomyelitis is believed to result from extension from a contiguous focus of infection in the maxillary antrum. Alternatively, organisms may be blood-borne, establishing infection in the rich vascular plexus surrounding tooth buds.<sup>244</sup> Although the hematogenous route may be important in certain cases, particularly those involving the premaxilla,<sup>240</sup> this explanation is not compatible with the fact that mandibular osteomyelitis or associated metastatic involvement of other structures is uncommon.<sup>242</sup> Yet another theory is that trauma or abrasion of the gum overlying the first molar is the primary route of introduction of organisms.<sup>243</sup>

The clinical course of maxillary osteomyelitis begins with acute onset of fever and nonspecific systemic symptoms. Shortly thereafter, redness and swelling of the eyelid appear and are frequently accompanied by conjunctivitis with a purulent discharge. Thrombosis of nutrient vessels and increasing edema may cause a proptosis or chemosis of the affected eye. In most infants, an early and diffuse swelling and inflammation of the cheek may localize to form an abscess or draining fistula below the inner or outer canthus of the eye. This is nearly always followed or accompanied by a purulent unilateral nasal discharge that is increased by pressure on the abscess. The alveolar border of the superior maxilla on the affected side is swollen and soft, as is the adjacent hard palate. Within a few days, abscesses and draining fistulas may form in these areas.<sup>247</sup> Sepsis and death are frequent in untreated cases. In most infants, the illness pursues a relatively chronic course characterized by discharge of premature teeth or numerous small sequestra of necrotic bone through multiple palatal and alveolar sinuses that have

formed. The entire course may evolve over several days in severe cases, or it may extend for several weeks in mild or partially treated cases.

Neonatal maxillary osteomyelitis is frequently confused with either orbital cellulitis or dacryocystitis.<sup>13,243,248</sup> The early edema and redness of the cheeks that accompany acute osteomyelitis constitute an important differentiating feature, which is not observed in orbital cellulitis and occurs only as a late sign in infection of the lacrimal sac. Neither of the latter conditions is associated with a unilateral purulent nasal discharge. The early onset, limited area of involvement, and Gram stain characteristic of ophthalmia neonatorum should be sufficient, in most cases, to permit diagnosis of this condition. CT can be helpful in assessing the extent of infection, as well as evaluating for possible complications such as cerebral abscess.<sup>247</sup>

Therapy for maxillary osteomyelitis should be directed toward early adequate drainage of the maxillary empyema and contiguous abscess and should include appropriate parenterally administered antibiotics. Because most infections are due to *S. aureus* and group A streptococci, systemic use of a penicillinase-resistant penicillin (or vancomycin) alone should be sufficient as initial therapy pending the results of bacterial cultures and sensitivity tests. The need for or desirability of instillation of antibiotics into the maxillary antrum is uncertain.

Before the advent of penicillin therapy, the mortality rate for maxillary osteomyelitis was high, ranging from 15% to 75% in various series.<sup>242,243,245,249</sup> Children who survived often had severe facial and dental deformities. Later studies<sup>242,243,249</sup> showed a mortality rate of closer to 5%, although sequelae such as stenosis of the lacrimal duct, ectropion, permanent loss of teeth, malocclusion, and facial hemiatrophy are still seen.<sup>11,241-243</sup> In many instances, these complications could have been prevented through early recognition of the nature of the illness and prompt institution of appropriate therapy.

In 1918, Helmholz recognized the cryptogenic nature and underdiagnosis of urinary tract infection (UTI) in the newborn.<sup>1</sup> His observations still hold true today. There are no specific signs of UTI in the newborn; the clinical presentation can vary, ranging from fever and other signs of septicemia to minimal changes such as alteration in feeding habits or poor gain in weight, or the infant may be without signs. The diagnosis of UTI in the neonate is made only by the examination and culture of a properly obtained specimen of urine.

The reported incidence, clinical manifestations, and prognosis of UTI in neonates have varied significantly. There are at least two reasons for discrepant results obtained in studies of UTI: different criteria have been used to define UTI, and infants with different characteristics have been studied. Before 1960, clean-voided specimens were used almost exclusively for examination and culture of urine. It is now clear that contamination is frequent when this method is used; Schlager and co-workers observed that 16 cultures of urine obtained by bag collection from 98 healthy newborns yielded greater than  $10^4$  colonies per mL of urine, with organisms that were found also on periurethral skin.<sup>2</sup> The only reliable methods for obtaining urine for bacteriologic study are percutaneous aspiration and urethral catheterization of bladder urine.

In the neonate, bacterial infections of the kidney and urinary tract usually are acquired at or after delivery. Fungal infections develop as opportunistic infections complicating a prolonged nursery stay in infants with risk factors such as

prematurity and use of intravascular catheters, parenteral alimentation, and broad-spectrum antibiotics, or after prolonged or intermittent catheterization of the urinary tract.<sup>3</sup> Viral infections, including rubella, herpes simplex, and cytomegalovirus infections, are responsible for in utero infection, although the organisms can be excreted in the urine for months after birth. Bacterial infections of the urinary tract (other than those related to *Neisseria gonorrhoeae*, *Staphylococcus aureus*, and group B streptococci) are reviewed here. For information about infection and disease of the kidney and urinary tract caused by other microorganisms, the reader is referred to the respective chapters on toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis, the mycoplasmas, *Candida*, group B streptococci, gonorrhea, staphylococcal infection, and neonatal diarrhea (*Salmonella*).

## EPIDEMIOLOGY

The incidence of UTI in infants in the first month of life varies, ranging from 0.1% to 1% in all infants,<sup>4-10</sup> and may be as high as 10% in low-birth-weight infants<sup>11</sup> and 12% to 25% in infants of very low birth weight evaluated for sepsis (Table 9-1).<sup>12,13</sup> In contrast with the increased incidence of bacteriuria among females in other age groups, infection of the urinary tract in the first 3 months of life is more frequent in males.<sup>2,4-9,14-16</sup>

Infection of the urinary tract is usually sporadic, but clusters of cases, closely related in time, have been reported from nurseries in Cleveland<sup>17</sup> and Baltimore.<sup>18</sup> A nursery epidemic caused by *Serratia marcescens* was responsible for UTI and balanitis. The outbreak was caused by contamination of a solution applied to the umbilical cord.<sup>19</sup>

Surveys of infants born in U.S. Army medical centers and subsequently hospitalized for UTI indicate that uncircumcised males have more UTIs than those reported in circumcised males in the first month and in months 2 to 12 of life (Table 9-2).<sup>10,20,21</sup> In 1982, Ginsburg and McCracken observed that 95% of 62 infant boys with UTI were uncircumcised.<sup>22</sup> A case-control study performed in 112 infant boys in whom suprapubic aspiration or bladder catheterization had been performed for investigation of acute illness showed that all infants with UTI were uncircumcised, compared with 32% of controls.<sup>23</sup> Infection was associated with anatomic abnormalities in 26% of cases. The records of more than 136,000 boys born in U.S. Army hospitals from 1980 to 1985 were reviewed through the first month of life to compare clinical courses in uncircumcised and circumcised boys.<sup>24</sup> Eighty-eight of 35,929 uncircumcised boys (0.24%) had UTI, 33 had concomitant bacteremia, 3 had meningitis,

Mean age at diagnosis (mo)	3.9	2.7	2.5

<sup>a</sup>Data from Wiswell TE, Smith FR, Bass JW. Decreased incidence of urinary tract infection in circumcised males. *Pediatrics* 75:901, 1985.

<sup>b</sup>Data from Wiswell TE, Roscelli JD. Corroborative evidence for the decreased incidence of urinary tract infections in circumcised male infants. *Pediatrics* 78:96, 1986.

2 had renal failure, and 2 died. Complications followed 0.19% of 100,157 circumcisions (including 20 UTIs), and all were minor except for three episodes of hemorrhage leading to transfusion. Meta-analysis of nine published studies through 1992 yielded an overall 12-fold increased risk of infection in uncircumcised boys.<sup>25</sup>

In 1989, the American Academy of Pediatrics (AAP) rescinded a 1971 position against circumcision, recognizing the relative safety of the procedure and protection against UTI in the first year of life.<sup>26</sup> More recent studies using case-control and cohort design also support an association, although magnitude of risk for uncircumcised males is reduced to three- to sevenfold.<sup>27,28</sup> In 1999, the AAP revised the recommendation, citing that although existing scientific evidence demonstrates potential medical benefits of newborn male circumcision, data are not sufficient to recommend its routine performance.<sup>29</sup> Ritual Jewish circumcision performed on the eighth day of life, when periurethral bacterial colonization has been established, appears to have attendant risk for UTI. An epidemiologic study in Israel revealed excessive UTIs in males only from days 9 to 20 of life (the postcircumcision period).<sup>30</sup> A case-control study identified performance by a nonphysician (mohel) versus a physician as a risk factor for UTI (odds ratio 4.34); the authors postulate technique of hemostasis and duration of the shaft wrapping as responsible factors.<sup>31</sup>

## MICROBIOLOGY

*Escherichia coli* continues to be responsible for the vast majority of community-acquired infections of the urinary tract in infants younger than 3 months of age, accounting for 90% to 93% of approximately 400 cases in reports from 1990 to 1998.<sup>32-34</sup> Many O serotypes of *E. coli* have been associated with these infections. UTI in neonates was associated with a limited number of O:K:H serotypes with P fimbriae, adhesive

**Table 9-3 Pathogens Responsible for Urinary Tract Infections in Neonatal Intensive Care Units**

Organism	Frequency (%) of Isolations of Each Pathogen		
	1969-1978 <sup>a</sup>	1989-1992 <sup>b</sup>	1991-2001 <sup>c</sup>
<i>Escherichia coli</i>	75.3	10.5	13.6
<i>Klebsiella</i> spp.	13.4	10.5	30.0
<i>Enterobacter</i> spp.	1.4	12.3	16.4
<i>Enterococcus</i> spp.	2.1	14.0	5.5
Coagulase-negative staphylococci	1.4	31.6	6.4
<i>Candida</i> spp.	—	12.3	18.2
Other	6.4	8.8	7.2

<sup>a</sup>Data from 139 patients in nurseries and intensive care nurseries from references 4, 5, 7, and 8.

<sup>b</sup>Data from 50 patients in neonatal intensive care units from references 39 and 40.

<sup>c</sup>Data from 110 patients in neonatal intensive care units from references 12, 13, and 42.

capacity, hemolysin production, and serum resistance.<sup>35-37</sup> The serotypes of *E. coli* associated with diarrhea, however, rarely cause UTI. Cultures of urine can be positive in infants with septicemia caused by group B streptococci, but primary infection of the urinary tract without septicemia is rare (see Chapter 13).<sup>16,38</sup> The incidence of neonatal UTI as a complication of intensive care has risen sharply in recent years; intensive care-associated UTI occurs in patients with and without urinary catheters.<sup>3</sup>

Microbiology of today's nosocomial UTI is dramatically different from that observed in the 1970s (Table 9-3), with *E. coli* supplanted by other Enterobacteriaceae genera, *Pseudomonas*, *Enterococcus*, *Candida*, and coagulase-negative staphylococci.<sup>3,12,13,39-42</sup> Multiple pathogens may be present;

Maherzi and colleagues identified more than one bacterial pathogen in 4 of 43 infants with UTI documented by aspiration of bladder urine.<sup>8</sup>

*S. aureus* and *E. coli* have been responsible for localized suppurative disease of the urinary tract in the neonate, including prostatitis, orchitis, and epididymitis.<sup>43-48</sup> Other examples of focal disease in the urinary tract include orchitis caused by *Pseudomonas aeruginosa*<sup>49</sup> and testicular abscess caused by *Salmonella enteritidis*.<sup>50</sup> Blood cultures frequently are positive in affected infants.

Bacteria responsible for infections of the circumcision site are discussed under "Infections of the Skin and Subcutaneous Tissue" in Chapter 10.

## PATHOGENESIS

In older children and adults, most UTIs are thought to occur by the ascending route after introduction of bacteria through the urethral meatus. Less frequently, blood-borne infection of the kidney occurs. In the neonate, it is frequently difficult to know whether UTI was the cause or the result of bacteremia. The predominance of males among infants younger than 3 months of age with UTI contrasts with the predominance of females in all other age groups. This difference may reflect increased risk of UTI in young uncircumcised males, increased prevalence of urinary and renal anomalies in males, transient urodynamic dysfunction, and vesicoureteral reflux (VUR), which predominantly affects male infants,<sup>51</sup> and the occasional UTI that complicates circumcision. Additionally, bacteremia is more frequent in male infants, and it is likely that hematogenous invasion of the kidney can cause UTI in neonates.

Anatomic or physiologic abnormalities of the urinary tract play a role in the development and consequences of infection in some infants. Obstructive uropathy and VUR are the most important. Infection often is the first indication of an abnormality. Infection was the presenting sign in half of 40 infants younger than 2 months of age with anomalies of the kidneys or ureters reported in 1980.<sup>52</sup> Congenital obstruction of the urinary tract was diagnosed in 5 of 80 children with UTI studied in Göteborg<sup>5</sup> and in 2 of 60 children studied in Leeds<sup>53</sup>; important radiologic abnormalities of the urinary tract were identified in 10 of 46 male infants and 3 of 13 female infants younger than 3 months of age from 1972 to 1982 in Christchurch, New Zealand.<sup>54</sup> Increasingly, antenatal ultrasonography identifies fetuses with significant anatomic abnormalities, and early neonatal intervention (with prophylactic use of antibiotics with or without surgery) decreases likelihood of infection.

VUR is identified in many infants with UTI who are examined by radiologic techniques. It is frequently the result of infection but also can be a primary defect predisposing to UTI. VUR is not a prerequisite for upper tract infection (i.e., pyelonephritis); fewer than half of children with pyelonephritis by scintigraphy had VUR in two studies.<sup>55,56</sup> Majd and co-workers found that 23 of 29 (79%) children hospitalized for UTI who were found to have reflux had pyelonephritis by scintigraphy; so did 39 of 65 (60%) of children without reflux.<sup>57</sup> VUR can be a congenital abnormality. Fetal ultrasonography demonstrated that 30 of 107 infants with prenatally diagnosed urinary tract abnormalities

had reflux, which was the only abnormality found postnatally in 10.<sup>58</sup> Gordon and colleagues observed that 16 of 25 infants with dilatation of the fetal urinary tract had reflux, which was of grade 3 to 5 severity in 79%.<sup>59</sup> Thirty-nine urinary tract abnormalities detected prenatally were compared with 46 urinary tract abnormalities found after first UTI in Austrian infants.<sup>60</sup> Obstructive lesions and multicystic dysplastic malformations of the kidneys accounted for 90% of all prenatally diagnosed malformations, and reflux accounted for only 10%. By contrast, reflux accounted for 59% of abnormalities detected after the first UTI. VUR detected prenatally has a male-to-female distribution of 6:1 (unlike VUR detected after UTI, when females predominate<sup>61</sup>), may be determined developmentally by the site of the origin of the ureteral bud from the wolffian duct, and in severe cases can be associated with congenital renal damage consisting of global parenchymal loss (so-called reflux nephropathy).<sup>62</sup> Gunn and colleagues performed ultrasound examinations of 3228 fetuses: No renal tract abnormalities were detected before 28 weeks of gestation.<sup>63</sup> Subsequently, 3856 fetuses were examined by ultrasonography after 28 weeks of gestation. Urinary tract anomalies were identified in 313 fetuses: 15 had major structural abnormalities, all of which were confirmed postnatally. In 298 (7.7%) of the fetuses, dilated renal pelvis with normal bladder was found; a majority of the cases resolved spontaneously, but 40 of the cases were confirmed postnatally to be due to serious abnormalities (usually obstruction or VUR).<sup>64</sup> Preterm infants in whom nosocomial UTI develops have a lower incidence of VUR than that noted in term infants with nosocomial UTI.<sup>65</sup> Isolated mild renal pyelectasis (i.e., less than 10 mm diameter of the collecting duct and without VUR) in fetuses is likely to be transient, unassociated with pathology or risk for UTI.<sup>66,67</sup> Fifty-four percent of such cases had resolved in the first postnatal month in one study, and 85% of the cases of moderate or severe pelviectasis had resolved or improved over the first 2 years of life.<sup>68</sup> In a long-term study performed in the United Kingdom of 425 infants with antenatally detected hydronephrosis, 284 had normal findings on neonatal ultrasound examination; negative predictive value of normal ultrasound findings for subsequent UTI in the first year of life was 99%.<sup>69</sup>

The relative contributions of reflux and infection in causing renal damage are debated, but there is growing consensus that postnatal damage correlates with episodes of infection. Follow-up of 108 cases of VUR diagnosed prenatally showed that when infections were prevented, 42% of cases with VUR grade 4 or greater followed medically resolved, and 16% of the patients improved within 18 months; renal damage did not progress in any case.<sup>62</sup> In another study, patients identified with VUR in early childhood were followed prospectively for an average of 9.5 years.<sup>70</sup> Either elimination of recurring UTIs or surgical correction of reflux prevented development of new renal scars. Four patients with unobstructed high-grade sterile reflux were followed for 6 to 10 years; none developed cortical scars. In a long-term study in Toronto of 260 infants with a diagnosis of prenatal hydronephrosis, 25 also had VUR (grade 3 or higher in 73%), received antibiotic prophylaxis, and did not have surgical correction during 4 years of follow-up. Breakthrough infection occurred in only 4 patients. Improvement was seen in a majority of the children with VUR, and there was no difference in renal

growth in children who had resolved versus unresolved VUR or high-grade versus low-grade VUR.<sup>71</sup>

Bacterial virulence factors are likely to play an important role in the pathogenesis of UTIs. Strains of *E. coli* causing UTI are a selected sample of the fecal flora. Pyelonephritic isolates belong to a restricted number of serotypes, are resistant to the bactericidal effect of serum, attach to uroepithelial cells, and produce hemolysins.<sup>72</sup> Pili on the bacterial cell surface that adhere to specific receptors on epithelial cells may play a role in development of UTI.<sup>35</sup> Data from Stockholm,<sup>35</sup> Dallas,<sup>36</sup> and Copenhagen<sup>37</sup> suggest that some of these features of pyelonephritic strains of *E. coli* can be demonstrated in UTIs in newborns.

The increased rate of UTIs in the uncircumcised male is likely to be associated with periurethral bacterial flora. During the first 6 months of life, uncircumcised males have significantly higher total urethral bacterial colony counts and more frequent isolation and higher colony counts of uropathogenic organisms such as *E. coli*, *Klebsiella-Enterobacter* species, *Proteus*, and *Pseudomonas*.<sup>73</sup> With increasing age, the foreskin is more easily retracted and penile hygiene improves; by 12 months of age, both the excessive periurethral flora and UTIs in uncircumcised males almost disappear.<sup>21,73</sup>

Natural defenses in the urinary tract include antibacterial properties of urine, antiadherence mechanisms, mechanical effects of urinary flow and micturition, presence of phagocytic cells, antibacterial properties of the urinary tract mucosa, and immune mechanisms.<sup>74</sup> There is scant knowledge about these mechanisms in the newborn.

## **PATHOLOGY**

The histologic appearance of acute pyelonephritis in newborns is similar to that in the adult.<sup>75</sup> Polymorphonuclear leukocytes are present in the glomeruli, the tubules, and the interstitial tissues. The renal pelvis can show signs of acute inflammation, with loss of the lining epithelium and necrosis. Focal suppuration can be present in the kidney, prostate, or testis. In disease of longer duration, the interstitial tissue is infiltrated with lymphocytes, plasma cells, and eosinophils. The number of glomeruli may be decreased, and some may be hyalinized. The epithelium of tubules is atrophic, and the lumen is filled with colloid casts. Pericapsular fibrosis is present in some infants. If the child dies within 6 months, there is little scarring or contraction of the kidney. Reversible hydronephrosis and hydroureter are observed manifestations of acute pyelonephritis in the neonate who has no anatomic abnormality or VUR. It is postulated that bacteria and endotoxins inhibit ureteral peristalsis.

Pathologic processes indicative of additional suppurative infections, such as otitis media, pneumonia, and meningitis, also can be seen in infants dying of acute infection of the urinary tract. Hepatocellular damage and bile stasis may be noted in liver sections from jaundiced infants.<sup>76</sup>

## **CLINICAL MANIFESTATIONS**

The signs of UTI in neonates are varied and nonspecific. In general, five patterns are observed: (1) septicemia associated

**Table 9-4 Clinical Manifestations of Urinary Tract Infections in Newborn Infants as Described in Selected Reports<sup>a</sup>**

Clinical Manifestation	% of Infants with Manifestations <sup>b</sup>
Failure to thrive	50
Fever	39
Vomiting	37
Diarrhea	25
Cyanosis	23
Jaundice	18
Irritability or lethargy	17

<sup>a</sup>Data from references 4, 5, 7, and 8.

<sup>b</sup>When sign was not mentioned in report, the number of infants in the report was removed from the denominator used to determine percentage of infants with manifestations.

with early-onset (within the first 5 days of life) or late-onset (after 5 days of age) disease (see Chapter 21); (2) acute onset of fever without apparent source; (3) insidious illness marked by low-grade fever or failure to gain weight; (4) no apparent signs; and (5) localized signs of infection, including balanitis, prostatitis, urethritis, and orchitis.

The most frequent signs of acute UTI are those associated with septicemia or fever, or both (see Chapter 21) (Table 9-4).<sup>4,5,7,8</sup> In infants with less acute infection, the presenting signs include poor weight gain or anorexia. Diarrhea and vomiting are common in these infants but do not appear to be the only factors responsible for failure to thrive. Fever is present in about half of such infants, although it may not be a presenting sign. Lethargy, irritability, seizures, and meningismus (in the absence of purulent meningitis) occur in some infants.<sup>5</sup> Enlargement of the liver and spleen and distention of the abdomen can be present. The kidneys may be enlarged or abnormal in shape or position, and anomalies of the urethra and penis also can occur. Signs associated with renal anomalies (e.g., a single umbilical artery, supernumerary nipples, spina bifida, low-set ears and anorectal abnormalities) are seen in some infants. Jaundice is an important feature of UTI and may be the presenting sign<sup>76-78</sup>; it is frequently sudden in onset and clears rapidly after adequate antimicrobial therapy. Many infants with UTI and jaundice have positive blood cultures.<sup>18,78</sup> Of 306 infants in one study admitted to hospital within 21 days of birth solely because of indirect hyperbilirubinemia (mean peak serum bilirubin level 18.5 mg/dL), 90% were breast-fed and none had a positive culture of urine or blood.<sup>79</sup> In another study, 12 of 160 (7.5%) infants younger than 8 weeks of age evaluated solely for jaundice had UTI confirmed by bladder catheterization. Renal ultrasound was abnormal in 6 of 11 infants. Infection was especially associated with elevated conjugated bilirubin and age of over 8 days.<sup>80</sup> A reported case of severe methemoglobinemia observed in a 3-week-old infant with *E. coli* UTI was postulated to be caused by nitrite-forming bacteria, but concurrent diarrhea, dehydration, and acidosis may have been precipitating factors.<sup>81</sup> Hyperammonemic encephalopathy due to *Proteus* infection in children with urinary tract obstruction or atony also has been described.<sup>82</sup>

UTI without apparent signs of illness also can occur. In some studies, infection detected during screening surveys was more frequent than infection identified after signs of illness<sup>4,6,9,83</sup>; infection was detected in 9 of 14 infants in a screening program in Christchurch<sup>4</sup> and in 8 of 10 premature infants whose UTI was diagnosed in a program in Oklahoma City.<sup>11</sup>

Abscesses of the prostate, testis, or epididymis usually present as signs of septicemia, including fever, vomiting, and diarrhea.<sup>43-50</sup> Local signs of inflammation, including tenderness and swelling over the surface of the infected organ, may be present. Urinary retention occurs in infants with prostatitis.<sup>45,46</sup> Renal abscess is rare in the neonate; at least case report in a neonate (with congenital nephrosis) has been published.<sup>84</sup>

UTI should be considered in the differential diagnosis for unexplained fever in early infancy. UTI was frequent in infants younger than 3 months of age with nonspecific signs of illness brought to the walk-in clinic at the Boston City Hospital; 3 of 9 febrile children (temperatures greater than 38.9°C) and 2 of 20 children with little or no temperature elevation (less than 38.9°C) had UTI.<sup>85</sup> Of 182 infants younger than 3 months of age presenting with fever at the Tripler Army Hospital in Hawaii, UTI was the most frequent bacterial infection; 20 of the infants (including 14 males) had UTI.<sup>86</sup> A 1-year study of children presenting to the emergency department of the Beilenson Hospital in Tel Aviv included 47 infants younger than 1 month of age; 8 of the infants had UTI, and 3 of these 8 also had bacteremia.<sup>87</sup> In Crain and Gershel's prospective study of 442 New York infants younger than 8 weeks of age with temperatures of 38.1°C (100.6°F) or more, 7.5% had UTI.<sup>32</sup> Of similarly aged infants studied by Hoberman and colleagues in Pittsburgh with temperatures of 38.3°C (101°F) or more, 14 of 306 (4.6%) infants had UTI.<sup>88</sup> Of 1298 febrile infants less than 90 days of age evaluated in Salt Lake City because of fever, 8% had serious bacterial infection and UTI accounted for 67% of infections identified.<sup>89</sup> In a study of 3066 infants under 3 months with fever who were evaluated by office-based pediatricians, 75% had laboratory testing performed; UTI was confirmed in 5.4%.<sup>90</sup> Rate of circumcision in the population can effect the rate of UTI. In the New York study, prevalence of UTI in boys (82% of whom were not circumcised) was 12.4%. In the Pittsburgh study, prevalence of UTI in boys (2% of whom were not circumcised) was only 2.9%. In a study of 162 febrile Japanese infants under 8 weeks of age, 22 (13.8%) had UTI; 18 were male, none of whom were circumcised.<sup>91</sup> In a study of 2411 febrile children younger than 24 months of age evaluated in an emergency department in Philadelphia, history of malodorous urine, prior history of UTI, and presence of abdominal tenderness were significantly associated with the diagnosis of UTI; findings, however, were present in less than 10% of infected infants, and only 8% to 13% of infants with findings had UTI confirmed.<sup>34</sup> In a retrospective study of 354 Boston infants younger than 24 months of age with UTI confirmed, irritability and decreased appetite were each reported in half of children; diarrhea, vomiting, lethargy, and congestion in one fourth; and malodorous urine, apparent dysuria, frequency of urination, and abdominal pain in less than 10%.<sup>16</sup>

## DIAGNOSIS

Infection of the urinary tract is defined as the presence of bacteria in urine that was obtained without contamination from the urethra or external genitalia. UTI should be considered in all infants older than 3 days of age who have fever or other signs of septicemia or who have subtle and nonspecific signs of failure to thrive during the first months of life. At present, no clinical finding or simple laboratory test adequately defines the location of infection in the urinary tract of the infant. It is assumed that bacteriuria in the neonate indicates infection throughout the urinary tract (including the kidney).

### Culture of Urine

Suprapubic needle aspiration of bladder urine is the most reliable technique for identifying bacteriuria. Although a negative result from culture of bag-collected urine indicates that the urine is sterile, 12% to 21% of bag-collected specimens yield results that are indeterminate or positive (colony count of 10<sup>4</sup>/mL or greater),<sup>2,32</sup> and positive results must be verified by aspiration of bladder urine or by catheterization. There is infrequently insufficient time for this stepwise approach before institution of therapy. The technique of needle aspiration of the bladder has been used extensively, and the cumulative experience indicates that it is technically simple and safe and that it causes minimal discomfort to the infant.<sup>92,93</sup> Although most infected urine specimens will have bacterial colony counts of 10<sup>5</sup>/mL or greater, any bacterial growth in urine obtained by suprapubic aspiration is believed to be significant.

Morbidity associated with suprapubic aspiration is minimal. Transient gross hematuria has been reported in 0.6% of 654 infants.<sup>93</sup> Gross bleeding that ceased only after cauterization was reported in one case.<sup>94</sup> Perforation of the bowel occurred in two cases, but this complication is avoided if the bladder is defined by palpation or percussion.<sup>95</sup> Hematoma of the anterior wall of the bladder,<sup>96,97</sup> peritonitis,<sup>98</sup> and anaerobic bacteremia<sup>99</sup> also have been reported after suprapubic aspiration. These reports warranted publication because the cases are very uncommon. The possibility of these complications should not deter the physician from using this technique for infants with suggested septicemia. However, suprapubic aspiration should not be performed if the infant has recently voided, has abdominal distention, has poorly defined anomalies of the urinary tract, or has a hematologic abnormality that might result in hemorrhage.

Suprapubic aspiration of bladder urine should be performed at least 1 hour after the patient has voided. The infant should lie supine, with the lower extremities held in a frog-leg position. The suprapubic area is cleansed with iodine and alcohol. A 20-gauge, 1½-inch needle attached to a syringe is used to pierce the abdominal wall and bladder approximately 1 inch above the symphysis pubis. The needle is directed caudally toward the fundus of the bladder, and urine is aspirated gently. Vigorous aspiration should be avoided because the mucosa can be drawn in to block the needle opening. The aspirated urine is sent to the laboratory immediately in a sterile tube. If the child urinates during the procedure, or if it cannot be done properly for other reasons, aspiration should be repeated after 1 to 2 hours. Ultrasound

examination may be useful in detecting the presence of urine in the bladder before suprapubic aspiration<sup>100,101</sup>; with ultrasound-guided aspiration, the success rate for acquisition of an adequate sample of urine improved from 60% to 96.4%.<sup>101</sup>

When it is important to obtain an immediate sample of urine and suprapubic aspiration cannot be performed for technical reasons (lack of experience of the physician, dehydration, or recent voiding), catheterization of the bladder is appropriate. The incidence of infection related to catheterization in infants is unknown. Urine for culture should be transported to the laboratory as soon as possible, but if a delay is unavoidable, the specimen must be refrigerated. Colony counts of  $10^3$ /mL of urine obtained by catheter may represent significant bacteriuria in this age group.<sup>102</sup> In multiple studies of young children evaluated because of fever (relatively few of whom were neonates), approximately 80% of those with bacteriuria had colony counts of  $10^5$ /mL or greater. Significant pyuria, elevated serum level of C-reactive protein (CRP), isolation of a single enteric organism, and abnormality on renal scintigraphy were each decreasingly associated with lower colony counts, with only rare positive tests in those children with colony counts of less than  $10^4$ /mL.<sup>15,16,33,103</sup>

### Culture of Blood and Cerebrospinal Fluid

Because bacteremia and meningitis frequently accompany UTI, cultures of the blood and cerebrospinal fluid should be obtained before therapy for UTI is begun if the neonate has fever or any signs of illness. Blood (but not necessarily cerebrospinal fluid) for culture also should be obtained from the neonate with UTI but without specific or nonspecific signs of infection. In the Göteborg studies,<sup>5</sup> lumbar puncture was performed before therapy in 31 neonates with UTI: 6 infants had purulent meningitis, and in 9 infants the cerebrospinal fluid was sterile but pleocytosis (22 to 200 white blood cells [WBCs] per  $\text{mm}^3$ ) was also present. Blood was obtained for culture in 32 infants and was positive in 12.

Bacteremia was present in 11 of 35 (31%) Dallas infants younger than 30 days of age with UTI. The infants had been considered healthy when discharged from the nursery and were evaluated because of fever. Older infants with UTI were less likely to be bacteremic; positive cultures of blood occurred in 5 of 24 infants (21%) with UTI aged 1 to 2 months, 2 of 14 infants (14%) aged 2 to 3 months, and 1 of 18 infants (5.5%) aged 3 months or older.<sup>22</sup> Similarly, in Boston, bacteremia was present in 17 of 80 (21%) of febrile infants with UTI younger than 1 month, 8 of 59 (13%) 1 to 2 months of age, and 8 of 116 (7%) 2 to 6 months of age; 4 neonates had meningitis. No clinical finding or laboratory test discriminated between bacteremic and nonbacteremic infants.<sup>16</sup> In surveillance for UTI among 203,399 infants born in U.S. Army hospitals from 1985 to 1990, 23% of non-circumcised infant boys with UTI younger than 3 months of age had concomitant bacteremia; incidence of bacteremia associated with UTI was not different from that in circumcised boys or girls with UTI.<sup>25</sup> Incidence of bacteremia in neonatal nosocomial UTI is higher than in community-associated infection, up to 38% in one study.<sup>12</sup> Incidence of bacteremia in community-associated UTI is higher in infants younger than 2 months of age (22%) than in older infants (3%).<sup>104</sup>

### Examination of Urine Sediment

Many studies and a meta-analysis assessing presence of WBCs in the urine of newborn infants have been performed.<sup>5,22,71,105-111</sup> Healthy infants can have up to 10 WBCs per  $\text{mm}^3$  of clean-voided urine.<sup>109</sup> Lincoln and Winberg obtained uninfected and clean-voided specimens of urine from infants younger than 1 week of age: male infants had up to 25 WBCs per  $\text{mm}^3$  and female infants up to 50 WBCs per  $\text{mm}^3$ .<sup>110</sup>

Neither presence nor absence of pyuria is completely reliable evidence for or against UTI. Many studies have assessed urine specimens for predictive values for UTI of WBCs, organisms, or detection by dipstick of leukocyte esterase or reduction of nitrate. The following results are limited to studies of acutely ill, usually febrile infants whose urine was obtained by catheterization (or suprapubic aspiration where stated). Methods of assessing pyuria and definitions of UTI vary. In 27% of unspun urine samples collected by suprapubic aspiration from Dallas infants with UTI (bacterial colony counts of  $10^5$ /mL or greater), fewer than 10 WBCs per high-power field were present.<sup>22</sup> Landau and co-workers reported that among infants younger than 4 months of age with positive urine cultures (colony counts of  $10^4$ /mL or greater), 4 of 49 (8.2%) with renal scintigraphy–diagnosed acute pyelonephritis had fewer than 5 WBCs per high-power field (400 $\times$ ) in fresh centrifuged urine, compared with 27 of 79 (34.2%) infants with UTI and negative results on scintigraphy.<sup>15</sup>

Quantifying WBCs in uncentrifuged urine using a counting chamber is the most reproducible test for pyuria. Hoberman and colleagues found pyuria (at least 10 WBCs per  $\text{mm}^3$  of unspun urine) absent in 22 of 190 (20%) febrile infants younger than 24 months of age with positive urine cultures (colony counts of  $5.0 \times 10^4$ /mL or greater) and present in 6.7% with negative cultures; a single patient of 15 without pyuria in whom renal scintigraphy was performed under protocol had a positive result.<sup>112</sup> In Hansson and co-workers' study of 366 infants younger than 1 year of age with symptomatic UTI (colony counts of  $10^3$ /mL or greater from suprapubic aspirate of urine), 80% had colony counts of  $10^5$ /mL or greater, 13% had counts of  $1 \times 10^4$  to  $9 \times 10^4$  per mL, and 7% had counts of  $1 \times 10^3$  to  $9 \times 10^3$  per mL. Pyuria was significantly associated with colony count. In children with UTI with colony counts of less than  $10^5$ /mL, sensitivity of pyuria (greater than 10 WBCs per  $\text{mm}^3$ ) was 69%, compared with 88% for children with at least  $10^5$  colonies per mL. Nitrate reduction test was highly insensitive; 44% of the patients had a positive result when the colony count was at least  $10^5$ /mL and 11% had a positive result with lower counts.<sup>33</sup> Renal scintigraphy was not performed in Hansson and co-workers' study to estimate significance of UTI, but VUR was present equally in infants with high (30%) and low (38%) colony counts.

Dipstick test for leukocyte esterase and nitrite is inadequate to exclude the diagnosis of UTI in infants. In Hoberman and colleagues' study, the test had sensitivity of 53% and positive predictive value of 82% for detecting 10 or more WBCs per  $\text{mm}^3$ ; nitrite determination had sensitivity of 31% in identifying urine cultures with growth of at least 50,000 colonies per mL.<sup>103</sup> Shaw and co-workers reported dipstick results in 3873 febrile children younger than 2 years of age evaluated for UTI; sensitivity of a positive result (trace

or greater for leukocyte esterase or positive nitrite) was 79% and positive predictive value was 46% for isolation of at least 10,000 colonies per mL from urine culture.<sup>113</sup>

Microscopic hematuria is present in some infants with UTI,<sup>3,44</sup> but gross hematuria usually is associated with other diseases (e.g., renal vein thrombosis, polycystic disease of the kidney, obstructive uropathy, Wilms' tumor).<sup>114</sup>

Usefulness of Gram stain of urine specimen in predicting bacteriuria has been studied prospectively in febrile infants younger than 24 months of age. Smears were prepared using 2 drops of uncentrifuged urine on a slide within a standardized marked area 1.5 cm in diameter, which was then air dried, fixed, and stained. Presence of at least one organism per 10 high-power fields examined using oil immersion lens was considered a positive result. Sensitivity and positive predictive value were 81% and 43%, respectively, for isolation of at least  $1 \times 10^4$  colonies per mL of urine in Shaw and colleagues' study<sup>113</sup> and 93% and 57%, respectively, for isolation of at least  $5.0 \times 10^4$  colonies per mL in Hoberman and co-workers' study.<sup>103</sup> Presence of both pyuria and bacteriuria increased positive predictive value for positive cultures in both studies to 85% and 88%, respectively.

Studies of neonates with early-onset septicemia indicate that the yield for culture of urine is low.<sup>12,13,115,116</sup> Thus, culture may be eliminated in evaluation of infants for presumed sepsis younger than 3 days of age. Examination of urine may occasionally assist in microbiologic diagnosis of early-onset septicemia, but initiation of antimicrobial therapy should not be delayed when there is difficulty in obtaining the specimen.

### Examination of Blood

The peripheral blood leukocyte count varies among infants with UTI. Although significantly higher neutrophil and band counts and band-to-neutrophil ratios are documented in young children with UTI, these do not reliably discriminate among presence, absence, or level of infection in the urinary tract or presence of bacteremia.<sup>15,16,112</sup> In studies from New Zealand,<sup>4</sup> half of the neonates had a peripheral blood leukocyte count of greater than 16,000/mm<sup>3</sup>, but no information was given about this measure in uninfected infants. Hemolytic anemia frequently accompanies jaundice when the latter is present in infants with UTI.<sup>78</sup> Results of the direct Coombs test are usually negative. The reticulocyte count can be normal or elevated.<sup>78</sup>

Signs of inflammatory response such as elevated erythrocyte sedimentation rate (ESR) or serum CRP or procalcitonin (PCT) have been shown to correlate significantly with abnormal renal scintigraphy findings suggestive of acute pyelonephritis in children with UTI. In 64 children studied, Majd and colleagues found abnormal scans in 78% of those with ESR of at least 25 mm/hour, compared with 33% of those with lower ESR.<sup>57</sup> Benador and co-workers found that ESR greater than 20 mm/hour or CRP level greater than 10 mg/L had sensitivity of 89% and specificity of 25% for identifying renal lesions among 73 children with UTI.<sup>56</sup> Stokland and colleagues correlated CRP level greater than 20 mg/L at the time of acute infection with resultant renal scar in 157 children reevaluated 1 year later; sensitivity of elevated CRP was 92%, and positive and negative predictive values were 41% and 80%, respectively.<sup>117</sup> In 153

children with fever and positive urine culture (colony count  $5.0 \times 10^4$ /mL or greater), Hoberman and co-workers reported significant correlations between evidence of pyelonephritis versus cystitis versus asymptomatic bacteriuria with mean peripheral WBC count (22.4/ $\mu$ L versus 14.6/ $\mu$ L versus  $11.7 \times 10^3$ / $\mu$ L, respectively); ESR (44.0 versus 26.8 versus 15.3 mm/hour, respectively); and CRP (10.1 versus 2.7 versus 1.3 mg/L, respectively).<sup>112</sup> When cutoff values of 1 ng/mL for PCT and 20 mg/L for CRP were used, rates of sensitivity for detection of pyelonephritis in infants with UTI were similar (92%), but specificity of PCT (62%) exceeded that of CRP (34%).<sup>118</sup>

### Chemical Determinations

Hyperbilirubinemia is present in many infants with UTI; the percentage of conjugated bilirubin often is determined by the age of the infant at the onset of jaundice.<sup>76</sup> During the first week of life, almost all of the bilirubin is unconjugated, but in the second week and thereafter, the fractionation is approximately equivalent. In 80 Boston infants younger than 1 month of age with UTI, 11 (14%) had jaundice and hyperbilirubinemia; only 4 had bacteremia.<sup>16</sup> With the exception of changes in serum bilirubin, the results of serum hepatic enzyme tests generally are normal or only slightly abnormal,<sup>76,78</sup> although toxic hepatitis and cholestasis unassociated with hemolysis were documented by liver biopsy in an older child with jaundice associated with UTI.<sup>119</sup> Azotemia and hyperchloremic acidosis are not unusual; serum bicarbonate measured less than 20 mEq/L in 34.1% of 354 young children with UTI in one study.<sup>16</sup>

### Radiologic Examination of the Urinary Tract

The major goal of investigation of the urinary tract in infants with UTI (and those with abnormalities noted prenatally) is to identify important and correctable lesions (including urethral strictures, renal anomalies, severe VUR, obstructive uropathy, and urethral valves in males) and to provide the opportunity to begin antibiotic prophylaxis against recurring UTIs in those with reflux or hydronephrosis in whom surgery is not indicated. Multiple new imaging modalities are available and are safer than intravenous pyelography.<sup>120</sup> Each provides unique evaluations.<sup>55,61,117,121-125</sup> Ultrasound examination is capable of showing the size, shape, and location of kidneys and contributes to the diagnosis with hydronephrosis, hydroureter, ureterocele, bladder distention, and stones, but less so with VUR. It is the most noninvasive study, the accuracy of which is dependent on the experience of the interpreter. It is an insensitive test for pyelonephritis but sometimes shows kidney enlargement with abnormal echogenicity. Renal ultrasonography performed to follow up on fetal studies should be postponed for at least 48 hours after birth to avoid a false-negative result from dehydration or low glomerular filtration rate characteristic of newborns.<sup>121</sup>

Renal cortical scintigraphy using technetium-99m-labeled dimercaptosuccinic acid or gluceptate is the most sensitive test for identifying acute pyelonephritis (i.e., focally or diffusely decreased cortical uptake of tracer without evidence of cortical loss, sometimes in an enlarged kidney) or chronic scarring (i.e., decreased uptake with corresponding cortical volume loss); it also provides an estimate of renal function.

This modality is the “gold standard” for diagnosis of acute pyelonephritis; 66% of 66 infants younger than 1 year of age with febrile UTI had a positive result on the renal scan in one study,<sup>56</sup> as did 75% of 153 children younger than 2 years of age in another study<sup>112</sup> and 66% of 94 children in another study.<sup>57</sup>

Voiding cystourethrography using radiographic or radionuclide methodology is the best study to visualize the bladder and urethra and to detect VUR; radionuclide scan is superior to the dye study for detection of intermittent reflux but is inferior for detection of urethral and bladder wall abnormalities and cannot be used to grade VUR. Both are invasive and pose discomfort attendant with catheterization. A 24-day-old male infant with ureterovesical junction obstruction was found to have *E. coli* septicemia and UTI 6 days after elective vesicourethrography, which did not show VUR.<sup>126</sup> Toxic reaction to the cystourethrography dye can occur in infants but is very uncommon.

Ultrasonography and cystourethrography have been recommended for all neonates with UTI judged to be other than that secondary to septicemia. Male infants with community-associated first UTI diagnosed before 8 weeks of age have a higher incidence of VUR or anatomic abnormalities (22% of 45 male infants in one Israeli study) than that noted in older children.<sup>127</sup> Ultrasonography is performed at the time of infection to identify major renal and ureteral abnormalities. Cystourethrography sometimes can be delayed to permit resolution of inflammatory VUR; however, in clinical studies, less than 50% of children with acute pyelonephritis proved to have VUR.<sup>33,57,122</sup> Renal scintigraphy is useful in diagnosis and management of selective cases of UTI.<sup>128,129</sup> Computed tomography (CT) is performed infrequently—for example, when a mass lesion or abscess is suspected. For infants who have undergone prenatal ultrasonography in an experienced center after 30 to 32 weeks of gestation and whose study findings were normal, repeat ultrasonography at the time of first UTI is not recommended by some experts.<sup>110,111</sup>

## MANAGEMENT

Management of UTI is aimed at halting infection rapidly, reconstituting normal fluid and acid-base status, and assessing medical or surgical interventions required to prevent subsequent episodes of UTI and kidney damage.

### Antimicrobial Therapy

Antimicrobial agents should be administered as soon as culture specimens of the blood, cerebrospinal fluid (if indicated), and urine have been obtained. Because the physician must assume that bacteremia is present in the neonate who has UTI and signs of septicemia, the choice of antimicrobial agents for initial therapy and the dosage schedule is the same as that outlined in Chapter 6 for septicemia (a penicillin and an aminoglycoside). A penicillinase-resistant penicillin (methicillin or oxacillin) should be used if an abscess of the kidney, prostate, or testis is present, which suggests infection with *S. aureus*. Vancomycin may be appropriate when methicillin-resistant *S. aureus* organisms are prevalent in the community or nursery. Patients who have suspected hospital-

acquired infection are frequently given vancomycin and an aminoglycoside as initial therapy because of the significant role of coagulase-negative staphylococci and *Enterococcus* species. The decision to use a third-generation cephalosporin is based on the patient's prior receipt of antibiotics, the patient's clinical state, and the knowledge of bacterial species indigenous in each neonatal intensive care unit (NICU). Extended-spectrum  $\beta$ -lactamase (ESBL)-producing organisms of the family Enterobacteriaceae are increasingly problematic in neonatal nosocomial infections, including UTI. Identification of such organisms may not be possible with routine susceptibility testing and may require special investigation. Infectious disease experts should be consulted to manage infections due to ESBL-producing pathogens and to aid in prospective surveillance for antibiotic-resistant microorganisms indigenous to a particular NICU. Gram stain of urine sediment is helpful in initiating empirical therapy for UTI, especially when use of amphotericin for potential *Candida* infection is considered. Therapeutic regimens should be reconsidered when the results of cultures and antimicrobial susceptibility tests are available.

Effective antimicrobial agents sterilize the urine within 24 to 48 hours. A second specimen of urine often is obtained for examination and culture at about 48 hours. Persistence of bacteriuria implies that treatment is ineffective or that a foreign body or obstruction is present.

The duration of antimicrobial therapy for UTI in neonates usually is 14 days. Longer therapy (up to 3 weeks) is necessary if there is a poor response or if an anatomic or physiologic abnormality suggests that relapse may occur if administration of the drug is not continued. Timing of change from parenterally to orally administered agents depends on rapidity of clinical and microbiologic response and the presence of bacteremia or anatomic, functional, or physiologic abnormalities and availability of a highly active oral agent. Parenteral therapy is usually given for at least 3 to 4 days in uncomplicated cases.<sup>130</sup> The urine should be examined and cultured frequently after conclusion of therapy so that relapse or recurrence of infection can be detected as soon as possible. Children with certain urinary tract anomalies, functional abnormalities, and higher grades of VUR are given prophylactic antibiotics continuously for extended periods until surgery is performed or the condition improves<sup>63,121</sup>; amoxicillin, 20 mg/kg per day divided in doses administered every 12 hours, is the agent most frequently used in the neonate. Systematic review of randomized controlled trials of prophylaxis reveals limited evidence for its efficacy.<sup>131</sup>

### Ancillary Therapy

Severe dehydration, electrolyte imbalance, azotemia, and shock can accompany UTI in the newborn. Fluid replacement must be calculated carefully for correction of these abnormalities. Transfusion of blood may be necessary in infants with hemolytic anemia. Incision and drainage of abscesses of the prostate and testis should be considered.

## PROGNOSIS

For patients with UTI and underlying genitourinary abnormalities, long-term control of infection is important. After

that, prognosis is dependent on severity of the lesion. The natural history of UTI in the newborn without underlying abnormality is incompletely described. Some infants with asymptomatic bacteriuria have infection that clears without use of antimicrobial agents.<sup>4,5,83,132</sup> Some infants with symptomatic infection respond readily to therapy and have no subsequent infections, whereas others have recurrences, although the number appears to be smaller than that for older children and adults. In the series from Göteborg<sup>5</sup> and Leeds,<sup>7</sup> recurrences occurred in 26% and 19% of the infants, respectively; the second episode usually occurred during the first few months after the initial infection.

It is possible that inflammatory changes in the kidney early in life may lead to subsequent impairment of growth and development of the kidney and to epithelial damage, fibrosis, and vascular changes, but it is uncertain how frequently these events take place. In a study of 25 children with UTI in whom renal scintigraphy demonstrated evidence of acute pyelonephritis and who underwent repeat scanning an average of 10.5 months later, 16 (64%) had corresponding scars.<sup>56</sup> In another study, 38% of 157 children (with median age 0.4 year at the time of asymptomatic UTI) had renal scars documented 1 year later.<sup>117</sup> Infants do not appear to be at increased risk for scarring; in 50 infants younger than 1 year of age with UTI and acute renal lesions, repeat scintigraphy after an average of 3 months showed scars in 40%.<sup>133</sup>

Obstructive lesions associated with reflux during the neonatal period may be associated with progressive renal damage, whereas children with unobstructive reflux regardless of severity appear not to have progressive renal damage if infection is assiduously prevented.<sup>51,58-60,63,121</sup> Repeat ultrasonography for follow-up evaluation after UTI in children in whom findings on a postnatal ultrasound examination were normal is not indicated.<sup>134</sup> In a study of 102 children with end-stage renal disease in Missouri from 1986 to 1995, damage from VUR and UTIs accounted for less than 1% of cases.<sup>135</sup> A prospective population-based study in Italy suggests that primary vesiculoureteral reflux in males leads to congenital renal hypoplasia, which is the predominant cause of chronic renal failure.<sup>136</sup>

## INFECTIONS OF THE LIVER

Bacterial infection of the hepatic parenchyma frequently is recognized as multiple, small inflammatory foci (microabscesses) observed as an incidental finding in infants dying with sepsis. Diffuse hepatocellular damage, often in conjunction with infection of several organ systems, may be present after transplacental passage of microorganisms to the fetal circulation. On rare occasions, liver involvement may take the form of a solitary purulent abscess. Metastatic focal infections of the liver associated with bacteremia resolve with antimicrobial therapy, are not recognized, or are found only at postmortem examination. Rarely are they clinically apparent as solitary<sup>1</sup> or multiple<sup>2</sup> large abscesses diagnosed during life.

Although metastatic infections are rare, it is difficult to ascertain their true incidence. In a survey of more than 7500 autopsies of children performed between 1917 and 1967, Dehner and Kissane<sup>3</sup> found only three neonates with multiple, small, pyogenic hepatic abscesses, whereas a review of approximately 4900 autopsies<sup>4</sup> performed at Los Angeles Children's Hospital between 1958 and 1978 revealed 9 such infants.<sup>5</sup> Among 175,000 neonates admitted between 1957 and 1977 to Milwaukee Children's Hospital, 2 died with hepatic microabscesses<sup>6</sup>; 3 such patients were seen among 83,000 pediatric patients admitted to New York Hospital between 1945 and 1983,<sup>7</sup> and 1 was reported at the University of Texas Medical Branch in Galveston between 1963 and 1984.<sup>8</sup> Most reviewers who have discussed postmortem observations of infants dying with neonatal sepsis have not described the occurrence of such secondary sites of infection<sup>9-16</sup> or have presented them as an occasional ancillary finding.<sup>17,18</sup>

Similarly, solitary hepatic abscesses in the newborn have also been reported rarely. About 30 such cases have been described.<sup>1,3,4,19-41</sup> These infections frequently are associated with prematurity and umbilical vein catheterization,<sup>5,6,21,22,25,28,32,34-41</sup> whereas solitary abscesses may occur because of bacteremia. For example, Murphy and Baker<sup>42</sup> describe a solitary abscess after sepsis caused by *Staphylococcus aureus*.

## Microbiology

Any bacteria that invade the bloodstream can cause multiple microabscesses in the liver. The etiologic agents in the infants described by Dehner and Kissane,<sup>3</sup> Moss and Pysher,<sup>5</sup> Chusid,<sup>6</sup> and Miedema and co-workers<sup>7</sup> included *Escherichia coli*, *S. aureus*, *Pseudomonas aeruginosa*, *Klebsiella* sp., *Enterobacter* sp., and *Listeria monocytogenes*. However, the causative bacteria of solitary abscesses are generally those colonizing the umbilical stump,<sup>43</sup> including *S. aureus* (11 cases); *E. coli* alone (3 cases); *E. coli* with *S. aureus* (2 cases) or enterococcus

(1 case); *Enterobacter* sp. (3 cases); *Klebsiella pneumoniae* alone (2 cases); *K. pneumoniae* with *Proteus* sp. (1 case); *P. aeruginosa* (1 case); *Staphylococcus epidermidis* with group F *Streptococcus* (1 case); and *Streptococcus pyogenes* (1 case). In three infants, the abscesses were described as "sterile."<sup>19,28,31</sup> Although one of these infants had received penicillin for 9 days before surgical drainage, it is possible that in all three cases the abscesses were caused by anaerobic bacteria that failed to grow under standard conditions of transport and culture. The presence of gas in seven abscesses<sup>25,28,34,35,39</sup> may indicate infection with anaerobes, a frequent cause of liver abscess in adults.<sup>44</sup>

The most common cause of intrauterine bacterial hepatitis, congenital listeriosis, characteristically involves the liver and adrenals (see Chapter 14). Typical lesions are histologically sharply demarcated areas of necrosis (miliary granulomatosis) or microabscesses containing numerous pleomorphic gram-positive bacilli.<sup>15</sup> Descriptions in the early 1900s of miliary necrosis of the liver related to "gram-positive argentophilic rodlike organisms" probably also represented infections with *L. monocytogenes*, which was not isolated and identified until 1926.<sup>26</sup>

Intrauterine tuberculosis results from maternal bacillemia with transplacental dissemination to the fetal bloodstream (see Chapter 19). Because the liver is perfused by blood with a high oxygen content<sup>45</sup> and is the first organ that encounters tubercle bacilli, it is often severely involved.<sup>15,44,46</sup> The presence of primary liver foci is considered *prima facie* evidence for the congenital nature of tuberculous lesions as a result of hematogenous spread through the umbilical vein.<sup>47</sup> However, closed-needle biopsy may be less accurate in the diagnosis of hepatic granulomas, and open biopsy may be required to confirm liver and regional node involvement.<sup>48</sup> Although generalized fetal infection may also arise through aspiration of contaminated amniotic fluid, the lesions acquired in this manner are usually most prominent in the lungs. In addition to hepatomegaly, a clinical picture of fever with elevated serum IgM and chorioretinitis (e.g., choroid tubercles) may be similar to that caused by other congenital infectious agents.<sup>49</sup> In a review by Abughal and co-workers,<sup>49</sup> positive sites of culture for tuberculosis included liver (8 of 9), gastric aspirate (18 of 23), tracheal aspirate (7 of 7), ear (5 of 6), and cerebrospinal fluid (3 of 10). Noncaseating granulomatous hepatitis, thought to be caused by a hypersensitivity reaction related to bacille Calmette-Guérin (BCG) vaccination, has also been described in a neonate,<sup>50</sup> but histologic and bacteriologic studies performed on liver biopsy specimens failed to identify the presence of acid-fast bacilli or BCG organisms.

On rare occasions, bacterial infection of the fetal liver has been reported in association with maternal tularemia,<sup>51</sup> anthrax,<sup>52</sup> typhoid fever,<sup>53</sup> and brucellosis.<sup>54</sup> It is uncertain whether the isolation of bacteria from the livers of stillborn fetuses is significantly associated with their clinical course.<sup>55,56</sup>

*Treponema pallidum* is the spirochete most commonly associated with transplacental hepatic infection (see Chapter 18). Pathologic changes in liver, found in up to 95% of infants dying with congenital syphilis,<sup>57</sup> may include those of diffuse hepatitis or focal areas of inflammation, both frequently accompanied by increased connective tissue and enlargement of the liver.<sup>15,57-59</sup> Involvement of liver has also

been documented, on the basis of isolation of organisms or their identification in histologic sections, in newborns with intrauterine infection caused by various *Leptospira* species (*Leptospira icterohaemorrhagiae*,<sup>60,61</sup> *Leptospira pomona*,<sup>62</sup> *Leptospira canicola*,<sup>63</sup> *Leptospira kasman*<sup>64</sup>). Transplacental infection of the fetus with *Borrelia recurrentis* causes little or no inflammation of liver parenchyma or biliary epithelium despite the presence of large numbers of spirochetes in the sinusoids.<sup>65-68</sup> Congenital infection has been suggested with *Borrelia burgdorferi*<sup>69</sup> (cause of Lyme disease); hepatic, central nervous system, and cardiac lesions may be observed, and widely disseminated lesions were reported to occur in other tissues.

## Pathogenesis

Infectious agents may reach the liver of the fetus or newborn by one of several pathways: transplacental or transorificial intrauterine infection; extension of thrombophlebitis of the umbilical vein; through the hepatic artery during the course of a systemic bacteremia; pylephlebitis due to a focus of infection in the drainage of the portal vein (mesenteric or splenic veins); direct invasion from contiguous structures or because of trauma or surgical inoculation; and extension up the biliary passages in cases of suppurative cholangitis. Abscesses with no apparent focus of infection seem to be relatively common in the newborn compared with older children.<sup>30</sup> Three such cases, all in infants with solitary hepatic abscesses, have been described.<sup>23,24,31</sup> Descriptions of the surgical findings, together with the nature of the lesions, suggest that an umbilical vein infection, obscured by the large collection of purulent material in the abscess, was the probable pathogenesis in all infants.

The mode of infection usually determines the pattern of hepatic involvement. Intense and prolonged seeding of the liver parenchyma, such as that which occurs in conjunction with intrauterine infection or neonatal sepsis, almost invariably results in diffuse hepatocellular damage or multiple small inflammatory lesions.<sup>3,5,6</sup> Umbilical vein thrombophlebitis, may cause an abscess of the falciform ligament<sup>70</sup> or extend into a single branch of the portal vein to produce a solitary pyogenic abscess,<sup>6,21,22,26,29,32,33</sup> or it can lead to disseminated foci of infection through dislodgment of septic emboli.<sup>6,71-74</sup>

The frequent use of umbilical catheters has been associated with an increase in the numbers of infants with solitary<sup>5,6,20-22,32,34-40</sup> or multiple<sup>5,75,76</sup> hepatic abscesses. In three large series, including almost 500 infants who died after placement of umbilical vein catheters, 29 infants were found to have purulent infections of hepatic vessels or parenchyma.<sup>37,75,77</sup> Use of venous catheters for infusion of hypertonic or acidic solutions may provide a necrotic focus for abscess formation,<sup>21,32,34-36,76,77</sup> and prolonged<sup>5,22,32,77</sup> or repeated<sup>63</sup> catheterization of a necrotic umbilical stump provides an ideal pathway for introduction of pathogenic organisms. It has been postulated that some hepatic abscesses have been caused by infusion of contaminated plasma<sup>28</sup> or by the use of nonsterile umbilical catheters.<sup>75</sup>

Although neonatal liver abscesses usually are caused by hematogenous dissemination of bacteria through the hepatic artery or umbilical vein, examples of infection arising from various other sources have been described. Solitary abscesses

have followed a presumed portal vein bacteremia caused by amebic colitis.<sup>19,20</sup> Direct invasion of adjacent liver parenchyma from purulent cholecystitis<sup>24</sup> or postoperative perihepatic abscesses<sup>5</sup> also has been observed. Ascending cholangitis, the most frequent cause of hepatic purulent infections in adults,<sup>30</sup> has not been implicated in the causes of newborn infections.

Disease due to embryonic anatomic errors is unique to newborns. Shaw and Pierog<sup>78</sup> described a newborn with umbilical herniation of a pedunculated supernumerary lobe of the liver; histologic examination showed numerous small foci of early abscess formation. Although signs and symptoms of sepsis appeared at 18 days of age, possibly the result of bacterial spread from the liver to the umbilical vein, the infant improved and ultimately recovered after removal of the polypoid mass on the 19th day of life.

Descriptions of “umbilical sepsis” and “acute interstitial hepatitis” recorded by Morison seem to indicate that his patients had acquired bacterial infections of umbilical vessels with widespread extension into portal tracts.<sup>79</sup> Although mild periportal parenchymal necrosis was observed in a few infants, hepatocellular damage was minimal or absent in most. Similar lesions have been found in infants dying with sepsis<sup>80</sup> and infantile diarrhea.<sup>81</sup>

## Clinical Manifestations

Multiple hepatic abscesses and diffuse hepatitis related to neonatal sepsis or transplacental fetal infection are usually recognized only at autopsy. Very few clinical manifestations referable to hepatocellular damage are evident before death. The signs and symptoms associated with these conditions are those of the underlying sepsis or of secondary metastatic complications such as meningitis, pneumonitis, or peritonitis.<sup>2,3,29,33,72,75</sup>

Solitary abscesses are indolent in terms of their development and clinical presentation. Although the suppurative umbilical focus or umbilical catheterization responsible for the introduction of microorganisms can usually be traced to the first week of life, evidence of hepatic involvement is usually not apparent before the second or third week. The abscess frequently becomes a source for the hematogenous dissemination of microorganisms, so that most infants have signs and symptoms of a bacteremia. Despite intense infection of the underlying vessels, inspection of the umbilical stump usually shows no evidence of inflammation or purulent discharge. The presence of hepatomegaly, a finding commonly associated with neonatal sepsis, also offers little aid in establishing a definitive diagnosis. In one half of infants for whom physical findings are clearly described, a well-delineated, often fluctuant or tender mass could be palpated in the epigastrium or right upper quadrant. On a few occasions, this mass was noticed by the infant's mother several days before the onset of systemic symptoms. Abscesses occur in the right or left lobe of the liver with almost equal frequency and are generally 3 cm or more in diameter at the time of surgical exploration.

## Diagnosis

Hematologic studies are of little value in establishing a diagnosis; leukocyte counts and sedimentation rates may be

normal or elevated. The serum levels of liver enzymes may also be normal<sup>25,38</sup> or elevated.<sup>5,23,36</sup>

Abdominal radiographs are usually normal or show non-specific displacement of the lower edge of the liver. In five infants, diagnosis was suspected from plain x-ray films by the presence of gas within the hepatic shadow.<sup>28,32,34,39</sup> Radiologic findings that commonly accompany hepatic abscess in older children, such as an altered contour of the diaphragm, right pleural effusion, and platelike atelectasis,<sup>82</sup> are rarely present in the neonate.

Ultrasonography should be the initial imaging study in newborns with clinical evidence of a hepatic abscess.<sup>83-86</sup> If negative, and the diagnosis is still strongly suspected, more sensitive techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) should be performed.<sup>83-88</sup> Enhancement with contrast agents may increase the definition of smaller abscesses. Because congenital cysts, arteriovenous malformations, and tumors with central necrosis or hemorrhage can mimic hepatic abscess, the diagnosis should always be confirmed by aspiration of purulent material at laparotomy or by means of percutaneous drainage with ultrasound or CT guidance.<sup>84,89,90</sup>

## Prognosis

The prognosis for infants with diffuse liver involvement related to fetal or neonatal sepsis is that of the underlying condition because hepatic function is rarely compromised sufficiently to determine the outcome. In most cases, pathologic changes in the liver are unsuspected before post-mortem examination.

Of 24 infants with solitary hepatic abscesses whose course was described, 8 died. Two infants died before antibiotics were available,<sup>26</sup> and the death of another was ascribed to cecal perforation.<sup>20</sup> Four newborns died with sepsis caused by organisms that were identical to those isolated from the abscess.<sup>21,25,33,34</sup> Prematurity was undoubtedly a major contributing factor in two of these deaths.<sup>21,25</sup>

## Treatment

Newborns with a solitary hepatic abscess have traditionally been treated with open surgical drainage in conjunction with antibiotic therapy. Developments in the therapy for pyogenic liver abscess during the past few years suggest that a reassessment of this approach may be in order.

Several investigators have described the use of percutaneous drainage of intrahepatic abscesses and cysts, guided by CT or ultrasonography, in neonates<sup>41,75,90</sup> and children.<sup>7,84,89</sup> When combined with antibiotic therapy and monitored by ultrasonography to ensure resolution, this treatment has been highly effective. It is questionable whether drainage contributed to recovery other than by aiding the selection of antibiotic coverage. Subsequently, patients have been successfully treated with empirical antibiotic therapy alone.<sup>91,92</sup> Conservative medical management in infants has been described in only two neonates and a 5-month-old infant.<sup>33,37,78</sup>

The risk of bacteremia and disseminated infection is high in neonates, and the need to identify infecting organisms to guide antibiotic coverage is of greater urgency in the first weeks of life. It is appropriate to ascertain a microbiologic

diagnosis with radiographically guided aspiration or drainage of any definable hepatic abscess in a newborn. When proper equipment (e.g., CT, ultrasonography) and experienced personnel are available, this can be attempted percutaneously.<sup>89,90</sup> When they are not available, open surgical drainage should be performed. Empirical antibiotic therapy should be reserved only for infants for whom it is believed that the risk of open or closed drainage would exceed the potential benefits.

If purulent material is obtained, initial antibiotic therapy can be selected on the basis of Gram staining results. In addition to *S. aureus* and the aerobic enteric organisms commonly associated with hepatic abscesses, anaerobic bacteria have been suspected as the cause of infection in a substantial number of patients.<sup>25,28,32,33,35,39</sup> If foul-smelling pus is aspirated or if Gram-stained smears show organisms with the characteristic morphology of anaerobes,<sup>33</sup> metronidazole,  $\beta$ -lactam and  $\beta$ -lactamase inhibitor combinations (e.g., piperacillin and tazobactam), clindamycin, or imipenem should be included in the initial regimen. Cultures of blood, cerebrospinal fluid, and urine should also be obtained before initiation of therapy.

If empirical antibiotic therapy is required, it must be adequate for infections caused by *S. aureus*, enteric organisms, and anaerobic bacteria. Oxacillin, gentamicin, and clindamycin is an appropriate combination. In nurseries where methicillin-resistant *S. aureus* or *S. epidermidis* infections have been a problem, substitution of vancomycin for oxacillin can provide coverage for these organisms. Gentamicin (and other aminoglycosides) and vancomycin levels must be monitored and dosages adjusted as necessary. Extended-spectrum cephalosporins (e.g., cefotaxime, cefepime, ceftazidime) may be used for enteric organisms and *Pseudomonas* sp., often obviating the need for aminoglycosides.

Definitive therapy is based on results of bacteriologic cultures that identify the bacteria and its antibiotic susceptibility. Adequate anaerobic transport and culture techniques must therefore be available if meaningful information is to be obtained. Duration of treatment is based on clinical response, cessation of drainage, and resolution of the abscess cavity as determined by serial ultrasonographic examinations. Parenteral therapy should be maintained for at least 2 weeks and may be individualized to longer therapy when necessary. In older children treated with multiple abscesses or in those for whom surgery is not feasible, therapy for up to 6 weeks or more has been recommended.

## SPLENIC ABSCESS

Similar to hepatic abscesses, splenic abscesses have been rarely described in infants.<sup>93</sup> Only 1 of 55 splenic abscesses occurred in an infant younger than 6 months. *S. aureus*, *Candida* sp., and streptococci were the most frequent causes. In 20 of 48 cases, hepatic abscesses coexisted with splenic abscess. In the single infant case, torsion of the splenic vessels was present, whereas in older children, other distant infections of hematologic conditions (e.g., hemoglobinopathy, hematogenous malignancy) were the associated comorbid conditions.

## INFECTIONS OF THE BILIARY TRACT

The development of ultrasonography has provided a safe and rapid means for evaluating the neonatal gallbladder. Consequently, an increasing number of reports have appeared within the past 10 years describing ultrasonographic changes seen in the first month of life, with hydrops,<sup>94,95</sup> cholelithiasis,<sup>95-100</sup> and transient distention of the gallbladder associated<sup>94,95,99,101-104</sup> or unassociated<sup>99,102,103,105-108</sup> with sepsis. Ultrasonographic criteria for separating normal from pathologically enlarged gallbladders and biliary tracts in neonates have also been described.<sup>109,110</sup>

Despite advanced technology and increased surveillance, cholecystitis in the neonate is observed infrequently. The literature has documented about 25 cases, of which 9 were seen in association with an epidemic of neonatal enteritis caused by *Salmonella enteritidis*.<sup>111</sup> Of the remaining infants, 16 were the subjects of isolated case reports<sup>24,103,112-123</sup> and 3 died of other causes with inflammatory changes in the gallbladder described as an incidental finding at autopsy.<sup>81,95,124</sup> A tissue diagnosis of "chronic cholecystitis" was established in an infant whose biliary disease apparently began at 6 days of age.<sup>125</sup>

The pathogenesis of this condition is uncertain; all but three cases<sup>99,118,122</sup> of cholecystitis in the newborn period have been acalculous. It is postulated that sepsis, dehydration, prolonged fasting (e.g., total parenteral nutrition), congenital obstruction, or a stone impacted in the cystic duct leads to biliary stasis and acute distention of the gallbladder. In most cases, resolution of the primary process permits restoration of the flow of bile and relief of distention. In some cases, prolonged obstruction leads to hydrops.<sup>94</sup> Cholecystitis rarely follows, perhaps because of a direct toxic effect of retained bile or because of ischemia related to elevated intraluminal pressure. Bacterial invasion by fecal flora is probably a secondary phenomenon.<sup>114,115,126</sup> Organisms that have been isolated from gallbladder contents or tissue include *E. coli*,<sup>114-116,123</sup> *Serratia marcescens*,<sup>103,117</sup> *Pseudomonas* sp.,<sup>115</sup> *Streptococcus faecalis*,<sup>123</sup> "*Streptococcus viridans*,"<sup>121</sup> *S. aureus*,<sup>123</sup> and *Clostridium welchii*.<sup>123</sup> "Gram-positive cocci" were identified by Gram stain in one patient.<sup>113</sup>

Infants with cholecystitis may become ill at any time during the first weeks of life; most cases are diagnosed in the third or fourth week. The typical clinical picture is one of sepsis together with signs of peritoneal inflammation and a palpable tender right upper quadrant or epigastric mass. Diarrhea frequently accompanies these findings. Although ultrasonography and radionuclide scintigraphy are helpful in suggesting the presence of gallbladder enlargement or inflammation, diagnosis can be confirmed only by surgical exploration.<sup>94,102,103,106,108</sup> Treatment consists of cholecystectomy or tube cholecystotomy, together with systemic antimicrobial therapy based on Gram stain, culture, and susceptibility studies. If a T tube is placed in the gallbladder, a cholangiogram should be done to confirm patency of the biliary system before the tube is removed.

Changes compatible with a diagnosis of ascending cholangitis have been described in histologic sections of liver specimens from infants who died with diarrhea accompanied by hepatocellular injury with cholestasis.<sup>91</sup> Bacteria were also identified in the biliary tree of 2 of 178 premature infants who died after placement of an umbilical venous catheter for

an exchange transfusion or for delivery of parenteral fluids.<sup>75</sup> The reasons for this association, if any, are unclear. An infant with spontaneous cholangitis caused by *Enterobacter agglomerans*, presenting as a fever of unknown origin at 3 weeks of age, has also been reported.<sup>127</sup>

Severe inflammation and fibrosis of extrahepatic bile ducts and diffuse changes in the portal tracts, resembling those found in biliary atresia, were found in a premature infant who died when 3 hours old of listeriosis.<sup>128</sup> The investigator postulated that occult prenatal infections with *L. monocytogenes* might be a rare cause of ascending cholangitis presenting as idiopathic biliary atresia at birth.

## INFECTIONS OF THE ADRENAL GLANDS

Multiple adrenal microabscesses are occasionally found as metastatic lesions associated with neonatal sepsis. Such abscesses are particularly characteristic of neonatal listeriosis (see Chapter 14). Solitary adrenal abscesses, however, are rare, and only about 25 such cases have been described.<sup>17,129-150</sup>

The spectrum of organisms responsible for adrenal abscesses is the same as that seen in neonatal sepsis, including *E. coli* (seven cases),<sup>17,129,130,135-138</sup> streptococcus group B (four cases),<sup>138-141</sup> *Proteus mirabilis* (three cases),<sup>131,132,144</sup> *S. aureus*,<sup>142,143</sup> *Bacteroides* sp.,<sup>133,145</sup> and two cases each of *Streptococcus pneumoniae* with *Bacteroides* sp.<sup>134</sup>; *Peptostreptococcus* sp.<sup>146</sup> was recovered from one case. Drainage of foul-smelling pus at surgery suggests that anaerobic bacteria may have been present in two infants from whom *E. coli* and *S. aureus* were isolated.<sup>136,142</sup> Cultures were not obtained from four patients.<sup>147-150</sup>

Fourteen abscesses were located on the right side, seven were located on the left, and three<sup>138,139,147</sup> were bilateral. Three fourths of the infants were male. The same laterality and sex predominance are seen with adrenal hemorrhage in the newborn,<sup>147,150-152</sup> and it has been postulated that formation of an adrenal abscess requires a preexisting hematoma as a nidus for bacterial seeding.<sup>137,138</sup> This theory of pathogenesis is further supported by clinical observations,<sup>134,135,139,146,147</sup> and by objective evidence (e.g., curvilinear calcifications<sup>130,132</sup>) documenting the presence of hemorrhage before development of an abscess.<sup>134,138,142,145,150</sup>

Most infants with adrenal abscess have presented in the third or fourth week of life with signs of sepsis and an abdominal or flank mass. A history of difficult delivery or intrapartum asphyxia has been observed in about one half of these infants and significant maternal fever or infection during labor in about one fourth.<sup>138,140,141,150</sup> Although a few infants are afebrile when first evaluated, a palpable mass is almost always present. Abscesses are usually 6 to 8 cm in diameter, with some containing as much as 200 mL of pus<sup>133</sup> and measuring up to 12 cm in diameter<sup>134</sup> or crossing the midline.<sup>146</sup>

Laboratory studies are helpful in the evaluation of a possible adrenal abscess. Most infants demonstrate a leukocytosis; about one third are anemic with a history of prolonged neonatal jaundice, both of which are features associated with adrenal hemorrhage. Urinary excretion of catecholamines and their metabolites (particularly vanillylmandelic acid and homovanillic acid), which is usually increased with neuroblastoma, is normal. Because most infants

with adrenal abscess are seen for evaluation of possible sepsis, a blood culture, lumbar puncture, urine culture, and chest radiograph should be obtained.

Ultrasonography has become a widely accepted modality for initial evaluation of all neonatal abdominal masses. With the presence of an adrenal abscess, ultrasound examination can help to define the extent and cystic nature of the lesion and often can demonstrate movable necrotic debris in the abscess cavity.<sup>132,137,138,141,142,144-148</sup> With serial examinations, abscesses can be distinguished from those masses associated with liquefying hematoma, adrenal cyst, hydronephrosis of an obstructed upper pole duplication, or necrotic neuroblastoma.<sup>138,140,150,153-154</sup> Intravenous pyelography demonstrates downward displacement of the kidney and compression of the upper calyces, which confirms the presence of a suprarenal mass.<sup>130-132,134,136,138,141,142,144-146,149</sup> A round, suprarenal, radiopaque halo or rim with central lucency, which is characteristic of adrenal abscess, may also be seen on early films<sup>137,139,143</sup> but is not pathognomonic.<sup>138</sup> Intravenous pyelography adds little diagnostic information to that provided by ultrasound studies. Experience with radionuclide scanning,<sup>140,142,143</sup> CT,<sup>138,144</sup> and MRI<sup>126</sup> in this condition is limited, but these modalities are likely to be as useful as ultrasonography.

Whatever diagnostic methods are used, concern about persisting signs of sepsis and the more than possible presence of an adrenal neoplasm usually encourage early efforts to establish a diagnosis. In the past, recommended management has been incision and drainage or resection of the abscess.<sup>134,138,141,144,150</sup> Needle aspiration under ultrasonographic guidance, combined with placement of a catheter for drainage and irrigation, has proved to be a useful alternative method<sup>88,130,131,143</sup> and probably will supplant open drainage as the preferred method. Antibiotic therapy should be based on Gram stain, culture, and susceptibility studies of abscess fluid and should be continued for 10 to 14 days provided drainage can be established.

The adrenals are infected in about 15% of infants with congenital syphilis.<sup>57,58</sup> In addition to the presence of spirochetes, the most frequent and characteristic change is an extraordinary amount of cellular connective tissue in the capsule.

## APPENDICITIS

Acute appendicitis is extremely rare in infants younger than 4 weeks of age. Reviews of more than 25,000 cases of appendicitis in infants and children in Great Britain,<sup>156</sup> Ireland,<sup>157</sup> Norway,<sup>158</sup> Germany,<sup>159</sup> and the United States<sup>160-165</sup> revealed only eight infants who presented during the neonatal period. Pediatric surgery centers in Germany,<sup>166</sup> Boston,<sup>167</sup> Cleveland,<sup>168</sup> Chicago,<sup>169</sup> and Detroit<sup>170</sup> found only four cases of neonatal appendicitis during the past 15 to 20 years. Since the condition was first described by Albrecht in 1905<sup>171,172</sup> and Diess in 1908,<sup>173</sup> approximately 65 cases of neonatal suppurative appendicitis have been reported in the literature with sufficient details to permit characterization of the clinical features,<sup>156,161,162,165,174-211</sup> and the following discussion is based on a review of those cases. Only infants with acute intra-abdominal appendicitis were considered. Those with appendicitis caused by other conditions, such as

Hirschsprung's disease,<sup>212,213</sup> necrotizing enterocolitis (NEC),<sup>214</sup> or incarceration in an inguinal hernia,<sup>215,216</sup> have not been included. An additional 25 to 30 cases that have been reported with incomplete clinical observations, listed in series of patients with neonatal peritonitis (see "Peritonitis") or mentioned in other review articles but not available for analysis, are also not included.

Inflammation of the appendix is more common in male newborns than in female newborns. In those reports in which the sex was stated, 40 cases occurred in males and 17 in females. Prematurity also appears to be a predisposing factor: 23 of the 49 infants whose birth weights were recorded weighed less than 2500 g at birth. The incidence of appendicitis in infants of multiple births (six twins and one triplet) appears to be higher than would be expected on the basis of low birth weight alone.

### Microbiology

Because obstruction of the appendiceal lumen is responsible for almost all cases of appendicitis,<sup>167</sup> it is intuitive that gram-negative enteric organisms resident in the bowel are usually isolated from the peritoneal fluid or periappendiceal pus of about 75% of infants. Specific etiologic agents have included *E. coli*, *Klebsiella*, *Enterobacter* sp., *Pseudomonas*, *Proteus* sp., untyped *Streptococcus*, *S. aureus*, and *Bacteroides* sp. These bacterial species have also been isolated from the peritoneal fluid of older children with appendicitis.<sup>164,167,217</sup> Attempts at isolation of anaerobic bacteria have been rarely described.

A single case of perforated amebic appendicitis with secondary bacterial peritonitis and multiple hepatic abscesses in a premature infant born in Great Britain has been reported. The *Entamoeba histolytica* observed in the wall of the necrotic appendix was presumably acquired from the infant's father, who was a carrier.<sup>20</sup>

A patient with gangrenous appendicitis associated with *Rhizopus oryzae* has also been reported.<sup>218</sup> It was postulated that the fungus colonized the infant's gut by transfer from an adhesive bandage used to secure an endotracheal tube.

### Pathogenesis

Obstruction of the appendiceal lumen has been generally accepted as the primary cause of appendicitis in all age groups. The relative rarity of this condition in the first month of life is therefore probably related to factors that serve to decrease the likelihood of obstruction. Such factors include a wide-based, funnel-shaped appendix; the predominantly liquid and soft-solid diet given to infants; the absence of prolonged periods in the upright position; and the infrequency of infections that cause hyperplasia of the appendiceal lymphoid tissue.<sup>164,219,220</sup>

The causes of luminal obstruction in the newborn period, when recognized, are often extrinsic to the appendix itself. Reports of appendicitis caused by the presence of ectopic pancreatic tissue,<sup>161</sup> a fecalith,<sup>175</sup> or meconium plug<sup>168</sup> are unusual exceptions. In 1911, it was suggested that sharp angulation of the appendix, bent on itself in the narrow retrocolic space, may be an important cause of obstruction,<sup>221</sup> however, this anatomy, found in 11 neonates with inflammatory changes in the appendix and noted among 200 con-

secutive autopsies in infants younger than 3 months at death, has not been repeated in the past 80 years.

Inflammation of the appendix with perforation has been described as the presenting illness in several infants with neonatal Hirschsprung's disease.<sup>212,214</sup> The association of these two conditions has been attributed to functional obstruction, increased intraluminal pressure, and fecal trapping that occur proximal to aganglionic segments. Suppurative appendicitis related to incarceration and strangulation of the cecum within an inguinal or scrotal hernia has been found in a significant number of infants.<sup>215,216</sup>

### Clinical Manifestations

The onset of neonatal appendicitis generally occurs during the first 2 weeks of life. Only 3 of 54 infants with this condition presented between the 21st and 20th days. The reasons for this phenomenon are unclear, particularly in view of the relatively even distribution of cases during the remainder of the first year of life.<sup>165</sup> Five cases of "prenatal" appendicitis have been described.<sup>222-226</sup> Of the four available for analysis, only one showed definite evidence of a suppurative process in the appendix and signs of bowel obstruction clearly present at birth<sup>222</sup>; however, cultures and Gram stain of the pus found at surgery were free of bacteria. Poisoning by mercuric chloride was suspected in one<sup>224</sup> of the remaining three cases, and the other two, who were said to have prenatal rupture of the appendix, were asymptomatic until the second<sup>222</sup> and twelfth<sup>226</sup> days of life.

The signs of neonatal appendicitis correspond to those of any of the various forms of intestinal obstruction that occur during the newborn period (Table 10-1).<sup>226</sup> Prominent early findings include abdominal distention, progressive and frequently bilious vomiting, and evidence of pain, as manifested by persistent crying, irritability, or "colic." Clinical features such as diarrhea, constipation, lethargy, or refusal to feed may also be evident but are too nonspecific to be helpful in establishing a diagnosis. The presence or absence of fever is an unreliable sign in appendicitis as in other forms of neonatal infection; temperature has been recorded as normal or subnormal in more than 50% of newborns with this condition. Abdominal tenderness and guarding are inconstant findings and, when present, are rarely localized to the appendiceal area. Physical signs of

Table 10-1 Signs of Intra-abdominal Neonatal Appendicitis in 55 Infants

Sign	Incidence (%)
Abdominal distention	90
Vomiting	60
Refusal of feedings	40
Temperature $\geq 38^{\circ}\text{C}$	40
Temperature $37^{\circ}\text{C}$ to $38^{\circ}\text{C}$	30
Temperature $\leq 37^{\circ}\text{C}$	30
Pain (crying, restlessness)	30
Lethargy	30
Erythema/edema of right lower quadrant	25
Mass in right lower quadrant	20
Diarrhea	20
Passage of bloody stools	20

sufficient specificity to indicate acute inflammation of the appendix are generally absent until late in the course of the illness, when gangrene and rupture may result in the formation of a localized intra-abdominal abscess or cellulitis of the anterior abdominal wall. Erythema or edema, or both, of the right lower quadrant has been observed in several patients. The presence of this finding, particularly when accompanied by a palpable mass in the right iliac fossa, indicates bowel perforation with peritonitis and should suggest a preoperative diagnosis of NEC or appendicitis (see “Necrotizing Enterocolitis”).

## Diagnosis

The diagnosis of appendicitis in the neonate is usually determined at surgery performed for evaluation of abdominal distention and suspected peritonitis. With the high incidence of prematurity associated with early appendicitis, bowel perforation from NEC has been a common preoperative consideration.<sup>207</sup> The two conditions can coexist, and in some cases, the appendix may participate in the process of ischemic necrosis and perforation.<sup>206,214</sup>

Laboratory studies are of little value in establishing a diagnosis of appendicitis in the newborn. White blood cell counts of less than 10,000/mm<sup>3</sup> were found in 10 of 30 infants for whom this determination was performed. Urinalyses are usually normal, although ketonuria, which reflects diminished caloric intake, hematuria, and proteinuria may be seen. Because bacteremia may accompany appendiceal perforation and peritonitis, a blood culture and evaluation for metastatic infection with lumbar puncture and chest radiography should be performed. The value of paracentesis for diagnosis of bowel perforation and peritoneal infection is discussed later (see “Necrotizing Enterocolitis”).

Radiologic examinations are occasionally helpful, but in most cases serve only to confirm a clinical impression of small bowel obstruction. The presence of an increased soft tissue density displacing loops of intestine from the right iliac fossa generally indicates appendiceal perforation with abscess formation and is perhaps the most reliable sign of acute appendicitis in the neonate. Extraluminal gas may be localized briefly to the right lower quadrant after rupture of the appendix.<sup>212</sup> The rapid development of an extensive pneumoperitoneum, however, obscures the site of origin of the escaping gas in most infants within a short time.<sup>227</sup> Ultrasonography may aid in detection of a periappendiceal abscess<sup>83</sup> but lacks sensitivity and specificity to be of assistance in establishing an early diagnosis of appendicitis.

## Prognosis

The overall mortality rate from appendicitis in the newborn is high but is improving. Eight of the newborns in the last 12 reported cases have survived, whereas of 60 infants with this condition for whom the outcome was recorded, 38 (64%) died. Survival was unrelated to birth weight. Among factors responsible for mortalities, three appear to be of primary importance: delay in diagnosis, a high incidence of perforation, and the rapid onset of diffuse peritonitis after appendiceal rupture.

Perforation has been identified at surgery or autopsy in 70% of newborns with acute appendicitis. The relative

frequency of this complication has been attributed to delays in establishing a diagnosis and to certain anatomic features of the appendix in young infants that predispose it to early necrosis and rupture. These features include a meager blood supply that renders the organ more vulnerable to ischemia; a cecum that is relatively smaller and less distensible than that of adults, thereby forcing a greater intraluminal pressure on the appendix; and the presence of a thin muscularis and serosa that readily lose their structural integrity under the combined effects of ischemia and increased internal pressure.<sup>164,182,183,192</sup>

After the appendix ruptures, infants are unable to contain infection efficiently at the site of origin. Rapid dissemination of spilled intestinal contents produces a diffuse peritonitis within hours because of the small size of the infant's omentum, which fails to provide an efficient envelope for escaping material; the relatively longer and more mobile mesenteries, which favor widespread contamination; and the small size of the peritoneal cavity, which also permits access of infected material to areas distant from the site of perforation.<sup>161,167,182,183</sup>

Peritonitis, accompanied by sepsis and by the massive outpouring of fluids, electrolytes, and proteins from inflamed serosal surfaces, is generally the terminal event in neonatal appendicitis. Deterioration of the infant's condition is often extremely rapid; failure to recognize the underlying illness and to institute appropriate therapy promptly is inevitably followed by a fatal outcome.

## Treatment

Surgical intervention is essential for survival of young infants with appendicitis. Because vomiting, diarrhea, and anorexia frequently accompany this condition, restoration of fluid and electrolyte balance is a major factor in ensuring a favorable outcome. Loss of plasma into the bowel wall and lumen of the dilated intestine may require additional replacement with whole blood, plasma, or an albumin equivalent. Optimal preparation often necessitates a delay of several hours but remains a major determining factor in the success of any surgical procedure done during the neonatal period.

The preoperative use of antibiotics has been recommended in infants with intestinal obstruction to achieve therapeutic blood levels of drug before the time of incision and possible contamination.<sup>168,228,229</sup> Although there are few data to support such a recommendation in neonates, any controversy regarding the need for prophylactic antibiotics is generally moot. Perforation, fecal spillage, and peritonitis occur so early in the course of neonatal appendicitis that almost all infants with this condition require treatment before the time of surgery. After the diagnosis of gangrenous or perforated appendicitis has been established and surgery performed, parenteral antibiotic therapy should be continued for 10 days. The combination of clindamycin (or metronidazole), gentamicin (or extended-spectrum cephalosporins), and ampicillin provides adequate coverage against most enteric pathogens and can be used for initial empirical therapy. Alternatively,  $\beta$ -lactam and  $\beta$ -lactamase inhibitor combinations such as ticarcillin plus clavulanate or piperacillin plus tazobactam or carbapenem antibiotics (e.g., imipenem) can be used alone to broadly cover enteric bacteria, *Pseudomonas* sp., and anaerobic bacteria. Until the infant is able to tolerate

alimentation, careful attention to postoperative maintenance of body fluids, electrolyte balance, nutrition, and correction of blood and plasma losses is vital to survival (see "Peritonitis" and "Necrotizing Enterocolitis").

## PERITONITIS

Peritonitis in the newborn is most commonly associated with perforation of the gastrointestinal tract, ruptured omphaloceles, or wound infections that follow abdominal surgery.<sup>230,231</sup> For this reason, diagnosis and treatment of neonatal peritonitis are less frequently the responsibility of the pediatrician or neonatologist than of the surgeon. It has been estimated that as many as 20% to 40% of gastrointestinal surgical problems in the neonatal period are complicated by bacterial peritonitis (see "Necrotizing Enterocolitis").<sup>186,232</sup> Between 1 and 10 cases per year have been reported in retrospective analyses of peritonitis diagnosed during the first month of life at pediatric surgical centers in the United States,<sup>232-234</sup> Great Britain,<sup>231,235</sup> Hungary,<sup>236</sup> Germany,<sup>237,238</sup> France,<sup>239</sup> and Zimbabwe.<sup>240</sup> Among almost 3000 infants admitted to a neonatal intensive care unit in Liverpool in 1981 to 1982, there were six cases of peritonitis, all from NEC perforation of the gastrointestinal tract.<sup>241</sup> Peritonitis was present in 4 (all of low birth weight) of 501 infants on whom consecutive autopsies were performed from 1960 through 1966 at St. Christopher's Hospital for Children in Philadelphia. These cases represented approximately 3% of all patients with inflammatory lesions associated with death in this age group.<sup>242</sup> Potter considered the peritoneum "one of the most frequent points of localization" in infants dying with sepsis.<sup>15</sup> Among 121 such infants autopsied from 1976 to 1988 at St. Mary's Hospital in Manchester, England, generalized peritonitis was found in 9 (7.4%).<sup>231</sup>

A preponderance of males (2.5:1)<sup>191,240,241</sup> and a high incidence of prematurity (33%)<sup>232,235-237</sup> have been found in unselected series of infants with this condition. These features are probably less a characteristic of bacterial peritonitis in the newborn than of the primary surgical and septic conditions that are responsible for its occurrence (particularly NEC). Among newborns with primary peritonitis, there appears to be a female preponderance.<sup>236,244</sup> A high incidence of congenital anomalies not involving the intestinal tract has also been observed among neonates with peritonitis.<sup>232,237,243,245</sup>

### Microbiology

The condition that permits bacteria to colonize the peritoneal surface determines the nature of the infecting organisms. Most infants in whom rupture of a viscus and fecal spillage have caused peritonitis are infected by bacteria considered to be part of the normal enteric microflora; however, prior use of antimicrobial agents and colonization patterns within a nursery are important factors in determining which organisms predominate. Although a mixed flora of two to five species can often be recovered,<sup>243</sup> single isolates have been reported in as many as a third of infants with peritonitis.<sup>246,247</sup> The predominant aerobic organisms usually include *E. coli*, *Klebsiella* sp., *Enterobacter* sp., *Pseudomonas* sp., *Proteus* sp., coagulase-negative and coagulase-

positive staphylococci, ungrouped streptococci, *Enterococcus*, and *Candida*.<sup>231,232,238,240,247-249</sup>

Techniques adequate for the isolation of anaerobic organisms have been used infrequently. In a series of 43 consecutive infants with gastrointestinal perforation and bacterial growth from peritoneal fluid, a mixed aerobic-anaerobic flora was isolated with *Bacteroides* sp. as the predominant anaerobes<sup>243</sup>; remaining specimens grew aerobic or facultative organisms alone and no culture yielded only anaerobes. In that series and others, the same organisms were frequently isolated from the peritoneal cavity and blood.<sup>233,243,245,249</sup>

In contrast to fecal flora isolated from infants with gastrointestinal perforation, gram-positive organisms predominated among neonates with "idiopathic primary peritonitis." This condition is caused by sepsis in most cases, but it also has often been associated with omphalitis. Specific organisms in one representative series included *S. pneumoniae* (three cases), ungrouped  $\beta$ -hemolytic *Streptococcus* (three cases), and *S. aureus*, *Pseudomonas* sp., and *E. coli* (one case each).<sup>232</sup> Gram-positive cocci were also the major isolates in other series of peritonitis associated with hematogenous dissemination of organisms or extension from a peripheral suppurative focus.<sup>10,26,33,71,244-254</sup> Many of the cases caused by *S. aureus* occurred before the advent of antibiotics or during the worldwide pandemic of staphylococcal disease in the late 1950s, whereas streptococci, particularly group B, have been a prominent cause in recent years.<sup>244,250-254</sup>

Rarely, peritonitis may be caused by *Candida albicans* in pure culture or mixed with gram-negative enteric organisms.<sup>231,255</sup> Because clinical findings in this condition are not different from those of bacterial peritonitis, the diagnosis is usually established by blood or peritoneal fluid culture. Severe hypothermia has been described as a possible predisposing cause of bowel perforation and peritonitis due to *Candida*.<sup>256</sup> In addition to well-recognized risk factors, such as prematurity, antibiotic therapy, and parenteral nutrition with deep venous catheters, NEC may also be a significant risk factor for systemic candidiasis, in which it was observed in 37% of 30 infants.<sup>257</sup> However, only a single infant in this series had a positive culture for *Candida* species from the peritoneum. Peritoneal catheters or peritoneal dialysis may also be a risk for direct inoculation of *Candida* organisms into the peritoneal space, which occurred in 1 of 26 children<sup>258</sup> (see Chapter 34).

### Pathogenesis

Acute bacterial peritonitis may occur whenever bacteria gain access to the peritoneal cavity, through intestinal perforation, by extension from a suppurative focus, or by the hematogenous route. Intrauterine peritonitis due to *L. monocytogenes* has been reported<sup>231</sup>; however, cases of "fetal peritonitis" described in earlier reports were actually examples of meconium peritonitis caused by intrauterine intestinal perforation.<sup>259,260</sup> Although bacterial colonization of the gastrointestinal tract in the first days of life may lead to infection in this condition, it is an aseptic peritonitis in its initial stages. A similar condition with focal perforation of the ileum or colon occurring postnatally has been described in very low birth weight infants. Blue-black discoloration of the abdomen, caused by meconium staining of the tissues of

Transmural migration (theory) <sup>265,279</sup>

the underlying skin, may be the first striking physical finding in these infants. Clinical, radiographic, and histopathologic evidence of infection or inflammation was notably absent in most cases.<sup>229</sup>

The various conditions that predispose to neonatal peritonitis are outlined in Table 10-2. The relative importance of each in the cause of this condition can be estimated from data collected in several large series. Among almost 400 newborns with peritonitis studied between 1959 and 1978, perforation of the intestinal tract was responsible for 72% of cases, with ruptured omphaloceles or gastroschisis responsible for 12%, hematogenous dissemination or "primary" peritonitis for 12%, and omphalitis and postoperative complications for 2% each.<sup>191,230,231,237,262,263</sup> A comprehensive review of neonatal peritonitis by Bell describes common sites and causes of gastrointestinal perforation and their relative frequencies (Figs. 10-1 and 10-2).<sup>230,243</sup>

No recent cases of neonatal peritonitis have been attributed to microorganisms entering the peritoneal cavity by traversing the bowel wall through the lymphatics or within macrophages (i.e., transmural migration). Evidence for the existence of this pathway is theoretical and is based primarily on retrospective analyses of pathologic data in humans, together with supporting observations made on laboratory animals.<sup>265,279</sup> Further confirmation is necessary before the transmural pathway can be accepted as an established source of peritoneal colonization by bacteria.

### Clinical Manifestations

Neonatal peritonitis is a disease primarily of the first 10 days of life; a significant number of infants have evidence of

**Figure 10-1** Causes of perforation in 60 neonates. (From Bell MJ. Peritonitis in the newborn—current concepts. *duo. perf.*, duodenal perforation; *strict.*, stricture. *Pediatr Clin North Am* 32:1181, 1985.)

**Figure 10-2** Sites of perforation in 60 neonates. (From Bell MJ. Peritonitis in the newborn—current concepts. *Pediatr Clin North Am* 32:1181, 1985.)

peritoneal infection within the first 24 hours.<sup>232,233,240,245</sup> An analysis of etiologic factors responsible for peritonitis in the newborn provides a ready explanation for this observation (see Table 10-2). Most cases of NEC<sup>243,280</sup> and spontaneous gastric perforation<sup>233,243,249,262</sup> occur within the first week. Ruptured omphaloceles and gastroschisis often develop early infections, and in infants with congenital obstruction, the onset of alimentation during the first 12 to 24 hours accentuates distention and ischemic necrosis of the bowel wall, which leads to early intestinal perforation. Exchange transfusions are performed most frequently within the first 1 or 2 days of life and may be followed by enterocolitis within 4 to 24 hours in infants in whom perforation ultimately occurs.<sup>281,282</sup> Neonatal sepsis, with potential peritoneal seeding of microorganisms, is more frequent during the first 48 hours of life than during any subsequent period.<sup>283</sup>

The variety of signs and symptoms present in a young infant with peritonitis were summarized most succinctly by Thelander<sup>249</sup> in 1939:

*The little patient looks sick. He is cyanotic; the respirations are rapid and grunting; the abdomen is distended, and the abdominal wall, the flanks and the scrotum or vulva are usually edematous. Frequently brawny induration of the edematous area, which may resemble erysipelas, is also present. Food is taken poorly or not at all. Vomiting is frequent and persistent. The vomitus contains bile and may contain blood. The stools are either absent or scant; some mucus or blood may be passed. The temperature may be subnormal, but varying degrees of fever have been reported. The blood count*

Fever	15
Diarrhea	15

<sup>a</sup>Data are based on patients described in references 232, 240, and 243. Redness, edema, and induration of the anterior abdominal wall, noted in only one series,<sup>243</sup> are also recognized as characteristic signs.

*is of little or no value. The hemoglobin content may be very high, which probably indicates only dehydration. The leukocytes may or may not respond with a rise.*

Although this review was limited to neonates with perforation of the intestinal tract, subsequent reports have corroborated the presence of these findings in infants with peritonitis resulting from a wide variety of causes.<sup>191,232,234-236,240,243,249</sup> Not all of the symptoms described may be encountered in any one patient; however, some are always present (Table 10-3).

The large overlap between signs of neonatal peritonitis and sepsis can make it difficult to differentiate the two on the basis of clinical findings. Signs of intestinal obstruction such as abdominal distention and vomiting, which are seen in 10% to 20% of newborns with sepsis,<sup>9,17,245</sup> may reflect a coexistent unrecognized peritonitis. Because the early use of antibiotics often cures hematogenous peritonitis in infants with septicemia, the diagnosis may be missed in infants who survive. It is noteworthy that peritonitis unassociated with perforation was found at postmortem examination in 4 of 20 infants with sepsis in 1933,<sup>10</sup> 9 of 73 premature infants dying with septicemia between 1959 and 1964,<sup>9</sup> and 9 of 121 such infants dying between 1976 and 1988.<sup>230</sup>

## Diagnosis

Demonstration of free intraperitoneal fluid by ultrasonography<sup>284</sup> or abdominal radiographs taken in the erect and recumbent positions can be helpful in the diagnosis of peritonitis, and is sometimes the only evidence of perforation. Absence of definition of the right inferior hepatic margin, increased density of soft tissue, and the presence of "floating" loops of bowel have been recorded as positive signs of ascites.<sup>227,285</sup> Diagnostic paracentesis can be useful in determining whether the fluid is caused by bacterial peritonitis,<sup>244,252,286,287</sup> hemoperitoneum, chylous ascites,<sup>288</sup> or bile peritonitis.<sup>289</sup>

The left lateral ("left-side down") decubitus film is of great value in showing small amounts of intraperitoneal gas.<sup>243</sup> Although pneumoperitoneum can be caused by mediastinal air dissecting from the chest into the abdomen,<sup>290,291</sup> free gas in the peritoneal cavity usually indicates intestinal perforation. An associated pneumatosis intestinalis should strongly suggest the diagnosis of NEC, but is not necessarily specific for this condition. Several patterns of intraperitoneal gas distribution have been described<sup>281-293</sup>: the air-dome sign, falciform ligament sign, football sign, lucent-liver sign, saddlebag sign, and gas in the scrotum. Absence of a gastric air-fluid level on an erect abdominal radiograph, together with a normal or decreased amount of gas in the small and large bowel, strongly favors a diagnosis of gastric perforation.<sup>293</sup> This finding is almost always accompanied by pneumoperitoneum.

In equivocal cases, metrizamide contrast studies of the bowel can be helpful in establishing a diagnosis of intestinal perforation.<sup>246,290</sup> Serial abdominal transillumination with a bright fiberoptic light is a useful bedside method for the early detection of ascites or pneumoperitoneum in the newborn.<sup>294</sup>

Failure to demonstrate free air in the peritoneal cavity does not, however, rule out a diagnosis of perforation, particularly if air swallowing has been reduced or prevented through orotracheal intubation, nasogastric suction, or use of neuromuscular blocking agents.<sup>286,290,295</sup> In some cases, the amount of gas in the bowel lumen is so small that even if perforation occurs the gas could escape detection. Alternatively, small leaks may become walled off and the free air reabsorbed.<sup>290,296,297</sup> In three large series of infants with peritonitis in whom a patent site of perforation was found at surgery, pneumoperitoneum was absent in 35% to 75%.<sup>232,243,245</sup>

Radiographic evidence of intestinal obstruction, although a common cause or consequence of peritonitis, lacks

sufficient specificity to be a consistent aid to diagnosis. A diffuse granular appearance of the abdomen, with one or more irregular calcific densities lying within the bowel lumen or in the peritoneal cavity, should suggest a diagnosis of meconium peritonitis with possible bacterial superinfection.<sup>260</sup>

## Prognosis

Prematurity, pulmonary infections, shock, and hemorrhage related to perforation of the intestinal tract, sepsis, and disseminated intravascular coagulopathy are often the factors responsible for the death of neonates, who may concurrently have peritonitis diagnosed at surgery or at postmortem examination. For this reason, case-fatality rates often represent the mortality rate among newborns dying with, rather than because of, infection of the peritoneal cavity.<sup>231,237,243</sup>

Before 1970, the incidence of fatalities was exceedingly high when peritonitis was associated with gastrointestinal perforation; mortality rates of 70% were observed in large series.<sup>191,232,235,236,238-240,245,297</sup> Heightened awareness of conditions associated with perforation, more rapid diagnosis, and improved surgical management have led to a doubling of survivors in recent years.<sup>237,238</sup> The cause of perforation appears to influence the likelihood of survival, with spontaneous gastric perforation having the lowest mortality rate (10%) and perforation of the duodenum caused by a feeding tube the highest (50%); NEC (40%) and all other causes (25%) occupy intermediate positions.<sup>243</sup>

As survival rates have improved, the number of nonlethal complications after perforation has risen proportionally. In one review, two thirds of surviving infants had significant postoperative complications pertaining to infection (e.g., bacteremia, wound infection, intra-abdominal abscess) or gastrointestinal tract dysfunction (e.g., esophageal reflux, obstruction, stomal stenosis).<sup>243</sup> Secondary surgical procedures to correct these problems were required in more than one half of the infants. Sixty percent required parenteral hyperalimentation for nutritional support during their recovery period.

The mortality rate among neonates with peritonitis from causes other than perforation of the bowel, such as sepsis,<sup>191,232,236,240</sup> omphalitis,<sup>240,277</sup> or a ruptured omphalocele,<sup>232,237,240</sup> although high in the past, has not been reassessed in the past few years.<sup>243</sup>

Early diagnosis and institution of appropriate surgical therapy are major factors in reducing the mortality rate.<sup>243</sup> It has been shown that infants operated on within 24 hours after the onset of symptoms have survival rates almost double those operated on between 24 and 48 hours and two and one half times higher than the rate for those whose surgery was delayed more than 48 hours.<sup>245</sup> Factors with an apparent adverse influence on prognosis include low birth weight,<sup>232,237,240,243,263</sup> low birth weight for gestational age,<sup>230</sup> congenital malformations,<sup>237</sup> male sex,<sup>231</sup> and initial serum pH of less than 7.30.<sup>231</sup>

## Treatment

The treatment of bacterial peritonitis is directed primarily toward correction of the causative condition.<sup>231</sup> Careful attention to preoperative preparation of the infant is

essential to survival. As soon as bowel obstruction or perforation is diagnosed, continuous nasogastric suction should be instituted for decompression and prevention of aspiration pneumonitis. Diagnostic needle paracentesis is also useful for relief of pneumoperitoneum and may facilitate exchange of gas by reducing the intra-abdominal pressure. Shock, dehydration, and electrolyte disturbances should be corrected through parenteral administration of appropriate electrolyte solutions, plasma, or plasma substitutes. If blood is discovered in fluid recovered by gastric suction or abdominal paracentesis, use of whole blood, packed red blood cells, or other fluids may be necessary to correct hypovolemia. Persistent bleeding must be evaluated for disseminated intravascular coagulation or thrombocytopenia, or both, and treated accordingly. Hypothermia, which frequently accompanies neonatal peritonitis, should be corrected before induction of anesthesia. Infants who are unable to tolerate oral or tube feedings within 2 or 3 postoperative days should be started on parenteral hyperalimentation.

If a diagnosis of peritonitis is established at the time of paracentesis or surgery, aerobic and anaerobic cultures of peritoneal contents should be taken before initiation of antibiotic therapy. Parenteral administration of a combination of gentamicin or an extended-spectrum cephalosporin with clindamycin and ampicillin should be continued for 7 to 10 days.<sup>216,229</sup> Other antibiotics that provide a broad spectrum against the enteric organisms, *Pseudomonas* sp., enterococci, and anaerobic organisms include the  $\beta$ -lactam and  $\beta$ -lactamase inhibitor compounds and the carbapenems. In the event of a poor clinical response, culture and susceptibility studies of the infecting organisms should be used as guides for modifying therapy.

Leakage of intestinal contents sometimes results in formation of a localized abscess rather than contamination of the entire peritoneal cavity. Management of infants with such an abscess should include antimicrobial therapy and surgical drainage of the abscess by the most convenient route.

## NECROTIZING ENTEROCOLITIS

NEC with necrosis of the bowel wall is a severe, often fatal, disease occurring with increasing frequency in recent years. The average annual NEC mortality rate is 13.1 per 100,000 livebirths; black infants, particularly males, are three times more likely to die of NEC than are white infants, and mortality rates are highest in the southern United States.<sup>298-308</sup> NEC occurs in about 5% of infants admitted to neonatal intensive care units; however, the incidence varies widely among centers and even from year to year at the same institution.<sup>309-322</sup> NEC predominantly affects infants with birth weights below 2000 g<sup>298,300,315,323-330</sup>; in several series, the frequency in infants younger than 1500 g was as high as 10% to 15%.<sup>298-301,316,317,321,329,331-335</sup> Only 5% to 10% of all cases of classic NEC occur in term infants.<sup>308,336-338</sup> It has been stated that occasional cases of NEC may be the price to be paid for the benefits of modern neonatal intensive care.<sup>339</sup> Although most reports of NEC emanate from the United States, Canada, and Great Britain, the condition occurs worldwide in countries maintaining neonatal intensive care units. In a review of NEC in two neonatal intensive care

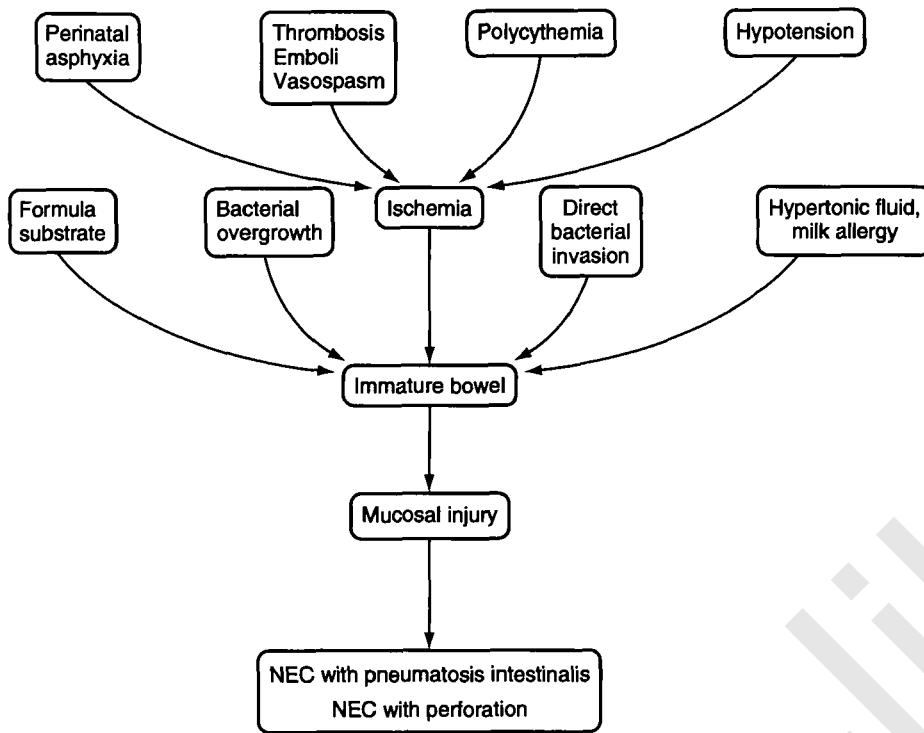

units of academic centers, NEC increased the risk for death (OR = 24.5), infections (OR = 5.7), and the need for central line placement (OR = 14.0).<sup>340</sup> Infants with surgical and medical NEC had lengths of stay of 60 and 22 days greater, respectively, than infants without NEC with additional costs of \$186,200 and \$73,700, respectively, resulting in additional hospital charges of \$216,666 per surviving infant.

## Pathology and Pathogenesis

Bowel wall necrosis of variable length and depth is the characteristic feature of NEC, with perforation in up to one third of affected infants generally in the terminal ileum or cecum, where microcirculation is poor.<sup>243,303,307,327,336,341-343</sup> The pathogenesis of NEC is not established, but most investigators agree that the initiating event is some form of stress to the immature gastrointestinal tract, which leads to disruption of the mucosal barrier, bacterial invasion and proliferation, and gas formation within the bowel wall (Fig. 10-3).<sup>315,323,324,345</sup> Surgical specimens from early stages of the disease show mucosal edema, hemorrhage, and superficial ulceration with very little inflammation or cellular response. By the second or third day, after progression to pneumatosis and transmural necrosis of the bowel wall, bacterial proliferation and the acute inflammatory reaction become more prominent.<sup>303,327</sup>

There has been much investigation and little agreement on the importance of various perinatal events in the causation of NEC.<sup>315,323,324,344</sup> Except for immaturity and possibly polycythemia, other factors originally thought to predispose to NEC have, on further study, occurred with equal frequency in control populations of infants.<sup>316,321,324,328,329,338,346,347</sup> Maternal complications of pregnancy, labor, and delivery and neonatal respiratory distress syndrome are thought to be unrelated to the development of NEC, whereas evidence linking NEC to birth asphyxia, hypotension, hypothermia, use of vascular catheters, exchange transfusion, feeding history, abnormalities of gut motility, neonatal achlorhydria, and the presence of patent ductus arteriosus is often contradictory. Each of these conditions, singly or together, may act as a stress leading to mucosal injury, but none has been consistently associated with NEC.<sup>348,349</sup> NEC has occurred among apparently healthy infants with no known predisposing risk factors.<sup>298,307,336,345</sup> Several studies (discussed later) suggest that early feeding of premature neonates may play a causal role in NEC. Dvorak and coinvestigators<sup>344</sup> have shown that maternal milk may be protective compared with artificial formulas in a neonatal rat model of NEC; similar to human NEC, artificial feeding of maternal milk reduced the incidence and severity of NEC injury and IL-10 expression was significantly increased when neonates were fed maternal milk.

Some epidemiologic observations suggest that NEC is an infectious contagious disease of nosocomial origin. The temporal clustering of cases at institutions, the association of some outbreaks with single infectious agents or alterations in bowel flora, and the possible beneficial effects of breastfeeding, oral nonabsorbable antibiotics, or infection control measures in reducing the incidence of disease suggest a possible nosocomial cause. Unfortunately, the evidence linking NEC to a specific infectious agent is often circumstantial or open to alternative interpretation. Evidence suggests that

**Figure 10-3** Pathogenesis of mucosal injury leading to necrotizing enterocolitis (NEC). (Adapted from Walsh MC, Kliegman RM. Necrotizing enterocolitis. *Pediatric Basics* 40:5, 1985.)

NEC is the end response of the immature gastrointestinal tract to multiple factors acting alone or in concert to produce mucosal injury, with colonization or invasion by the microorganisms representing only one part of the continuum of that disease process.<sup>282,289,290,307</sup>

### Microbiology

Descriptions of sporadic outbreaks of NEC in neonatal intensive care units have led to a search for transmissible agents, including bacterial, viral, and fungal pathogens.<sup>304,315,323,324,345,350-355</sup> Predominance of a single organism in stool, blood, bowel wall, or peritoneal cavity of infants during epidemics of NEC has implicated a number of agents including *Klebsiella* sp.,<sup>301,312,330,343,356-358</sup> *Enterobacter* sp.,<sup>359</sup> *E. coli*,<sup>360,361</sup> *Pseudomonas* sp.,<sup>362,363</sup> *Salmonella* sp.,<sup>364</sup> *S. epidermidis* and other coagulase-negative staphylococci,<sup>365</sup> *S. aureus*,<sup>366</sup> rotavirus,<sup>367,368</sup> coronavirus,<sup>369</sup> coxsackievirus B2,<sup>370</sup> and *Torulopsis glabrata*.<sup>371</sup>

The analogous pathology of necrotizing enteritis caused by *Clostridium septicum*<sup>3672</sup> and *Clostridium perfringens* in domestic animals,<sup>314,358,373</sup> older children, and adults<sup>374</sup> favored suggestions that *Clostridium* species might act as a primary pathogen in NEC.<sup>315,323,324,345,355,375</sup> Several reports provided evidence that *C. perfringens*,<sup>314,376-379</sup> *Clostridium difficile*,<sup>347,380</sup> or *Clostridium butyricum*, acting alone<sup>381,382</sup> or synergistically with *Klebsiella*,<sup>383</sup> was able to evoke NEC. Subsequent studies, however, indicated that these species were often acquired from the nursery environment<sup>385,386</sup> and could frequently be recovered from healthy neonates.<sup>374,386-392</sup> Clostridial cytotoxin, which had been recovered from the stool of infants involved in an outbreak of NEC,<sup>347,380</sup> has also been found in the stool of up to 90% of normal infants.<sup>347,379,385,391-393</sup> The role of *Clostridium* sp. in NEC remains unclear.<sup>355,375</sup>

The  $\delta$ -toxins, hemolysins of coagulase-negative staphylococci<sup>394</sup> and *S. aureus*, have also been proposed as possible primary toxins capable of producing NEC in infants. Frequent colonization by  $\delta$ -toxin staphylococci and higher levels of toxin production by associated strains causing NEC have been reported,<sup>395</sup> as well as one outbreak with  $\delta$ -toxin-producing *S. aureus* strains.<sup>366</sup> Prospective studies have documented significant shifts in aerobic bacterial bowel flora within 72 hours before onset of clinical NEC<sup>396</sup>; the observed shift results from preclinical changes in the intestinal environment. This suggests that bacteria isolated at the time of onset were present because of possible intraluminal changes and are not directly involved in NEC.

Pending further experimental or epidemiologic observations, the weight of evidence indicates that although bacteria or bacterial toxins may play a primary or secondary role in the pathogenesis of NEC, the occasional association of this condition with a single organism probably reflects patterns of intestinal colonization prevalent in the nursery at the time of an outbreak.<sup>315,323,324,345</sup> Despite intensive efforts to identify a specific infectious agent or toxin in the cause of NEC, there have yet to be convincing reports implicating the same pathogen in more than one outbreak.<sup>355</sup>

### Clinical Manifestations

Signs of NEC usually develop in the first 7 days of life,<sup>308,336,397</sup> and 50% or more cases are recognized within 5 days of birth.<sup>298,327,330,398,399</sup> Small, immature newborns often develop illness later, during the second to the eighth week,<sup>332,334</sup> whereas low-risk, term infants may become ill shortly after delivery, as early as the first 24 hours.<sup>337</sup>

NEC is a disease with a wide spectrum of manifestations, ranging from a mild gastrointestinal disturbance to a fulminant course characterized by early bowel perforation,

**Table 10-4 Modified Bell's Staging Criteria and Recommendations for Therapy for Necrotizing Enterocolitis**

Stage	Signs			Treatment
	Systemic	Intestinal	Radiologic	
IA (suspected)	Temperature instability apnea, bradycardia, lethargy	Elevated residuals, mild abdominal distention emesis guaiac- positive stools	Normal, mild ileus	NPO, antibiotics for 3 days
IB (suspected) IIA (definite), mild	Same as IA Same as IB	Frank rectal blood Same as IB plus absent bowel sounds ± abdominal tenderness	Same as IA Dilatation, ileus, pneumatosis intestinalis	Same as IA NPO, antibiotics for 7-14 days if examination is normal in 24-48 hr
IIB (definite), moderate	Same as IIA with mild metabolic acidosis, mild thrombocytopenia	Same as IIA with definite abdominal tenderness ± abdominal cellulitis or right lower quadrant mass	Same as IIA plus portal gas ± ascites	NPO, antibiotics for 14 days
IIIA (advanced), bowel intact	Same as IIB plus hypotension, bradycardia, severe apnea, respiratory/ metabolic acidosis, disseminated intravascular coagulation, neutropenia	Same as IIB plus peritonitis, marked tenderness, abdominal distention	Same as IIB with ascites	Same as IIB plus 200 mL/kg fluid, inotropic agents, assisted ventilation, paracentesis
IIIB (advanced), bowel perforated	Same as IIIA	Same as IIIA	Same as IIIA plus pneumoperitoneum	Same as IIIA plus surgery

NPO, nothing by mouth.

peritonitis, sepsis, and shock.<sup>323,400,402</sup> A staging system (Table 10-4) taking these clinical variations into account may be useful in guiding patient evaluation and therapy.<sup>323,403</sup> The apparent stage of disease for an individual infant disease usually can be defined on the second day of illness. An infant who exhibits only mild systemic and intestinal signs 24 to 48 hours after onset is unlikely to develop a more serious illness.<sup>323</sup>

The classic presentation of NEC includes a triad of abdominal distention, retention of gastric contents, and gastrointestinal bleeding.\* These findings are often preceded or accompanied by signs consistent with sepsis, such as lethargy, poor feeding, temperature instability, apnea, and bradycardia. Diarrhea is variable, rarely observed in some series<sup>323</sup> but common in others.<sup>334,361</sup> Progression of bowel wall necrosis leading to perforation, peritonitis, and sepsis is reflected in deteriorating vital signs accompanied by persistent acidosis,<sup>404</sup> clotting disorders, and circulatory collapse. Redness, induration, and edema of the anterior abdominal wall are commonly described in the advanced stages of NEC. In the absence of aggressive medical and surgical intervention, the course is rapidly downhill once late signs appear.

## Diagnosis

Radiographic signs of NEC are largely nonspecific,<sup>402</sup> and interobserver variability in the interpretation of films is substantial.<sup>404</sup> However, roentgenographic examination of the abdomen remains the most reliable aid in establishing a diagnosis of NEC.<sup>298,319,327,404,405</sup> Ileus with generalized bowel dilatation and abdominal distention are the earliest radiologic findings. Increasing distention, separation of loops by peritoneal fluid or edema of the bowel wall, a gasless abdomen, pneumatosis intestinalis, and hepatic or portal air occur as NEC worsens. A persistent single dilated loop of bowel remaining relatively unchanged in shape and position in serial films is strongly suggestive<sup>406-408</sup> but not diagnostic<sup>407,409</sup> of localized bowel ischemia with impending perforation.

If free air or ascites is absent on initial abdominal examination, supine and left lateral decubitus films should be obtained every 6 to 8 hours until improvement or definitive surgery or invasive diagnostic measures have ruled out the presence of perforation. When perforation occurs, it is usually within the first day after diagnosis<sup>341</sup> but may be delayed for as long as 5 or 6 days.<sup>410</sup> Although the presence of pneumoperitoneum<sup>245,281,292</sup> or intraperitoneal fluid generally indicates perforation, its absence does not exclude perforation.<sup>222,243,245</sup> In one study,<sup>341</sup> only 63% of infants with NEC and proven perforation had free air, 21% had ascites, and 16% had neither.

\*See references 292, 303, 316, 318, 320, 325, 333, 338, 387, 392.

When plain films are normal or equivocal, other studies may be diagnostic. A metrizamide gastrointestinal series may demonstrate intestinal perforation or abnormalities of the bowel wall, mucosa, or lumen.<sup>246,290,411</sup> Real-time ultrasonography may reveal portal venous and hepatic parenchymal gas in standard radiographs.<sup>341,412,413</sup> Serial abdominal transillumination with a fiberoptic light has been described as a bedside method for early detection of ascites or pneumoperitoneum, although its sensitivity when compared with standard radiographic methods has not been determined.<sup>294</sup>

A rapid and direct means of establishing the presence of intestinal necrosis or perforation is by abdominal paracentesis.<sup>414-416</sup> Use of the procedure is unnecessary in infants to rule out NEC or in those improving on medical therapy. It is generally reserved for infants suspected, on the basis of clinical, radiographic, and laboratory findings, of having intestinal gangrene. When performed properly, paracentesis is safe and accurate, as described by Kosloske<sup>416</sup>: The abdomen is palpated to locate any masses or enlarged viscera. After an antiseptic skin preparation, a small needle (22 or 25 gauge) is inserted carefully in the flank, at a 45-degree angle. It is advanced slowly and aspirated gently until free flow of 0.5 mL or more of peritoneal fluid is obtained. Any volume less than 0.5 mL is considered a dry tap and cannot be accurately interpreted. The color and appearance of the fluid are noted, and the fluid is transported immediately to the laboratory—preferably in the syringe with air expelled and the needle covered with a cork or rubber stopper—for Gram staining and for aerobic and anaerobic cultures. A positive paracentesis consists of brown fluid or bacteria on the unspun fluid.

The accuracy of paracentesis in determining the need for an operation is between 90% and 95%.<sup>415,416</sup> False-positive results are rare; false-negative results are quite common. Patients with a dry tap should be closely observed under medical therapy with continuing serial paracenteses until indications for or against surgical intervention are clearly defined. Infants with a positive result should undergo exploratory surgery immediately.

Thrombocytopenia and disseminated intravascular coagulation are the most common hematologic complications,<sup>298,330,354,414,417-419</sup> particularly in the presence of bowel gangrene or perforation.<sup>303,419,420</sup> Platelet-activating factor (PAF) has been used to assist in the staging of NEC<sup>421</sup>; a cut-off level of 10.2 ng/mL had a positive predictive value of 100% in identifying infants with stage II or III NEC. Leukopenia and absolute granulocytopenia, apparently caused by margination of white blood cells rather than bone marrow depletion,<sup>422</sup> also have occurred during early stages of the illness.<sup>417,418</sup> A low absolute granulocyte count persisting for 2 to 3 days is associated with a poor prognosis. Hemolytic anemia has been reported in association with NEC related to *C. perfringens*.<sup>378</sup> No consistent urinary abnormalities have been described for NEC, although increased D-lactate excretion, reflecting heightened enteric bacterial activity, may occur.<sup>423</sup> Increased amounts of fecal-reducing substances have been found in almost three fourths of formula-fed premature infants during early stages of NEC, before the onset of abdominal distention, poor feeding, or emesis.<sup>424</sup> Although not readily available, levels of growth factors in urine have been found to be much higher in children with stage II and III NEC<sup>425</sup>; such an analysis might

identify children at higher risk of complications and the need for surgical intervention.

The evaluation of patients with NEC should include culture of blood, cerebrospinal fluid, urine, and stool. The likelihood of bacteremia accompanying NEC depends on the severity of bowel involvement; the reported incidence has varied from 10% to 67% among symptomatic infants. Combined data from several large studies showed positive blood cultures in about one third of newborns with NEC.<sup>303,304,353,410</sup> The usual organisms have been *E. coli*, *Klebsiella* sp., *S. aureus*, and *Pseudomonas* sp., whereas enterococci and anaerobic bacteria were isolated occasionally. A spectrum of organisms similar to those causing sepsis have been isolated from the peritoneal fluid.<sup>303,312,334,354,410</sup> Meningitis may accompany bacteremia, occurring in approximately 1% of NEC cases.<sup>337,426</sup>

## Treatment

Early and aggressive treatment must be initiated for any infant suspected of having NEC.<sup>315,323</sup> The modified Bell staging system of NEC may guide diagnostic studies, management, antibiotics, and surgical consultation and intervention (see Table 10-4). Umbilical catheters should be removed whenever possible, oral feedings should be stopped, and nasogastric tube drainage should be instituted. Fluid and electrolyte deficits and maintenance require rigorous attention; blood, plasma, or colloid infusions are often necessary for volume expansion and maintenance of tissue perfusion.

After appropriate cultures (i.e., blood, cerebrospinal fluid, urine, and stool) are obtained, parenteral antibiotic therapy should be started with clindamycin and gentamicin or an extended-spectrum cephalosporin and ampicillin. In nurseries where coagulase-negative staphylococcal colonization or infection is prevalent, initial therapy with vancomycin may replace ampicillin.<sup>427</sup> The  $\beta$ -lactamase and  $\beta$ -lactamase inhibitor combinations (e.g., piperacillin plus tazobactam), can replace gentamicin, ampicillin, and clindamycin, covering anaerobic, gram-negative enteric aerobic, and many gram-positive pathogens. Gentamicin and vancomycin dosages should be modified as necessary on the basis of serum levels. Despite anecdotal evidence that oral nonabsorbable aminoglycosides prevent gastrointestinal perforation in infants with NEC,<sup>428</sup> later controlled studies did not corroborate this finding<sup>429</sup>; their use is not routinely recommended. The need for inclusion of clindamycin to provide activity against anaerobic bacteria in the management of NEC has been questioned.<sup>430</sup>

After immediate treatment has been started, follow-up studies should be instituted. These include serial examinations with measurement of abdominal girth; testing of stools for blood; levels of serum electrolytes, blood glucose, and arterial blood gases; complete blood cell count and platelet count; urine-specific gravity; and supine and left lateral decubitus abdominal radiographs. These tests should be considered as often as every 6 to 8 hours until the infant's clinical condition stabilizes. Attention to vital functions should be provided as necessary on the basis of clinical, laboratory, or radiographic studies. Parenteral nutritional support through a central or peripheral vein must be started as soon as possible.

Early recognition and prompt initiation of medical therapy may reduce the need for surgery. Generally accepted criteria for surgical exploration are a deteriorating clinical condition despite appropriate medical therapy, signs of peritonitis, presence of free air within the abdomen, or a positive paracentesis result. The principles of surgical preparation and management have been discussed by several investigators.<sup>305,416,431,432</sup> In addition to laparotomy with removal of necrotic bowel, closed peritoneal drainage has been proposed as an alternative in very small infants, with a resultant survival of more than 50%.<sup>433</sup>

## Prevention

The first observations implicating bacterial proliferation as a factor in pathogenesis of NEC prompted efforts at suppression of gut flora with topical antibiotics in the hope of preventing NEC. Attempts to prevent NEC by giving oral kanamycin or gentamicin prophylactically in the first hours of life, before any signs of bowel involvement are recognized, have generated contradictory data. In controlled clinical trials, a significant reduction in the incidence of NEC in treated premature infants was shown in some,<sup>331,434-437</sup> whereas in others, investigators were unable to demonstrate any protective effect.<sup>437,438</sup> Studies of vancomycin<sup>439</sup> have shown a significant reduction in NEC in high-risk infants. Previous studies revealed selective growth of resistant organisms in bowel flora<sup>331,438,440</sup> and evidence of significant systemic absorption of aminoglycoside antibiotics,<sup>429,441,442</sup> suggesting that oral aminoglycoside prophylaxis is not free of potential risks. Potential risk factors, however, have not been examined in vancomycin trials. Until additional evidence is presented indicating clear-cut benefits from the use of oral aminoglycosides or vancomycin, it does not appear that either should be used routinely for prevention of NEC in premature infants. Epidemiologic evidence that early use of parenteral ampicillin and aminoglycoside therapy may delay or decrease the risk of NEC has not been confirmed in controlled studies.<sup>343</sup> Oral probiotics have been suggested to alter the bowel flora of the infant to reduce the incidence and severity of NEC. Infants fed breast milk and a product including *Lactobacillus acidophilus* and *Bifidobacterium infantis* had a reduced incidence and severity of NEC compared with those of infants fed breast milk alone.<sup>343a</sup>

Excessive or accelerated feedings have been associated with increased frequency of endemic NEC,<sup>443</sup> and some have recommended a schedule of slow advancement of daily feeding volumes limited to about 20 mL/kg/day. NEC infants are more likely to have been fed earlier, to have received full-strength formulas sooner, and to have received larger feeding volumes and increments, and stress and associated respiratory problems may make such infants more vulnerable to NEC.<sup>245,309-314,444</sup> Prior studies of the use of a feeding regimen employing prolonged periods of bowel rest in high-risk infants has been successful in preventing NEC in some nurseries<sup>315</sup> but totally without value in others.<sup>317,324</sup> Later studies have added additional support for standardized feeding schedules in low-birth-weight infants (500 to 2500 g); all have used maximum volumes no greater than 20 mL/kg/day, with feeding beginning at 24 to 72 hours after birth, depending on birth weight and gestational age.<sup>325,326</sup> Both synthetic formulas and breast milk have been successful. Carrion and

Egan<sup>445</sup> have suggested that relative hypochlorhydria of the neonate may contribute to NEC and found that hydrochloric acid supplements (0.01 to 0.02 1.0 N HCl/mL of formula) significantly reduced NEC rates and lowered gastric pH. Additional studies have shown that standardized feedings begun at a median of 4 days after onset of NEC can be associated with an abbreviated time until institution of full enteral feedings, a reduced incidence of the use of central catheters and catheter infections, and ultimately, a shorter hospital stay.<sup>446</sup>

Many NEC "epidemics" in neonatal intensive care units, lasting 2 weeks to 7 months, have been reported from centers worldwide.<sup>343,354,355,447,448</sup> Although the microbiologic agents associated with these outbreaks have varied, institution of strict infection control measures was often useful in bringing about a significant decrease in the incidence of NEC; the reasons for success are less clear. However, results have been sufficiently impressive to recommend that enforcement of bedside enteric precautions, together with cohorting of infants and staff, be instituted when two or more cases of NEC occur in a nursery.<sup>323,355,449</sup>

The use of human breast milk has been claimed, largely on the basis of experimental evidence, to exert a protective effect against the development of NEC. Unfortunately, there are no prospective, controlled studies demonstrating any benefit from the feeding of colostrum or breast milk to human neonates. A study demonstrating the protective effect of an orally administered IgA-IgG preparation suggests a possible way to provide benefits of high levels of functionally active antibodies in the gastrointestinal tract.<sup>450</sup>

## Prognosis

The mortality rate of NEC is difficult to determine because mild cases of suspected NEC are probably more common than is recognized.<sup>323,400,401</sup> In studies in which analysis has been limited to infants with "definite NEC," mortality figures vary from 20% to 40%.<sup>308,315,324,334-338,397,402,404,415</sup> Several longitudinal studies have shown a significant improvement in outcome.<sup>308,319,404,451</sup> A poor prognosis has been linked with very low birth weight, associated congenital defects, bacterial sepsis, disseminated intravascular coagulation, intestinal perforation, and persistent hemodynamic or respiratory instability.<sup>329,350,397,410</sup> Surgical intervention, generally reserved for the sickest infants with more extensive bowel involvement, is also associated with higher mortality rates.<sup>329,397,401,404,416</sup>

Infants who survive the acute phase of illness generally do well, although NEC may recur in 5% to 10%.<sup>308,334,451,452</sup> In addition to surgical complications (e.g., short-bowel syndrome, anastomotic leaks, fistula formation), enteric strictures are probably the most common delayed complication in surviving infants, occurring in 4% to 20%. Usually found at sites of ischemia and necrosis in terminal ileum or colon,<sup>298,327,453</sup> these strictures often become apparent within a few weeks but may be delayed as long as 18 months. When multiple strictures occur, the intervening normal bowel may form an enterocyst.<sup>405,454</sup> Clinically, strictures present as frequent episodes of abdominal distention, often with vomiting, obstipation, or hematochezia. Diagnosis is confirmed by gastrointestinal contrast studies. Surgery with removal of the stenotic site is necessary to effect a cure.

Long-term follow-up of low-birth-weight infants with severe NEC (i.e., Bell's stages II and III) has documented higher rates of subnormal body weight (15% to 39%) and head circumference (30%) in addition to significant neurodevelopmental impairment (83%).<sup>455</sup> Clinical observations suggest that infants with bowel resection for NEC are at increased risk of sepsis, occurring from 1 week to 3 years (mean, 4 months) later. Almost all had had a central venous catheter in place for parenteral nutrition at the time of infection. Enteric bacilli were responsible for more than 40% of the bacteremias, whereas only 20% were caused by staphylococcal species, which are the usual causes of catheter sepsis. Several infants had two or more episodes of sepsis, and 2 of 19 died as a direct consequence of infection.<sup>445</sup>

## ENDOCARDITIS

Neonatal bacterial endocarditis, previously uncommon, has been recognized more frequently in recent years. About 60 cases that meet clinical and bacteriologic criteria sufficient to establish this diagnosis have been reported in the literature<sup>457-485</sup>; 35 have been reported in the past 2 decades. The prolonged survival of critically ill infants and the increased use of intravascular catheters, together with advances in the diagnostic sensitivity and availability of echocardiography, may be responsible for rising recognition of endocarditis. In a 35-year review of 76 cases of endocarditis in children, 10% of patients were younger than 1 year; the youngest patient was 1 month old.<sup>486</sup> Sixty-two (83%) had congenital heart disease, and 77% had had prior surgery. Central venous catheters were additional significant risk factors. For example, at the University of New Mexico in a level III nursery with 3200 to 3500 admissions annually, 12 cases of endocarditis occurred in children younger than 3 months.<sup>487</sup> Organisms isolated from these 10 cases included *S. aureus* (6 cases), *Klebsiella pneumoniae* (1 case), *Enterobacter cloacae* (2 cases), *Candida* sp. (1 case), alpha-streptococci (1 case), and coagulase-negative staphylococci (1 case). Three patients had congenital heart disease with early surgical intervention; all had surgically implanted catheters or intravenous access devices, one had NEC, and one had an associated osteomyelitis.

Etiologic agents of bacterial endocarditis in the newborn have been identified by isolation from blood cultures or morphologic characteristics of organisms entrapped within valvular vegetations examined at autopsy. On this basis, the causative organisms have included *S. aureus* in 36 infants\*<sup>443,460,489</sup>; streptococci in 6 infants<sup>443,460,489</sup>; *S. epidermidis*<sup>468,469,488</sup> and streptococcus group B<sup>462,472,476</sup> each in 5 infants; *S. pneumoniae*,<sup>460,489</sup> *P. aeruginosa*,<sup>461,467</sup> and *S. marcescens*<sup>465,477</sup> in 2 each; and *Neisseria gonorrhoeae*,<sup>460</sup> *S. faecalis*,<sup>490</sup> *Streptococcus salivarius*,<sup>71</sup> and mixed alpha-hemolytic *Streptococcus*, *K. pneumoniae*, and *P. mirabilis*<sup>468</sup> in 1 each. Despite widespread cardiovascular involvement associated with congenital syphilis, there is no conclusive evidence that this disease produces valvular heart lesions in infected infants.<sup>58</sup> *Candida* endocarditis has become increasingly prevalent, particularly associated with the use of central venous catheters.

Factors that predispose a newborn to endocarditis are not well understood, although intravascular catheters are certainly associated with endocarditis. Unlike older children, in whom congenital heart disease is often associated with endocarditis,<sup>492</sup> cardiac anomalies were found in only nine of the reported cases in neonates in series before 1994.<sup>458,463,465,468,472,473,478,494</sup> Bacteremia arising from an infected umbilical stump,<sup>459-461</sup> conjunctivitis,<sup>460</sup> and skin lesions<sup>460,482</sup> were the presumed sources of valvular involvement in six infants; the invasive organisms associated with these conditions and with neonatal endocarditis in general can infect normal heart valves.<sup>495</sup> Nevertheless, the greater frequency of bacterial and fungal<sup>481,493,496-502</sup> endocarditis in newborns in recent years, particularly in association with prematurity or placement of central vessel catheters or both, indicates that other, more complex mechanisms may also be operative in some cases.<sup>467-470,484,488,493,503</sup>

Observations in laboratory animals and autopsy studies of adults have shown that damage to the intracardiac endothelium with formation of a sterile platelet-fibrin thrombus at the site of the injury is often the initiating event in a patient with endocarditis.<sup>504</sup> Endocardial trauma caused by placement of cardiac catheters, disseminated intravascular coagulation, and various nonspecific stresses associated with prematurity such as hypotension and hypoxia has been implicated in the genesis of thrombi.<sup>468,484,488,495,505,506</sup> Non-bacterial thrombotic endocarditis or verrucous endocarditis usually remains uninfected and is described as an incidental finding at autopsy.<sup>467,484,506,507</sup> With bacteremia, however, implantation of organisms may lead to valvular infection. Whether this mechanism or that of direct bacterial invasion is primarily responsible for valvulitis is not known. A similar pathogenesis has been postulated for formation of mycotic aortic aneurysms in newborns.<sup>480,510,511</sup>

Endocarditis should be suspected in any neonate, particularly a premature infant, with an indwelling vascular catheter, evidence of sepsis, and new or changing heart murmurs. When these findings are accompanied by persistent bacteremia or signs of congestive heart failure in the absence of underlying heart disease, the diagnosis must be considered seriously. Although Janeway's lesions,<sup>484</sup> a generalized petechial rash,<sup>479,490,493</sup> and splinter hemorrhages<sup>490</sup> have been seen, murmurs characteristic of semilunar valve insufficiency, Osler's nodes, Roth's spots, arthritis, and other findings typical of valvular infection in adults and older children have not been observed in neonates. However, multiple septic emboli with involvement of the skin, bones, viscera, and central nervous system are relatively common findings.\*

Two-dimensional echocardiography has proved to be an invaluable rapid, noninvasive method for diagnosing endocarditis.<sup>469-472,478,504,515</sup> Although it cannot differentiate between infected and sterile vegetations and other valvular lesions (discussed later), imaging is quite specific, and false-positive readings are uncommon. Unfortunately, less certainty can be placed on a negative report. Despite detection of vegetations with echocardiography as small as 2 mm, the number of false-negative examinations is significant<sup>478,484,516</sup>; in one series, two of three infants with thrombotic valvular lesions 3 to 7 mm in diameter had normal two-dimensional

\*See references 445-447, 450, 453-455, 457, 458, 465-477, 479-500.

\*See references 445, 447, 449, 450, 454-456, 458-464, 468, 469, 471, 475, 477, 479, 498-500.

echocardiograms.<sup>484</sup> A diagnosis of bacterial endocarditis should be considered in any infant with a compatible history and physical findings regardless of the results obtained by echocardiography. Widespread use of new techniques such as transesophageal echocardiography, which provides detailed views of the mitral and tricuspid valves, and color flow Doppler imaging, which can identify areas of turbulence as blood passes over vegetations or through narrowed valve leaflets, may greatly improve diagnostic accuracy in the future.<sup>515</sup>

When endocarditis is suspected, specimens of blood, cerebrospinal fluid, and urine obtained by catheterization or suprapubic aspiration should be sent for bacterial and fungal culture. Because blood drawn from a central catheter often contains organisms colonizing the line but not necessarily present in the systemic circulation, at least two *peripheral* venous blood cultures should be obtained before antimicrobial therapy is initiated. Volumes of 1 to 5 mL, depending on the infant's size, should be adequate.<sup>504</sup>

Routine laboratory studies are helpful in supporting a diagnosis of endocarditis in the newborn. The leukocyte count, differential count, and platelet count are usually indicative of sepsis rather than cardiac valve infection in particular. Microhematuria has been reported, although rarely.<sup>484,490</sup> A chest radiograph should be obtained to determine signs of cardiac failure or pulmonary or pleural space infection. CT or MRI of the brain can be helpful in an infant with neurologic signs, particularly if left-sided endocarditis or a right-to-left shunt exists. Baseline determinations of inflammatory markers are useful and can be used for assessing the efficacy of the therapy; both the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level have been used.

Intravenous therapy with a penicillinase-resistant penicillin and an aminoglycoside should be started after appropriate cultures have been obtained. In nurseries where methicillin-resistant *S. aureus* or *S. epidermidis* infections have been a problem, vancomycin should be substituted initially for the penicillin antibiotic.<sup>504,515,516</sup> If endocarditis caused by *Enterococcus* sp. is suspected, ampicillin should be added or substituted for the penicillinase-resistant penicillin. After the infecting organism is isolated and antibiotic susceptibilities have been determined, specific antimicrobial therapy can be instituted. Between 4 and 8 weeks of parenteral treatment is usually adequate, depending on the susceptibility of the organism, response to therapy assessed clinically by reduction or elimination of the observed vegetations, and laboratory response. The CRP level often normalizes 2 to 3 weeks before the ESR, and blood cultures are usually sterile after 3 to 5 days of effective therapy. However, *Candida* sp. may persist for weeks despite the use of active antifungal drugs. Dosage and efficacy should be monitored weekly with clinical and bacteriologic response with or without serum antibiotic and bactericidal levels.<sup>515,517</sup> Determination of serum bactericidal titers (Schlichter's assay) is of uncertain value and has never been validated in neonatal endocarditis.<sup>504,515,518</sup> Efficacy of treatment may also be monitored with serial echocardiograms taken until vegetations remain stable in size or disappear.<sup>478,479,481,488,493</sup>

Intravascular catheters must be removed whenever possible and the tip of the removed catheter should be cultured.<sup>504,519</sup> Extremely large or mobile vegetations occluding an outflow tract or posing a high risk of embolism may have to be removed surgically.<sup>476,478,481</sup> In infants with right-sided

endocarditis, demonstration of decreased pulmonary blood flow through the use of ventilation-perfusion scan can be of value in confirming the presence of emboli, particularly if there is clinical evidence of increasing respiratory effort and diminished peripheral oxygen saturation.<sup>476</sup>

With the availability of echocardiography, improved clinical awareness, and early diagnosis, prognosis has improved. Although there were infrequent survivors before 1973,<sup>495</sup> the first survivors with proven endocarditis were reported in 1983.<sup>478,479,484</sup> Approximately two thirds of subsequent cases have been cured. Death is usually the result of overwhelming sepsis, often in conjunction with cardiac failure. Early reconstructive surgery for infants who fail medical management may be helpful but has been reported in only a limited number of cases.<sup>520,521</sup>

Inspection of the heart at autopsy has shown the mitral valve to be infected, alone or in combination with other valves, in about one half the patients. The tricuspid valve was involved in 12 infants, pulmonary valve in 7, aortic valve in 6, infected mural thrombi in 12, and an unspecified site in 3. Microscopic examination of valve cusps has revealed the characteristic lesions of endocarditis, with multiple small, confluent, friable vegetations composed principally of bacteria and thrombi surrounded by inflammatory exudate.<sup>458,482,484</sup> On gross inspection, these vegetations are easily confused with noninflammatory lesions such as those of nonbacterial thrombotic endocarditis, blood cysts,<sup>522</sup> developmental valvular defects,<sup>523</sup> or hemangiomas or other vascular anomalies.<sup>524</sup> Cases described as fetal endocarditis in the literature are almost certainly examples of these types of lesions.<sup>508,523,525</sup>

## PERICARDITIS

Purulent pericarditis is a very unusual complication of neonatal sepsis. Approximately 20 cases of proven bacterial origin have been reported within the past 50 years.<sup>512,527-538</sup> No single causative agent has predominated. *S. aureus* was responsible for seven cases,<sup>512,527-529</sup> *E. coli* was isolated from three patients,<sup>529,534,535</sup> *Haemophilus influenzae* was found in two,<sup>530,537</sup> and *Salmonella wichita*,<sup>531</sup> *Klebsiella*,<sup>538</sup> and *P. aeruginosa*<sup>536</sup> were isolated from single cases. One early review of *Pseudomonas* sepsis described suppurative pericarditis in four neonates.<sup>532</sup> Another report on the recovery of *Pseudomonas* from the pericardium of premature infants dying of septicemia and meningitis during a nursery outbreak is difficult to evaluate because details of clinical and autopsy findings were not given.<sup>539</sup> Cases caused by *Candida* sp. and *Mycoplasma hominis* have also been described.<sup>493,499,540</sup> The causes of a pericardial effusion in three fetuses with multiple congenital anomalies, myocardial hypertrophy, and pericarditis are uncertain. Although the inflammatory exudate found at autopsy contained polymorphonuclear leukocytes in addition to lymphocytes, no evidence of bacterial infection was found.<sup>541</sup>

Virtually every infant with pericarditis has associated septic foci; pneumonia and multiple pulmonary abscesses are the most common sites. Involvement of pericardium may occur by direct extension from adjoining lung abscesses or by hematogenous spread of bacteria.<sup>527</sup> The presence of infectious processes elsewhere is sufficiently frequent to

warrant the suggestion that pericarditis should be suspected in all infants who develop clinical signs of "heart failure" or a sudden increase in the size of the cardiac silhouette during the course of a purulent infection such as meningitis, pneumonia, or omphalitis.<sup>530,542</sup>

Neonates with bacterial pericarditis generally present with signs and symptoms suggesting sepsis and respiratory distress. Poor feeding, listlessness, emesis, or abdominal distention may be seen in the presence of tachypnea, tachycardia, and cyanosis of various degrees. More specific signs of cardiac involvement became apparent with the accumulation of increasing amounts of pericardial effusion. Unfortunately, the clinical findings of cardiac tamponade are extremely subtle and difficult to differentiate from those of myocardial disease with right-sided heart failure. A rapid pulse, quiet precordium, muffled heart sounds, neck vein distention, and hepatomegaly are findings common to both entities. More specific signs of tamponade, such as narrow pulse pressure or respiratory variations in pulse volume of more than 20 mm Hg (i.e., pulsus paradoxus), are technically difficult to obtain in neonates without an arterial catheter in place. A pericardial friction rub is absent in more than 50% of older infants and children and in most neonates with purulent pericarditis.

Rapid enlargement of the cardiac silhouette, a globular heart shape with widening of the base on tilting, and diminished cardiac pulsation on fluoroscopic examination are of little value in differentiating pericardial effusion from cardiac dilation.<sup>543</sup> The early ST segment elevation and subsequent T wave inversion seen on the electrocardiogram reflect subepicardial damage or inflammation and are similar to changes seen with primary myocarditis. Diminution in the amplitude of the QRS complex by fluid surrounding the heart is not a constant finding. Confirmation of the presence of a pericardial effusion is usually obtained by two-dimensional echocardiography.<sup>512,543</sup> In some cases, CT scan can also be helpful in delineating the extent of a pericardial effusion.<sup>544</sup>

The causes of neonatal pericardial effusion include viral pericarditis,<sup>545</sup> intrapericardial teratoma,<sup>546</sup> maternal lupus,<sup>547</sup> immune and nonimmune<sup>548</sup> fetal hydrops, congenital diaphragmatic defects,<sup>549</sup> chylopericardium,<sup>550</sup> and central venous catheter perforation of the right atrium.<sup>551</sup>

A definitive diagnosis of purulent pericarditis can be made only by obtaining fluid at surgery or through needle aspiration. Care and experience are necessary to facilitate aspiration while avoiding the risks of cardiac puncture or laceration.<sup>541</sup> Accurate monitoring of needle position can usually be obtained through CT guidance, with echocardiographic or fluoroscopic imaging, or by attaching the exploring electrode (V lead) of an electrocardiograph to the needle and by looking for injury current if contact is made with the epicardial surface of the heart.

When fluid is obtained, it should be sent for analysis to the laboratory in the aspirating syringe with the air expelled and the needle covered with a cork or rubber stopper. In addition to cell count and protein and glucose levels, Gram and acid-fast stains should be performed together with cultures for bacteria, viruses, mycobacteria, and fungi. Rapid identification of bacterial antigens by latex agglutination or by counterimmunoelectrophoresis of pericardial fluid, urine, or serum may also help to establish an etiologic diagnosis.<sup>552</sup>

Purulent pericarditis is a medical and surgical emergency. Therapy must be directed toward relief of the cardiac tamponade through adequate pericardial drainage and toward resolution of the infection. Both modes of treatment are essential for successful therapy for bacterial pericarditis in the newborn. Not a single infant with suppurative pericarditis has recovered when treated by antibiotics alone.<sup>527</sup> Although repeated needle aspirations or catheter drainage<sup>553</sup> may be sufficient, the frequent occurrence of loculations of pus, particularly with staphylococcal infection, suggests that open surgical pericardiostomy is the method of choice to achieve adequate drainage.

Cultures of blood, cerebrospinal fluid, and urine should be obtained before instituting antimicrobial therapy. Initial therapy should be based on results of Gram stain or antigen detection tests of the pericardial fluid. If no organisms can be identified, treatment can be started with penicillinase-resistant penicillin and an aminoglycoside (or extended-spectrum cephalosporin) until definitive culture and susceptibility data are available. In nurseries where methicillin-resistant *S. aureus* infection has been a problem, vancomycin should be substituted for penicillin.<sup>517</sup>

The prognosis of neonatal purulent pericarditis is very poor; only three survivors have been reported<sup>1512,529,538</sup> before the last decade of the 20th century. Treatment of these patients consisted of needle aspirations, drainage, and systemic antibiotic therapy, and in one case, treatment was combined with local instillation.

## MEDIASTINITIS

Purulent mediastinitis has been reported in 11 infants younger than 6 weeks, although it is likely that a great many more cases occur than have been reported in the literature and that it is a frequent complication of cardiothoracic surgery performed in the neonatal period. Six of the reported patients acquired their mediastinal abscess through blood-borne dissemination of organisms<sup>554-556</sup> or by extension from a focus of infection in an adjacent retropharyngeal abscess,<sup>557</sup> pleural or pulmonary abscess,<sup>527,555</sup> or vertebral osteomyelitis.<sup>558</sup> One infant developed infection as a complication of surgery for esophageal atresia.<sup>555</sup> *S. aureus* was the causative organism in four infants, and *S. pneumoniae*, *Clostridium* sp., and mixed *S. aureus* and *E. coli* were causative in one infant each. Organisms were not identified in four cases.

Traumatic perforation of the posterior pharynx or esophagus, often the result of resuscitative efforts in infants involving endotracheal or gastric intubation, produces a potential site for entry of microorganisms.<sup>559-566</sup> Although retropharyngeal abscess,<sup>567</sup> an infected pseudodiverticulum, or pyopneumothorax may occur as a consequence, purulent mediastinitis has been reported only three times as a complication,<sup>556,560,561</sup> but it is probably more common than is reported. At least one case of mediastinitis has occurred as the result of overly vigorous passage of a nasogastric tube through an atretic esophageal pouch.<sup>560</sup> Low (intrathoracic) perforations are said to have a higher risk of mediastinitis and abscess formation than those in the cervical region.<sup>562</sup>

Early symptoms are nonspecific and are similar to those of any septic process in a neonate. As purulent fluid accumulates in the mediastinum, it places increasing pressure

on the esophagus, trachea, and tributaries of the superior vena cava and thoracic duct, bringing about rapid development of dysphagia, dyspnea, neck vein distention, and facial cyanosis or edema. To maintain a patent tracheal airway, an afflicted infant will lie in an arched position with head extended in a manner very similar to that seen in neonates with congenital vascular ring. A halting, inspiratory, staccato type of breathing, probably because of pain, is also characteristic. Ultimately, the abscess may point on the anterior chest wall or in the suprasternal notch.

Usually, mediastinitis is first suspected when widening of the mediastinum is observed on a chest radiograph obtained for evaluation of respiratory distress. Forward displacement of the trachea and larynx may accompany these findings when retropharyngeal abscess is associated with mediastinitis. Infection after traumatic perforation of the esophagus or pharynx is often accompanied by pneumomediastinum with or without a pneumothorax.<sup>560,562</sup>

Contrast studies performed to define the cause of respiratory or feeding difficulties in infants with mediastinitis may result in flow of radiopaque fluid into an esophageal laceration, mimicking the findings of an atresia, duplication, or diverticulum of the esophagus.<sup>562,563</sup> In such cases, endoscopy often demonstrates a mucosal tear confirming the diagnosis.<sup>563,564</sup>

Treatment should be directed toward establishment of drainage and relief of pressure on vital structures through a mediastinotomy and placement of drainage tubes. The use of a tracheostomy or endotracheal tube may be necessary for maintenance of an adequate airway.

Initial empirical antimicrobial therapy with clindamycin (or metronidazole), ampicillin, and an aminoglycoside (or extended-spectrum cephalosporin) should be started after cultures of the blood and cerebrospinal fluid have been obtained. More limited empirical antibiotic therapy could be provided with a  $\beta$ -lactam and  $\beta$ -lactamase inhibitor combination alone, such as piperacillin plus tazobactam, ampicillin plus sulbactam, or ticarcillin plus clavulanate. Specific therapy can subsequently be determined by the results of bacteriologic studies of these sources or purulent fluid obtained at surgery.

## ESOPHAGITIS

The esophagus is infrequently a focus for infection of the fetus or newborn.<sup>568</sup> Esophageal atresia is associated with congenital rubella (see Chapter 28). Severe esophagitis has also been reported in neonates with congenital cytomegalovirus infection.<sup>569</sup> The esophagus may be involved in infants with congenital Chagas' disease identified by signs of dysphagia, regurgitation, and megaesophagus.<sup>570</sup> Esophageal disease may follow mediastinitis in the neonate (discussed earlier). Only occasional cases of bacterial esophagitis in a neonate have been reported; for example, a 940-g male infant developed signs of sepsis on the fifth day of life and died 5 hours later.<sup>569</sup> Premortem blood cultures were positive for *Bacillus* sp. Examination at autopsy revealed histologic evidence of esophagitis with pseudomembranous necrosis of squamous epithelium and many gram-positive bacilli. No other focus of infection was evident.

## INFECTIONS OF ENDOCRINE ORGANS

Endocrine glands other than the adrenal are rarely involved in fetal or neonatal infection. Neonatal suppurative thyroiditis in a term Laotian infant was reported by Nelson.<sup>571</sup> The infant presented with a left anterior neck mass at 3 days of age. At surgery, a cystic mass within the left lobe of the thyroid was identified. Purulent material within the mass grew *S. viridans* and nonhemolytic streptococci.

Orchitis has been described in a 10-week-old neonate caused by *S. enteridis*.<sup>572</sup> This infant presented with symptoms of sepsis and diarrhea, subsequently developing unilateral scrotal swelling and erythema on the fifth day after onset of illness. Ultrasound examination of the testis showed a patchy increased echo intensity; the diagnosis was confirmed at exploratory surgery to rule out testicular torsion. Three other cases of infection of the testes caused by *Salmonella* sp. in infants younger than 3 months have been described.<sup>572</sup>

## INFECTIONS OF THE SALIVARY GLANDS

Neonatal infections of salivary glands are uncommon, but when such infections occur, involvement of the parotid is the most frequent,<sup>573-578</sup> and submandibular gland infection is infrequent.<sup>574-579</sup> Most infections are caused by *S. aureus*,<sup>573-576</sup> but *E. coli*,<sup>576</sup> *P. aeruginosa*,<sup>576</sup> and group B streptococci (see Chapter 13) have also been implicated in suppurative parotitis. Not surprisingly, oral anaerobic bacteria, including *Bacteroides* sp. and *Peptostreptococcus* sp., may be found in mixed or isolated infections in more than one half of the cases.<sup>577</sup> Infections of the salivary glands occur more frequently in premature and male infants<sup>576,579</sup> and most commonly present during the second week of life. The oral cavity is the probable portal of entry for the infecting organism. However, blood-borne bacteria may invade the salivary glands. Dehydration with resultant decreased salivary flow may be a predisposing cause in some infants.

The clinical manifestations of salivary gland infection include fever, anorexia, irritability, and failure to gain weight. There may be swelling, tenderness, or erythema over the involved gland. Purulent material may be expressed from the ductal opening with or without gentle pressure over the gland.

The diagnosis is made by culture, Gram stain, or both, of the pus exuding from the duct or by percutaneous aspiration of a fluctuant area. If microscopic examination of the Gram stain does not suggest a responsible pathogen, initial antibiotic therapy should be directed against *S. aureus*, *E. coli*, and *P. aeruginosa* (i.e., penicillinase-resistant penicillin or vancomycin plus an aminoglycoside or extended-spectrum cephalosporin with activity against *Pseudomonas* organisms). If there is a strong suspicion of involvement with anaerobic bacteria (i.e., negative aerobic cultures or failure to respond to therapy directed at aerobic pathogens), consideration should be given to adding or substituting antibiotics appropriate for anaerobic bacteria (e.g., clindamycin, metronidazole in combination with other antibiotics or a  $\beta$ -lactam and  $\beta$ -lactamase antibiotic alone). The duration of therapy should extend throughout the period of inflammation, continuing 3 to 5 days after signs of local inflammation have disappeared. Incision and drainage often may be required; surgical drainage should be considered if there is not a

prompt response to therapy within 72 hours or if fluctuance of the gland becomes apparent. Careful attention to preservation of the function of the seventh cranial nerve is important when considering incision and drainage.

## INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

Bacterial infections of the skin of the newborn may manifest as maculopapular rash, vesicles, pustules, bullae, abscesses, cellulitis, impetigo, erythema multiforme, and petechiae or purpura. In a review of 2836 neonatal infections in Finland, only 6 were characterized as cellulitis.<sup>579a</sup> Most infections of skin are caused by *S. aureus*; such staphylococcal diseases include bullous impetigo, chronic furunculosis, scalded skin syndrome, and breast abscesses (see Chapter 17). Cellulitis frequently accompanied by adenitis and bacteremia may be caused by group B streptococci (see Chapter 13). Cutaneous infections caused by many other bacteria are discussed in this section; however, most microorganisms that cause disease in the neonate may produce cutaneous infections, and when relevant, those infections are discussed in other chapters. For additional information on bacterial infections of the skin, the reader is referred to the text by Solomon and Esterly<sup>580</sup> and the reviews by Swartz and Weinberg<sup>581</sup> and Frieden.<sup>582</sup> Excellent color photographs are included in the *Color Atlas of Pediatric Dermatology* by Weinberg and co-workers.<sup>583</sup>

### Pathogenesis

The skin of the newborn has unique characteristics, including absent microflora at birth; the presence of vernix caseosa; a less acid pH than that of older children; and often the presence of surgical wounds, including the severed umbilical cord, a circumcision site, and catheter wounds. The infant is immediately exposed to other infants, personnel, and the nosocomial environment. After the staphylococcal pandemic of the 1950s, information on the colonization of the skin, predisposing factors responsible for neonatal skin infection, bacterial transmission in the nursery, the inflammatory response of the skin to bacterial invasion, virulence factors of staphylococci, and methods of prevention of cross-infection became available. These studies are described in part in Chapters 17 and 35 and have been reviewed elsewhere.<sup>584</sup>

Cutaneous bacterial infection may be a primary event or the result of systemic infection. Septicemic embolic infection may occur at widely separated sites, whereas local infections often occur at a site with an identifiable predisposing cause. Procedures resulting in breaks in the cutaneous continuity, such as forceps abrasions or wounds at fetal electrodes or at venipuncture sites, may be readily identified. The necrotic umbilical cord is a site for proliferation of microorganisms that may invade local tissues.

Infection of the circumcision site remains a concern, because it is the most common surgical procedure in children in the United States. Speert<sup>585</sup> found that cleanliness was frequently disregarded by professional circumcisers as late as the 19th century. Operators were frequently uneducated, were dirty, and often spat on their instruments. Erysipelas, tetanus, and diphtheria have long been recognized as complications of unsterile surgical technique performed

on newborns. In a now obsolete and prohibited part of the Orthodox Jewish circumcision ritual, the operator applied his lips to the fresh circumcision wound and sucked a few drops of blood. Such practices were responsible for transmission of syphilis and tuberculosis in neonates in the past. In one report,<sup>586</sup> a 4-month-old infant presented with a penile ulcer, bilateral inguinal adenopathy, and a draining inguinal sinus caused by *Mycobacterium tuberculosis* after the "barber" spat on his razor before circumcision. Reports of 43 cases of tuberculosis associated with circumcision had been published by 1916.<sup>585</sup> Subsequent case reports of severe infection after circumcision include bacteremia related to group B streptococci,<sup>587</sup> local infection and fatal staphylococcal pneumonia,<sup>588</sup> staphylococcal scalded skin syndrome,<sup>589,590</sup> necrotizing fasciitis,<sup>591</sup> and bullous impetigo.<sup>592</sup> Two reports of necrotizing fasciitis after Plastibell circumcision emphasize severe infection as a potential risk of this procedure.<sup>593</sup> One infection caused by *S. aureus* and *Klebsiella* sp. was associated with prolonged convalescent and multiple surgical repairs, whereas a second infant survived staphylococcal necrotizing fasciitis after 14 days of intravenous antibiotic treatment.

The incidence of infection after elective circumcision was investigated at the University of Washington Hospital<sup>594</sup> during the period 1963 to 1972. Infection, defined as the presence of pus or erythema, occurred in 0.41% of 5521 infants and was more frequently associated with the use of a disposable plastic bell (Plastibell, 0.72%) than with the use of a metal clamp (Gomco, 0.14%). Wound cultures were infrequently available, and the microbiologic diagnosis was uncertain for most infants. It is clear that circumcision infection is uncommon, but local spread of infection may be devastating and lead to systemic infection.

Intrapartum fetal monitoring with scalp electrodes and intrauterine pressure catheters and measurements of fetal blood gases through scalp punctures have been associated with infections related to herpesvirus (see Chapter 26), *Mycoplasma* (see Chapter 16), and a variety of aerobic and anaerobic bacteria. Bacterial infections have varied from pustules to abscesses or fasciitis.<sup>578-581</sup> Infection rates are relatively low, varying from 0.1% to 4.5%<sup>597,598</sup>; however, severe infections, including fasciitis, meningitis, and osteomyelitis have occurred as severe complications. A review<sup>599</sup> of causative organisms in fetal scalp monitor infections found that 61% of infections were polymicrobial, involving anaerobic bacteria, aerobic gram-positive cocci, and gram-negative bacilli.

A multitude of specific virulence factors may be important determinants of disease. Some phage types of *S. aureus* are responsible for local tissue damage and systemic disease; other staphylococci elaborate toxins that result in bullae and other cutaneous pathology. Groups A and B streptococci are responsible for cellulitis and impetigo in the infant. *P. aeruginosa* may invade and proliferate in small blood vessels, thereby causing local necrosis and eschar formation (i.e., ecthyma gangrenosum). Infections with *Clostridium* sp. cause disease in devitalized tissues such as the umbilical stump.<sup>600</sup> Similarly, organisms usually considered commensals, such as diphtheroids, might be responsible for infection of the cord and fetal membranes.<sup>601</sup>

## Microbiology

The skin of the infant is colonized initially by microorganisms present in the maternal birth canal. The skin of infants delivered by cesarean section is usually sterile at birth. After birth, microorganisms may be transferred to the skin during handling by the parents and nursery personnel. The prevalent organisms on the skin during the first few days of life include coagulase-negative staphylococci, diphtheroids, and gram-negative enteric bacilli (including *E. coli*).<sup>602,603</sup> The umbilicus, genitalia, and adjacent skin areas (groin and abdomen) are colonized first; and organisms then spread to the nose, throat, conjunctivae, and other body sites. Organisms present in the nursery environment colonize neonatal skin after a few days in the nursery. *S. aureus*, group B streptococci, and various species of gram-negative bacilli may be present, but the microbiologic flora differs among nurseries and from time to time in the same nursery. Use of soaps and antiseptic solutions modifies the flora on the skin of the newborn. Hexachlorophene decreases colonization with staphylococci and diphtheroids, but gram-negative organisms are unaffected or may increase after use of this agent.<sup>604</sup>

## Epidemiology

Male infants are more susceptible to skin infections caused by *S. aureus* than are female infants. Thompson and co-workers<sup>605</sup> demonstrated that males were colonized more frequently in every body site cultured, including the nose, groin, rectum, and umbilicus. Their review of studies indicated that in England, the United States, and Australia, approximately 50% more males had skin lesions than did females. Although the incidence of breast abscesses is equal in males and females during the first 2 weeks of life, such abscesses are more frequent thereafter in females.<sup>606</sup> The reason for this pattern is unclear, but Rudoy and Nelson<sup>606</sup> hypothesized that physiologic breast enlargement may play a role. Hormone production in the female infant after the second week might account for the increase in abscesses of the breast.

Infections caused by methicillin-resistant *S. aureus* (MRSA) involving the skin of children and neonates have markedly increased. The *mecA* gene responsible for resistance to oxacillin and nafcillin is often closely linked to a gene responsible for skin invasion. Before 1997, epidemic MRSA infections occurred in neonatal units involving infections of the respiratory tract, nasopharynx, gastrointestinal tract, eye, blood, wounds or umbilicus<sup>607</sup>; these infections were usually restricted to single nurseries and involved a single genetic variant of MRSA. Since 1990, MRSA infections acquired in the community have been reported with increased frequency,<sup>608</sup> including in infants as young as 2 weeks old. Up to 91% of these infections have involved the skin and soft tissues and, unlike typical nosocomial MRSA, community-acquired MRSA organisms have frequently remained susceptible to trimethoprim-sulfamethoxazole and clindamycin. At the University of New Mexico, continued surveillance of MRSA-colonized and -infected infants in the neonatal intensive care units has shown that by 2003, more than one half of all isolates are now community acquired.

Seasonal variation in the frequency of neonatal skin infections has been reported by Evans and co-workers,

who conducted a series of studies at Harlem Hospital (New York).<sup>609</sup> The prevalence of *S. aureus*, *E. coli*, and streptococci in the nares and umbilicus of infants was lowest in the autumn and usually highest in the summer or spring. No seasonal variation was observed for *S. epidermidis* or *Enterobacter* sp. The investigators concluded that seasonal differences must be considered in investigations of bacterial colonization of the newborn skin and that high humidity may favor gram-negative colonization.

The time of onset of skin lesions associated with sepsis may be early (during the first week of life) or late (up to several weeks or months after birth). Disease acquired in the nursery usually becomes apparent after 5 days of age. Many skin lesions do not appear until after the infant has left the nursery; the observed incidence of skin disease caused by bacteria should include surveillance of infants in the home during the first month of life. Physicians responsible for neonatal care must be alert to the unusual occurrence of skin lesions. The introduction of a new and virulent bacterium, an alteration in technique, or the use of contaminated materials must be considered as possible causes of an increased incidence of such infections.

## Clinical Manifestations

Infants who have skin infections that remain localized that are not invasive or part of a systemic infection have few general signs of disease, such as fever, alteration in feeding habits, vomiting, or diarrhea. These signs may be present when significant tissue invasion occurs, as in abscesses or extensive cellulitis. The various cutaneous manifestations that result from infectious diseases are listed in Table 10-5.

Among the common and least specific lesions are maculopapular rashes; these rashes may be caused by viruses (measles, rubella, or enteroviruses), fungi (*Candida* sp.), or bacteria (streptococci or staphylococci), or they may be unassociated with any infectious process. Erythema multiforme lesions have been observed in cases of sepsis related to *S. aureus*,<sup>610</sup> streptococci,<sup>580</sup> and *P. aeruginosa*.<sup>611</sup> Virtually any rash may be associated with bacterial infection. In an outbreak of sepsis caused by *Achromobacter* in premature infants,<sup>612</sup> illness was marked by respiratory distress, including apnea and cyanosis, but was characterized by a rash consisting of indurated, erythematous lesions with sharply defined borders that began on the cheeks or chest and spread rapidly to adjacent areas.

Cellulitis, erysipelas, and impetigo are usually associated with streptococcal infection (group A or B),<sup>613</sup> although impetigo caused by *S. aureus* or *E. coli* has also been reported in infants.

Vesicles, commonly associated with infections by herpesviruses, also are seen on occasion during early stages of skin lesions caused by *S. aureus*, *H. influenzae*,<sup>614</sup> *L. monocytogenes*,<sup>615</sup> and *P. aeruginosa*. *Streptococcus* group B,<sup>616</sup> *S. aureus*, *P. aeruginosa*, herpes simplex virus, and *T. pallidum* may also be responsible for bullous lesions. Pustules commonly occur in staphylococcal diseases but also occur in infections caused by *L. monocytogenes* and, rarely, in skin infections with *H. influenzae*.<sup>617</sup>

Ecthyma gangrenosum is a local manifestation of infection with *P. aeruginosa*.<sup>618,619</sup> Lesions begin as a vesicular eruption on a wide erythematous base. Vesicles

<sup>b</sup>See appropriate chapter for further discussion.

<sup>c</sup>Including infections acquired in utero.

rupture and form an indurated black eschar followed by larger sharply demarcated, painless necrotic areas, resulting from a small vessel vasculitis with necrosis of the adjacent tissue. The organisms are present in purulent material underlying the necrotic membrane. These lesions are particularly more common adjacent to nose, lip, ear, mouth, and perineum, resulting in avascular necrosis and loss of tissue. *P. aeruginosa* may be grown in pure culture from blood and lesions. Among 48 infants described in one outbreak, lesions appeared within the first 2 weeks of life; most infants died within 3 days of onset.<sup>620</sup> Ecthyma is relatively specific for *Pseudomonas* infections, but similar or identical lesions have rarely been described in infections due to

*S. aureus*, *Aeromonas hydrophila*, *S. marcescens*, *Aspergillus* sp., or *Mucor* sp.<sup>621</sup>

Many infants with *Candida* infections have cutaneous manifestations. In a report by Baley and Silverman,<sup>622</sup> 18 infants with systemic candidiasis were described; 8 had a burnlike truncal erythema, and 9 other infants had typical candidal diaper rashes or maculopapular rashes of the axillae or neck.

Abscesses of the skin and subcutaneous tissue are usually caused by *S. aureus* and, less frequently, by streptococci of groups A or B<sup>623,624</sup> or by gram-negative enteric bacilli.<sup>625-633</sup> Community-acquired MRSA organisms are even more likely to produce skin infections with abscess formation. Organisms

that colonize the skin over an area that has been disrupted by an abrasion or other wound may invade the subcutaneous tissue and produce an abscess. *Haemophilus* sp.,<sup>634-636</sup> *Gardnerella vaginalis*,<sup>637</sup> *Bacteroides* sp.,<sup>638</sup> molluscum contagiosum,<sup>639</sup> *Drosophila myiasis*,<sup>640</sup> scabies,<sup>641</sup> and *Candida*<sup>642</sup> are examples of diverse causes of cutaneous abscesses; virtually any bacterial, fungal, or parasitic agent that is normally or transiently on skin may become a pathogen. *E. coli*, *Klebsiella* sp., *P. aeruginosa*,<sup>623,628,643</sup> *N. gonorrhoeae*,<sup>644</sup> and *Bacteroides fragilis*<sup>645</sup> have caused wound infections in infants whose scalps were lacerated by forceps, fetal electrodes, or instruments used for obtaining blood from the scalp in utero. An extensive outbreak of systemic disease caused by *S. marcescens* in a neonatal intensive care nursery in Puerto Rico included wound infections at the site of intravenous infusions.

A cephalohematoma may become infected during sepsis or from manipulation of the cephalohematoma, such as through diagnostic or therapeutic needle puncture<sup>646</sup> or by puncture from a fetal monitor. Infections may be caused by *Bacteroides* sp.,<sup>638</sup> *E. coli*,<sup>625,626</sup> and *P. aeruginosa*.<sup>647</sup> The infection may be associated with meningitis<sup>647</sup> or with osteomyelitis of the underlying skull.<sup>625,626</sup>

*S. aureus* is the most frequent etiologic agent in breast abscess, but gram-negative enteric bacilli may become more common.<sup>627,631,632</sup> Of 36 cases with mastitis seen in Dallas during a 16-year period, 32 cases were caused by *S. aureus*, 1 was caused by *E. coli*, and 2 were caused by *Salmonella* sp.; and both *E. coli* and *S. aureus* were isolated from one abscess.<sup>648</sup> Forty-one cases of mastitis in neonates were managed at Children's Hospital (Boston) from 1947 to 1983.<sup>649</sup> *S. aureus* was responsible for 29 of 34 cases with an identifiable bacterial pathogen. All cases occurred in term infants during weeks 1 to 5 of life. Bilaterality and extramammary foci were rare. One third of infants were febrile, and most had elevated white blood cell counts (>15,000 cells/mm<sup>3</sup>). Other reports have identified group B streptococci<sup>624</sup> and *P. mirabilis*<sup>629</sup> as causes of breast abscesses. Brook<sup>632</sup> found that 5 of 14 breast abscesses contained anaerobic bacteria (i.e., *Bacteroides* sp. and *Peptostreptococcus*), but *S. aureus*, group B streptococci, or enteric bacteria predominated; anaerobic bacteria occurred alone in only 2 of 14 cases.

Paronychia may occur in neonates after injury to the cuticle. The lesion is usually caused by *S. aureus* or  $\beta$ -hemolytic streptococci.<sup>650</sup> The authors of a report on an outbreak of paronychia in a Kuala Lumpur nursery suggest but do not prove that the lesions were caused by an anaerobic *Veillonella* sp.<sup>651</sup>

Omphalitis is defined by the presence of erythema or serous or purulent discharge from the umbilical stump or periumbilical tissues. A review by Cushing<sup>652</sup> provided a useful discussion of the pathophysiology, microbiology, diagnosis, and management of omphalitis. The incidence of infection is more frequent in low-birth-weight infants and in those with complications of delivery. A survey of infants born at the Royal Woman's Hospital in Brisbane<sup>653</sup> identified an incidence of approximately 2% among term infants. The mean age of presentation of omphalitis was 3.2 days. Perhaps because hexachlorophene bathing was used, gram-negative bacilli were more frequently associated with infection than were gram-positive cocci. However, microbiologic results are difficult to interpret because swabs of the site of infection do

not exclude surface contaminants unless cultures are taken with extreme care and precision.

A series from the United States<sup>654</sup> found that periumbilical fasciitis was more frequent in males but did not find that umbilical catheterization, low birth weight, or septic delivery was associated with a high risk; overall, the incidence of omphalitis was equal in males and females. In this series, omphalitis presented as discharge, cellulitis, or fasciitis; gram-positive organisms were found in 94% of cultures, and gram-negative bacteria were found in 64%. *S. aureus* was the most frequent isolate, with *E. coli* and *Klebsiella* sp. the next most common. Group A streptococci have been responsible for nursery outbreaks that may include an indolent form of omphalitis characterized by erythema and oozing of the umbilical stump for days to weeks, accompanied by pustular lesions of the abdominal wall in some cases.<sup>655</sup> Neonatal tetanus usually occurs as a result of contamination of the umbilical wound by *Clostridium tetani* at delivery.

Acute necrotizing fasciitis is a bacterial infection of subcutaneous tissue and fascial sheath.<sup>630,656,657</sup> Infection can arise in an operative wound or in a focal infection such as a breast abscess, or there may be no apparent predisposing cause. Necrotizing fasciitis has been reported after circumcision<sup>591</sup> and as a complication of insertion of a fetal monitor.<sup>595</sup> The trunk and extremities are the areas most commonly involved; inflammation spreads rapidly along fascial planes, producing thrombosis and extensive necrosis, with infarcts developing in overlying skin. Vesicles and bullae appear, and the skin may become blue-gray or black. Myositis and bacteremia may accompany fasciitis. Staphylococci, group B streptococci,<sup>658</sup> *E. coli*, *P. aeruginosa*, anaerobic bacteria,<sup>596</sup> and mixtures of gram-positive and gram-negative bacteria have been associated with this disease. The bacteria are present in skin lesions, deep fascia, and in some cases, blood. The mortality is high despite the use of fasciotomy, wide debridement, and antibiotics.

Perirectal abscesses may occur in newborns. Unlike older children, most newborns with perirectal abscess do not have underlying immunodeficiency, although infants with acquired or congenital immunodeficiency often present with this condition. The most common cause of perirectal abscess is *S. aureus*, *E. coli*, or other enteric bacilli;<sup>659,660</sup> however, anaerobic bacteria can also be involved. *S. aureus* and enteric bacilli may be more common in infants and newborns.<sup>660</sup> Recent rectal surgery for conditions such as Hirschsprung's disease or imperforate anus (myotomy or rectal dilatation) may be predisposing causes in infants; as in older children, neutropenia may be associated with an increased risk for perirectal abscess.

Otitis externa is uncommon in the newborn. Victorin<sup>661</sup> described an outbreak of neonatal infections in which *P. aeruginosa* was cultured from seven infants with suppuration of the auditory canal. The author suggested that this outbreak was caused by contaminated bath water used in the nursery.

## Diagnosis

The appearance of a skin lesion alone may be sufficiently typical to suspect certain etiologic agents (e.g., ecthyma gangrenosum), but more often, the appearance is non-specific. A microbiologic diagnosis should be sought to

provide specific therapy. The lesion and the surrounding tissue should be cleaned with 70% ethanol to prevent contamination from organisms that colonize the surface. If crusts are present, they should be lifted with a sterile swab to provide drainage, and cultures should be obtained from the base of the lesion. Vesicles and pustules can be aspirated with a needle (20 to 25 gauge) attached to a syringe, or they can be opened and exudate collected on a sterile swab. In general, swabs are not preferred for specimen collection because swab materials bind or inactivate bacterial organisms. Aspiration of abscesses is important; more than one aspiration may be required because the suppurative focus may not be easily distinguished from the surrounding inflammatory tissue. Aspiration of the leading edge or point of maximal inflammation of an area of cellulitis may be of value and should be performed if no other suppurative or purulent sites are available for culture. A small needle (25 or 26 gauge) should be attached to a tuberculin or other small-volume syringe filled with 0.25 to 0.50 mL of sterile non-bacteriostatic saline; the needle should be inserted into the area of soft tissue to be sampled, with continuous, gentle aspiration applied to the syringe. If no fluid is returned to the syringe, a small amount of fluid should be injected and immediately aspirated back into the syringe. Collected material may be sent to the laboratory in the syringe for Gram stain and culture, or, alternatively, the contents may be washed into a tube of bacteriologic broth medium for transport and subsequent culture.

If swabs are used, care must be taken that the material does not dry before it is plated on bacteriologic media. Swabs preferentially should be directly inoculated or rinsed in bacteriologic media and immediately transported to the microbiology laboratory. Alternatively, they may be refrigerated or placed in appropriate transport media if more than a few hours will elapse before inoculation of media in the laboratory. Whenever sufficient material is available (on swabs or in liquid), several slides should be prepared for Gram staining.

It is often difficult to distinguish petechiae from vascular dilatation. Pressure with a glass slide on the border of the lesion is a simple and reliable method for detecting extravasation of red blood cells. If the lesion disappears on pressure, it is probably caused by dilatation of small vessels, whereas persistence of the lesion after application of pressure indicates extravasation of red blood cells. Bacteria may be present in petechial lesions that occur in infants with bacterial sepsis. Blood obtained by aspiration or gentle scraping with a scalpel at the center of the petechiae may reveal the causative organism on Gram stain or culture.

### Differential Diagnosis

Sclerema neonatorum, milia, and erythema toxicum are noninfectious lesions that are often confused with infections of the skin.<sup>662</sup> Bullous and purpuric lesions may be caused by noninfectious disorders, including mast cell diseases (e.g., urticaria pigmentosa), histiocytosis X, acrodermatitis enteropathica, dermatitis herpetiformis, epidermolysis bullosa, congenital porphyria,<sup>580</sup> and pemphigus vulgaris.<sup>663</sup> A syndrome of generalized erythroderma, failure to thrive, and diarrhea has been associated with various forms of immunodeficiency.<sup>664</sup>

Sclerema neonatorum is a diffuse, spreading, waxy hardness of the skin and subcutaneous tissue that occurs during the first weeks of life.<sup>646,666</sup> The subcutaneous tissue seems to be bound to underlying muscle and bone. This condition is usually seen on the thighs, buttocks, and trunk. Although associated with sepsis in some infants, sclerema also afflicts infants with dehydration, acidosis, and shock. Most evidence supports the hypothesis that sclerema is a manifestation of shock and insufficiency of the peripheral circulation. When it occurs in infants with generalized infection, sclerema is associated with a poor prognosis. In a review of cases of sepsis at The New York Hospital, sclerema was detected in 6 of 71 infants, 5 of whom died.<sup>667</sup>

Milia are yellow or pearly white papules that are 1 mm in diameter and usually found scattered over the cheeks, forehead, and nose.<sup>662,668</sup> The lesion is a small cyst formed from retention of sebum in sebaceous glands. Because the cyst is capped by a shiny surface of epidermis, it may be confused with a small pustule. Milia are common; Gordon<sup>668</sup> estimated that 40% of healthy newborns have milia. The lesions are common in the first few weeks of life. These cysts may be distinguished from staphylococcal pustules by aspiration and Gram stain of the material.

Erythema toxicum consists of several types of lesions, including 1- to 3-mm, yellow-white papules or pustules on an erythematous base, erythematous macules, or diffuse erythema. These lesions are usually present on the trunk but may involve the head and neck and extremities as well. Most lesions appear within the first hours of life and are uncommon after 2 days of age. Erythema toxicum is uncommon in low-birth-weight or premature infants.<sup>669</sup> The affected infants have no signs of systemic illness or local irritation. A smear of the contents of pustules reveals the presence of eosinophils and an absence of bacteria. Other noninfectious pustular lesions of newborns include neonatal pustular melanosis, which is marked by a mixed infiltrate that has a predominance of neutrophils,<sup>670</sup> and infantile acropustulosis, which is characterized by an eosinophilic infiltration of the skin.<sup>671,672</sup>

Bullae may occur on the skin of the wrist or forearm and usually are caused by trauma.<sup>673</sup> Sucking of the extremity by the infant is believed to cause the bullae, which contain sterile serous fluid.

Purpura may be caused by noninfectious causes, including trauma, erythroblastosis fetalis, or less frequently, coagulation disorders, maternal drug ingestion, congenital leukemia, and congenital Letterer-Siwe disease.

Diaper rash is primarily a contact dermatitis associated with soilage of the skin by urine and stool.<sup>674-676</sup> The rash may occur as a mild erythema or scaling, a sharply demarcated and confluent erythema, or discrete shallow ulcerations. A beefy red, confluent rash with raised margins, satellite (e.g., folliculitis) oval lesions, or discrete vesicular-pustular lesions indicates secondary invasion by *C. albicans* or *S. aureus*. Systemic infectious illnesses that manifest as disseminated rashes (e.g., herpes, varicella, syphilis) may be characterized by early typical lesions in the diaper area.

### Treatment

The treatment of localized skin lesions consists of the use of local antiseptic materials, systemic antimicrobial

agents, and appropriate incision and drainage or debridement.

Hexachlorophene (3% detergent emulsion) and chlorhexidine (4% solution) are of value in cleaning small, abraded areas and discrete pustular lesions. Because of the concern over its neurotoxicity and cutaneous absorption, hexachlorophene should not be used on large open areas of skin (see Chapter 17).

Systemic antibiotics should be considered for therapy whenever there is significant soft tissue infection with abscess or cellulitis. The specific antibiotic choice should be made on the basis of the microbiology of the lesion; streptococci may be treated effectively with penicillin G, ampicillin, or extended-spectrum cephalosporins (i.e., cefotaxime or ceftriaxone), whereas staphylococci generally must be treated with penicillinase-resistant penicillins or vancomycin. Infections due to gram-negative enteric bacilli may be treated with aminoglycosides or extended-spectrum cephalosporins based on the results of susceptibility testing. Infections due to *Pseudomonas* organisms can be effectively treated with aminoglycosides or ceftazidime.

Local heat and moist dressings over areas of abscess formation may facilitate localization or spontaneous drainage. Indications for incision and drainage of abscesses in infants are the same as for those in older children and adults.

## Prevention

Prevention of local skin infections is best provided by appropriate routine hygiene, maintenance of the integrity of skin (i.e., avoidance of drying, trauma, or chemical contact), frequent diaper changes, and hygienic care of the umbilicus or other wounds or noninfectious skin inflammation. The following measures of skin care are recommended by the Committee of the Fetus and Newborn of the American Academy of Pediatrics<sup>676</sup> to prevent infection:

1. The first bath should be postponed until the infant is thermally stable.
2. Nonmedicated soap and water should be used; sterile sponges (not gauze) soaked in warm water may be used.
3. The buttocks and perianal should be cleaned with fresh water and cotton or with mild soap and water at diaper changes.
4. Ideally, agents used on the newborn skin should be dispensed in single-use containers.
5. No single method of cord care has proved to be superior, and none is endorsed.<sup>676</sup>

Cord care may include application of alcohol, triple dye (i.e., brilliant green, proflavine hemisulfate, and crystal violet) or antimicrobial agents such as bacitracin. Alcohol hastens drying of the cord but is probably not effective in preventing cord colonization and omphalitis. A randomized study of triple dye, povidone-iodine, silver sulfadiazine, and bacitracin ointment showed comparability in antimicrobial control.<sup>677</sup>

During nursery outbreaks, the Centers for Disease Control and Prevention recommend the judicious use of hexachlorophene bathing.<sup>678</sup> Daily hexachlorophene bathing of the diaper area<sup>679</sup> and umbilical cord care with 4% chlorhexidine solution<sup>680</sup> have demonstrated efficacy for prevention of staphylococcal disease (see Chapter 17).

## CONJUNCTIVITIS AND OTHER EYE INFECTIONS

Conjunctivitis in the newborn usually results from one of four causes: infection with *N. gonorrhoeae*, infection with *S. aureus*, inclusion conjunctivitis caused by *Chlamydia trachomatis*, or chemical conjunctivitis induced by silver nitrate solution.<sup>681,682</sup> Less commonly, other microorganisms have been implicated as a cause of conjunctivitis, including group A and B streptococci, *S. pneumoniae*, *H. influenzae* (nontypeable<sup>609</sup> and group b<sup>683</sup>), *P. aeruginosa*, *Moraxella* (*Neisseria*) *catarrhalis*,<sup>684</sup> *Neisseria meningitidis*,<sup>685</sup> *Corynebacterium diphtheriae*,<sup>686</sup> *Pasteurella multocida*,<sup>687</sup> *Clostridium* sp.,<sup>688</sup> herpes simplex virus, echoviruses, *M. hominis*, and *Candida* sp. In addition to meningococcal infections, other neisserial species can be confused with gonococcal infections; *Neisseria cinerea* has been reported to cause conjunctivitis that was indistinguishable from gonococcal infection.<sup>689</sup> An epidemic of erythromycin-resistant *S. aureus* conjunctivitis affected 25 of 215 newborns during a 10-month period; control of the epidemic was achieved by identification of staff carriers and substitution of silver nitrate prophylaxis for erythromycin.<sup>690</sup> The major causes of conjunctivitis in the neonate are discussed in Chapter 12 and Chapter 17. Cultures of the conjunctivae of neonates with purulent conjunctivitis and from the comparable eyes of a similar number of infants chosen as controls revealed significant differences, suggesting causality for *S. viridans*, *S. aureus*, *E. coli*, and *Haemophilus* sp.<sup>691,692</sup>

Compared with chemical (e.g., silver nitrate) conjunctivitis, other noninfectious causes for conjunctivitis occur only rarely. Eosinophilic pustular folliculitis has been described since 1970<sup>693</sup>; although this disease usually occurs after 3 months of age, some infants younger than 4 to 6 weeks have been described. These infants present with recurrent crops of pruritic papules primarily affecting the scalp and brow. Biopsy specimens reveal folliculitis with a predominant eosinophilic infiltrate; most infants also have a leukocytosis and eosinophilia. Other acute or chronic cutaneous conditions may also manifest as conjunctival or periorbital inflammation, such as seborrhea, atopic dermatitis, acropustulosis of infancy, and erythema toxicum (see "Infections of the Skin and Subcutaneous Tissue").

In a review by Hammerschlag,<sup>694</sup> the incidence of the two major pathogens ranged from 17% to 32% for *C. trachomatis* and 0% to 14.2% for *N. gonorrhoeae* in four United States studies. In other developed countries such as England,<sup>695</sup> investigators found 8 cases of gonococcal infection and 44 cases of chlamydial infection among 86 newborns with ophthalmia neonatorum; in Denmark,<sup>696</sup> investigators found that 72% of infants with conjunctivitis at 4 to 6 days after birth had positive cultures, but 70% were caused by staphylococci (both *S. aureus* and *S. epidermidis*), and that chlamydiae were isolated from only 2 of 300 newborns. The incidence and microbiology of neonatal conjunctivitis is dependent on the incidence of transmissible infections in the maternal genital tract or the nursery and the use and efficacy of chemoprophylaxis. In Nairobi, Kenya, in a hospital where ocular prophylaxis had been discontinued, the incidence of gonococcal and chlamydial ophthalmitis was 3.6 and 8.1 cases per 100 livebirths, respectively<sup>697</sup>; whereas in Harare, Zimbabwe, in a hospital where prophylaxis

also was not used, the most common cause of conjunctivitis was *S. aureus*.<sup>698</sup> The introduction of tetracycline ointment for prophylaxis at Bellevue Hospital (New York City) led to an overall increase in conjunctivitis associated with an increase in the incidence of gonococcal infection<sup>699</sup> because of the emergence of tetracycline resistance among gonococci.

Infections related to *P. aeruginosa* deserve special attention. Although uncommon, pseudomonal conjunctivitis may be a devastating disease if not recognized and treated appropriately.<sup>699</sup> The infection is usually acquired in the nursery, and the first signs of conjunctivitis appear between the 5th and 18th days of life. At first, the clinical manifestations are localized to the eye and include edema and erythema of the lid and purulent discharge. In some children, the conjunctivitis progresses rapidly, with denuding of the corneal epithelium and infiltration with neutrophils. With extension of the corneal infiltration, perforation of the cornea may occur. The anterior chamber may fill with fibrinous exudate, and the iris can adhere to the cornea. Subsequent invasion of the cornea by small blood vessels (pannus) is characteristic of pseudomonal conjunctivitis. The late ophthalmic complications may be followed by bacteremia and septic foci in other organs.<sup>700</sup>

Pseudomonal eye infections in neonates can occur in epidemic form, with subsequent high rates of mortality and ophthalmic morbidity. Burns and Rhodes<sup>700</sup> reported a series of eye infections caused by *P. aeruginosa* in premature infants with purulent conjunctivitis rapidly progressing to septicemia, shock, and death in four infants. Five other children with conjunctivitis alone survived, but one child required enucleation. Drewett and co-workers<sup>701</sup> described a nursery outbreak of pseudomonal conjunctivitis believed to be caused by contaminated resuscitation equipment; of 14 infected infants, 1 became blind, and another had severe corneal opacities. Rapidity of the course of this infection is indicated in a case report of a 10-day-old infant who developed a corneal ulcer with perforation within 2 days after first observation of a purulent discharge.<sup>702</sup> An outbreak of four cases of *Pseudomonas* conjunctivitis in premature infants occurred within a period of 2 weeks at the American University of Beirut Medical Center<sup>703</sup>; no cause for the outbreak was found.

A review by Lohrer and Belohradsky<sup>704</sup> of bacterial endophthalmitis in neonates underlines the importance of *P. aeruginosa* in invasive bacterial eye infections ranging from keratitis to panophthalmitis. The literature review included 16 cases of invasive eye infections in neonates; 13 were caused by *P. aeruginosa*, and the others were cases of endophthalmitis caused by group B streptococci and *S. pneumoniae*. Other opportunistic gram-negative pathogens associated with outbreaks of infections in nurseries may also include conjunctivitis as a part of the infection syndrome. In a report by Christensen and co-workers,<sup>705</sup> a multiply antibiotic-resistant *S. marcescens* was responsible for 15 cases of pneumonia, sepsis, and meningitis and for 20 cases of conjunctivitis, cystitis, and wound infection over a 9-month period in a neonatal intensive care unit.

Dacryocystitis may complicate a congenital lacrimal sac distention (i.e., dacryocystocele). Harris and DiClementi<sup>706</sup> described an infant who presented on day 4 of life with edema and erythema of the lower lid. Purulent material

emerged from the puncta after moderate pressure over the lacrimal sac; *S. marcescens* was grown from the material.

The physician responsible for management of the child with purulent conjunctivitis must consider the major causes of the disease and must be alert to the rare pathogen. In hospitals that practice Credé's method (i.e., silver nitrate application), purulent conjunctivitis during the first 48 hours of life is almost always caused by chemical toxicity.<sup>707</sup> After the first 2 days, the pus of an exudative conjunctivitis must be carefully examined by Gram stain for the presence of gram-negative intracellular diplococci, gram-positive cocci in clusters, and gram-negative bacilli. Appropriate cultures should be used for isolation of the organisms concerned. If the smears are inconclusive and no pathogens are isolated on appropriate media and if the conjunctivitis persists, a diagnosis of inclusion or chlamydial infection is likely.<sup>706,798,709</sup>

The treatment of gonococcal and staphylococcal conjunctivitis is discussed in Chapters 12 and 17. Chlamydial conjunctivitis is reviewed in Chapter 11.

If infection with *Pseudomonas* species is suspected, treatment should be started at once with an effective parenteral antibiotic such as an aminoglycoside (e.g., tobramycin, amikacin, or gentamicin) with or without an antipseudomonal penicillin or ceftazidime (see Chapter 35) and with a locally applied ophthalmic ointment. The use of subconjunctival gentamicin or other antipseudomonal aminoglycoside is of uncertain value; however, if the cornea appears to be extensively involved, there is a risk of rapid development of endophthalmitis, and the subconjunctival injection of antibiotics should be considered in consultation with an ophthalmologist. If the diagnosis is confirmed, this regimen is continued until the local signs of *Pseudomonas* infection resolve.

Recommendations for ocular chemoprophylaxis are discussed in chapter 12 on gonococcal and Chapter 11 on chlamydial infections. Additional information is available in the 2000 edition of the Report of the Committee on Infectious Diseases published by the American Academy of Pediatrics.<sup>710</sup>

In 1911, Lindner and colleagues identified typical intracytoplasmic inclusions in infants with a nongonococcal form of ophthalmia neonatorum called inclusion conjunctivitis of the newborn (ICN) or inclusion blennorrhoea.<sup>1</sup> Mothers of affected infants were found to have inclusions in their cervical epithelial cells, and fathers of such infants had inclusions in their urethral cells. For 50 years, cytologic demonstration of chlamydial inclusions in epithelial cells was the only diagnostic procedure available. When methods to isolate *Chlamydia trachomatis* were developed, first in the yolk sac of the embryonated hen's egg and then in tissue culture, studies again demonstrated this organism as the etiologic agent for conjunctivitis in the newborn infant and then confirmed the maternal genital tract reservoir for transmission of this agent.<sup>2</sup> Although ICN was studied for 60 years, it was not until the late 1970s, with the impetus of the report by Beem and Saxon<sup>3</sup>, that the importance of chlamydial infection of the respiratory tract in infants was recognized.

*C. trachomatis* now is appreciated as the most common sexually transmitted pathogen in Western industrialized society.<sup>4</sup> Although most *C. trachomatis* infections in men and women are asymptomatic, infection can lead to severe reproductive complications in women. The infection can be

transmitted from an infected mother to her newborn during delivery, producing conjunctivitis or pneumonia. *C. trachomatis* is the most common cause of conjunctivitis in infants younger than 1 month of age worldwide and often is a cause of afebrile pneumonia in infants younger than 3 months of age.

## EPIDEMIOLOGY AND TRANSMISSION

*C. trachomatis* is the most common bacterial cause of sexually transmitted infections in the United States.<sup>5,6</sup> Reported prevalence rates in the United States have ranged from 2% to 7% among female college students, from 4% to 12% among women attending a family planning clinic, and from 6% to 20% among men and women attending a clinic for sexually transmitted diseases or persons entering correctional facilities.<sup>7,8</sup> In the United Kingdom, recent data suggest that the rate of infection among young women exceeds 10%.<sup>9</sup> Prevalence rates have declined in areas where screening and treatment programs have been implemented.<sup>10</sup> Many men and most women infected with *C. trachomatis* are either asymptomatic or minimally symptomatic, and presentation for diagnosis is a result of a routine screening program, or of presence of symptoms in a contact. In gonococcal infections, by contrast, symptoms develop in most infected persons, who then present acutely for care. Regional estimates are hampered by underdiagnosis and underreporting of cases. Because symptoms are absent or minimal in most women and many men, a large reservoir of asymptomatic infection is present that can sustain the pathogen within a community.

Age younger than 20 years is the demographic factor in women most strongly associated with chlamydial infection (relative risk is 2 to 3.5 among women younger than 25 years compared with older women).<sup>6</sup> Although the prevalence of chlamydial infection is increased among black or economically disadvantaged persons, broad socioeconomic and geographic distribution of infection exists.<sup>5,11,14,17</sup> Other risk factors for cervical chlamydial infection in women are anatomic or hormonal (e.g., use of depot forms of medroxyprogesterone acetate<sup>18</sup> or ectopy following use of oral contraceptives),<sup>13,19</sup> behavioral (e.g., number of sexual partners),<sup>11,12</sup> and microbiologic (e.g., concurrent gonorrhea).<sup>5,12</sup>

For purposes relevant to this chapter, the major method of transmission of *C. trachomatis* is sexual. The child-to-child and intrafamilial infecting patterns that predominate in trachoma-endemic areas have not been proved to cause disease in newborns.<sup>20</sup> Chlamydiae cause between one third and one half of nongonococcal urethritis cases in men, and concomitant infections with gonococci are common in men and women.<sup>6,21</sup>

An infant born to a mother with a chlamydial infection of the cervix has a 60% to 70% risk of acquiring the infection

during passage through the birth canal.<sup>22-24</sup> Conjunctivitis develops in 20% to 50% of exposed infants, and pneumonia in 10% to 20%. The rectum and vagina of infants exposed during delivery also may be infected, but a clear-cut relationship with disease in these sites has not yet been elucidated.<sup>25,26</sup> In utero transmission is not known to occur. Infection after cesarean section occurs rarely, usually in association with at-term or premature rupture of the membranes. No evidence exists to support postnatal transmission from the mother or other family members.

Studies in the 1980s identified *C. trachomatis* in 14% to 46% of infants younger than 1 month of age with conjunctivitis.<sup>27-29</sup> The prevalence of neonatal *Chlamydia* inclusion conjunctivitis has decreased in recent years in areas where screening and treatment of chlamydial infection in pregnant women constitute routine practice.<sup>30</sup>

No evidence exists to suggest that infants with chlamydial infections should be isolated. Transmission of the organism to other infants in nurseries or intensive care units has not been reported. Standard precautions consisting of hand hygiene between patient contacts is recommended. Use of protective gloves, masks or face shields, and nonsterile gowns are recommended for performing procedures likely to generate splashes of body fluids, secretions, or excretions.

## MICROBIOLOGY

### The Pathogen

Chlamydiae are obligate intracellular parasites that cause a variety of diseases in animal species at virtually all phylogenetic levels. Traditionally, the order Chlamydiales has contained one genus with four recognized species: *Chlamydia trachomatis*, *Chlamydia psittaci*, *Chlamydia pneumoniae*, and *Chlamydia pecorum*. Recent taxonomic analysis involving the 16S and 23S rRNA genes have found that the order Chlamydiales contains at least four distinct groups at the family level and suggested splitting the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*.<sup>31</sup> The genus *Chlamydophila* would contain *C. pneumoniae*, *C. pecorum*, and *C. psittaci*. This new classification continues to be controversial, and for the purposes of this chapter these organisms all are referred to as *Chlamydia*.

*C. psittaci* is responsible for psittacosis, a chlamydial infection contracted by human beings from infected birds that is characterized by interstitial pneumonitis. It should be suspected in any patient with atypical pneumonia who has had contact with birds. *C. pneumoniae* causes pneumonia, pharyngitis, and bronchitis in humans and may accelerate atherosclerosis. Epidemiologic studies have revealed that *C. pneumoniae* is a fairly common cause of infection in school-aged children and young adults; along with *Mycoplasma*, it probably is the most common cause of community-acquired pneumonia in these age groups. It is not known to cause disease in newborns and therefore is not discussed further.

The species *C. trachomatis* is associated with a spectrum of diseases and contains serologically distinct variants (up to 18) known as serovars. Serovars A, B, Ba, and C cause ocular trachoma, a major cause of blindness in many developing countries. Ocular trachoma is considered the most common cause of preventable blindness in the world. Three serovars,

L<sub>1</sub>, L<sub>2</sub>, and L<sub>3</sub>, are associated with lymphogranuloma venereum, a sexually transmitted disease that is rare in the United States but remains quite prevalent in many developing countries, and are particularly prevalent in tropical and subtropical areas. Perinatal transmission is rare with lymphogranuloma venereum. Serovars D to K produce infection of the genital tract—urethritis and epididymitis in the male, cervicitis and salpingitis in the female—the most prevalent chlamydial diseases. Major complications of female genital tract disease include acute pelvic inflammatory disease, ectopic pregnancy, infertility, and infant pneumonia and conjunctivitis.

Like gram-negative bacteria, chlamydiae have an outer membrane that contains lipopolysaccharide and membrane proteins, but their outer membrane contains no detectable peptidoglycan, despite the presence of genes encoding proteins for its synthesis.<sup>32</sup> This recent genomic finding is the basis for the so-called chlamydial peptidoglycan paradox, for it has been known for years that chlamydial development is inhibited by  $\beta$ -lactam antibiotics. Although chlamydiae contain DNA, RNA, and ribosomes, during growth and replication they obtain high-energy phosphate compounds from the host cell. Consequently, they are considered energy parasites. The chlamydial genome size is only 660 kDa, which is smaller than that of any other prokaryote except mycoplasmas. All chlamydiae encode an abundant protein, the major outer membrane protein (MOMP) that is surface exposed in *C. trachomatis* and *C. psittaci*, but not in *C. pneumoniae*.<sup>33</sup> MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

### Chlamydial Developmental Cycle

The biphasic developmental cycle of chlamydiae is unique among microorganisms and involves two highly specialized morphologic forms shown in Figure 11-1. The extracellular form, or elementary body (EB), contains extensive disulfide cross-links both within and between outer membrane proteins, giving it an almost sporelike structure that is stable outside of the cell. The small (350 nm in diameter) infectious EB is inactive metabolically. The developmental cycle is initiated when an EB attaches to a susceptible epithelial cell. A number of candidate adhesions have been proposed, but their identity and that of associated epithelial cell receptors remain uncertain. One documented mechanism of entry into the epithelial cell is by receptor-mediated endocytosis through clathrin-coated pits,<sup>34</sup> but evidence suggests that chlamydiae may exploit multiple mechanisms of entry.<sup>35</sup> The process of EB internalization is very efficient, suggesting that EBs trigger their own internalization by cells that are not considered professional phagocytes.

Once the EB is inside the cell, surface antigens of the EB appear to prevent fusion of the endosome with lysosomes, protecting itself from enzymatic destruction. Evading host attack by antibody- or cell-mediated defenses, it reorganizes into the replicative form, the reticulate body (RB). RBs successfully parasitize the host cell and divide and multiply. As the RB divides by binary fission, it fills the endosome—now a cytoplasmic inclusion—with its progeny. After 48 to 72 hours, multiplication ceases, and nucleoid condensation occurs as the reticulate bodies transform to new infectious EBs. The EBs then are released from the cell by cytolysis,<sup>36</sup> or

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

**Figure 11-1** The *Chlamydia trachomatis* developmental cycle. Infection is initiated by elementary bodies (EBs). **0 Hr**, Immediately after endocytosis, EBs are found within tightly associated membrane vesicles. **2 Hr**, Within a few hours, EBs differentiate into the larger, metabolically active reticulate bodies (RBs). **18 Hr**, As the RBs multiply, the inclusion increases in size to accommodate the bacterial progeny. RBs are typically observed juxtaposed to the inclusion membrane. **36 Hr**, As the infection progresses, increasing numbers of chlamydiae are observed unattached in the interior of the inclusion. These unattached organisms are, for the most part, EBs and intermediate developmental forms. EBs accumulate within the inclusion even as RBs, still associated with the inclusion membrane, continue to multiply, until the cell undergoes lysis at 40 to 48 hours following infection. (In Stephens RS [ed]. *Chlamydia, Intracellular Biology, Pathogenesis, and Immunity*. Washington, D.C., ASM Press, p 102.)

by a process of exocytosis or by extrusion of the whole inclusion,<sup>37</sup> leaving the host cell intact. The last mechanism may explain the frequency of asymptomatic or subclinical chlamydial infections. The release of the infectious EBs allows infection of new host cells to occur.

## **PATHOGENESIS**

### **Conjunctivitis**

Chlamydiae replicate extensively in epithelial cells of the conjunctiva and cause considerable inflammation. The cells of the inflammatory reaction are mostly polymorphonuclear leukocytes. Conjunctivitis in a majority of untreated patients resolves spontaneously during the first few months of life. Occasionally, infants maintain persistent conjunctivitis, and the pannus formation (neovascularization of the cornea) and scarring typical of trachoma have been reported.<sup>2,38</sup> Loss of vision is rare. Micropannus and some scarring may occur in infants if they do not receive treatment within the first 2 weeks of the disease course.<sup>39</sup> If the infection is treated early, no ocular sequelae develop.

### **Pneumonia**

The nasopharynx is the most frequent site of perinatally acquired chlamydial infection, with approximately 70% of infected infants demonstrating a positive result on cultures at that site.<sup>40,41</sup> Most of these infections are asymptomatic and may persist for up to 29 months.<sup>42</sup> Chlamydial pneumonia develops in only about 30% of infants with nasopharyngeal infection. Conjunctivitis is not a prerequisite for development of pneumonia.

## **PATHOLOGY**

In inclusion conjunctivitis, the affected conjunctiva is highly vascularized and edematous. Inclusions are found in the conjunctival epithelial cells. A massive polymorphonuclear leukocyte infiltration occurs, and pseudomembrane formation may be seen. Lymphoid follicles such as are seen in adults or older children with chlamydial infection of the conjunctiva usually are not observed until the disease has been active for 1 to 2 months. Because in most infants the conjunctivitis spontaneously resolves by that time, lymphoid follicles are not commonly observed.

Because the pneumonia is rarely fatal and in most infants the course is relatively benign, there has been little occasion to obtain lung specimens. When such specimens have been obtained, no characteristic features have been described. Examination of biopsy material has shown pleural congestion and alveolar and bronchiolar mononuclear cell infiltrates with eosinophils, along with focal aggregations of neutrophils.<sup>43,44</sup>

## **CLINICAL MANIFESTATIONS**

The principal clinical manifestations in infants are conjunctivitis, occurring in the first 3 weeks of life (usually 7 to 10 days), and pneumonia, which occurs within the first 3 months (typically about 6 to 8 weeks).

### **Conjunctivitis**

Inclusion conjunctivitis (ICN) usually has an incubation period of 5 to 14 days after delivery, or onset may be earlier if amniotic membranes ruptured prematurely. Conjunctivitis develops in approximately one third of infants exposed to

**Figure 11-2** An infant with chlamydial conjunctivitis. (In Long S, Pickering LK, Prober CG [eds]. *Principles and Practice of Pediatric Infectious Diseases*. New York, Churchill Livingstone, 2003, p 904.)

chlamydiae during vaginal delivery.<sup>22,33,45-47</sup> Disease manifestations can vary widely and range from mild conjunctival injection with scant mucoid discharge to severe mucopurulent conjunctivitis with chemosis and pseudomembrane formation. The eyelids swell, and the conjunctivae become injected and swollen (Fig. 11-2). The "pseudomembrane" consists of inflammatory exudate that adheres to the inflamed surface of the conjunctiva. Except for micropannus formation, the cornea usually is spared. The duration of the illness typically is 1 to 2 weeks but ICN can last a few days to several weeks.

### Pneumonia

Neonatal chlamydial pneumonia was first reported in 1975, and the characteristic clinical picture was described in 1977.<sup>3,48</sup> Most infants with chlamydial pneumonia are symptomatic before the eighth week of life. The illness is characterized by the insidious development of nasal obstruction or discharge, tachypnea, and a repetitive staccato cough. In some infants, these clinical features appear as early as the second week of life, initially involving the upper respiratory tract. Characteristically, infants have been symptomatic for 3 or more weeks before presentation. Most are only mildly or moderately ill and are afebrile. A history of conjunctivitis can be elicited, or the presence of conjunctivitis noted, in half of the cases.<sup>49</sup> Apnea may develop in some infants. Bilateral crepitant inspiratory rales are prominent and out of proportion to the

degree of comfort indicated by the infant's breathing; expiratory wheezes are distinctly uncommon. Hyperinflation of the lungs usually accompanies the infiltrates found on chest radiographs, but in most infants this is quite mild. Infiltrates most commonly are bilateral and interstitial; reticulonodular patterns and atelectasis also have been described.<sup>50</sup> Possible laboratory findings include a distinctive peripheral eosinophilia (fewer than 400 cells per  $\text{mm}^3$ ), mild arterial hypoxemia in some patients, and elevated serum immunoglobulins. Untreated disease can linger or recur. In very young infants, infection may be more severe and associated with apnea, but the requirement for mechanical ventilation for this illness is rare.

### Perinatal Infections at Other Sites

Infants born to *Chlamydia*-positive mothers also can become infected in the rectum and urogenital tract.<sup>24</sup> Despite the presence of clinical abnormalities, these infections may go undiagnosed and persist for up to 3 years.<sup>24</sup> Consequently, differentiating infection acquired perinatally from infection due to sexual abuse can be particularly difficult in young children.

## DIAGNOSIS

### Conjunctivitis

Several nonculture methods are approved by the Food and Drug Administration (FDA) for the diagnosis of chlamydial conjunctivitis. These methods include enzyme immunoassays (EIAs)—specifically, Chlamydiazyme (Abbott Diagnostics, Chicago) and MicroTrak EIA (Genetic Systems, Seattle)—and direct fluorescent antibody assays (DFAs) using fluorescein-conjugated monoclonal antibodies to stain chlamydial EBs in a smear, including Syva MicroTrak (Genetic Systems) and Pathfinder (Sanofi-Pasteur, Chaska, Minn.). These tests perform well on conjunctival specimens, with sensitivities of greater than 90% and specificities of 95% or greater.<sup>28,51,52</sup>

In resource-poor settings, a useful diagnostic method is examination of Giemsa-stained conjunctival scrapings for the presence of blue-stained intracytoplasmic inclusions within epithelial cells. The sensitivity of this diagnostic method varies, ranging from 22% to 95%, depending on the technique of specimen collection and the examiner's expertise. This method also allows visualization of bacteria, such as gonococci, and of cytologic features suggestive of viral infection. Isolation of the chlamydiae from conjunctival scrapings inoculated into tissue cell culture is a more reliable, although more costly, method of diagnosis. Serologic diagnosis of chlamydial conjunctivitis (in contrast to pneumonia) is not reliable because of the presence of maternally transmitted IgG antibody and the unreliable appearance of IgM antibody in this infection.

Even if a firm diagnosis of chlamydial conjunctivitis is established, the possibility of a dual infection, particularly with *Neisseria gonorrhoeae*, should be kept in mind. For this reason, appropriate studies by stain and culture of the conjunctival exudate always should be performed.

Highly sensitive nucleic acid amplification tests (NAATs) are commercially available for the diagnosis of genital chlamydial infection in adolescents and adults.<sup>53,54</sup> NAATs

have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. These tests have a high sensitivity, detecting perhaps 10% to 20% more cases of genital chlamydial infection than is possible with culture, while retaining high specificity.<sup>55</sup> Information on the use of NAATs in children is limited, but preliminary data suggest that polymerase chain reaction (PCR) assay is equivalent to culture for the detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.<sup>56</sup>

## Pneumonia

EIAs and DFAs for chlamydia do not perform well with nasopharyngeal specimens and are not approved for this purpose. The definitive diagnosis of pneumonia can be made by culture of the organism from the respiratory tract. *Chlamydia* culture has been defined by the Centers for Disease Control and Prevention (CDC) as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions by fluorescent antibody staining.<sup>5</sup> The likelihood of obtaining a positive culture result is enhanced by obtaining a specimen by deep suction of the trachea or by collecting a nasopharyngeal aspirate rather than obtaining a specimen with a swab.<sup>3,57</sup> An acute microimmunofluorescence serum titer of *C. trachomatis*-specific immunoglobulin (Ig) M greater than 1:32 also is diagnostic. Detection of *C. trachomatis*-specific IgG is not diagnostic because passively transferred maternal antibodies may persist at high titers for months. The serologic test of choice is the microimmunofluorescence procedure of Wang and Grayston,<sup>58</sup> in which elementary bodies are used as antigen. Only a few clinical laboratories perform this test.

Indirect evidence of chlamydial pneumonia includes hyperinflation and bilateral diffuse infiltrates on chest radiographs, eosinophilia with peripheral blood counts of 0.3 to 0.4 × 10<sup>9</sup>/L (300 to 400/μL) or more, and increased total serum IgG (less than 5 g/L [500 mg/dL]) and IgM (greater than 1.1 g/L [110 mg/dL]) concentrations. The absence of these findings, however, does not exclude the diagnosis of *C. trachomatis* infection.

## DIFFERENTIAL DIAGNOSIS

### Conjunctivitis

Inclusion conjunctivitis must be distinguished from that produced by pyogenic bacteria, particularly *N. gonorrhoeae*. Gonococcal ophthalmia usually occurs at an earlier age, typically 2 to 5 days after birth, although overlap in age at onset can occur. Gonococcal disease usually is more rapidly progressive than that due to *C. trachomatis*. Gonococcal infection can be diagnosed presumptively by examination of the Gram-stained smear of the exudate and confirmed by culture of the exudate. Staphylococcal conjunctivitis usually is acquired in the nursery or home environment. It is characterized more by purulent discharge than by redness. This and other forms of pyogenic conjunctivitis—which may be due to *Streptococcus pneumoniae*, *Haemophilus* species, or gram-negative bacteria such as *Pseudomonas aeruginosa*—can easily be diagnosed by Gram stain and culture of the exudate.

Of the viral infections, neonatal herpes simplex (see Chapter 26) is the most important. This infection is characterized by vesicle formation and lesions of the skin as well as the conjunctiva. Corneal involvement may occur. Adenovirus infection of the newborn is very rare but has been described.

Chemical conjunctivitis related to instillation of silver nitrate at birth also can produce marked redness and a purulent discharge. These signs begin on the first day of life and disappear after a few days, however, thereby distinguishing this entity from a chlamydial infection.

## Pneumonia

The afebrile, tachypneic infant presenting with a staccato cough in the first 3 months of life is very likely to have chlamydial disease. Cytomegalovirus (CMV) can produce an interstitial pneumonia in preterm newborns who receive transfusions from CMV-positive donors; however, it often produces clinical signs in other organ systems. Congenital infection by the rubella virus and *Toxoplasma gondii* also produces multiorgan involvement, as does perinatal infection with the herpes simplex virus. Adenovirus or parainfluenza virus infection can cause an interstitial pneumonia, but without the characteristic staccato cough or eosinophilia. Respiratory syncytial virus (RSV), a common cause of pneumonia in early infancy, often produces fever in the early stages, and wheezing due to airway obstruction is typical. RSV infection is not associated with eosinophilia. RSV infection can be rapidly diagnosed by performing an EIA of a nasopharyngeal wash specimen. Many pyogenic bacteria may produce lower respiratory tract infections in infancy. Group B β-hemolytic streptococci, *S. pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and the coliform group of bacteria are the most common. Affected infants generally are much sicker, are more toxic and febrile, and have pulmonary consolidation rather than interstitial infiltrates. *Bordetella pertussis* classically causes a paroxysmal cough with or without accompanying fever, but lymphocytosis is a nonspecific diagnostic clue, and apnea occurs in infants younger than 6 months of age. In infants with *Pneumocystis jiroveci* pneumonia, a characteristic syndrome develops that includes subacute diffuse pneumonitis with dyspnea at rest, tachypnea, oxygen desaturation, nonproductive cough, and fever. Most have an underlying immune disorder.

## PROGNOSIS

### Conjunctivitis

If untreated, inclusion conjunctivitis can persist for many weeks, but it usually resolves spontaneously without complications. The scarring that occurs in trachoma that leads to lid deformities is not seen. Superficial corneal vascularization and conjunctival scar formation can occur, however.<sup>38,39,59</sup>

### Pneumonia

Without treatment, affected infants usually are ill for several weeks, with frequent cough, poor feeding, and poor weight gain. A small number require oxygen, and fewer require

ventilatory support. Beem and colleagues<sup>60</sup> found in a series of 11 infants that the duration of the clinical course was between 24 and 61 days, with a mean of 43 days, and that death was exceptionally rare. Follow-up evaluation of a small cohort of children who had *C. trachomatis* pneumonia in infancy demonstrated an increased prevalence of chronic cough and abnormal lung function when compared with that in age-matched controls.<sup>61</sup>

## THERAPY

Topical treatment of inclusion conjunctivitis is not recommended, primarily because of failure to eliminate concurrent nasopharyngeal infection. Recommended therapy for conjunctivitis or pneumonia is oral erythromycin, 40 mg/kg/day in 4 divided doses for 14 days. The failure rate is around 20%, and a second course of therapy may be required.<sup>62,63</sup> Problems with compliance and tolerance are frequent. Oral sulfonamides can be used after the immediate neonatal period for infants who do not tolerate erythromycin. Convincing evidence suggests that this treatment shortens the clinical course of pneumonia and eliminates the organism from the respiratory tract. Beyond specific antimicrobial therapy, the infants require standard supportive care measures, with attention to nutrition and to fluid status. Oxygen and ventilatory therapy may be required in a minority of cases. A specific diagnosis of *C. trachomatis* infection in an infant should prompt treatment of the mother and her sexual partner(s).

An association between orally administered erythromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants younger than 6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis.<sup>64,65</sup> The risk of IHPS after treatment with other macrolides (e.g., azithromycin dihydrate, clarithromycin) is unknown. Because confirmation of erythromycin as a contributor to cases of IHPS requires additional investigation and because alternative therapies are not as well studied, the American Academy of Pediatrics continues to recommend use of erythromycin for treatment of *C. trachomatis* infection in infants. Parents of infants given erythromycin should be informed about the signs and potential risks of developing IHPS. Cases of pyloric stenosis developing after use of oral erythromycin should be reported to the Food and Drug Administration as an adverse drug reaction. One small study suggests that a short course of orally administered azithromycin, 20 mg/kg in a single daily dose for 3 days, may be effective.<sup>30</sup>

Prophylactic therapy of infants born to mothers known to have untreated chlamydial infection is not indicated, because the efficacy of such prophylaxis is unknown. Such infants should be monitored for signs of infection and to ensure appropriate treatment if infection develops. If adequate follow-up cannot be ensured, prophylaxis may be considered.

## PREVENTION

Because *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, an effective prevention

measure is screening and treatment of pregnant women for *C. trachomatis* infection before delivery. The CDC currently recommends screening all pregnant women during their first prenatal visit, and during the third trimester if they are at high risk (age younger than 25 years or other risk factors such as new or multiple sexual partners).<sup>5</sup> Either erythromycin base (2 g/day in four divided doses) or amoxicillin (1.5 g/day in three divided doses) for 7 days is the recommended treatment regimen for pregnant women. Half-doses of erythromycin daily for 14 days may be given in pregnant women intolerant of the full-dose regimen. Because these regimens are not highly efficacious, a second course of therapy may be needed. Azithromycin (1 g orally in a single dose) is an alternative; preliminary data suggest that it is safe and effective.<sup>66</sup> Doxycycline and ofloxacin are contraindicated during pregnancy.

Ocular prophylaxis with topical erythromycin or tetracycline has reduced the incidence of gonococcal ophthalmia but does not appear to be effective against *C. trachomatis*.<sup>67</sup> Thus, the only means of preventing chlamydial infection of the newborn is treatment of maternal infection before delivery.

Ongoing efforts to develop a *C. trachomatis* vaccine to protect persons from genital tract infection have concentrated primarily on the use of peptides derived from the MOMP or recombinant synthetic MOMP polypeptides as immunogens. Future work may incorporate molecular technology and our increasing understanding of the host response to chlamydiae to develop one or more new vaccines. Stimulation of long-term mucosal immunity in the genital tract is a challenge; it is unclear whether all genital infections could be prevented or whether only more invasive disease, such as salpingitis, might be preventable using vaccine technology.

Infections of the fetus and newborn infant due to *Neisseria gonorrhoeae* are restricted primarily to mucosal surfaces of the newborn infant. The most common condition related to infection by this organism during the neonatal period is ophthalmia neonatorum, or neonatal conjunctivitis. *N. gonorrhoeae* produces purulent conjunctivitis in the newborn that, if untreated may lead to blindness. This is the primary disease entity discussed in this chapter.

Ophthalmia neonatorum had been a well-recognized entity, affecting between 1% and 15% of newborns, in Europe and North America when Hirschberg and Krause first described neonatal infection due to *N. gonorrhoeae* in an infant with purulent conjunctivitis in 1881.<sup>1</sup> Shortly thereafter, the topical instillation of silver nitrate into the newborn's eyes immediately after birth dramatically reduced the incidence of this disease due to *N. gonorrhoeae*, albeit with the complication in most infants of milder conjunctivitis, limited to the first 24 hours of life, due to the silver nitrate.<sup>2,3</sup> Use of erythromycin or tetracycline ointments for this purpose has proved to be efficacious for preventing gonococcal ophthalmia, with markedly reduced problems related to the chemical conjunctivitis seen with silver nitrate.<sup>4-6</sup> Systemic neonatal infection is unusual, but infants may present with a variety of clinical syndromes (in particular, arthritis), which implies that dissemination of the bacteria does occur.<sup>7,8</sup> Maternal systemic infection during pregnancy also is rare, and transplacental congenital infection of the fetus has not been described. Maternal genital mucosal infection, however, may result in an ascending infection, with chorioamnionitis leading to premature rupture of the placental membranes and preterm delivery.<sup>9</sup> In developed countries, screening and treatment of pregnant women for gonococcal infections with tracing of named contacts, along with the use of neonatal ophthalmic prophylaxis, have substantially reduced the incidence of gonococcal ophthalmia neonatorum. In medically developing areas, improvements in access to medical

care, as well as aggressive pilot programs for prevention and treatment of sexually transmitted diseases (STDs) in conjunction with HIV infection/acquired immunodeficiency syndrome (AIDS) prevention strategies, have continued to decrease the incidence of gonococcal infection and its complications, such as ophthalmia neonatorum, in areas where these interventions have been introduced.<sup>10</sup> Despite the overall decreasing prevalence of *N. gonorrhoeae* infection worldwide, however, gonococcal ophthalmia neonatorum remains a significant illness.

### EPIDEMIOLOGY AND TRANSMISSION

The incidence of neonatal gonococcal illness is related to the prevalence of *N. gonorrhoeae* colonization among women of childbearing age, and to the rates of acute infection during pregnancy. This is quite variable worldwide and now is heavily influenced by the human immunodeficiency virus type 1 infection (HIV-1) epidemic. In general, once antibiotic treatment for gonorrhea became available in the mid-20th century, rates of infection among women decreased worldwide, as these agents became more readily accessible and health care programs improved. With the emergence of penicillin chromosomal resistance, the development of penicillinase production by some strains, and the expansion of the AIDS epidemic in the 1990s, however, rates began to rise again during that decade. In response, efforts to control this infection—which some authorities had hoped could ultimately be eliminated by the middle of this century—have been increased.

Estimates by the World Health Organization (WHO) of the burden of gonorrheal disease in various regions at the end of the twentieth century are presented in Table 12-1.<sup>11</sup> Although these estimates are useful in indicating areas of high burden of disease, considerable variation within regions exists. This variation is reflected in the differences seen in the number of reported cases of gonorrhea among women in North America. In the United States, during 2001, 361,705 cases of gonorrhea were tallied, resulting in a reported prevalence of 128 cases per 100,000 population, which was similar to that reported in 2000 (129 per 100,000), 1999 (132 per 100,000), and 1998 (131 per 100,000).<sup>12</sup> Overall, no changes have been noted in the prevalence rate among women in the United States during these years. The prevalence among women has equaled that among men since 1998. Infection rates have fallen since 1986, when the prevalence among women was approximately 310 cases per 100,000 population. Further significant differences are noted among populations in the United States, however, when rates are compared for groups of different races or ethnicity and for location. The prevalence among blacks in the United States is still considerably higher than in other ethnic groups but dropped

**Table 12-1 WHO Estimated Numbers of Cases of Gonorrhea in Adults 1999**

Geographical Location	Estimated No. of Cases
North America	1.5 million
Latin America	7.5 million
Western Europe	1 million
Eastern Europe and Central Asia	3.5 million
East Asia	3 million
South and Southeast Asia	27 million
North Africa and the Middle East	1.5 million
Sub-Saharan Africa	17 million
New Zealand and Australia	120,000

WHO, World Health Organization.

Data from World Health Organization. Global prevalence and incidence of selected curable sexually transmitted infections. Overview and estimates. WHO/CDS/CSR/EDC/2001. 10:1-50, 2001.

from approximately 2100 cases per 100,000 population in 1986 to around 800 per 100,000 in 2001. The background prevalence also differs significantly among the various states, with 6 states reporting rates greater than 200 per 100,000 in 2001, 17 states reporting between 100 and 200 cases per 100,000 and the rest reporting less than 100 per 100,000. The United States has set a goal of reducing the national prevalence of gonorrhea to less than 19 cases per 100,000 among adults. In 2001, 8 states reported a prevalence of disease below this target goal. In Canada, however, rates of gonorrhea are considerably lower than in the United States. Canada has placed an emphasis on STD control as well but has an exclusively publicly funded health care system. Gonorrhea prevalence rates have decreased steadily from 1980, when the prevalence among women was 166 per 100,000 population. The highest rates at that time were among women 15 to 19 and 20 to 24 years of age, which were extremely high at 510 and 598, respectively, per 100,000. In 2000, the prevalence among women was approximately 15 per 100,000, which actually represented an increase from 1997, when rates had dropped to a low of 11 per 100,000. The increase occurred primarily among women aged 15 to 19 and 20 to 24 years; in these age groups, rates increased from 69 and 60, respectively, per 100,000 in 1997 to 96 and 73 per 100,000. In 1997, Canada had set as its goal the elimination of endemic transmission of *N. gonorrhoeae* by the year 2010. This increase in prevalence has led to a call for an assessment of STD control and reporting procedures in Canada to determine why the previously observed declines in prevalence had stopped.<sup>13</sup>

Factors that increase a pregnant woman's risk of acquiring *N. gonorrhoeae* infection are similar to those that increase the risk of acquisition of any other sexually transmitted infection.<sup>14</sup> The prevalence of *N. gonorrhoeae* in the population or network in which she socializes and chooses her sexual partners will determine the likelihood of exposure to this pathogen. Women who have multiple sexual partners or whose partners have multiple sexual contacts increase their risk of exposure to *N. gonorrhoeae*. Women who do not use condoms or other barrier protection will increase their risk of acquisition of *N. gonorrhoeae* infection on exposure to the organism. It is unknown whether women who are HIV positive have an increased risk of infection by *N. gonorrhoeae*

on exposure to it. Factors associated with an increased likelihood of at-risk behavior that results in an increased risk of gonococcal infection among pregnant women include younger age, unmarried status, homelessness, problems with drug or alcohol abuse, prostitution, low-income professions, and, in the United States, being black. Gonococcal infections are diagnosed more frequently in the summer months in the United States, probably reflecting transient changes in social behavior during vacations.<sup>15</sup> Varying gonococcal rates reported in various studies worldwide reflect the differences in risk among the populations studied. In a recent study in Brazil, involving a cross-sectional study of 200 women aged 14 to 29 years who attended an HIV testing site in central Rio de Janeiro, the prevalence of gonorrhea was high at 9.5%. Of the 200 women, 8% were HIV infected, confirming that the population studied had a high risk of STD exposure.<sup>16</sup> The prevalence of gonorrhea among 547 pregnant women attending a first-visit antenatal hospital clinic during 1999 and 2000 in Vila, Vanuatu, was 5.9%, but no women were found to be HIV infected at that time.<sup>17</sup> The occurrence rates of gonorrhea were quite high among this population, reflecting the prevalence in the general population. A study in Thailand in 1996 that investigated the prevalence of STDs among pregnant women, where case reporting suggested a marked decrease in STDs following a campaign promoting condom use during commercial sex, showed that the prevalence of gonorrhea was extremely low at 0.2%.<sup>18</sup> By contrast, in a population in Nairobi, where condom use was advocated for commercial sex workers but not promoted to the same extent as in Thailand and not routinely practiced by the at-risk general population, in a cross-sectional study of 520 women seeking treatment at an STD clinic, 4% were infected with gonorrhea and 29% were HIV positive.<sup>19</sup> In Nigeria, where the prevalence of HIV infection is low, the rate of gonorrhea also is lower among pregnant women. In a cross-sectional study, 230 pregnant women attending the antenatal clinic of a teaching hospital in Nigeria from January 2000 to December 2000 were screened randomly to determine the prevalence of common STDs; 1.3% were found to have gonorrhea.<sup>20</sup>

*N. gonorrhoeae* usually is transmitted from the infected maternal cervix during vaginal delivery. Ascending infection does occur, however, in the instance of prolonged ruptured membranes and has been observed after cesarean section delivery following ruptured membranes.<sup>21-24</sup> It has been estimated that colonization and infection of the neonate occur in only one third of instances in which the mother is infected.<sup>25</sup> The infant's mucous membranes become colonized when swallowing contaminated fluid during labor and delivery.

In instances of congenital infection, it is speculated that the chorioamnion is infected through an ascending infection.<sup>26</sup> Premature rupture of membranes then occurs, with early onset of labor and premature delivery or septic abortion.<sup>9,27-29</sup> This association was dramatically shown in one study in which premature rupture of membranes occurred in 6 (43%) of 14 women with untreated gonococcal infection during pregnancy, compared with 4 (3%) of 144 women whose infection had been treated.<sup>29</sup> Thus, screening and treatment programs for gonococcal infections during pregnancy are appropriate to reduce the risk of adverse pregnancy outcomes related to maternal infection.

## MICROBIOLOGY

*N. gonorrhoeae* is a gram-negative diplococcus. It utilizes glucose for growth but not maltose, sucrose, or lactose. This is one of the characteristics used to distinguish *N. gonorrhoeae* isolates from *N. meningitidis* and other colonizing *Neisseria* species such as *N. cinerea*, *N. flava*, *N. subflava*, *N. lactamica*, *N. mucosa*, and *N. sicca*. *N. gonorrhoeae* produces acid only when grown in glucose. In addition, the organism is oxidase positive, hydroxyproplylaminoptidase positive, nitrate negative, DNase negative, catalase positive, strongly superoxol positive, and colistin resistant.<sup>30</sup> It is an obligate aerobe but lacks superoxide dismutase, which moderates the effects of oxygen radicals in most other aerobic bacteria. When grown in anaerobic conditions, virulent strains express a lipoprotein called Pan 1. Its function is unknown, but it elicits an immunoglobulin M (IgM) antibody response in acute infection.

When cultured in the laboratory, *N. gonorrhoeae* forms four different colony types. Pinpoint colonies, classified as type 1 and type 2, usually are only seen on primary isolation. What distinguishes these colony types from the large granular colonies classified as types 3 and 4 is the presence of pili, which are thin bacterial appendages on the cell surface that are involved in attachment to mammalian cells. *N. gonorrhoeae* has the genetic capacity to turn on and turn off the expression of pili.<sup>31</sup> With repeated subculturing at 37°C, the genes are no longer expressed and the pili disappear, resulting in colonial-type changes, with type 1 colonies shifting to type 4 and type 2 colonies to type 3. Associated with this change is a reduction in virulence.<sup>32</sup> *N. gonorrhoeae* also may form colonies that are either opaque or clear. This characteristic is related to the presence of a specific surface protein called outer membrane protein II. Transparent colonies lack outer membrane protein II and are more resistant to phagocytosis. Individual strains can also shift from forming opaque to forming clear colonies.<sup>33</sup>

Colonial morphology is of no use in differentiating gonococcal types or strains. Strains can be differentiated by auxotyping. Different strains have differing stable auxotrophic requirements for amino acids, purines, pyrimidines, or vitamins. Typing based on these requirements has been useful in some epidemiologic surveys. Additionally, enzyme-linked immunosorbent typing, based on differences in protein I, can be done. Nine distinct strains are detectable with this typing system. It is clinically relevant in that type 1 and type 2 strains are more likely to disseminate in adult patients. Use of serologic typing schemes can detect three serogroups: WI, WII, and WIII. Strains 1 to 3 are usually found in serogroup WI, strains 4 to 8 in serogroup WII, and strain 9 in serogroup WIII.<sup>34</sup> Finally, strains also are typed by coagulation testing following exposure to monoclonal antibodies made against the outer membrane protein I. Two major serogroups exist: 1A, which has 26 subgroups, and 1B, with 32 subgroups.<sup>35</sup> The combination of auxotyping and serologic typing is now used in most epidemiologic studies to determine the linkages among infected persons.<sup>36</sup>

## PATHOGENESIS

To produce infection, *N. gonorrhoeae* first attaches to epithelial cells, penetrates into them, and then destroys the

infected cells. Attachment to epithelial cells is related to the presence of pili, as well as the outer membrane protein II.<sup>37</sup> Penetration of the gonococcus into cells is through either phagocytosis or endocytosis.<sup>38-40</sup> Several bacteria usually are present in each infected cell, but whether this represents invasion of the cell by multiple organisms or growth and multiplication of organisms within the infected cell is unknown. Gonococci possess a cytotoxic lipopolysaccharide and produce proteases, phospholipases, and elastases that ultimately destroy the infected cells. Some strains of gonococci appear to be relatively less susceptible to phagocytosis and are thus thought to be more capable of causing disseminated infection. Gonococci are found in the subepithelial connective tissue very quickly after infection. This dissemination may be due to the disruption of the integrity of the epidermal surface with cell death, or the gonococci may migrate into this area by moving between cells. Epithelial cell death triggers a vigorous inflammatory response, initially with neutrophils and then macrophages and lymphocytes in untreated patients.

Human serum contains IgM antibody directed against lipopolysaccharide antigens on the gonococcus, which inhibits invasion. An IgG antibody against a surface protein antigen, however, also is normally present on some gonococci that are classified as serum-resistant gonococci; this antibody blocks the bactericidal action of the antilipopolysaccharide IgM antibody.<sup>41,42</sup> These serum-resistant strains are the most common ones involved in systemic infections in adults and probably in neonates as well.<sup>43</sup> Of note, infants' sera, in which maternal IgM antibody is absent, do not demonstrate serum bactericidal activity against *N. gonorrhoeae*<sup>44</sup>; thus, in theory, infants should be highly susceptible to invasive infection. Because such infection does not occur frequently, additional protective factors must function to prevent it.

*N. gonorrhoeae* produces IgA1 protease, which inactivates secretory IgA by cleaving it at the hinge region. This inactivation facilitates mucosal colonization and probably plays a role in the poor mucosal protection seen against subsequent gonococcal reinfection. It also is a proinflammatory protein and can trigger the release of proinflammatory cytokines from human monocytic subpopulations and a dose-dependent T<sub>H</sub>1-type T-cell response.<sup>45</sup> Although symptomatic gonococcal infection triggers a brisk inflammatory response, it does not produce a significant immunologic response.<sup>46</sup> There is very little immunologic memory; as a result, recurrent infections occur easily on re-exposure. Epidemiologic evidence suggests that at least partial protection is obtained against subsequent infection with the same serotype.<sup>47</sup> In general, however, antibody responses are modest after initial infection, and no evidence of a boosting effect has been found when antibody levels are studied in response to subsequent infections. Also, adults with mucosal gonococcal infections have a discernible decreased CD4<sup>+</sup> count, which recovers with treatment or clearance of the infection. Thus, it has been speculated that the gonococci actually have a suppressive effect on the host immune response. In support of this theory, *N. gonorrhoeae* Opa proteins recently were shown to be able to bind CEACAM1 expressed by primary CD4<sup>+</sup> T lymphocytes and to suppress their activation and proliferation.<sup>48</sup> This immune suppressive effect may have significant consequences in populations with co-existing epidemics of gonorrhea and

HIV infection/AIDS. In a study of prostitutes in Nairobi, the presence of gonococcal cervicitis has been shown to reduce the interferon-g production by HIV-1 epitope-specific CD8<sup>+</sup> T-lymphocyte populations, demonstrating a deleterious effect of gonococcal cervicitis on HIV-1 immune control and susceptibility.<sup>49</sup>

Because only approximately one third of neonates exposed to *N. gonorrhoeae* during vaginal delivery become colonized and infected, additional protective innate factors obviously are in effect. Recently, significant antibacterial polypeptide activity has been demonstrated both in human amniotic fluid and within the vernix caseosa.<sup>50,51</sup> The presence of a number of antibacterial polypeptides in the vernix may be important for surface defense against gonococcal infection, but specific studies have yet to be done.

Antibiotic resistance to penicillin, tetracycline, the quinolones, and spectinomycin has become problematic in many regions.<sup>52</sup> Penicillin resistance can be a result of either alterations in the penicillin-binding protein or the production of penicillinase.<sup>53-55</sup> By 1991, 11% of all strains of *N. gonorrhoeae* in the United States were penicillinase producing, and 32% of all strains were resistant to at least one antimicrobial agent. As a result, penicillin is no longer recommended for primary therapy for gonococcal disease in the United States and in other regions where these strains are commonly found.

## **PATHOLOGY**

In most affected infants, gonococcal disease manifests itself as infection of mucosal membranes. The eye is most frequently involved, but funisitis and infant vaginitis, rhinitis, and urethritis also have been observed.<sup>56-59</sup> Primary mucosal infection by *N. gonorrhoeae* involves the columnar and transitional epithelia. When pharyngeal colonization is looked for, it is found in 35% of ophthalmia neonatorum cases.<sup>60</sup> Systemic infection is rarely observed among neonates, but cases of meningitis and arthritis have been described.<sup>61-70</sup> Gonococcal scalp abscesses attributed to intrauterine fetal monitoring, omphalitis, and gingival abscess also have been reported.<sup>71-77</sup> One case of gonococcal ventriculitis has been reported in an infant who received a ventriculoamniotic shunt in utero.<sup>78</sup>

## **CLINICAL MANIFESTATIONS**

Ophthalmia neonatorum due to *N. gonorrhoeae* is classically an acute purulent conjunctivitis that appears from 2 to 5 days after birth. Occasionally, however, the initial presentation is more subacute, or the onset may be delayed beyond 5 days of life.<sup>79,80</sup> Asymptomatic colonization has been documented.<sup>81</sup> Infants who become infected in utero may have symptoms at or shortly following birth.<sup>21,22,79</sup> Typically, early in the illness, tense edema of both lids develops, followed by profuse purulent conjunctival exudates (Fig. 12-1). If treatment is delayed, the infection progresses beyond the superficial epithelial layers of the eye to involve the subconjunctival connective tissue of the palpebral conjunctivae and the cornea. Infection of the cornea can lead to ulcerations, perforation, or rarely panophthalmitis. In some

**Figure 12-1** Bilateral acute gonococcal ophthalmia neonatorum. Appearance after inappropriate topical therapy for 2 weeks with neomycin-polymyxin B-bacitracin (Neosporin), sulfonamide, and chloramphenicol ophthalmic ointments.

instances it may result in loss of the eye.<sup>82</sup> Neonatal sepsis, arthritis, and skin abscesses due to *N. gonorrhoeae* are not clinically distinguishable from conditions caused by other bacterial pathogens more commonly associated with these syndromes in this age group.

## **DIAGNOSIS**

Clinicians should suspect gonococcal ophthalmia neonatorum in an infant in whom purulent conjunctivitis develops during the first week of life, or if what was thought to be chemical conjunctivitis is prolonged beyond 24 to 48 hours.

Gram stain of the exudate usually reveals the gram-negative intracellular bean-shaped diplococci typical of *N. gonorrhoeae*, which will provide a presumptive diagnosis. Other *Neisseria* species—in particular, *N. meningitidis*—cannot be distinguished from the gonococcus by Gram stain appearance. *N. gonorrhoeae* must be isolated and tested for antibiotic susceptibility before a definitive diagnosis is made. A definitive diagnosis is important because of the public health and social consequences of the diagnosis of gonorrhea in an infant. If gonococcal ophthalmia neonatorum is suspected on the basis of the Gram stain appearance, cultures should be obtained from additional mucosal sites in the infant. The mother and her sexual partner(s) also should be tested for gonorrhea. Additional testing of the infant, the mother, and her sexual partner(s) for other sexually transmitted infections, including HIV infection, is strongly recommended.<sup>83,84</sup>

Isolation of *N. gonorrhoeae* from the exudate by culture is the diagnostic “gold standard.” Samples of the exudate should be collected by swabbing and should be inoculated directly onto blood agar, MacConkey’s agar, and chocolate agar or chocolate-inhibitory media. The inhibitory medium should be placed in a commercial carbon dioxide incubator or candle jar to provide an adequate concentration of carbon dioxide and should then be incubated at 36° C. Cultures are examined daily for the presence of typical colonies. Colonies resembling

*N. gonorrhoeae* are further identified by Gram stain, by a positive oxidase test, and by utilization of glucose but not maltose, sucrose, or lactose. Antibiotic sensitivity and penicillinase production should be tested. Further testing to confirm the identification of the isolate may be carried out in a reference laboratory if desired. Newer DNA- and polymerase chain reaction (PCR)-based technologies have replaced gonococcal cultures in many laboratories.<sup>85-87</sup> These assays have a high degree of sensitivity and actually detect more true cases of gonorrheal infection in adults than can be achieved by current culture methods. When correctly used, they also are very specific. Their suitability for diagnosis of gonorrheal infections in children without the additional use of culture methods, with the associated legal implications in older children, has not been extensively studied, however. Additionally, extensive use of these methods for primary diagnosis impairs the tracking of antimicrobial resistance patterns.

If gonococcal ophthalmia neonatorum is presumptively or definitively diagnosed, then testing also should be conducted for other sexually transmitted pathogens, in particular, *Chlamydia trachomatis*, because the two organisms frequently are found to co-infect pregnant women.<sup>88</sup> Also, the diagnosis of gonococcal infection in the neonate should trigger an investigation of the infant's mother and her sexual partner or partners for STDs.

## DIFFERENTIAL DIAGNOSIS

At present, *N. gonorrhoeae* causes less than 1% of cases of ophthalmia neonatorum in North America, western Europe, Australia, and New Zealand and in areas and communities elsewhere where there is access to prenatal care and STD prevention programs. In other areas, the risk of gonococcal ophthalmia is higher depending on the prevalence of gonococcal infection among the pregnant women in the population. Even in areas with high prevalence rates, however, ophthalmia due to *N. gonorrhoeae* accounts for less than 5% of the cases of neonatal conjunctivitis. The other organisms that can produce conjunctivitis in the newborn period and the relative overall frequency of resultant

infections, the usual time of presentation since birth, and relative severity are shown in Table 12-2. In general, conjunctivitis seen within 24 hours of birth usually is assumed to be a reaction to silver nitrate, if this has been used for prophylaxis. As described previously, however, in the instance of prolonged rupture of membranes and premature delivery, symptomatic gonococcal ophthalmia may be observed during this period as well. Also, some infants have a less acute course, with appearance of symptoms after 5 days of age. Therefore, reliance on the timing between 2 and 5 days after delivery of the onset of symptoms may be an unreliable clinically distinguishing feature. The possibility of gonococcal infection should be considered in every neonate with conjunctivitis present after 24 hours of birth, and the appropriate diagnostic testing to detect the organism should be done. In some instances, neonates with gonococcal ophthalmia neonatorum may be infected by additional pathogens, in particular, *C. trachomatis*.

The differential diagnosis of cutaneous or systemic gonococcal infection of the neonate includes the bacterial or fungal pathogens that are frequently involved in these types of infections during this time period and are discussed in more detail in Chapters 6 and 10.

## TREATMENT (THERAPY/MANAGEMENT)

The principles of management of STDs in any age group apply when a neonate is determined to have a suspected or confirmed gonococcal infection. As stated previously, investigation and treatment of the mother and her sexual contacts for *N. gonorrhoeae* are essential, as is the investigation of the infant, the mother, and her sexual contacts for other sexually transmitted infections. STDs are like wolves—they travel in packs.

As discussed previously, because a significant proportion of gonococci worldwide is resistant to penicillin, either by decreased penicillin binding or by penicillinase production, this antibiotic is no longer recommended for therapy unless the infecting isolate has been tested and found to be sensitive. Most recommendations and guidelines for the treatment of gonococcal ophthalmia neonatorum identify

Table 12-2 Differential Diagnosis of Ophthalmia Neonatorum

Etiologic Condition/Agent	Percentage of Cases	Relative Severity	Usual Time of Onset after Delivery
Chemical conjunctivitis	Dependent on use	+	6-24 hours
<i>Neisseria gonorrhoeae</i>	<1	+++	2-5 days
<i>Neisseria meningitidis</i>	<1	++	2 days-2 weeks
<i>Neisseria cinerea</i>	<1	+	2 days-2 weeks
Herpes simplex virus	<1	++	2-14 days
<i>Chlamydia trachomatis</i>	2-40	+	5 days-2 weeks
Other bacteria	30-50	++	2 days-2 weeks
Group A and B streptococci			
<i>Staphylococcus aureus</i>			
<i>Haemophilus species</i>			
<i>Klebsiella pneumoniae</i>			
<i>Escherichia coli</i>			
<i>Pseudomonas aeruginosa</i>			
Enterococcus			
Pneumococcus			

Table 12-3 Recommended Treatment for Neonatal Gonococcal Infections

Condition	Recommended Therapy
Ophthalmia neonatorum	Ceftriaxone 25-50 mg/kg IV or IM in a single dose, not to exceed 125 mg; topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered
Gonococcal meningitis, arthritis, or scalp lesions	Ceftriaxone 25-50 mg/kg/day IV or IM in a single daily dose for 7 days or cefotaxime 25 mg/kg IV or IM every 12 hours for 7 days, with a duration of 10-14 days if meningitis is documented or 14 days if arthritis is documented
Known exposure at birth but asymptomatic	Ceftriaxone 25-50 mg/kg IV or IM in a single dose, not to exceed 125 mg

ceftriaxone as the agent of choice (Table 12-3).<sup>83,84</sup> Regimens using this drug have been studied and shown to be effective.<sup>89-91</sup> Kanamycin is an alternative but is not as effective, with a failure rate of approximately 5%.<sup>92</sup> Ceftriaxone should be administered cautiously to hyperbilirubinemic infants, especially those born prematurely. Infants who have gonococcal ophthalmia should be hospitalized and evaluated for signs of disseminated infection (e.g., sepsis, arthritis, meningitis). One dose of ceftriaxone is adequate therapy for gonococcal conjunctivitis. Treatment of disseminated infection in the neonate should be done in consultation with an expert in infectious diseases. Infants born to mothers who have documented untreated infection are at high risk of acquiring *N. gonorrhoeae*. If the membranes have been ruptured, if the infant is premature, or if close follow-up cannot be ensured, treatment for ophthalmia neonatorum rather than use of eye prophylaxis is recommended.

## PROGNOSIS

With early recognition and appropriate treatment, cure rates for gonococcal ophthalmia and other neonatal manifestations of gonococcal infection in the newborn are close to 100%. By contrast, permanent corneal damage after gonococcal ophthalmia neonatorum was usual in the preantibiotic era.

## PREVENTION

Prevention of gonococcal infection of the fetus and neonate is best done by preventing gonococcal infection of the mother. One way to accomplish this goal is by the reduction of the prevalence of *N. gonorrhoeae* in the core high-risk populations that serve as its reservoir for pregnant women. Targeted treatment and prevention campaigns among commercial sex workers, sexually active adolescents and young adults who have multiple partners, and groups with other risk factors that result in increased high-risk sexual activity, such as those with street drug and alcohol abuse problems and homosexual men who have multiple contacts, will reduce the prevalence in the general population. Education of youth before sexual maturity about the risks of STDs and about ways in which they can protect themselves from acquiring such diseases does not increase the rates of sexual activity among adolescents and should be encouraged as a joint responsibility of their parents or primary care providers and the schools. Provision of accessible health care

with readily available antibiotics that are appropriate and effective against circulating strains of *N. gonorrhoeae* also is imperative for this purpose. Finally, to support optimal health behaviors, persons of all ages need to be able to feel confident that they will not be stigmatized for seeking health care for an STD.

Because infection with *N. gonorrhoeae* during pregnancy may result in adverse pregnancy outcomes, such as premature rupture of membranes and preterm delivery, screening of pregnant women for infection in early pregnancy is advisable. Women identified as having gonococcal infection should receive prompt treatment.<sup>83,84</sup> Recommended treatment includes the use of cefixime 400 mg orally, in a single dose if available, or ceftriaxone 125 mg intramuscularly in a single dose. Women for whom a third-generation cephalosporin is contraindicated should receive spectinomycin 2 g intramuscularly as a single dose. Either erythromycin or amoxicillin is recommended for treatment of presumptive or diagnosed co-infection with *C. trachomatis*. Follow-up cultures to ensure eradication of the infection are imperative. Testing for other STDs should be done, and the mother should be offered HIV testing. In addition, counseling related to avoidance of further infection is an important component of management. Tracing and treatment of sexual contacts are necessary to reduce the risk of subsequent infection. In one recent study in Louisiana, of 751 pregnant women whose charts were reviewed retrospectively, 5.1% were diagnosed with gonorrhea at the first prenatal visit and 2.5% acquired the infection during their pregnancy.<sup>93</sup> Therefore, women whose sexual behavior or social circumstances place them at risk of acquiring sexually transmitted infection during pregnancy should be retested for gonorrhea (and other STDs), in the third trimester. Retesting is most conveniently done at the time of screening for group B  $\beta$ -streptococci.

Since the late 1800s, eye prophylaxis has been the hallmark of prevention of gonococcal ophthalmia neonatorum. Currently, many jurisdictions mandate the use of ocular prophylaxis for newborns through legislation. Most others recommend and encourage its use. The issue is controversial in areas of low prevalence of *N. gonorrhoeae* infection and among populations with extremely low risk of the disease. In these situations, the concerns regarding the complications of the use of the prophylactic agents must be balanced against the actual risk of the disease and the ability, or the wish, to provide an alternate management approach involving close observation of the infant with early therapy if necessary.

At present, data from clinical trials support the use of 1% silver nitrate, 0.5% erythromycin, 1% tetracycline, or

2.5% povidone-iodine for prophylaxis against gonococcal ophthalmia neonatorum.<sup>4-6,83,84,94-98</sup> All of the agents are less effective against chlamydial conjunctivitis, however, and to date, there is no truly effective ocular agent to prevent this infection. Most agents are well tolerated, although a chemical conjunctivitis commonly is seen after instillation of silver nitrate. This reaction involves epithelial desquamation and a polymorphonuclear leukocytic exudate<sup>99</sup> and usually appears within 6 to 8 hours and disappears within 24 to 48 hours. A mild chemical conjunctivitis may be seen in from 10% to 20% of infants who received povidone-iodine prophylaxis as well. Use of antibiotic agents has the potential to lead to increased antibiotic resistance in other colonizing bacteria, which could lead to outbreaks of infection in the nursery.<sup>100</sup>

Failure of prophylaxis does occur. If the illness is established by the time of delivery, ocular prophylaxis is ineffective. Irrigation of the eyes with saline too soon after the application of silver nitrate has been suggested by some experts to be the cause of such failure. In extremely rare instances, infection may be acquired after prophylaxis had been provided. On occasion, the erythromycin eye ointment may not have penetrated to the eye itself as a result of difficulties in keeping the infant's eye exposed during application of the ointment.

At present, specific prophylaxis given immediately (minimum delay of 1 hour) after birth, using any of the following regimens, is recommended by most professional societies and government bodies: (1) 1% silver nitrate in single-dose ampules, (2) 0.5% erythromycin ophthalmic ointment in single-use tubes, or (3) 1% tetracycline ophthalmic ointment in single-use tubes. Povidone-iodine also is a safe and effective alternative in resource-poor countries.

 Immunoprophylaxis

Lancefield group B  $\beta$ -hemolytic streptococci were first recorded as a cause of human infection in 1938, when Fry<sup>1</sup> described three patients with fatal puerperal sepsis. Sporadic cases were reported during the next 3 decades, but this microorganism remained unknown to most clinicians until the 1970s, when a dramatic increase in the incidence of septicemia and meningitis in neonates caused by group B streptococci was documented from geographically diverse regions.<sup>2-4</sup> The emergence of group B streptococcal infections in neonates was accompanied by an increasing number of these infections in pregnant women and non-

pregnant adults. In pregnant women, these infections commonly were manifested as localized uterine infections or chorioamnionitis, often with bacteremia, and had an almost uniformly good outcome with therapy. In other affected adults, who typically had underlying medical conditions, however, group B streptococcal infection often resulted in a fatal outcome.<sup>8</sup>

The reason for the emergence of group B streptococci as a significant neonatal pathogen remains obscure. The severity and magnitude of infections attributed to these microorganisms stimulated intense investigational effort, in the hope that an understanding of the epidemiology and pathogenesis of these infections could result in the development of methods for their effective control and prevention. Even so, the incidence of perinatal infection associated with group B streptococci remained stable until the early 1990s.<sup>9,10</sup> Case-fatality rates had fallen but remained substantial in comparison with those reported for other invasive bacterial infections in infants.

Within the past decade, several notable events have occurred. A shift in the distribution of serotypes causing invasive infection has been noted. Serotype V group B streptococci now are responsible for a substantial proportion of infections in the newborn, as well as among pregnant women and nonpregnant adults.<sup>11-15</sup> Capsular serotypes VII and VIII have been described, bringing the number of serotypes causing invasive human disease to nine.<sup>16</sup> Infections caused by serotype Ia have increased, those due to type II have decreased, and type III remains a dominant cause of meningitis and of late-onset infection. The reason for this serotype shift is not known, but it has important implications for the development of vaccines to prevent group B streptococcal infections. The complete genomes of serotype III and serotype V group B streptococci have now been sequenced by two groups of investigators, opening new avenues for the identification of novel potential vaccine targets.<sup>17,18</sup>

The consensus guidelines developed in 1996 by the Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Pediatrics (AAP) to prevent early-onset disease in neonates through intrapartum maternal chemoprophylaxis represent a notable achievement of the past decade.<sup>19-21</sup> The implementation of these guidelines effected a substantial decline in the incidence of neonatal infection for the first time in 2½ decades.<sup>22</sup> A population-based comparison of strategies concluded that routine culture-based screening for group B streptococci during pregnancy is more effective than the risk-based approach in prevention of early-onset disease.<sup>23</sup> In 2002, this finding led to the adoption of revised guidelines for prevention of perinatal group B streptococcal disease by universal screening for colonization of all pregnant women during the third

trimester of gestation.<sup>24</sup> Finally, ongoing testing of group B streptococcal vaccines in healthy adults offers promise that immunoprophylaxis to prevent maternal and infant group B streptococcal disease may become a reality in the near future.

## THE ORGANISM

*Streptococcus agalactiae* is the species designation for streptococci belonging to Lancefield group B. This bacterium is a facultative gram-positive diplococcus with an ultra-structure similar to that of other gram-positive cocci.<sup>25</sup> Before Lancefield's classification of hemolytic streptococci in 1933,<sup>26</sup> this microorganism was known to microbiologists by its characteristic colonial morphology, its narrow zone of  $\beta$ -hemolysis surrounding colonies on blood agar plates, and its double zone of hemolysis that appeared when plates were refrigerated an additional 18 hours beyond the initial incubation.<sup>27</sup> Occasional strains (approximately 1%) are designated  $\alpha$ -hemolytic or nonhemolytic streptococci because they either produce a lesser zone of hemolysis or demonstrate none at all, respectively; these strains can cause human infection, although infrequently.<sup>28,29</sup> Group B streptococci are readily cultivated in a variety of bacteriologic media. Isolation from certain body sites (the respiratory, genital, and gastrointestinal tracts) can be enhanced by use of broth medium containing antimicrobial agents that inhibit growth of other bacterial species indigenous to these sites.<sup>30,31</sup>

### Colonial Morphology and Identification

Colonies of group B streptococci grown on sheep blood agar medium are 3 to 4 mm in diameter, produce a narrow zone of  $\beta$ -hemolysis, are gray-white, and are flat and mucoid.  $\beta$ -Hemolysis for some strains is apparent only when colonies are removed from the agar.

Definitive identification of group B streptococci requires detection of the group B-specific antigen common to all strains through use of hyperimmune grouping antiserum. Laboratory tests that permit presumptive identification<sup>28,32</sup> include bacitracin and sulfamethoxazole-trimethoprim disk susceptibility testing (92% to 98% of strains are resistant),<sup>28,32</sup> hydrolysis of sodium hippurate broth (99% of strains are positive),<sup>28,32</sup> hydrolysis of bile esculin agar (99% to 100% of strains fail to react),<sup>28,32</sup> pigment production during anaerobic growth on certain media (96% to 98% of strains produce an orange pigment),<sup>33,34</sup> and CAMP (Christie-Atkins-Munch-Petersen) testing (98% to 100% of strains are CAMP positive).<sup>32,35,36</sup> This last test is based on the production of CAMP factor, a thermostable extracellular protein<sup>37</sup> that, in the presence of the beta toxin of *Staphylococcus aureus* (a sphingomyelinase), produces synergistic hemolysis when grown on sheep blood agar. A "spot" CAMP test, employing a crude beta toxin-containing filtrate derived from a broth culture of *S. aureus*, allows rapid (30-minute) identification of group B streptococci from a single colony of the primary isolation plate with an accuracy equal to that of the standard CAMP test.<sup>38</sup> Hippurate hydrolysis is an accurate method for presumptive identification of group B streptococci, but the requirement for 24 to 48 hours of incubation limits its usefulness. Group B strains can be differentiated from other streptococci by a combination of

the CAMP test, the bile esculin reaction, and bacitracin sensitivity testing.<sup>32</sup> Biochemical micromethods identify group B streptococci with reasonable accuracy after a 4-hour incubation period.<sup>39</sup>

Definitive microbiologic identification of group B streptococci requires serologic methods to detect the group B carbohydrate antigen. Lancefield's original method required acid treatment of large volumes of broth-grown cells to extract or solubilize the group B antigen from the cell wall.<sup>40</sup> Supernatants were brought to neutral pH and mixed with hyperimmune rabbit antiserum prepared by immunization with the group B-variant strain (090R) (devoid of type-specific antigen), and precipitins in capillary tubes were recorded. Less time-consuming techniques subsequently were developed, but all employ hyperimmune group-specific antiserum to identify the group B antigen in intact cells, broth culture supernatants, or cell extracts. Commercial availability and simplicity make latex agglutination-based assays the most practical and frequently used methods by hospital laboratories.<sup>41</sup>

### Strains of Human and Bovine Origin

Before the dramatic increase in the incidence of human group B streptococcal infections in the 1970s, these microorganisms were associated principally with bovine mastitis.<sup>42</sup> Modern veterinary practices have largely controlled epidemics of bovine mastitis due to *S. agalactiae*, but sporadic cases still occur. The relationship between strains of human and bovine origin has been questioned for years. To date, no studies have shown that cattle are a reservoir for transmission of group B streptococci to humans. Substantial evidence indicates several biochemical, biologic, and serologic differences between human and bovine isolates.<sup>43,44</sup> Pattison and associates<sup>43</sup> were unable to serotype 75% of their bovine strains employing antisera that had enabled them to classify all of their human isolates. This nontypeability of bovine strains has been confirmed by others.<sup>42</sup> Among typeable bovine strains, patterns of serotype distribution distinct from those of human isolates have been noted. Using the concept of "herd type" for serologic typing, Jensen<sup>45</sup> demonstrated that the distribution of group B streptococci from newly infected herds was not the same as that of human urogenital strains. Other distinguishing characteristics for bovine strains include their unique fermentation reactions, their decreased frequency of pigment production, and their usual susceptibility to bacitracin. Protein X, rarely found in human strains, is commonly present in pathogenic bovine isolates.<sup>46</sup>

### Serologic Classification

Lancefield defined two cell wall carbohydrate antigens for group B streptococci employing hydrochloric acid (HCl)-extracted cell supernatants and hyperimmune rabbit antisera: (1) the group B-specific or "C" substance common to all strains of this species and (2) the type-specific or "S" substance that allowed classification into four serotypes: Ia, Ib, II, and III.<sup>47-49</sup> Group B streptococcal strains originally were classified as serotypes I, II, and III. Strains designated as type I were later shown by Lancefield<sup>48</sup> to have both cross-reactive and antigenically distinct polysaccharides. When antisera raised to two different type I strains were made type

specific by reciprocal cross-absorption with streptococcal cells, the antigenically distinct type Ia and type Ib polysaccharides were defined.<sup>48</sup> The serotype of group B streptococci historically designated as type Ic was characterized by Wilkinson and her co-workers.<sup>50</sup> These strains possessed the type Ia capsular polysaccharide and a protein antigen common to type Ib, up to 60% of type II, and rare type III strains.<sup>51,52</sup> This protein antigen originally was called the “type Ibc antigen” and now has been renamed *C protein*.

The nomenclature of antigens was revised in the 1980s. Now, the polysaccharide antigens of group B streptococci are designated as type antigens and the protein antigens as additional markers for supplementary characterization of serotypes.<sup>53,54</sup> The formerly designated type Ic strains are now designated type Ia/c because they possess the Ia polysaccharide antigen and the C protein antigen. Type IV was identified as a new serotype in 1979, when 62 strains were described that possessed type IV polysaccharide alone or with one of the protein antigens.<sup>51</sup> More recently, new antigenically distinct serotypes, V through VIII, have been recognized and characterized.<sup>55-61</sup> Strains of group B streptococci from patients with serious infections that cannot be serologically classified continue to account for less than 3% of isolates.

The serotyping scheme of Lancefield is based on precipitin reactions of whole cell acid extracts with group B-specific and capsular type-specific rabbit antisera. The biologic relevance of these serologically defined type-specific antigens has been investigated employing mouse protection experiments. Rabbit antibodies directed against the capsular polysaccharides provide passive protection to mice challenged with lethal doses of mouse virulent strains containing homologous but not heterologous polysaccharide antigens.<sup>48,58</sup> Cross-protection also occurs when antibodies against the C protein and the type Ia and Ib strains that share this antigenic determinant are tested. Rabbit antibodies directed against the group B-specific antigen do not protect mice from lethal challenge.<sup>62</sup>

The C protein antigen consists of two components, one sensitive to trypsin and pepsin and the other sensitive only to pepsin.<sup>50</sup> Rabbit antibodies raised to these proteins are partially mouse protective.<sup>63</sup> The  $\beta$  C protein is present in about 10% of human group B streptococcal isolates. The  $\alpha$  components of C proteins are present in approximately one half of isolates and in most of those strains bearing capsular polysaccharides other than III.<sup>51</sup> Strains expressing  $\alpha$  C are less readily opsonized, ingested, and killed by leukocytes in the absence of specific antibody than are  $\alpha$ -negative strains.<sup>64</sup> Strains bearing both the  $\alpha$  and the  $\beta$  C protein components possess increased resistance to opsonization in vitro.

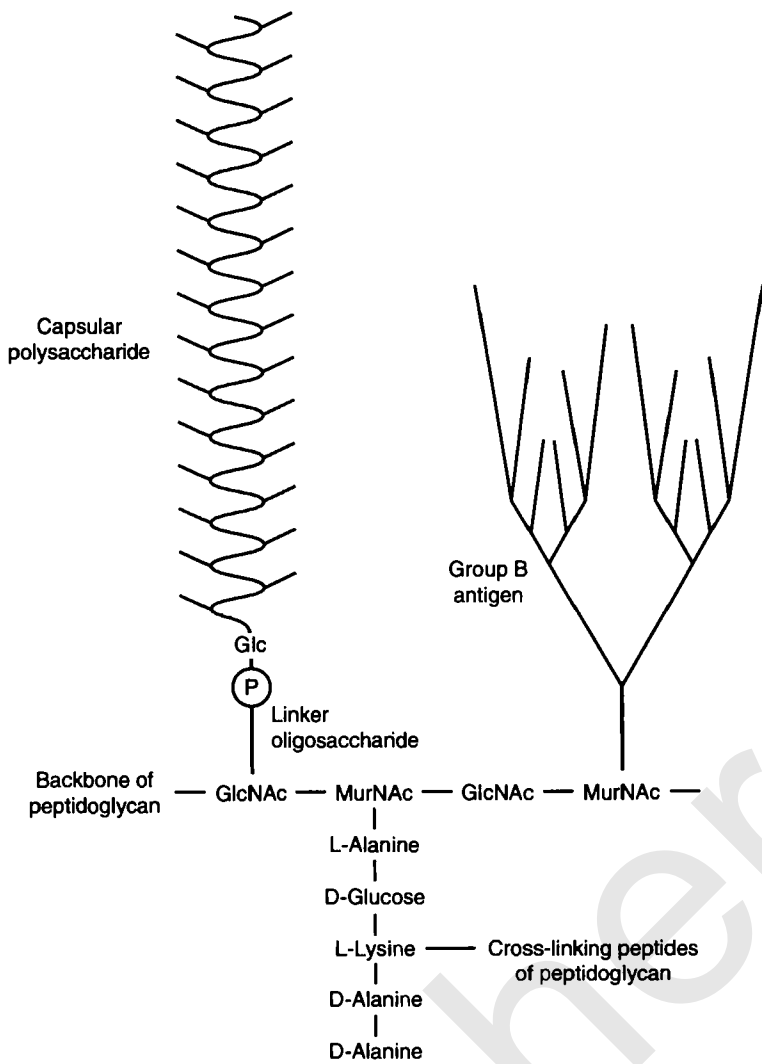

The  $\alpha$  C protein consists of a series of tandem repeating units, and in naturally occurring strains, the repeat numbers may vary. The number of repeating units expressed alters antigenicity and influences the repertoires of antibodies elicited.<sup>65</sup> Two distinct protective epitopes are present within the  $\alpha$  C protein. The use of one or two repeat units of  $\alpha$  C proteins elicits antibodies that bind all  $\alpha$  C proteins with equal affinity, suggesting their potential usefulness as vaccine candidates.<sup>66,67</sup> The  $\beta$  antigen appears as a single protein of molecular mass between 124 and 134 kDa. The  $\beta$  antigen, but not the  $\alpha$  antigen, binds the Fc region of human IgA.<sup>68-70</sup>

In addition to the group B, capsular polysaccharide type-specific, and C protein antigens, some group B streptococci contain surface proteins designated X and R antigens. These were first described by Pattison and co-workers,<sup>71</sup> who introduced reagents for their detection in an attempt to further classify nontypeable strains. The X and R antigens are immunologically cross-reactive. R antigens are found in a majority of type II and type III strains but are rare in type Ia or Ib strains.<sup>72</sup> Four distinct immunologic species of R antigen have been described. Of these, R4 is the most prevalent in isolates recovered from humans, and it is expressed almost exclusively in type II and type III strains.<sup>73</sup> A distinct surface protein, designated Rib, is expressed by most invasive strains, including almost all serotype III strains. It is immunologically unrelated but, like alpha C protein, has an extremely repetitive structure.<sup>74</sup> A new R-like protein designated BPS (group B-protective surface protein) is expressed by a number of clinically relevant group B streptococcal serotypes and is a protective antigen in a mouse model.<sup>75</sup> It has a repetitive structure but shows no sequence similarity to Rib or alpha C protein. By contrast, a laddering protein from type V group B streptococci does share sequence homology with alpha C protein.<sup>76</sup> Thus, a family of surface proteins with a repetitive structure exists that may have a role in immunity to infection. The role of the R proteins in human immunity, if any, remains to be defined, however. A recently described protein named Sip (for surface immunogenic protein) is distinct from other known surface proteins. It is produced by all serotypes of group B streptococci and confers protection against experimental infection.<sup>77</sup>

## Ultrastructure

Early concepts regarding the cellular structure of  $\beta$ -hemolytic streptococci suggested a thick, rigid peptidoglycan layer external to the cytoplasmic membrane, which was surrounded by concentric layers of cell wall antigens. The group-specific carbohydrate was believed to be “covered” by the surface type-specific antigen, which for group A streptococci is M protein and for group B is capsular polysaccharide. Electron microscope definition indicated that the group B antigenic determinant was not accessible for binding to group B-specific antibody.<sup>25</sup> Evidence now supports a model of the group B streptococcal cell surface in which the group B carbohydrate and the capsular polysaccharide are independently linked to the cell wall peptidoglycan (Fig. 13-1).<sup>78</sup>

Standard techniques for demonstrating bacterial capsules (India ink or “quellung reaction”) do not visualize capsules on group B streptococci, but these microorganisms are encapsulated. Immunoelectron techniques reveal abundant capsular polysaccharide on the surface of Lancefield prototype strains Ia, II, and III, whereas less dense capsules are found on type Ib/c and type Ia/c strains (Fig. 13-2).<sup>25</sup> Similarly, incubation of the reference strains of serotypes IV, V, and VI with homologous type-specific antisera led to visualization of a thick capsular layer.<sup>58,79</sup> The type-specific polysaccharides are surface structures on group B streptococcal cells. Ultrastructural studies also demonstrate that the C protein antigen also has a surface location on type Ia and type Ib cells.<sup>25</sup> The degree of encapsulation of group B streptococcal strains is a function of in vitro manipulation and of serotype. Expression of the capsular polysaccharide is not constitutive; rather, such

**Figure 13-1** Schematic representation of a proposed model for the independent linkage of capsular polysaccharide and group B carbohydrate to peptidoglycan of the group B streptococcus. Group B carbohydrate is linked to *N*-acetylmuramic acid (MurNAc), and capsular polysaccharide is linked by a phosphodiester bond and oligosaccharide linker to *N*-acetylglucosamine (GlcNAc).<sup>78</sup> (From Deng L, Kasper DL, Krick TP, Wessels MR. Characterization of the linkage between the type III capsular polysaccharide and the bacterial cell wall of group B *Streptococcus*. *J Biol Chem* 275:7497, 2000.)

**Figure 13-2** Electron micrographs of thin sections of group B streptococcal strains: **A**, type Ia (090); **B**, type Ia/c (A909). Both are stained with ferritin-conjugated type Ia-specific rabbit antibodies. The type Ia strain is representative of the large capsules found in Lancefield prototype II strain (18RS21) and type III isolates from infants with meningitis (M732), whereas the type Ia/c strain is representative of the much smaller capsules occurring in Lancefield prototype strains Ia/c (A909) and Ib/c (H36B). expression varies during growth *in vitro* and in primary cultures isolated from different sites of infection.<sup>80,81</sup>

### Immunochemistry of Polysaccharide Antigens

Lancefield's serologic definition of the antigens of group B streptococci was achieved by their extraction from whole cells by dilute HCl and heat treatment.<sup>48,49</sup> Additional purification methods were necessary for isolation of the group B-specific from type-specific polysaccharide antigens. The chemical composition of the group B polysaccharide initially was determined for B antigen extracted from whole cells of the laboratory-adapted variant strain 090R, devoid of capsular polysaccharide.<sup>82,83</sup> In later studies, group B antigen was isolated from type III cells employing alcohol fractionation techniques with hot formamide extracts of whole cells.<sup>84</sup> With the use of rigorous biochemical methods for structural determination, the group B antigen was shown to contain L-rhamnose, D-galactose, 2-acetamido-2-deoxy-D-glucose, and D-glucitol. It is composed of four different oligosaccharides, designated I, II, III, and IV, that are linked by one type of phosphodiester bond to form a complex, highly branched multiantennary structure.<sup>85</sup> Inhibition studies have shown that antibodies to the group B polysaccharide are dominated by those specific for a trirhamnopyranoside epitope.

Extensive studies of the HCl-extracted type-specific polysaccharides have been reported in the past. The HCl antigens from type Ia, Ib, II, and III organisms are small-molecular-mass ( $1.5$  to  $5.0 \times 10^4$  daltons), neutral polysaccharides that contain identical constituents—galactose, glucose, and 2-acetamido-2-deoxyglucose—in repeating units of a core structure. When more gentle techniques are employed for the extraction of these type-specific capsular polysaccharides from whole cells, large-molecular-mass ( $5 \times 10^5$  to  $1 \times 10^6$  daltons), acidic polysaccharides with an additional antigenic determinant are isolated. These “native” antigens form a partial identity with the HCl antigens from homologous strains by immunodiffusion with type-specific antisera. The additional antigenic determinant on the more complete type-specific polysaccharides is the acid-labile sugar sialic acid.<sup>86</sup> Acid hydrolysis of “native” polysaccharides results in degradation to core structures that are immunochemically identical to the homologous HCl-extracted antigens. Isolation of the immunologically more complete polysaccharides requires that growth of cells and extraction of antigens be performed under conditions that maintain neutral pH.<sup>86</sup>

The capsular polysaccharides of type Ia, type Ib, and type III group B streptococci have a five-sugar repeating unit containing galactose, glucose, N-acetylglucosamine, and sialic acid in a ratio of 2:1:1:1.<sup>86-89</sup> The type II and type V polysaccharides have a seven-sugar repeating unit, whereas those of types IV and VII consist of six-sugar repeating units, and that of type VIII consists of four.<sup>57-59,90-92</sup> The molar ratios vary, but the component monosaccharides are the same, with two exceptions. First, no N-acetylglucosamine is present in the type VI polysaccharide. In addition, the recently described type VIII capsular polysaccharide is the only structure that contains rhamnose in the backbone structure.<sup>60</sup> Each antigen has a backbone repeating unit of two (Ia, Ib), four (II), or three (II, IV, V, VII, VIII) monosaccharides to which one or two side chains are linked. Sialic acid as a

terminal side chain residue is a consistent feature of the group B streptococcal capsular polysaccharides. With the exception of type II polysaccharide, which has a galactose terminal side chain sugar, sialic acid is the exclusive terminal sugar of the side chain(s).

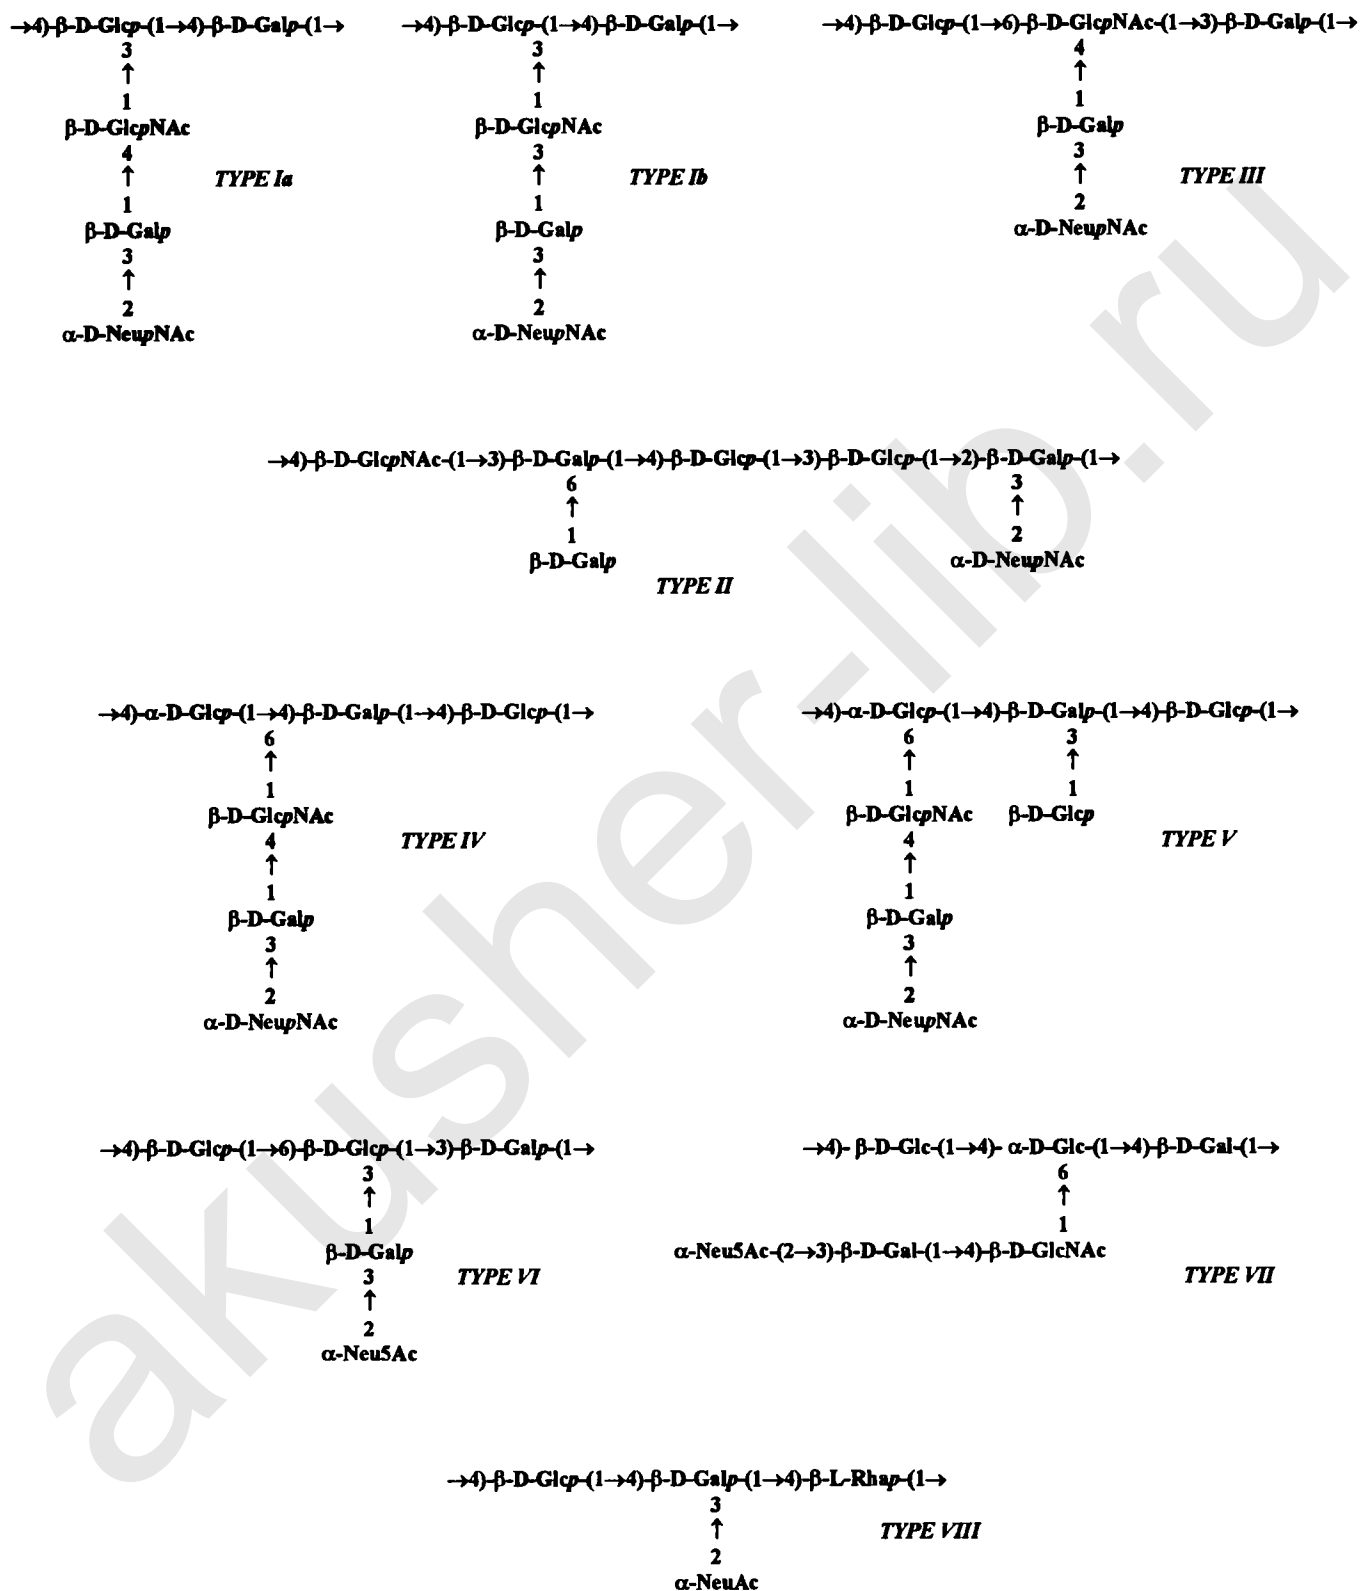

The repeating unit structures of the group B streptococcal polysaccharides, determined by methylation analysis combined with gas-liquid chromatography/mass spectrometry, are schematically represented in Figure 13-3. The structures of the type Ia and type Ib polysaccharides differ only in a single monosaccharide side chain linkage, although there are differences in the tertiary configuration of the molecules.<sup>93</sup> These monosaccharide linkages are critical to their immunologic specificity and also explain their immunologic cross-reactivity.<sup>48,94</sup>

The type Ia, Ib, and III polysaccharides have a high degree of structural homology with two human serum glycoproteins. The terminal  $\alpha$ -D sialic acid [2→3]- $\beta$ -D-galactose of these polysaccharides is identical to the end group of human M and N blood group substances.<sup>95</sup> The type Ib polysaccharide has a repeating unit that is virtually identical to those of certain oligosaccharides present in human milk.<sup>96</sup> For the type III polysaccharide, a graded increase in relative affinity of antigen-antibody binding was observed as oligosaccharide size increased from 3 to 92 repeating units.<sup>97</sup> One implication of this difference in antibody-binding affinity, estimated to exceed 300-fold, is that binding interaction with an oligosaccharide on a host glycoprotein would be of very low affinity, and unlikely to result in activation of potentially damaging immune effector mechanisms. The type III polysaccharide also can form extended helices. The position of the conformational epitope along these helices is potentially important to binding site interactions.<sup>98,99</sup> Another structural homology is that between the HCl-extracted type III polysaccharide and the immunochemically identical type 14 pneumococcal polysaccharide.<sup>100</sup> This observation stimulated investigations concerning the immunodeterminant specificity of human immunity to type III group B streptococci and of antibody recognition of conformational epitopes as a facet of the host immune response.<sup>101</sup>

Because human immunity to type III strains correlates with antibody to the intact rather than to the desialylated capsular polysaccharide antigen, isolation of intact polysaccharides with sialic acid moieties has been necessary for the study of human immunity. Growth of cells in highly buffered media or by pH titration achieves the conditions of neutral pH necessary for isolation of immunologically complete antigens.<sup>82</sup> Yield of polysaccharides extracted from whole cells by these gentle neutral buffer techniques is low, however. Improvements in preparative methods through use of chemically defined, pH-controlled growth medium, treatment of bacterial cells with enzymes<sup>102</sup> to release capsule into the medium, and serial chromatographic procedures to ensure purity<sup>89</sup> now allow for isolation of large quantities of intact polysaccharides.

### Growth Requirements and Bacterial Products

The nutritional requirements of several human and bovine strains of group B streptococci, examined in a chemically defined medium, reveal reasonable homogeneity in vitamin requirements. Group B streptococci also are quite homo-

**Figure 13-3** Repeating unit structures of group B streptococcal capsular polysaccharides type Ia,<sup>93</sup> type Ib,<sup>93,94</sup> type II,<sup>90,92</sup> type III,<sup>88,89</sup> type IV,<sup>91</sup> type V,<sup>57</sup> type VI,<sup>61</sup> type VII,<sup>59</sup> and type VIII.<sup>60</sup>

geneous in their amino acid requirements during aerobic or anaerobic growth.<sup>103</sup> Provision of a glucose-rich environment enhances the number of viable group B streptococci during stationary phase and the amount of capsular polysaccharide present on type III cells elaborated into the growth medium.<sup>104</sup> In a modified chemically defined medium, the expression of capsule during continuous growth is regulated by the growth rate.<sup>80</sup> Group B streptococcal invasiveness is enhanced by a fast growth rate and is optimal in the presence of at least 5% oxygen.<sup>105,106</sup>

Group B streptococci elaborate a number of products, including the soluble type-specific capsular polysaccharides,<sup>86</sup> hemolysin,<sup>107</sup> pigment,<sup>108</sup> CAMP factor,<sup>35</sup> hippuricase,<sup>28,109</sup> nucleases,<sup>110</sup> superoxide dismutase,<sup>111</sup> protease,<sup>112</sup> an oligopeptidase, and lipoteichoic acid (LTA).<sup>113</sup> The hemolysin or hemolysins of group B streptococci are an extracellular product of almost all strains and are active against the erythrocytes from several mammalian species. The hemolysin that produces the  $\beta$ -hemolysis surrounding group B colonies on blood agar plates has been isolated and characterized.<sup>106</sup> When it was tested with known inhibitors of other streptococcal hemolysins (phospholipids, trypan blue, proteases, cholesterol), it was inhibited only by phospholipids. The hemolysin was not detected in supernatants of broth cultures, suggesting either that it exists in a cell-bound form or that it is released by cells and rapidly inactivated.

After growth to stationary phase, group B streptococci produce two types of pigment resembling a beta carotenoid.<sup>108</sup> Pigment, like hemolysin, is formed and released by an active metabolic process, retaining its properties only in the presence of a carrier molecule. A potential role for pigment as a virulence factor is proposed but unproved. No relationship between the group B streptococcal hemolysin and CAMP factor has been determined.<sup>106</sup>

The CAMP phenomenon—the elaboration of CAMP factor by group B streptococci—was described in 1944 by Christie, Atkins, and Munch-Petersen.<sup>35</sup> Skalka and Smola<sup>114</sup> reported that a partially purified CAMP factor was lethal in experimental infection. Subsequently, the finding of non-specific binding of the CAMP factor to immunoglobulins in a protein A-like fashion led Jürgens and co-workers<sup>115</sup> to suggest the term *protein B* for CAMP factor. The cloning and expression of CAMP factor in *Escherichia coli* will aid investigations of its mode of action and role, if any, in the pathogenesis of human infections.

Group B streptococci can hydrolyze hippuric acid to benzoic acid and glycine, and this property has been useful historically to distinguish group B streptococci from other  $\beta$ -hemolytic groups.<sup>28,104</sup> Ferrieri and co-workers isolated and characterized the hippuricase of group B streptococci.<sup>109</sup> This enzyme is cell associated and is trypsin and heat labile. It is antigenic in rabbits, but its relationship to bacterial virulence, if any, has not been studied.

Most strains of group B streptococci have an enzyme that inactivates complement component C5a by cleaving a peptide at the carboxyl terminus.<sup>116,117</sup> Group B streptococcal C5a-ase appears to be a serine esterase; it is distinct from the C5a-cleaving enzyme (termed *streptococcal C5a peptidase*) produced by group A streptococci,<sup>118</sup> although the genes that encode these enzymes are similar.<sup>119</sup> C5a-ase contributes to the pathogenesis of group B streptococcal disease by rapidly inactivating the neutrophil agonist C5a, thereby preventing

the accumulation of neutrophils at the site of infection.<sup>116</sup> Naturally occurring immunoglobulin G (IgG) antibodies can neutralize the enzyme in serum or plasma, but C5a-ase associated with the bacterial surface of encapsulated type III group B streptococci is not inactivated by IgG, suggesting that this capsule provides protection from neutralization of the enzyme.<sup>120</sup>

Another group of enzymes elaborated by nearly all group B streptococci are the extracellular nucleases.<sup>110</sup> Three distinct nucleases—designated I, II, and III by Ferrieri and colleagues<sup>109</sup>—have been physically and immunologically characterized. All are maximally activated by divalent cations of calcium plus manganese. These group B streptococcal nucleases are immunogenic in animals, and neutralizing antibodies to these antigens are detectable in sera from pregnant women known to be genital carriers of group B streptococci. The relationship between this latter observation and the pathogenesis of human infection, if any, is unknown.

An extracellular product that may relate to the virulence of group B streptococci in humans is neuraminidase (sialidase), considered by some investigators to be a hyaluronate lyase.<sup>121,122</sup> Maximal levels are detected during late exponential growth in a chemically defined medium. Subsequently, proteases may degrade neuraminidase. The neuraminidases from some of the serotypes of group B streptococci have been purified and partially characterized. These have a molecular size of approximately  $1 \times 10^5$  daltons and a limited range of activity on sialic acid substrates when compared with other bacterial neuraminidases. Type III polysaccharide is resistant to type III group B streptococcal neuraminidase.<sup>123,124</sup>

Elaboration of large quantities of neuraminidase may be a virulence factor for type III group B streptococci. Almost all type Ia, Ib, and II strains are low producers, whereas type III strains are either high producers or nonproducers.<sup>125</sup> When type III strains isolated from infants with invasive infection were compared with those isolated from healthy colonized infants, the former were significantly more often high neuraminidase producers. Musser and co-workers<sup>126</sup> identified a high neuraminidase-producing subset of type III strains that were responsible for a majority of serious group B streptococcal infections.

The role of type-specific polysaccharides as virulence factors acting independently has been evaluated in a murine model.<sup>127</sup> The amount of extracellular capsular polysaccharide produced by type III strains correlated with virulence in chick embryos<sup>128</sup> and mice<sup>129</sup> and with invasiveness in susceptible infants. Mutants defective in capsular polysaccharide synthesis were cleared efficiently in a murine model.<sup>130</sup> The finding that group B streptococcal strains with low buoyant density produce higher amounts of type-specific capsular polysaccharide and are more resistant to phagocytic killing than are high-density variants, coupled with the identification of a group of genetically related organisms with increased capsule production that causes a majority of the cases of invasive type III disease, corroborates this concept.<sup>131</sup>

Group B streptococci synthesize acylated (lipoteichoic) and deacylated glycerol teichoic acids that are cell associated and can be readily extracted and purified.<sup>113</sup> Strains from infants with early- or late-onset disease have higher levels of cell-associated and native deacylated LTA,<sup>113</sup> and this product may contribute to attachment to human cells.<sup>132,133</sup>

## EPIDEMIOLOGY AND TRANSMISSION

Historically, *S. agalactiae* was known to cause bovine mastitis rather than human perinatal infection. When the organism became recognized as a human pathogen, epidemiologic studies examined whether bovine and human strains were biologically related and whether transmission from bovine sources to humans might occur. Employing culture, physiologic, and serologic properties as strain markers, investigators concluded that transmission from cows was exceedingly rare.<sup>42-44,71,134</sup> In addition, during the past decades when it has been a dominant human pathogen in the United States, a majority of the population has lacked exposure to the two possible modes of transmission: (1) proximity to dairy cattle (direct contact) and (2) ingestion of unpasteurized milk.

### Asymptomatic Infection (Colonization) in Adults

Group B streptococcal infection limited to mucous membrane sites has been designated as *asymptomatic infection, colonization, or carriage*. Direct comparisons of the prevalence of colonization reported in the literature are virtually impossible because of differences in the ascertainment techniques employed for study. Several factors influence the accuracy of detecting colonization in a given population: the choice of bacteriologic media, the body sites sampled, the number of cultures obtained, and the time interval chosen for study. Isolation rates are significantly higher with use of broth rather than solid agar media; with media containing substances inhibitory for normal flora (usually antibiotics); and with selective broth rather than selective solid agar media.<sup>135</sup> Among selective broth media chosen, Todd-Hewitt broth with gentamicin (4 to 8 µg/mL) or colistin (or polymyxin B) (10 µg/mL) and nalidixic acid (15 µg/mL), with or without sheep red blood cells, has been the most useful for accurate detection of group B streptococci from genital and rectal cultures.<sup>135,136</sup> These media inhibit the growth of most gram-negative enteric bacilli, as well as other normal flora, that make isolation of streptococci from these sites difficult. Use of broth media enables detection of low numbers of organisms that escape detection when inoculation of swabs is directly onto solid agar.<sup>30,135-137</sup>

Isolation rates also are influenced by body sites selected for culture. Female genital culture isolation rates double with progression from the cervical os to the vulva.<sup>138,139</sup> In addition, culture sampling of both lower genital tract and rectal sites increases group B streptococcal colonization rates 10% to 15% above that found if a single site is cultured.<sup>9,140,141</sup> The urinary tract also is an important site of group B streptococcal infection, especially during pregnancy, when infection usually is manifested as asymptomatic bacteriuria.<sup>142,143</sup> Therefore, to accurately predict the likelihood of neonatal exposure to group B streptococci at delivery, maternal culture specimens from the lower vagina, vulva, or periurethral area and rectum should be collected (see "Prevention" later on).

In neonates, selection of optimal body sites for detection of colonization also influences prevalence rates. In the first 24 hours of life, external auditory canal cultures are more likely to yield group B streptococci than those from anterior nares, throat, umbilicus, or rectum,<sup>3,140</sup> and isolation of organisms from the ear canal is a surrogate for the degree of

contamination from amniotic fluid and vaginal secretions sequestered during the birth process. After the first 48 hours of life, throat and rectal sites are the most common sources of group B streptococci,<sup>144,145</sup> and positive cultures indicate true colonization (multiplication of organisms at mucous membrane sites), not just maternal exposure. Beyond the neonatal period, the throat and the rectum continue to be the most common sites for detection of group B streptococcal colonization, and this predominance persists until sexual debut, when the genitourinary tract becomes a common site of colonization in both sexes.<sup>146-150</sup>

The prevalence of group B streptococcal colonization also is influenced by the number of cultures obtained from a single site and the interval during which these are collected in an individual patient. An early longitudinal study in which women were evaluated throughout pregnancy with sequential lower vaginal cultures identified colonized women as having chronic, transient, intermittent, or indeterminant carriage of group B streptococci.<sup>151</sup> A more recent longitudinal cohort study of 1248 nonpregnant young women found that, among women who were culture negative at enrollment, almost one half acquired vaginal colonization during follow-up study at three 4-month intervals.<sup>152</sup> Other longitudinal studies found that nearly one half of women vaginally colonized at delivery had negative antenatal culture results.<sup>153,154</sup> In a longitudinal study of 5586 pregnant women by Boyer and associates,<sup>154</sup> initial cultures were performed during the second trimester in two thirds of the women; the overall predictive value of a positive prenatal vaginal or rectal culture result for colonization at delivery was 67%. The predictive value of a positive prenatal culture result was highest (73%) in women with vaginal and rectal colonization and lowest (60%) in those with rectal colonization only. Thus, if colonization is to be detected with maximal accuracy on a single occasion, lower vaginal and rectal cultures should be performed. Cultures performed from 1 to 5 weeks before delivery are accurate in predicting group B streptococcal colonization status at delivery in term parturients. Within this interval, the positive predictive value is 87% (95% confidence interval [CI] 83 to 92) and the negative predictive value is 96% (95% CI 95 to 98). Culture specimens collected within this interval perform significantly better than those collected 6 or more weeks before delivery.<sup>155</sup>

The primary reservoir for group B streptococci is the lower gastrointestinal tract.<sup>3,156</sup> The recovery of group B streptococci from the rectum alone is three to five times more common than from the vagina,<sup>141</sup> the rectal-to-vaginal isolation ratio exceeds 1,<sup>154</sup> and the rectal site more accurately predicts persistence<sup>141</sup> or chronicity of carriage.<sup>143</sup> These observations support the rationale for obtaining rectal as well as lower vaginal cultures to define maternal carriage during pregnancy. Fecal carriage or rectal colonization with group B streptococci has been documented in patients ranging in age from 1 day<sup>157</sup> to 70 to 80 years.<sup>158</sup> Additional compelling evidence supporting the intestine as the primary reservoir of colonization by group B streptococci includes their isolation from the small intestine of adults<sup>159</sup> and their association with infections resulting from surgery of the upper or lower intestinal tract.<sup>160</sup> Rectal colonization also may contribute to the importance of group B streptococci as a urinary tract pathogen and for the resistance of genital tract colonization to eradication by antibiotics.<sup>161</sup>

Table 13-1 Group B Streptococcal Colonization Rates in Diverse Populations of Women and Men

Population	Sites Cultured	Prevalence Rates (%)	Representative Reference Nos.
Pregnant women	Throat	2-5	2, 3, 15, 152, 171
	Vaginal and/or rectal	20-36	164, 165, 172
	Rectal	16-22	135, 156, 164
Nonpregnant women	Throat	3-12	3, 136
	Vaginal and/or rectal	29-34	155, 163
	Rectal	11-37	139, 148, 173, 174
Venereal disease clinic enrollment	Vaginal and/or rectal	24-40	173, 174
	Rectal	24-40	173, 174
Heterosexual men	Throat	4-11	136, 175
	Urethra or urine	2-27	138, 163
Homosexual men	Throat	19	176
	Urethra	23	176

Outlining methods to prevent group B streptococcal infection have relied on data from prospective active surveillance studies.<sup>162</sup> Group B streptococci are common constituents of the genital microflora at delivery, and the prevalence rates of colonization in a given population are similar for each trimester of gestation.<sup>2,151,153</sup> Pregnancy does influence colonization rates, but few data are available for matched populations of pregnant and nonpregnant women.<sup>9,148</sup> Several factors have been assessed for their possible influence on genital carriage in women. Sexual activity is an important risk factor for vaginal colonization, but not for rectal-only colonization, in young nonpregnant women. In a longitudinal cohort study of 1248 nonpregnant young women, specific factors—African American race, having multiple sex partners during a preceding 4-month interval, having frequent sexual intercourse within the same interval, and having sexual intercourse within the 5 days before the follow-up visit—were independently associated with vaginal acquisition of group B streptococci.<sup>152</sup> These findings suggest either that the organism is sexually transmitted or that sexual activity alters the microenvironment to make it more permissive to colonization. In another study of 499 college women, group B streptococci were isolated significantly more often from sexually experienced women, women studied during the first half of the menstrual cycle, those with an intrauterine device, and women 20 years of age or younger.<sup>148</sup> Colonization with group B streptococci also occurs at a high rate in healthy college students and is associated with having engaged in sexual activity, tampon use, milk consumption, and hand washing done four times daily or less.<sup>163</sup>

Colonization with group B streptococci can elicit a systemic immune response. In a group of pregnant women evaluated at the time of admission for delivery, vaginal or rectal colonization with serotype Ia, II, III, or V was associated with significantly higher serum concentrations of IgG specific for the colonizing serotype compared with non-colonization.<sup>164</sup> Moderate concentrations of Ia, Ib, II, III, and V capsular polysaccharide-specific IgG also were found in association with colonization during pregnancy.<sup>165</sup> Maternal colonization with type III was least likely to be associated with these serotype-specific antibodies.

A higher prevalence of colonization with group B streptococci has been found among pregnant diabetic patients than among controls.<sup>166</sup> Prolonged carriage (over a 3-year

interval) has been reported significantly more often in women who use tampons than in women who do not.<sup>167</sup> Colonization also appears to be more frequent among teenage women than among those 20 years of age or older,<sup>148,151,153</sup> and among women with three or fewer pregnancies than in those with more than three.<sup>151,153,168</sup> Ethnicity is related to colonization rates. In one large multicenter U.S. pregnancy study, colonization rates were highest in Hispanic women of Caribbean origin, followed by African Americans, whites, and other Hispanics (predominantly Mexicans).<sup>168</sup> In other recent assessments of geographically and ethnically diverse populations, the rate of colonization at delivery was significantly higher among African American women than in other racial or ethnic groups.<sup>152,164,169</sup> A large inoculum of vaginal group B streptococcal colonization also was more common among African American than among Hispanic or white women.<sup>170</sup>

Factors that do not influence the prevalence of genital colonization in nonpregnant women include use of oral contraceptives<sup>148</sup>; marital status; presence of vaginal discharge or other gynecologic signs or symptoms,<sup>148</sup> carriage of *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, or *Mycoplasma hominis*<sup>168</sup>; and infection with *Neisseria gonorrhoeae*.<sup>138,139</sup>

Asymptomatic infection of the genital or lower gastrointestinal tract with group B streptococci occurs in men as well as in women (Table 13-1). Of sexual partners of genitally colonized women, urethral isolation of group B streptococci can be found in at least one half.<sup>2,9,138,149</sup> Genital isolation rates are significantly greater in sexually active than in virgin women<sup>148</sup> and in patients attending venereal disease clinics than in those attending other outpatient facilities.<sup>138,177</sup> Molecular typing techniques have confirmed that sexual partners often carry identical strains. In contrast with agents such as *N. gonorrhoeae* or genital mycoplasmas, genital infection with group B streptococci is not related to genital symptoms.<sup>148,174,177</sup>

Group B streptococci have been isolated from vaginal or rectal sites or both in 15% to 30% of pregnant women (Table 13-2). These variations in colonization rates relate to intrinsic differences in populations (age, parity, socioeconomic status, geographic location) and to lack of standardization in culture methods employed for study. True population differences account for some of the disparity in these reported prevalence rates. When selective broth media are used and vaginal and rectal samples are cultured, the overall prev-

<sup>a</sup>Overall carrier rate, multiple sites, given in brackets.

<sup>b</sup>Not specified by site positive.

alence of maternal colonization with group B streptococci by region is 12% in India and Pakistan, 19% in Asia and the Pacific Islands, 19% in sub-Saharan Africa, 22% in the Middle East and North Africa, 14% in Central and South America, and 26% in the United States.<sup>164,205</sup> The reported rates of colonization among pregnant women range from 1.5% to 22% in eastern Europe, from 7% to 30% in western Europe, from 10% to 25% in Scandinavia, and from 2.3% to 18.5% in the southern part of Europe.<sup>206</sup> The prevalence rates of pharyngeal colonization among pregnant and nonpregnant women and heterosexual men are similar<sup>3,136,175</sup>; however, the rate approaches nearly 20% in homosexual men.<sup>176</sup> No definite relationship between isolation of group B streptococci from throat cultures of adults or children and symptoms of pharyngitis has been proved,<sup>207</sup> but some investigators have suggested that these organisms can produce acute pharyngitis.<sup>175</sup>

### Asymptomatic Infection in Infants and Children

The prevalence of group B streptococcal colonization in children appears to differ from that in adults. In a study of 100 girls between 2 months and 16 years of age, Hammerschlag and co-workers<sup>146</sup> isolated group B streptococci from cultures of samples from lower vaginal, rectal, or pharyngeal sites or all three in 20%. Although the prevalence of positive pharyngeal cultures in girls 11 years of age or older (5%) was similar to that reported for women, the prevalence in younger girls (15%) resembled that reported

for neonates.<sup>3,144,145</sup> Rectal colonization was detected frequently in girls younger than 3 or older than 10 years of age (about 25%) but was uncommon in those between 3 and 10 years of age. In a similar study of prepubertal boys and girls, Mauer and colleagues<sup>147</sup> isolated group B streptococci from cultures of vaginal, anal, or pharyngeal specimens or all three in 11% of patients. Pharyngeal (5% each) and rectal (10% and 7%) isolation rates were similar for boys and for girls, respectively. Persson and co-workers<sup>157</sup> detected a lower (4%) rate of fecal carriage of group B streptococci among healthy boys and girls, and Cummings and Ross<sup>208</sup> found that only 2% of English schoolchildren had pharyngeal carriage of group B streptococci. Thus, the gastrointestinal tract is the most frequent site for carriage during infancy and childhood in both boys and girls, and genital colonization in girls is uncommon before puberty.<sup>209</sup> Whether the latter finding is related to environmental influences in the prepubertal vagina or to lack of sexual experience before puberty or both awaits further study.

### Transmission of Group B Streptococci to Neonates

The presence of group B streptococci in the maternal genital tract at delivery is a significant determinant of colonization and infection in the neonate. Exposure of the neonate to the organism occurs either by the ascending route in utero through ruptured membranes or by contamination during passage through the birth canal. Prospective studies have

<sup>a</sup>Time of newborn culture collection varied from <30 minutes after birth to 48-72 hours of age in these studies; therefore, rates of colonization depended on maternal inoculum when assessment was performed shortly after birth.

<sup>b</sup>Exact data are not listed.

ND, not determined.

indicated vertical transmission rates of 29% to 85%, with a mean rate of approximately 50% (Table 13-3), among neonates born to women in whom group B streptococci were isolated from cultures of vagina or rectum, or both, at delivery. Conversely, only about 5% of infants delivered of culture-negative women become asymptotically infected at one or more sites during the first 48 hours of life.

The risk of a neonate's acquiring colonization by the vertical route correlates directly with the intensity of colonization (inoculum size). Neonates born to heavily colonized women are more likely to acquire carriage at mucous membrane sites than those born to women with low colony counts of group B streptococci in vaginal cultures at delivery.<sup>217</sup> Boyer and associates<sup>154</sup> found that rates of vertical transmission were substantially higher in women with heavy than in those with light colonization (65% versus 17%) and that colonization at multiple sites and development of early-onset disease were more likely among infants born to heavily colonized mothers.

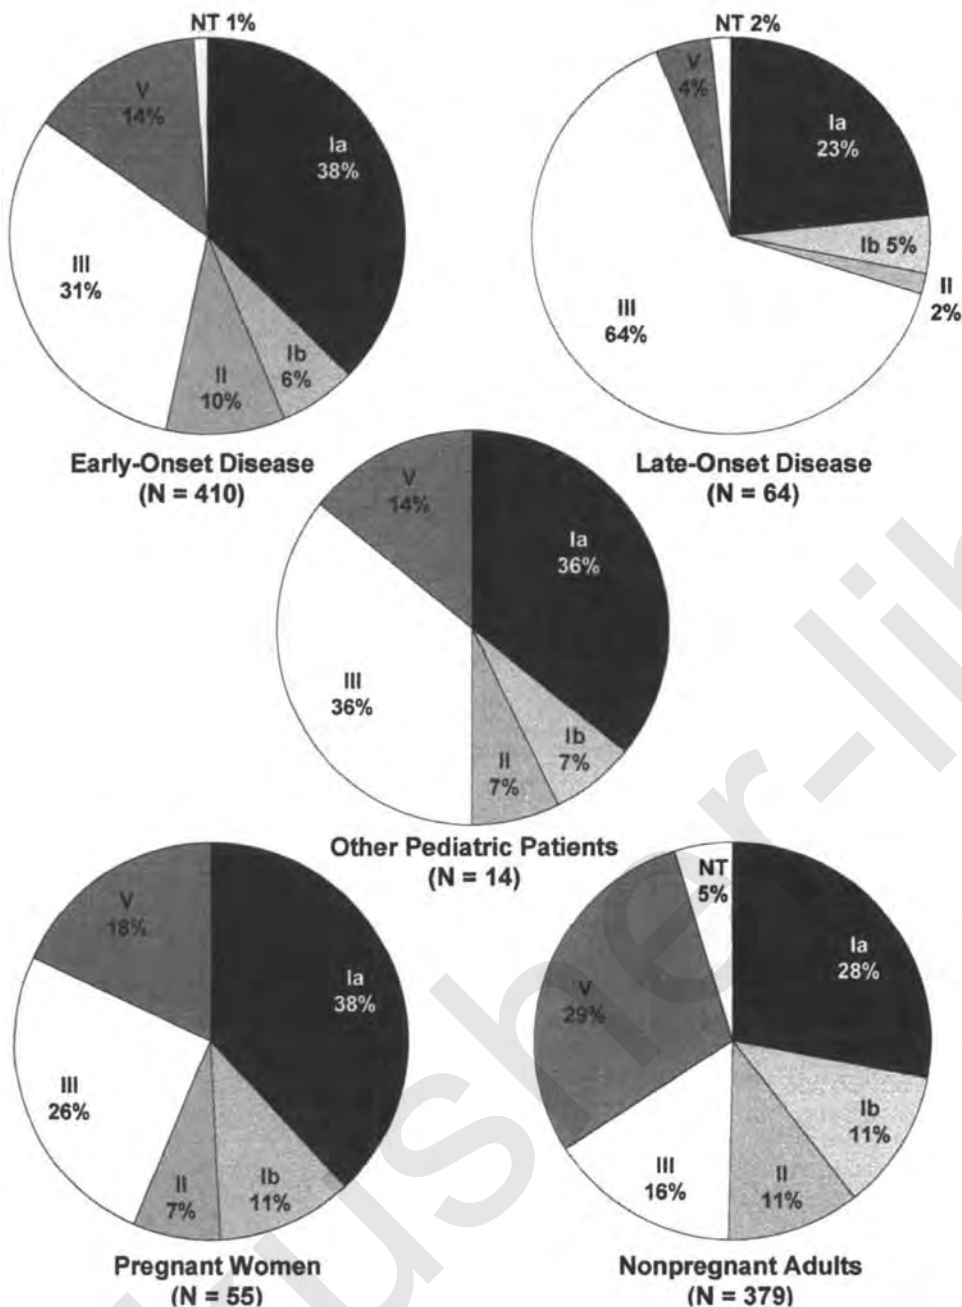

The likelihood of colonization in a neonate born to a woman who is culture positive at delivery is unrelated to maternal age, race, parity, or blood type or to duration of labor or method of delivery.<sup>2,3,135,144,179,217</sup> Whether preterm or low-birth-weight neonates are at higher risk for colonization from maternal sources than term infants remains unclear.

Most infected neonates have group B streptococci that are limited to surface or mucous membrane sites. This results from contamination of the oropharynx, gastric contents, or gastrointestinal tract by swallowing of infected amniotic fluid or maternal vaginal secretions. Healthy infants colonized from a maternal source demonstrate persistence of infection at mucous membrane sites for weeks.<sup>9,144</sup> The distribution of

serotypes in group B streptococcal isolates from mothers is comparable to that in isolates from healthy neonates.

Besides exposure during birth, other sources for group B streptococcal colonization in the neonate have been established. Horizontal transmission from hospital or community sources to neonates is an important, albeit less frequent, mode for transmission of infection.<sup>144,145,210,215,216,218</sup> Cross-contamination from maternally infected to uninfected neonates can occur from hands of nursery personnel.<sup>215</sup> Unlike group A streptococci, which can produce epidemic disease in nurseries, group B streptococci rarely exhibit this potential, and isolation of neonates with a positive result on skin, umbilical, throat, or gastric cultures is not indicated. An epidemic cluster of five infants with late-onset bacteremic infection related to type Ib group B streptococci occurred among very low birth weight infants in a neonatal intensive care unit.<sup>219</sup> None of the index cases were colonized at birth, establishing that nosocomial acquisition had occurred. Phage typing identified two overlapping patterns of susceptibility believed to represent a single epidemic strain. Epidemiologic analysis suggested infant-to-infant spread by means of the hands of personnel, although acquisition from two nurses colonized with the same phage-type serotype Ib strain was not excluded. The control measures instituted prevented additional cases. This and other reports<sup>210,215</sup> indicate that cohorting of culture-positive infants during an outbreak coupled with implementation of strict hand hygiene for infant contact significantly diminishes nosocomial acquisition.

Community sources afford potential for transmission of group B streptococci to the neonate. Indirect evidence has suggested that this mode of infection is infrequent.<sup>2,15,144,152,199</sup> Only 2 of 46 neonates culture-negative for group B streptococci when discharged from the newborn nursery acquired

**Figure 13-4** Schematic representation of group B streptococcal serotypes isolated from a variety of patient groups. N, number of patient isolates studied; NT, nontypeable strains. (Data from refs. 11, 12, 13, 162.)

mucous membrane infection at 2 months of age.<sup>220</sup> Presumably, the mode of transmission is fecal-oral. Whether acquired by vertical or horizontal mode, infection of mucous membrane sites in neonates usually persists for weeks or months.<sup>144,172,210</sup>

### Serotype Distribution of Isolates

The differentiation of group B streptococcal strains into serotypes based on capsular polysaccharide or cell surface protein antigens has provided an invaluable tool in defining the epidemiology of human infection. In the 1970s and 1980s, virtually all studies in which a large number of group B streptococcal strains were isolated from asymptomatic neonates, children, or adults revealed an even distribution into serotypes I, II, and III. This distribution also was

reported for isolates from neonates with early-onset infection without meningitis.<sup>52,221,222</sup> As late as 1990, serotypes other than I, II, or III accounted for less than 5% of isolates.

Since 1992, a number of reports from hospitals representing diverse regions throughout the United States and Canada have documented the emergence of serotype V as a frequent cause of colonization and invasive disease.<sup>11-16,162,223,224</sup> The serotype distribution of group B streptococcal strains isolated from different patient groups during the 1990s is shown in Figure 13-4. In two reports, type V has been the predominant serotype among invasive isolates from nonpregnant adults.<sup>12,13</sup> Type V causes a substantial proportion of cases of early-onset disease and of infection among pregnant women. During the 1990s, serotype Ia increased in prevalence and a corresponding

decline occurred in serotype II strains as a cause of perinatal group B streptococcal disease.<sup>162</sup> Serotype III strains, which account for approximately 90% of isolates from infants with meningitis, continue to be isolated from two thirds to three quarters of infants with late-onset disease.<sup>224</sup> The emergence of type V is not due to a clone, but a majority of type V isolates do have one subtype pattern that has been present in the United States since 1975.<sup>15</sup> Serotypes VI, VII, and VIII rarely cause human disease in the United States, but recent reports indicate that types VI and VIII are the most common serotypes isolated from healthy Japanese women.<sup>225,226</sup>

### Molecular Epidemiology

Epidemiologic investigation of group B streptococcal infections was hampered for many years by the lack of a discriminatory typing system.<sup>227</sup> Initial investigations employed phage typing in combination with serologic classification to differentiate between infant acquisition of group B streptococci from maternal or nosocomial sources.<sup>228</sup> This technique proved useful in determining the source of infection in the nursery environment.<sup>219</sup> Although plasmids have been described in a few group B streptococci,<sup>229</sup> their usefulness as epidemiologic markers is limited.

More recently, multilocus enzyme electrophoresis,<sup>230-232</sup> restriction enzyme fragment length polymorphism (RFLP) analysis, pulsed-field gel electrophoresis (PFGE),<sup>233</sup> and a random-amplified polymorphic DNA (RAPD) assay<sup>234</sup> have been employed for molecular characterization of group B streptococcal isolates associated with human disease. RFLP analysis has indicated that some geographically and epidemiologically distinct isolates have identical patterns, suggesting dissemination of a limited number of clones in the United States.<sup>235</sup> These techniques have shown the molecular relatedness of mother-infant and twin-twin strains<sup>226,234</sup> and have documented mother-to-infant transmission associated with ingestion of infected mother's milk.<sup>235</sup> Compared with conventional electrophoresis, PFGE generates more easily defined patterns with fewer and better-separated bands.<sup>233</sup> Although additional study will be required to define their role for subspecies strain differentiation, it is clear that PFGE and RAPD assay have distinct advantages over some of the previously employed typing schemes.

Molecular characterization has been employed to explore the role of virulence clones in contributing to invasive disease.<sup>9</sup> Type III group B streptococci have been classified into three major phylogenetic lineages on the basis of bacterial DNA restriction digest patterns (RDPs).<sup>236</sup> Most cases of type III neonatal invasive disease appear to be caused by strains with the RDP type III-3. The genetic variation that distinguishes RDP type III-3 strains appears to occur within localized areas of the genome that contain known or putative virulence genes.<sup>237-239</sup> Using genomic subtractive hybridization to identify regions of the genome unique to virulent RDP type III-3 strains, a surface protein was identified that mediates epithelial cell invasion.<sup>240</sup> Using multilocus sequence typing (MLST), 10 allelic profiles were identified among type III isolates recovered from neonates with invasive disease and from colonized pregnant women.<sup>241</sup> The allelic profiles converged into three groups on concatenation. There was an equal distribution of these groups among colonizing and

invasive isolates. The finding that isolates with different capsular serotypes have the same sequence type suggests that capsular switching may occur.<sup>241,242</sup> One PFGE group bearing a gene from the capsular synthesis operon has been demonstrated in type III strains causing neonatal meningitis but not in type III colonizing strains.<sup>243</sup> Additional studies will be required to elucidate the difference in virulence between the clones identified by these techniques.<sup>244</sup>

### Incidence of Infection in Neonates and Parturients

Two clinical syndromes occur among young infants with group B streptococcal disease that are epidemiologically distinct and relate to age at onset.<sup>2,245</sup> Historically, the attack rates for the first of these syndromes, designated *early-onset* because it appears within the first 6 days of life (mean onset, 12 to 18 hours), have ranged from 0.7 to 3.7 per 1000 live births (Table 13-4). The attack rates for *late-onset* infection (at 7 to 89 days of age) have ranged from 0.5 to 1.8 per 1000. A multistate active surveillance program that identified cases of invasive disease in a population of 10.1 million persons in 1990 reported an incidence of 1.4 and 0.3 per 1000 live births for early- and late-onset disease, respectively.<sup>250</sup> The incidence of disease was significantly higher among African Americans than among whites. The crude incidence was higher among Hispanic whites than among the non-Hispanic white population. The multistate surveillance findings are in accord with a cohort study conducted in Atlanta indicating a higher risk for early- or late-onset disease among African American infants than among those of other ethnic origins.<sup>10</sup> There was a statistically significant decline in the incidence of early-onset disease in some surveillance areas from 1993 to 1995.<sup>253</sup> The rates for late-onset and adult disease remained stable. This decline occurred in association with the implementation of measures to prevent early-onset infection through intrapartum chemoprophylaxis. Current data indicate that the incidence of early-onset disease decreased by 65% from 1993 to 1998, from 1.7 to 0.6 per 1000 live births. It is estimated that 3900 early-onset infections and 200 neonatal deaths were prevented in 1998 by the use of intrapartum antibiotics.<sup>22</sup>

The male-to-female ratio for early- and late-onset group B streptococcal infection is approximately 1:1. Before 1996, 20% to 25% of all infants with group B streptococcal disease had onset after the first 6 days of life. Although attack rates for early-onset group B streptococcal disease are stratified by birth weight, the highest rates occur in lower-birth-weight categories.<sup>247,256</sup> Nevertheless, full-term infants still account for a majority of the early-onset cases.

The importance of the group B streptococcus as a common pathogen for the perinatal period relates to the pregnant woman as well as her infant. Multistate surveillance data indicate that 5% to 10% of cases of invasive group B streptococcal disease occur in pregnant women.<sup>22,250</sup> Bacteremia is the most common manifestation, accounting for approximately two thirds of cases. Bacteremic chorioamnionitis and endometritis each account for approximately 10% of cases, and infection can manifest earlier in gestation as septic abortion.<sup>22</sup> Colonization with group B streptococci has been reported to increase the occurrence of post-caesarean section morbidity manifested as fever, endometritis, and

bacteremia,<sup>257</sup> as well as the overall frequency of pelvic infection in the puerperium.<sup>258</sup> Postpartum endometritis occurs with a frequency of 2.0% and clinically diagnosed intra-amniotic infection occurs in 2.9% of women vaginally colonized with group B streptococci at the time of delivery. The risk of intra-amniotic infection is greater in women with heavy colonization.<sup>259</sup> Implementation of intrapartum chemoprophylaxis has been associated with a significant decline in the incidence of invasive disease in pregnant women, from 0.29 per 1000 live births in 1993 to 0.23 per 1000 live births in 1998.<sup>22</sup>

## IMMUNOLOGY AND PATHOGENESIS

### Host-Bacterial Interactions Related to Pathogenesis

The prevalence and severity of group B streptococcal disease in neonates have stimulated intensive investigation to elucidate the pathogenesis of infection. The unique epidemiologic and clinical features of group B streptococcal disease pose several basic questions that provide a framework for hypothesis development and experimental testing: How does the organism colonize pregnant women and gain access to the infant prior to or during delivery? Why are newborn infants, especially those born prematurely, uniquely susceptible to infection? What allows group B streptococci to evade host immune defenses? How do these organisms gain entry to the bloodstream and cross the blood-brain barrier to produce meningitis? Do specific factors that injure host tissues induce the sepsis syndrome?

Advances in knowledge of pathogenesis have been achieved through development of *in vitro* systems and animal models. Refinement of molecular genetic techniques has yielded isogenic mutant strains varying solely in the production of a particular component (e.g., capsular polysaccharide). Such mutants are important in establishing the biological relevance of a given trait and its requirement for virulence *in vivo*. The recent sequencing of two complete group B streptococcus genomes has provided additional context for interpretation of experimental data and comparison to other well-studied pathogens.<sup>17,18</sup>

Although the group B streptococcus has adapted well to asymptomatic colonization of healthy adults, it remains a potentially devastating pathogen to susceptible infants. This section reviews the current understanding of virulence mechanisms, many of which are revealed or magnified by the unique circumstances of the birth process and the deficiencies of neonatal immune defense. The group B streptococcal virulence factors defined to date, with mode of action and proposed role in pathogenesis, are shown in Table 13-5. Key stages in the molecular, cellular, and immunologic pathogenesis of newborn infection are summarized schematically in Figure 13-5.

### Maternal Colonization

The presence of group B streptococci in the genital tract of the mother at delivery determines whether or not a newborn infant is at risk for invasive disease. Among infants born to colonized women, the risk of early-onset disease is approximately 30-fold that for infants born to women with a negative result on prenatal cultures.<sup>260</sup> A direct relationship exists between the degree (inoculum size) of group B streptococcal vaginal colonization, the risk of vertical trans-

Table 13–5 Group B Streptococcal Virulence Factors in Pathogenesis of Neonatal Infection

Virulence Factor	Molecular or Cellular Action(s)	Proposed Role in Pathogenesis
<b>Host Cell Attachment/Invasion</b>		
C surface protein	Binds cervical epithelial cells	Epithelial cell adherence, invasion
Fibrinogen receptor, FbsA	Binds fibrinogen in extracellular matrix	Epithelial cell attachment
Lipoteichoic acid	Binds host cell surfaces	Epithelial cell attachment
C5a peptidase, ScpB	Binds fibronectin in extracellular matrix	Epithelial cell adherence, invasion
Surface protein Lmb	Binds laminin in extracellular matrix	Epithelial cell attachment
Spb1 surface protein	Promotes epithelial cell uptake	Invasion of epithelial barriers
<i>iagA</i> gene	?Alteration in bacterial cell surface	Promotes blood-brain barrier invasion
<b>Injury to Host Tissues</b>		
$\beta$ -Hemolysin/cytolysin	Lyses epithelial and endothelial cells	Damage and spread through tissues
Hyaluronate lyase	Cleaves hyaluronan or chondroitin sulfate	Promotes spread through host tissues
CAMP factor	Lyses host cells (co-hemolysin)	Direct tissue injury
<b>Resistance to Immune Clearance</b>		
Exopolysaccharide capsule	Impairs complement C3 deposition/activation	Blocks opsonophagocytic clearance
C5a peptidase, ScpB	Cleaves and inactivates human C5a	Inhibits neutrophil recruitment
CAMP factor	Binds to Fc portion of IgG, IgM	Impairment of antibody function
Serine protease, CspA	Cleaves fibrinogen, coats GBS surface with fibrin	Blocks opsonophagocytosis
Fibrinogen receptor, FbsA	?Steric interference with complement function	Blocks opsonophagocytosis
C protein	Nonimmune binding of IgA	Blocks opsonophagocytosis
$\beta$ -hemolysin/cytolysin	Lyses neutrophils/macrophages, proapoptotic	Impairment of phagocyte killing
Superoxide dismutase	Inactivates superoxide	Impairment of oxidative burst killing
Carotenoid pigment	Antioxidant effect blocks H <sub>2</sub> O <sub>2</sub> , singlet oxygen	Impairment of oxidative burst killing
<i>D/t</i> operon genes	Alanylation of lipoteichoic acid	Interferes with antimicrobial peptides
Penicillin-binding protein 1a	Alteration in cell wall composition	Interferes with antimicrobial peptides
<b>Activation of Inflammatory Mediators</b>		
Cell wall lipoteichoic acid	Binds host pattern recognition receptors (TLRs)	Cytokine activation
Cell wall peptidoglycan	Binds host pattern recognition receptors (TLRs)	Cytokine activation
$\beta$ -Hemolysin/cytolysin	Activation of host cell stress response pathways	Triggers iNOS, cytokine release

mission, and the likelihood of serious disease in the newborn.<sup>217,246</sup> Consequently, a critical step in the pathogenesis of invasive disease in the newborn caused by group B streptococci is colonization of pregnant women.

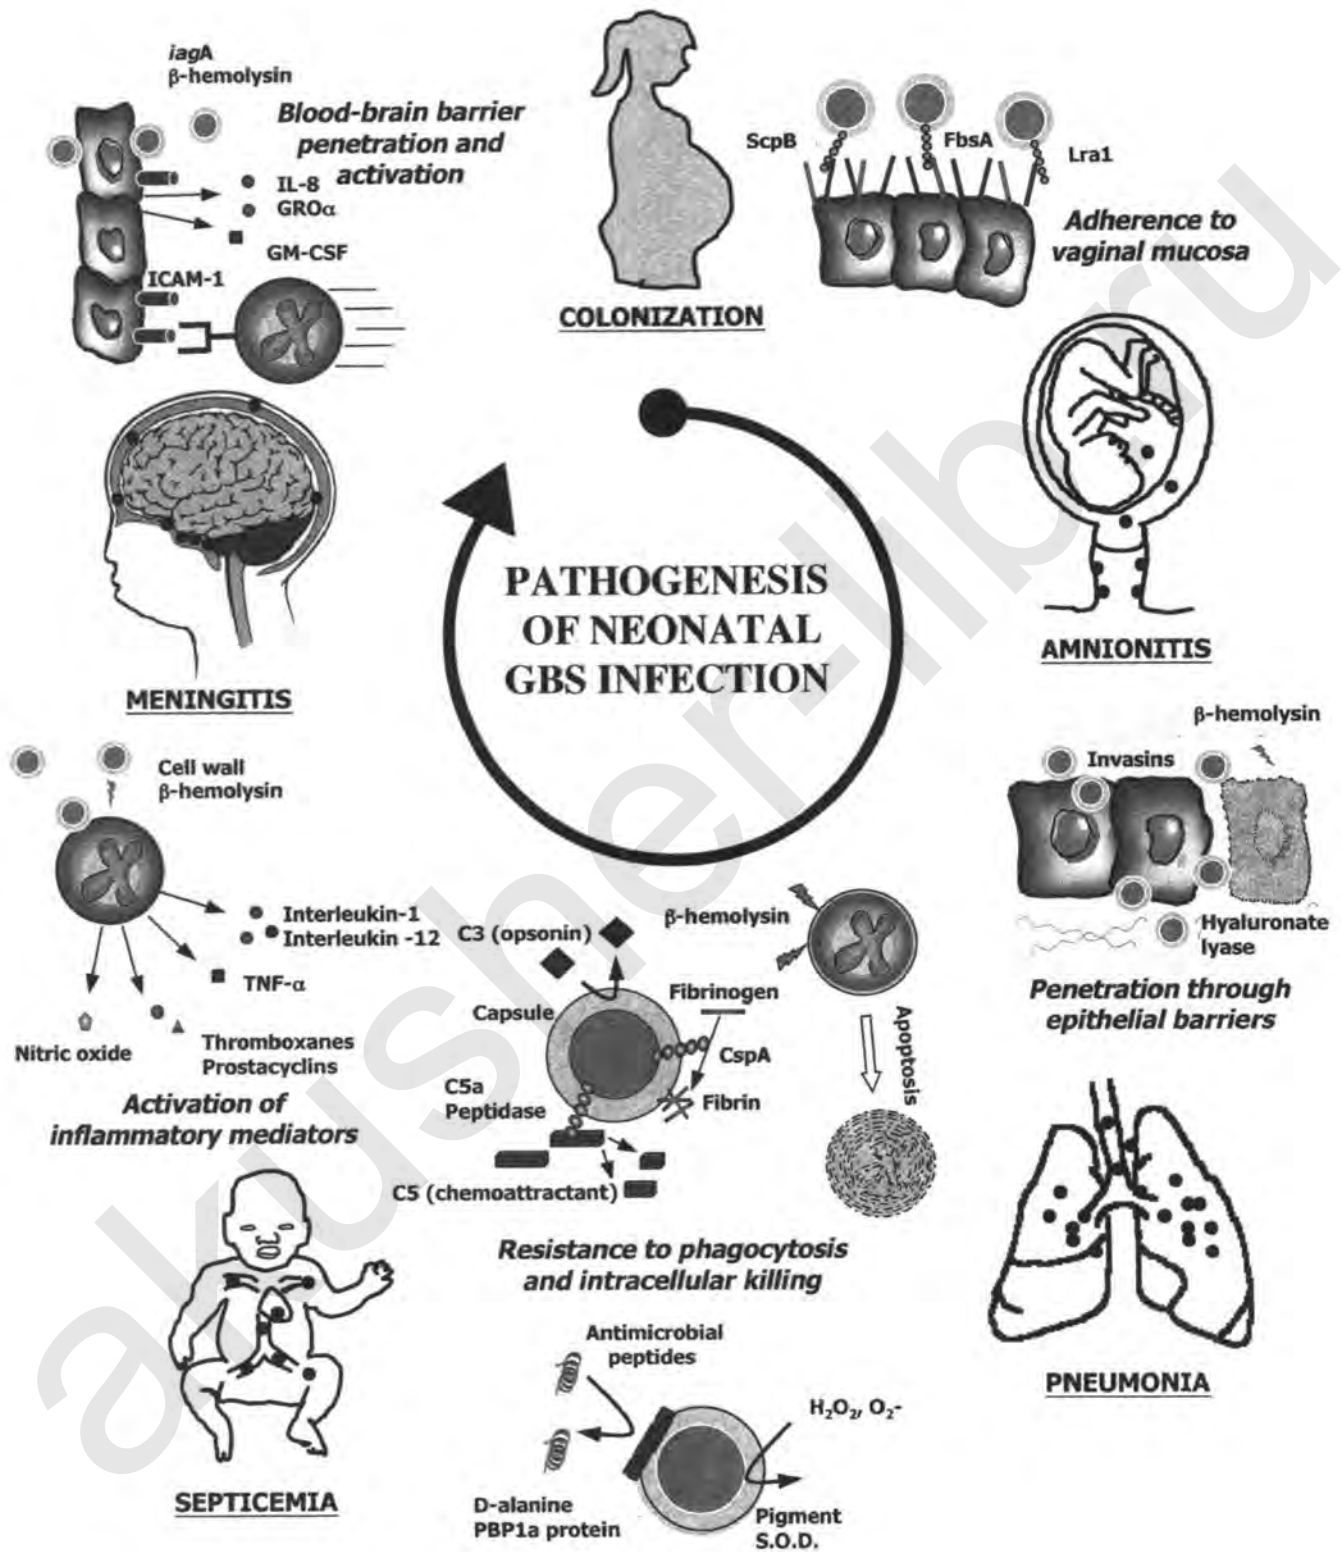

To establish colonization of the female genital tract, group B streptococci must adhere successfully to the vaginal epithelium. Compared with other microorganisms, group B streptococci bind very efficiently to exfoliated human vaginal cells or vaginal tissue culture cells,<sup>261,262</sup> with maximal adherence at the acidic pH characteristic of vaginal mucosa.<sup>263,264</sup> A low-affinity interaction with epithelial cells is mediated by its amphiphilic cell wall-associated LTA, whereas higher-affinity interactions with host cells are mediated by hydrophobic surface proteins. Soluble LTA competitively inhibits epithelial cell adherence<sup>265,266</sup> and decreases vaginal colonization of pregnant mice.<sup>267</sup> Epithelial cell binding is inhibited by pretreatment of the organism with a variety of proteases,<sup>264,268,269</sup> by preincubating the cells with hydrophobic group B streptococcal surface proteins, or by preincubating the organism with antibodies to these proteins.<sup>270</sup>

Recent investigations reveal that high-affinity protein-mediated interactions with epithelium generally proceed through an intermediary. Group B streptococci effectively

bind the extracellular matrix components fibronectin, fibrinogen, and laminin, which in turn interact with host cell-anchored proteins such as integrins. Binding occurs to immobilized fibronectin in the solid but not the liquid phase, suggesting that this interaction requires close proximity of multiple fibronectin molecules and group B streptococcal adhesins.<sup>271</sup> Recently, a genome-wide phage display technique revealed a fibronectin-binding property associated with the surface-anchored group B streptococcal C5a peptidase, ScpB.<sup>272</sup> The dual functionality of ScpB was confirmed by decreased fibronectin binding of isogenic ScpB mutants and the direct interaction of recombinant ScpB with solid-phase fibronectin.<sup>272,273</sup> Similar targeted mutagenesis studies demonstrate that adherence of group B streptococci to laminin involves a protein adhesin called Lmb,<sup>274</sup> whereas attachment to fibrinogen is mediated by repetitive motifs within the surface-anchored protein FbsA.<sup>275</sup>

### Ascending Amniotic Infection

Group B streptococci can reach the fetus in utero through ascending infection of the placental membranes and amniotic fluid. Alternatively, the newborn may become contaminated with the organism on passage through the birth canal. Infection by the ascending route plays a pivotal

**Figure 13-5** Pathomechanisms for different types of neonatal group B streptococcal infection. GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; SOD, superoxide dismutase; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ . (Adapted from Doran KS, Nizet V. Molecular pathogenesis of neonatal group B streptococcal infection: no longer in its infancy. *Mol Microbiol* 54:23-31, 2004.)

role in early-onset disease. A direct relationship exists between the duration of membrane rupture prior to delivery and attack rate for early-onset disease,<sup>276</sup> whereas an inverse relation exists between the duration of membrane rupture and the age at which clinical signs of early-onset pneumonia and sepsis first appear.<sup>277</sup> When the duration of membrane rupture was 18 hours or less, the attack rate was 0.7 per 1000 live births; when it was more than 30 hours, the attack rate increased to 18.3 per 1000.<sup>276</sup> Histologic examination of placentas from women with group B streptococcal chorioamnionitis shows bacterial infiltration along a choriodecidual course, implying that ascending infection may be a primary trigger in many instances of premature rupture.<sup>278</sup>

Group B streptococci may promote membrane rupture and premature delivery by several mechanisms. Isolated chorioamniotic membranes exposed to the organism have decreased tensile strength and elasticity and therefore are prone to rupture.<sup>279</sup> Peptide fragments released from these membranes indicate that proteases are produced that degrade placental tissue. The presence of group B streptococci at the cervix activates the maternal decidua cell peroxidase-hydrogen peroxide-halide system, promoting oxidative damage to adjacent fetal membranes.<sup>280</sup> Group B streptococci also can modify the arachidonic acid metabolism of cultured human amnion cells, favoring production of prostaglandin E<sub>2</sub>,<sup>281,282</sup> which is known to stimulate the onset of labor. Stimulation of chorionic cell release of macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ) and interleukin-8 (IL-8) from human chorion cells recruits inflammatory cells that may contribute to infection-associated preterm labor.<sup>283</sup>

It appears that on occasion, group B streptococci can penetrate into the amniotic cavity through intact membranes. Clinically, this mechanism of entry is suggested by anecdotal reports of neonates with fulminant early-onset infection following delivery by cesarean section and no identifiable obstetric risk factors.<sup>9,284,285</sup> Migration of the organism through freshly isolated chorioamniotic membranes has been documented by scanning and transmission electron microscopy.<sup>286</sup> Group B streptococci invade primary chorion cells efficiently *in vitro* and are capable of transcytosing through intact chorion cell monolayers without disruption of intracellular junctions.<sup>287</sup> They also secrete an enzyme that degrades hyaluronic acid, an important component of the extracellular matrix that is abundant in placental tissues.<sup>288</sup> Theoretically, the action of the group B streptococcal hyaluronate lyase on the extracellular matrix could facilitate amniotic invasion by the organism.<sup>289</sup>

Amniotic fluid supports the proliferation of group B streptococci,<sup>290</sup> although some strains replicate more efficiently than others.<sup>291</sup> When group B streptococci gain access to the uterine cavity and proliferate in the amniotic fluid, a large inoculum can be delivered to the fetal lung. This results in a continuum of intrapartum (stillbirth) to early postpartum infant death.<sup>246,291-295</sup> *In utero* infection probably accounts for the 40% to 60% of newborns with early-onset disease who have poor Apgar scores and in whom pulmonary signs develop within a few hours of birth.<sup>276,292</sup> Such infants almost invariably display clinical or histologic evidence of congenital pneumonia. Conversely, when group B streptococci are encountered in the immediate peripartum period or on passage through the birth canal, a lesser inoculum is delivered to the neonate. Although a small but meaningful risk of sub-

sequent invasive disease exists, the great majority of newborns who are contaminated with group B streptococci through swallowing of infected vaginal secretions will have asymptomatic colonization limited to mucosal surfaces and remain healthy.

### **Pulmonary and Bloodstream Entry**

Early-onset group B streptococcal disease is heralded by respiratory symptoms including tachypnea, hypoxia, cyanosis, and pulmonary hypertension.<sup>296</sup> One third to more than one half of infants are symptomatic at birth or within 4 to 6 hours after delivery. Autopsies in fatal early-onset cases reveal that 80% have histologic evidence of lobar or multilobar pneumonia,<sup>295,297</sup> characterized by dense bacterial infiltration, epithelial cell damage, alveolar hemorrhage, interstitial inflammatory exudate, and hyaline membrane formation.<sup>294,298</sup> When pneumonia develops in newborn primates exposed by intra-amniotic injection of group B streptococci, bacterial density reaches 10<sup>9</sup> to 10<sup>11</sup> organisms per gram of lung tissue.<sup>299</sup> Also, in experimental animals, an inverse relationship exists between age and ability to clear group B streptococci from the lung following aerosol challenge.<sup>300,301</sup> The poorer resolution of pneumonia in preterm than in term rabbits reflects quantitative deficiency of pulmonary alveolar macrophages, mandating the recruitment of neutrophils as a secondary phagocytic defense mechanism.<sup>302</sup>

Group B streptococcal disease rarely is limited to the initial pulmonary focus but spreads to the bloodstream and is circulated through other organs and tissues. The capacity of group B streptococci to cause disruption of the lung epithelial and endothelial barrier evidently involves the process of intracellular invasion, direct cytolytic injury, and damage induced by the inflammatory response of the newborn host. Intracellular invasion of both alveolar epithelial and pulmonary endothelial cells by group B streptococci was first noted in newborn macaques following intra-amniotic challenge<sup>299</sup> and later confirmed in human tissue culture lines derived from both cellular barriers.<sup>303,304</sup> Electron microscopy studies *in vivo* and *in vitro* demonstrate that host cytoskeletal changes are triggered that lead to endocytotic uptake of the bacterium within a membrane-bound vacuole. Uptake requires induction of protein kinase signal transduction pathways in the host cell that are mediated by calmodulin and phosphatidylinositol-3 (PI-3) kinase.<sup>305,306</sup>

Cellular invasion is correlated with virulence potential. Clinical isolates of group B streptococci from infants with bloodstream infections invade epithelial cells better than do strains from the vaginal mucosa of asymptomatic women.<sup>307</sup> Invasion is reduced by trypsin treatment or protein synthesis inhibition, suggesting the involvement of specific bacterial surface proteins in the process.<sup>303,307</sup> Genetic phenotyping of type III strains identified a particular restriction digest pattern (RDP III-3) characteristic of a majority of the isolates from invasive neonatal infection.<sup>308</sup> Subtractive hybridization studies identified a gene unique to these strains encoding the surface-anchored protein, Spb1, required for maximal epithelial cell invasion.<sup>240</sup> Similarly, elimination of the genes encoding the fibronectin-binding C5a peptidase, ScpB, or the antiphagocytic  $\alpha$  C surface protein each significantly reduced epithelial cell invasion by group B streptococci.<sup>273,309</sup> By contrast, the capsular polysaccharide decreases intracellular

invasion, presumably through steric interference of certain receptor-ligand interactions.<sup>310</sup>

Although cellular invasion may play a principal role in bloodstream penetration in late-onset group B streptococcal infection, damage to the lung barrier often is evident in severe early-onset infection. Alveolar exudate and hemorrhage in autopsy studies of infants with group B streptococcal pneumonia attest to significant pulmonary epithelial and endothelial cell injury.<sup>294,311</sup> The cellular damage appears to result largely from the actions of the  $\beta$ -hemolysin/cytolysin. This toxin is responsible for the characteristic  $\beta$ -hemolytic phenotype displayed by the organism when grown on sheep's blood agar. Mutagenesis and heterologous expression studies have identified a single open reading frame, *cylE*, as necessary for group B streptococcal  $\beta$ -hemolysin/cytolysin expression and sufficient to confer  $\beta$ -hemolysis when cloned in *E. coli*.<sup>312,313</sup> *CylE* is a predicted 79-kDa protein sharing no homology to the toxin, streptolysin S, that is responsible for  $\beta$ -hemolysis in group A, C, F, and G streptococci.<sup>314</sup> This pore-forming toxin lyses lung epithelial and endothelial cells and compromises their barrier function.<sup>315,316</sup> At subcytolytic doses, it promotes intracellular invasion and triggers the release of IL-8, the principal chemoattractant for human neutrophils.<sup>317</sup> Mutants lacking hemolysin expression are less virulent than the corresponding wild-type strains in mouse, rat, and rabbit models of group B streptococcal pneumonia.<sup>318-320</sup>

The cytolytic, pro-invasive, and pro-inflammatory effects of the group B streptococcal  $\beta$ -hemolysin/cytolysin all are neutralized by dipalmitoyl phosphatidylcholine (DPPC), the major phospholipid constituent of human lung surfactant.<sup>315,317</sup> This finding may explain in part the enhanced risk in premature, surfactant-deficient neonates for severe lung injury and invasive disease from group B streptococcal infection. Treatment with exogenous surfactant reduces histologic evidence of lung inflammation, improves lung compliance, and mitigates bacterial growth in preterm rabbits infected with group B streptococci.<sup>321,322</sup> Clinical studies exploring the effect of surfactant administration on human infants with group B streptococcal sepsis also suggest a beneficial effect.<sup>323,324</sup>

### Capsular Polysaccharide and Immune Resistance

On penetration of group B streptococci into the lung tissue or bloodstream of the newborn infant, an immunologic response is recruited to clear the organism. Central to this response are host phagocytic cells including neutrophils and macrophages. Effective uptake and killing by these cells require opsonization of the bacterium by specific antibodies in the presence of complement.<sup>325-327</sup> Neonates are particularly prone to invasive disease because of their quantitative or qualitative deficiencies in phagocytic cell function, specific antibody, or the classic and alternate complement pathways. In addition to these newborn host susceptibilities, group B streptococci possess a number of virulence determinants that seek to thwart each of the key components of effective opsonophagocytic killing. Chief among these factors is the sialylated group B streptococcal polysaccharide capsule.

The serotype-specific epitopes of group B streptococcal capsular polysaccharides are created by different arrangements of four monosaccharides (glucose, galactose, *N*-acetylglucosamine, and sialic acid) into a unique repeating unit (see "Immunochemistry of Polysaccharide Antigens" under "The

Organism" earlier), but unfailingly these structures contain a terminal sialic acid bound to galactose in an  $\alpha 2 \rightarrow 3$  linkage. The enzymatic machinery for capsule biosynthesis is encoded in the single long transcript of a 16-gene operon now fully sequenced in type Ia, type III, and type V strains. Recently, elegant experiments have shown that the heterologous expression of a single polymerase gene (*cpsH*) from this operon can cause a group B streptococcal type Ia strain to express type III capsule epitopes, and vice versa.<sup>328</sup>

The conserved group B streptococcal terminal  $\alpha 2 \rightarrow 3$  sialic acid capsular component is identical to a sugar epitope widely displayed on the surface of all mammalian cells.<sup>329</sup> Furthermore, the terminal  $\alpha 2 \rightarrow 3$ -linked sialic acid is over-expressed in humans, who in evolution have lost the genes to produce the alternative sialic acid, Neu5Gc. One can hypothesize that the group B *Streptococcus* is a particularly troublesome newborn pathogen because its sialylated capsule has undergone selection to resemble host "self" and avoid immune recognition. In fact, in comparison with wild-type strains, isogenic capsule-deficient mutants of group B streptococci elicit greater degrees of pro-inflammatory cytokine release from human cells.<sup>330</sup> These observations probably reflect a combination of decreased immune recognition as a result of capsule molecular mimicry of host epitopes, and increased access of host pattern recognition molecules (e.g., Toll-like receptors) to the cell wall components LTA and peptidoglycan hidden beneath the "cloak" of the polysaccharide capsule.

The properties of group B streptococcal capsular polysaccharide have been studied most thoroughly in serotype III organisms. Sialic acid is a critical element in the epitope of the type III capsule that confers protective immunity. After treatment with sialidase, the altered capsular polysaccharide fails to elicit protective antibodies against group B streptococcal infection. Moreover, protective antibodies derived from native type III capsule do not bind to the altered (asialo) capsule backbone structure.<sup>331</sup> Human infants who possess antibodies that react only to the desialylated capsule remain at high risk for invasive disease.

The correlation of capsular sialic acid and virulence was first noted in studies employing sialidase to remove the critical surface epitope. Sialidase-treated type III group B streptococci are opsonized more effectively by complement through the alternative pathway and are consequently more readily phagocytosed by human neutrophils in vitro.<sup>332</sup> Sialidase treatment also results in diminished lethality of the organism in neonatal rats.<sup>333</sup> Serial subculture of a wild-type strain in the presence of type III-specific antiserum allows identification of variants that do not express the terminal sialic acid component of the polysaccharide capsule. These strains possess a 1000-fold greater median lethal dose (LD<sub>50</sub>) following tail-vein injection in mice.<sup>334</sup>

More definitive evidence for the role of type III capsule in virulence is provided by the construction of isogenic capsule-deficient mutants by transposon mutagenesis or targeted allelic replacement.<sup>335-337</sup> In comparison with the parent strains, isogenic capsule mutants are susceptible to opsonophagocytosis in the presence of complement and healthy adult neutrophils.<sup>338</sup> Situated at the convergence of the classic and alternative pathways, deposition of C3 on the bacterial surface, with subsequent cleavage and degradation to opsonically active fragments C3b and iC3b, is a pivotal

element in host defense against invasive infections. C3 deposition and degradation occur on the surface of group B streptococci representing a variety of serotypes.<sup>339</sup> The extent of C3 deposition by the alternative pathway, however, is inversely related to the size and density of the polysaccharide capsule present on the surface of type Ib and type III strains.<sup>338,340</sup> C3 fragments bound to the acapsular mutant are predominantly in the active form, C3b, whereas the inactive form, C3bi, is predominantly bound to the surface of the parent strain. Less C3b is bound by the asialo capsule mutant than by the acapsular mutant, and less C3bi is bound by asialo capsule mutant than by the wild-type strain.<sup>338</sup> These studies prove that type III capsular polysaccharide—in particular, the sialic acid residues—inhibit the alternative complement pathway by blocking binding of C3 to the organism and promoting inactivation of C3b.

The type III group B streptococcal acapsular mutants also are significantly less virulent in animal models of infection. In a model of pneumonia and bacteremia, neonatal rats have been inoculated with either the parent strain or an acapsular mutant by intratracheal injection. In animals that receive the acapsular mutant, fewer group B streptococci are recovered per gram of lung, more bacteria are associated with resident alveolar macrophages, and the animals become significantly less bacteremic than animals that receive the parent strain.<sup>341</sup> Subcutaneous injection of the acapsular or asialo mutants in neonatal rats results in similar LD<sub>50</sub> values that are at least 100-fold greater than those obtained with the parent strain.<sup>336,342</sup> Mouse passage of various serotypes of group B streptococci is followed by increases in sialylated capsule content that correlate with increased virulence.<sup>343</sup> Taken together, these data provide compelling evidence that the capsule protects the organism from phagocytic clearance during both the initial pulmonary phase and the later bacteremic phase of early-onset infection.

### **Noncapsular Factors That Interfere with Immune Clearance**

The ability of group B streptococci to avoid opsonophagocytosis is enhanced by surface proteins that can act in concert with capsular polysaccharide. For example, serotype II strains displaying both components of the C protein antigen are more resistant to phagocytic killing than are serotype II strains lacking C protein.<sup>344,345</sup> A potential mechanism is that strains bearing the C protein antigen display increased non-immune binding to serum IgA and decreased C3 deposition on their surface.<sup>346</sup> The  $\beta$  antigen of C protein binds human IgA,<sup>347,348</sup> and IgA deposited nonspecifically on the bacterial surface probably inhibits interactions with complement or IgG.<sup>346</sup> A cell surface protease, CspA, targets host fibrinogen, producing adherent fibrin-like cleavage products that coat the bacterial surface and interfere with opsonophagocytic clearance.<sup>349</sup> Mutational studies also have attributed an antiphagocytic property to a group B streptococcal surface fibrinogen-binding protein.<sup>275</sup>

Following phagocytic uptake of pathogens, neutrophils and macrophages seek to kill the engulfed bacteria by generation of reactive oxygen products and other antimicrobial substances. Streptococci are often thought of as “extracellular pathogens,” but these organisms can survive for prolonged periods within the phagolysosome of macrophages.<sup>350,351</sup> Although group B streptococci lack the neutralizing enzyme

catalase, they are more than 10 times resistant to killing by hydrogen peroxide than is catalase-positive *S. aureus*.<sup>352</sup> Several mechanisms for enhanced intracellular survival have been identified. The organism possesses an endogenous source of the oxygen metabolite scavenger glutathione.<sup>352</sup> Another defense against oxidative burst killing is the enzyme superoxide dismutase (SodA), as evidenced by the fact that a SodA mutant is highly susceptible to macrophage killing and survives poorly in vivo.<sup>353</sup> Finally, group B streptococci produce an orange carotenoid pigment, a property unique among hemolytic streptococci and genetically linked to the *cyl* operon encoding the  $\beta$ -hemolysin/cytolysin. The free-radical scavenging properties of the carotenoid neutralize hydrogen peroxide, superoxide, hypochlorite, and singlet oxygen, thereby providing a shield against several elements of phagocyte oxidative burst killing.<sup>354</sup> The antioxidant effects of glutathione, SodA, and carotenoid pigment appear to compensate for the lack of catalase and explain the unexpected persistence of group B streptococci within host phagolysosomes.

Cationic antimicrobial peptides, such as defensins and cathelicidins produced by host phagocytes, also are an important component of immune defense.<sup>355,356</sup> The group B streptococcal *ponA* gene codes for an extracytoplasmic penicillin-binding protein (PBP1a) that promotes resistance to phagocytic killing independent of capsule.<sup>357</sup> Group B streptococcal mutants with deletion of the PBP1a gene are less virulent following both lung and systemic challenge, and this is correlated to an increased susceptibility to defensins and cathelicidins.<sup>358</sup> Another way in which the organism avoids antimicrobial peptide clearance is through the D-alanylation of LTA in the bacterial cell wall. This requires activity of gene products that are encoded by the *dlt* operon. A *dltA* mutant exhibits decreased negative surface charge that impedes cationic host defense peptides from reaching their cell membrane target of action.<sup>359</sup>

Direct cytotoxicity to host phagocytes represents another important virulence mechanism for immune resistance. The *cylE*-encoded  $\beta$ -hemolysin/cytolysin toxin produces direct cytolytic injury to macrophages and induces macrophage apoptosis over a longer interval. With highly hemolytic strains or with a large bacterial inoculum, killing of the phagocyte appears to outpace the phagocyte's microbicidal mechanisms, allowing bacterial proliferation in vitro in a murine bacteremia model.<sup>354</sup> Group B streptococci may trigger macrophage apoptosis by  $\beta$ -hemolysin/cytolysin-dependent<sup>360</sup> and  $\beta$ -hemolysin/cytolysin-independent mechanisms.<sup>361</sup> Addition of an inhibitor of  $\beta$ -hemolysin/cytolysin blocks cytolysis and reduces apoptosis of macrophages, thereby restoring phagocytic killing.<sup>354</sup>

Deficiencies in the neutrophil response to group B streptococci have been documented in newborn infants. Neutropenia and depletion of the marrow neutrophil storage pool are frequent findings in infants with septicemia<sup>362</sup> and are correlated with poor clinical outcome.<sup>296</sup> Whereas neutrophilia and an increase in granulocytic stem cells develop in adult rats infected with group B streptococci, severe neutropenia without a change in stem cell counts develops in neonatal rats.<sup>363</sup> Fatal infection in neonatal rats is associated with failure of recovery of depleted myeloid storage pools.<sup>364</sup> The explanation for this finding may be that the proliferative rate of neutrophils in noninfected neonatal

animals already is maximal or near maximal and cannot further increase in response to bacterial challenge.<sup>365</sup>

Group B streptococci actively contribute to poor mobilization of neutrophils by production of an enzyme that cleaves and inactivates human C5a, a complement component that stimulates neutrophil chemotaxis.<sup>366</sup> Expression of C5a peptidase reduces the acute neutrophil response to sites of infection in C5a knockout mice reconstituted with human C5a.<sup>367</sup> The enzymatic activity of soluble C5a peptidase is neutralized by serum from normal human adults, in large part because of naturally occurring IgG antibodies.<sup>366</sup> IgG also neutralizes C5a peptidase on the surface of a capsule-deficient group B streptococcal mutant but fails to neutralize the enzyme on the surface of the intact encapsulated type III parent strain. Thus, the capsule serves to protect the cell-associated C5a peptidase from inactivation by naturally occurring antibodies.

### **Inflammatory Mediators and Sepsis**

When failures in epithelial barrier function and immunologic clearance allow group B streptococci to establish bacteremia in the neonate, development of sepsis or septic shock is the consequence. Intravenous infusion of group B streptococci in animal models produces similar pathophysiologic changes to human newborn infection, including hypotension, persistent pulmonary hypertension, tissue hypoxemia and acidosis, temperature instability, disseminated intravascular coagulation, neutropenia, and ultimately, multiple organ system failure. These similarities have allowed in vivo experiments to elucidate the patterns in which the organism activates host inflammatory mediators to induce sepsis and circulatory shock.

Animal models in which group B streptococci are infused intravenously demonstrate a biphasic host inflammatory response.<sup>368-370</sup> The acute phase (up to 1 hour following infusion) is manifested by increased pulmonary artery pressure and decreased arterial oxygenation and is associated with a rise in serum levels of thromboxanes. Pulmonary hypertension and hypoxemia persist through the late phase (2 to 4 hours), in which a progressive pattern of systemic hypotension, decreased cardiac output, and metabolic acidosis develops together with hematologic abnormalities, organ system dysfunction, and increase in inflammatory markers, such as thromboxanes, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and prostacyclins. If thromboxane and prostacyclin production is blocked by inhibition of the cyclooxygenase pathway in rabbits or lambs infused with group B streptococci, decreased myocardial dysfunction and a significant rise in systemic blood pressure are observed.<sup>371-373</sup>

Infusion of group B streptococci produces pulmonary hypertension in piglets and isolated piglet lung preparations, suggesting a direct interaction of the organism with target cells in lung microvasculature.<sup>374,375</sup> Live but not heat-killed organisms induce release of the vasoactive eicosanoids, prostacyclin and prostaglandin E<sub>2</sub>, from cultured lung microvascular cells.<sup>376</sup> Experiments using specific antagonists have further implicated the host inflammatory mediators leukotriene D<sub>4</sub><sup>377</sup> and thromboxane A<sub>2</sub><sup>378</sup> as components of the pulmonary vascular response in pneumonia.

The cytokine interleukin-12 (IL-12) has an important role in the systemic response to group B streptococcal infection. IL-12 elevation occurs 12 to 72 hours after challenge in the neonatal rat. Pretreatment with a monoclonal antibody

against IL-12 results in greater mortality and intensity of bacteremia, whereas therapeutic administration of IL-12 is associated with a lower mortality rate and bloodstream replication of the organism.<sup>379</sup> By contrast, interleukin-1 (IL-1), a known stimulator of cyclooxygenase and lipooxygenase pathways, appears to occupy a proximal position in the deleterious cytokine cascade of septic shock.<sup>380</sup> Treatment with an IL-1 receptor antagonist improves cardiac output and mean arterial pressure and increases duration of survival in piglets receiving a continuous infusion of group B streptococci.<sup>381</sup>

Controversy exists regarding the precise role of TNF- $\alpha$  in neonatal septicemia. TNF- $\alpha$  often is detected in the blood, urine, or cerebrospinal fluid (CSF) of infants with invasive disease.<sup>382</sup> Although infusion of group B streptococci in piglets is associated with TNF- $\alpha$  release during the late phase of hemodynamic response, the TNF- $\alpha$  inhibitor pentoxifylline has only modest effects on pulmonary hypertension, hypoxemia, and systemic hypotension.<sup>383</sup> Marked improvement in these hemodynamic parameters is seen only when pentoxifylline treatment is combined with indomethacin inhibition of thromboxane and prostacyclin synthesis.<sup>384</sup> Serum TNF- $\alpha$  levels in the mouse and rat also rise after challenge; however, administration of polyclonal or monoclonal anti-TNF- $\alpha$  antibody does not affect overall mortality rate in these animal models.<sup>384,385</sup>

Studies have sought to establish the components of group B streptococci cell wall that trigger the host cytokine cascade. Host release of IL-1 and IL-6 is stimulated by soluble cell wall antigens.<sup>386</sup> Cell wall preparations also cause nuclear factor kappa-B (NF- $\kappa$ B) activation and TNF- $\alpha$  release from human monocytes in a manner requiring CD14 and complement receptor types 3 and 4.<sup>387</sup> The group B polysaccharide and peptidoglycan are more effective stimulators of TNF- $\alpha$  release from monocytes than is LTA or capsular polysaccharide.<sup>388</sup> Knockout mouse studies indicate that cell wall peptidoglycan-induced activation of p38 and NF- $\kappa$ B depends on the cytoplasmic toll-like receptor (TLR) adapter protein MyD88 but does not require the pattern recognition receptor TLR2 or TLR4.<sup>389</sup> An additional, undefined secreted factor appears to activate phagocytes through TLR2 and TLR6.<sup>390</sup>

Another pro-inflammatory molecule contributing to the pathogenesis of group B streptococcal septicemia is the  $\beta$ -hemolysin/cytolysin. The  $\beta$ -hemolysin/cytolysin acts to stimulate inducible nitric oxide synthase in macrophages, leading to release of nitric oxide, an important factor in the early sepsis cascade.<sup>391</sup> In a mouse model of bacteremia and arthritis,  $\beta$ -hemolysin/cytolysin expression is associated with higher mortality, increased bacterial loads, greater degrees of joint injury, and release of the pro-inflammatory cytokines IL-6 and IL-1 $\alpha$  systemically and intra-articularly.<sup>392</sup> Challenge of rabbits with isogenic group B streptococcal mutants showed that  $\beta$ -hemolysin/cytolysin production was associated with significantly higher degrees of hypotension, increased mortality, and evidence of liver necrosis with hepatocyte apoptosis.<sup>393</sup> Partially purified  $\beta$ -hemolysin/cytolysin preparations produce significant hypotensive actions when infused in rats and rabbits, including death due to shock.<sup>394</sup>

### **Blood-Brain Barrier Penetration and Meningitis**

The pathophysiology of group B streptococcal meningitis varies according to age at onset. In early-onset disease, autopsy

studies demonstrate little or no evidence of leptomenigeal inflammation, despite the presence of abundant bacteria, vascular thrombosis, and parenchymal hemorrhage.<sup>2,311</sup> By contrast, infants with late-onset disease usually have diffuse purulent arachnoiditis with prominent involvement of the base of the brain.<sup>395</sup> Similar age-related differences in central nervous system pathology are evident in the infant rat model of invasive disease.<sup>396</sup> These histopathologic differences reflect underdevelopment of the host immunologic response in the immediate neonatal period, with a higher proportion of deaths resulting from overwhelming septicemia.

To produce meningitis, group B streptococci must penetrate human brain microvascular endothelial cells, the single-cell layer constituting the blood-brain barrier. Intracellular invasion and transcytosis of human brain microvascular endothelial cell tissue culture monolayers have been shown *in vitro*.<sup>397</sup> Serotype III strains, which account for a majority of the isolates causing meningitis, invade more efficiently than strains of other common serotypes. Recently, a transposon mutant library of type III group B streptococci was screened in tissue culture assays for alterations in invasiveness. Hypoinvasive mutants were identified with disruptions in *iagA*, sharing homology to genes encoding diglucosyldiacylglycerol synthase. Allelic replacement of *iagA* confirms the *in vitro* phenotype, and the *iagA* knockout mutant does not produce meningitis in mice.<sup>397</sup> At high bacterial densities, invasion by group B streptococci of brain microvascular endothelial cells is accompanied by evidence of  $\beta$ -hemolysin/cytolysin-induced cellular injury.<sup>398</sup> Correspondingly,  $\beta$ -hemolysin/cytolysin knockout mutants show decreased blood-brain barrier penetration and decreased lethality from meningitis *in vivo*.<sup>330</sup>

The host inflammatory response to group B streptococci contributes significantly to the pathogenesis of meningitis and central nervous system injury. The initiation of the inflammatory response is triggered through the sentinel function of the blood-brain barrier endothelium, which activates a specific pattern of gene transcription for neutrophil recruitment, including production of chemokines (e.g., IL-8, Gro $\alpha$ ), endothelial receptors (intercellular adhesion molecule-1 [ICAM-1]), and neutrophil activators (granulocyte-macrophage colony-stimulating factor [GM-CSF]).<sup>330</sup> A vascular distribution of cortical lesions in neonatal rats with group B streptococcal meningitis indicates that disturbances of cerebral blood flow contribute to neuronal damage.<sup>399</sup> Inflammation of individual brain vessels can lead to focal lesions, whereas diffuse alterations of cerebral blood flow could cause generalized hypoxic/ischemic injury and cerebral edema.<sup>399,400</sup> Arteriolar dysfunction is associated with the presence of oxygen free radicals thought to be a byproduct of the phagocytic killing by infiltrating neutrophils.<sup>401</sup>

In the neonatal rat, simultaneous intracisternal administration of dexamethasone with group B streptococci leads to a marked reduction in subarachnoid inflammation, vasculopathy, and neuronal injury.<sup>399</sup> In the neonatal rat model of meningitis, TNF- $\alpha$  production by astrocytes, microglial cells, and infiltrating leukocytes appears to contribute to apoptosis of hippocampal neurons,<sup>402</sup> further increasing blood-brain barrier permeability.<sup>403</sup> Intraventricular inoculation of newborn piglets with group B streptococci results in an early sharp rise in CSF TNF- $\alpha$  levels, followed shortly by prostaglandin release and neutrophil influx.<sup>404</sup> The

Table 13-6 Risk Factors for Early-Onset Group B Streptococcal Disease

Risk Factor	Representative Reference Nos.
Maternal colonization at delivery	3, 148, 247
High-density maternal colonization	153, 217, 246
Rupture of membranes before onset of labor	246, 251
Preterm delivery	251
Prolonged rupture of membranes	251, 405
Chorioamnionitis	406
Intrapartum fever	251
Intrauterine monitoring	251, 405
Maternal postpartum bacteremia	7
Twin pregnancy	407, 408
Group B streptococcal bacteriuria or urinary tract infection	251
Cesarean section	245, 246
Low level of antibody to infecting serotype	409
Young maternal age (<20 years)	251, 405
Previous infant with group B streptococcal infection	407, 408
Maternal race/ethnicity	10, 162, 164, 251

magnitude of the observed TNF- $\alpha$  response and inflammatory cascade is markedly increased when an isogenic nonencapsulated mutant is tested in place of the type III parent strain,<sup>404</sup> suggesting that a component of the underlying cell wall and not capsule is responsible for inducing the central nervous system inflammatory response.

## Host Factors Relating to Pathogenesis

### Risk Factors for Early-Onset Infection

Infant and maternal factors that increase risk for early-onset group B streptococcal infection are summarized in Table 13-6. The most obvious risk determinant is exposure to the organism through maternal colonization at delivery. Maternal race or ethnicity is correlated significantly with early-onset group B streptococcal disease, with enhanced risk for infants born to African American and Hispanic mothers compared with that for infants born to white mothers.<sup>162,164,251</sup> Risk correlates directly with density of maternal genital inoculum.<sup>217</sup> Although symptomatic early-onset disease develops in only 1% to 2% of infants born to colonized women, this rate is considerably increased if there is premature onset of labor (before 37 weeks of gestation) (15%),<sup>247</sup> chorioamnionitis or interval between rupture of membranes and delivery longer than 18 hours (11%),<sup>246,247</sup> twin pregnancy (35%),<sup>407,408</sup> or maternal postpartum bacteremia (10%).<sup>7</sup>

Women who report a history of asymptomatic bacteriuria or urinary tract infection are more likely to deliver infants with group B streptococcal infection. Group B streptococcal bacteriuria is a predictor of high inoculum colonization, which is a known risk factor.<sup>410</sup> Heavy group B streptococcal colonization in the second trimester of pregnancy was associated in one study with increased risk of delivering a preterm, low-birth-weight infant.<sup>411</sup> Among infants born to mothers with premature rupture of membranes at term gestation, maternal chorioamnionitis and colonization with

group B streptococci are strong predictors of neonatal infection.<sup>412</sup> Vaginal colonization with group B streptococci also is an independent risk factor for the development of chorioamnionitis.<sup>413</sup>

Although prolonged interval after rupture of membranes (more than 18 hours) before delivery and preterm delivery (before 37 weeks of gestation) often are concomitant risk factors in neonates with early-onset group B streptococcal infection, the latter is an independent contributor to neonatal risk, probably from immaturity of host defense mechanisms. It is estimated that the incidence of early-onset group B streptococcal infection is 10 to 15 times higher in premature than in term neonates.<sup>246,276</sup> Even when incidence is corrected for preterm gestation (less than 37 weeks) and low birth weight (less than 2500 g), Pass and co-workers<sup>407</sup> reported that twin pregnancy was an independent risk factor for invasive early-onset group B streptococcal septicemia. The explanation for this increased risk in twins<sup>407,408</sup> is undefined but may be related to genetic factors regulating host susceptibility or to virulence of disease-producing strains.

### **Antibody to Capsular Polysaccharide**

Lancefield's studies demonstrated that antibodies directed against the type-specific surface antigens of group B streptococci protected mice from lethal challenge with strains containing these antigens.<sup>62</sup> Baker and Kasper<sup>409</sup> demonstrated in 1976 that neonates at risk for early- or late-onset group B streptococcal disease involving type III strains were those whose mothers had very low serum concentrations of antibodies to the type III capsular polysaccharide at delivery. A similar correlation was reported for neonates with type II and type III early-onset disease.<sup>414</sup> Absence of opsonic activity in response to the infecting strains was associated with a low concentration of these type-specific IgG antibodies in maternal serum or with failure to actively transport sufficient concentrations transplacentally before delivery of a premature infant.<sup>415-419</sup> Extremely premature infants have low total IgG concentrations in their sera, because approximately 60% of maternally derived IgG is transported to the fetus during the last 10 weeks of pregnancy.

Employing a radioactive antigen-binding assay, Baker and colleagues<sup>420</sup> detected low levels (less than 1.7  $\mu\text{g/mL}$ ) of type III capsular polysaccharide-specific antibodies in sera from each of 32 infants with invasive disease. Women with type III group B streptococcal genital colonization at delivery whose infants remained well had greater than 2.0  $\mu\text{g/mL}$  of type III-specific antibodies significantly more often than did women in whose infants type III early-onset disease developed. Quantitative determination of antibodies to type III group B streptococcal polysaccharide by enzyme-linked immunosorbent assay (ELISA) indicates that these antibodies are predominantly of the IgG isotype.<sup>421,422</sup>

Capsular type-specific antibodies also are important in the pathogenesis of early-onset infection related to serotypes Ia, Ib, and II.<sup>416,423</sup> Using ELISA standardized by quantitative precipitation,<sup>424</sup> 1.0, 0.2, and 1.3  $\mu\text{g/mL}$  of IgG to serotypes Ia, Ib, and II, respectively, were protective in experimental models of infection.<sup>418,425-427</sup> Among pregnant women at delivery, approximately 15% to 20% have capsular polysaccharide type-specific IgG in levels presumed to protect against invasive disease. These concentrations of IgG are

significantly more likely to be found in the sera of women colonized with the homologous group B streptococcal serotype.<sup>164,165,428</sup> A recent prospective, multicenter hospital-based, case-control study of mothers delivering infants with type Ia, III, or V early-onset sepsis and matched colonized control mothers delivering healthy infants has quantified the maternal serum concentrations of type Ia, III, and V capsular polysaccharide-specific IgG at delivery that protects neonates from early-onset disease. For types Ia and III, maternal IgG concentrations of 0.5  $\mu\text{g/mL}$  or higher corresponded to 90% risk reduction. For type V, the same antibody concentration corresponded to 70% risk reduction.<sup>429</sup> Gray and co-workers<sup>430</sup> noted a similar correlation between low concentrations of type II-specific antibodies in maternal delivery sera and susceptibility of infants to invasive infection. Human antibody to the group B polysaccharide is not protective against invasive infant disease.<sup>431</sup>

Antibodies to the capsular polysaccharides of group B streptococci correlate with *in vitro* opsonic activity (on chemiluminescence<sup>414,432</sup> and opsonophagocytic<sup>344,345,346,433</sup> assays) and with *in vivo* protection in experimental animal models of infection.<sup>434-436</sup> The factor or factors that explain the apparent relationship between asymptomatic mucosal infection and acquired specific humoral immunity in adults are unknown. A majority of adults and children have very low, presumably nonprotective levels of serotype-specific antibodies in their sera; nevertheless, the colonized pregnant woman who is likely to infect her neonate with group B streptococci at birth is also the one in whom passive protection of her infant is most likely. These antibodies appear to persist at a given concentration throughout gestation in the overwhelming majority of women.<sup>417</sup>

Although neonates with early-onset type III group B streptococcal sepsis are uniformly deficient in type III-specific IgG, most neonates born to women with type III genital colonization and low levels of type III IgG in their sera remain well.<sup>415-417</sup> Kim and co-workers<sup>437</sup> demonstrated opsonic and protective activity by cord sera that appeared to be independent of type-specific antibody or complement. Boyer and associates<sup>438</sup> reported that IgM-specific antibody, absent in serum from neonates, was detectable by 3 months of age and exceeded 0.5  $\mu\text{g/mL}$  in sera from all infants after 7 months. They proposed that the development of IgM-specific antibody in infancy may account for the marked decline in type III group B streptococcal infection after early infancy, but this finding has not been confirmed, and is unlikely in view of the short half-life of IgM.

Low concentrations of IgG to type III capsular polysaccharide are uniformly found in the acute sera of infants with late-onset type III infection.<sup>409,414-416</sup> In a study of 28 infants with late-onset bacteremia and 51 with meningitis, Baker and co-workers<sup>420</sup> detected low levels of antibodies to type III capsular polysaccharide in acute sera from all infants. These low levels in term infants with late-onset type III group B streptococcal infection correlated with maternal levels at delivery.<sup>415,420</sup>

It is important to employ antigens with "native" or intact type III polysaccharide specificity in evaluating human immunity to type III group B streptococci.<sup>439,440</sup> Kasper and colleagues<sup>331</sup> used gently extracted (native) and HCl-treated (core) type III group B streptococcal and pneumococcal type 14 antigens to study sera from infants with invasive type

III infection and their mothers. Concentrations of type III-specific antibodies in sera of sick infants and their mothers had uniformly low binding to fully sialylated, type III polysaccharide. Opsonic immunity correlated with antibodies to fully sialylated but not to desialylated type III polysaccharide or to type 14 pneumococcal antigen. Among infants recovering from type III disease in whom a significant increase in antibodies to the fully sialylated polysaccharide developed, no detectable rise in the acid-degraded or core antigen was seen. Thus, human immunity to type III group B streptococci relates to antibodies to capsular type III polysaccharide with an intact protective epitope.

An extension of this concept comes from studies in which adults have been immunized with either type III polysaccharide or pneumococcal polysaccharide vaccine.<sup>439,440</sup> Adults with low concentrations of type III antibodies in their sera before immunization responded to type III polysaccharide vaccine with a significant increase in type III-specific antibodies. This response was not observed when the structurally related type 14 pneumococcal polysaccharide was used as an immunizing agent. Among adults with moderate to high levels of antibodies to type III polysaccharide, however, significant rises in level of this antibody developed after pneumococcal polysaccharide vaccine. This finding suggests that the structurally similar antigen could elicit secondary B cell proliferation in previously primed adults.

### **Mucosal Immune Response**

Genital colonization with group B streptococci may elicit specific antibody responses in cervical secretions. Women with group B streptococcal type Ia, II, or III rectal or cervical colonization have markedly elevated levels of both IgA and IgG to the colonizing serotype in their cervical secretions when compared with those in cervical secretions from noncolonized women. Elevated amounts of IgA and IgG to the protein antigen, R4, also have been found in women colonized with type III strains (most type III strains contain R4 antigen) compared with those in noncolonized women.<sup>441,442</sup> These findings suggest that a mucosal immune response occurs in response to colonization with group B streptococci. Induction of mucosal antibodies to surface group B streptococcal polysaccharide or protein antigens may prevent genital colonization, thereby diminishing vertical transmission of infection from mothers to infants.

### **Serum Opsonins**

The interactions between antibodies to group B streptococcal capsular polysaccharides and serum complement components have been explored in detail. Shigeoka and co-workers<sup>325</sup> demonstrated that type-specific antibody was required for opsonization of type Ia, type II, and type III group B streptococci by adult and neonatal sera and that classic complement pathway participation was necessary for maximal opsonization of type I, type II, and several type III strains.<sup>443</sup> Capsular type-specific antibodies also facilitate alternative complement pathway-mediated opsonization and phagocytosis of type III group B streptococci.<sup>332</sup> A linear relationship between concentration of type III polysaccharide-specific antibodies and the rate constant of killing of type III strains has been reported.<sup>444</sup> Furthermore, the efficacy of these specific antibodies is determined, at least in part, by the number of antibody molecules that bind to each bacterium.<sup>445</sup>

Opsonic activity against type III group B streptococci has been shown *in vitro* for IgG subclasses 1, 2, and 3, as well as for IgM antibodies.<sup>446-449</sup> An IgA monoclonal antibody to the type III capsular polysaccharide activated C3 and conferred protection against lethal infection.<sup>450</sup> Type III-specific antibodies also facilitate C3 fragment deposition in the early phases of opsonization, although both encapsulated and genetically derived acapsular mutants can deposit C3 and support its degradation.<sup>451</sup> An inverse correlation between extent of encapsulation and C3 deposition by the alternative pathway has been verified.<sup>452</sup>

In contrast with these findings for type III strains, clinical isolates of type Ia group B streptococci can be efficiently opsonized, phagocytosed, and killed by neutrophils from healthy adults by the classic complement pathway in the absence of antibodies.<sup>453</sup> Surface-bound capsular polysaccharide of type Ia strains mediates C1 binding and activation.<sup>454,455</sup> Thus, an intact classic complement pathway is necessary for opsonization of clinical isolates of type Ia group B streptococci. For type Ib group B streptococci, a role for capsule size and density in modulating C3 deposition has been reported using a whole-bacterial-cell ELISA.<sup>340</sup> Variability among these strains in their capacity for C3 deposition by the alternative pathway also has been shown.<sup>456</sup>

The strain-to-strain variability in opsonization of type II strains of group B streptococci, originally identified by Shigeoka and associates,<sup>325</sup> has been confirmed. Type II strains possessing  $\alpha$  and  $\beta$  components of the C protein antigen are more resistant to opsonization than are strains lacking both components.<sup>344</sup> Strains lacking type II polysaccharide but having both components of protein antigen C are readily opsonized. However, neither the presence of the C antigen components nor the concentration of type II polysaccharide-specific antibodies in a serum fully explains all strain variation. Contribution by other opsonically active antigens (e.g., R proteins) or an IgA-mediated blocking effect may modulate phagocytosis of some type II strains. The IgA receptor for group B streptococci is antigenically unrelated to that of group A streptococci, but it binds to the same region in IgA.<sup>457,458</sup> Despite the complexity of type II opsonins, it is clear that complement is essential for effective opsonophagocytosis and that integrity of the classic complement pathway is critical.

Evaluation of neutrophil-mediated killing of type IV and type V group B streptococci also reveals that complement and capsular polysaccharide-specific antibodies are participants in opsonophagocytosis.<sup>459,460</sup> When complement is limited, type-specific antibodies have an important role in facilitating killing. In sufficient concentration, however, the complement in agammaglobulinemic serum promotes opsonization, phagocytosis, and killing of type IV and type V group B streptococci.

Quantitative deficiencies of complement components from both the classic and the alternative complement pathways have been defined in sera from normal newborns, when compared with those of their mothers or with levels in healthy adults. Maturation occurs in an age-related fashion by 6 months of age.<sup>461</sup> Efficient function of the alternative pathway has been demonstrated in neonatal sera for a variety of bacteria, including group B streptococci.<sup>462</sup> Deficient classic pathway activity in newborn sera correlated significantly with low C4 and C1q levels; this could be corrected by

addition of fresh-frozen plasma.<sup>463</sup> The results of the study by Baker and co-workers,<sup>464</sup> in which pregnant women were immunized with purified type III group B streptococcal polysaccharide, suggest that deficient function of the alternative pathway may be overcome in neonatal as in adult sera if the concentration of type III-specific antibodies is sufficient. Among infants surviving type III group B streptococcal meningitis, transient development of type-specific antibodies, predominantly of the IgM isotype, has been noted, and efficient opsonophagocytosis occurs during convalescence.<sup>465</sup> Once specific IgM concentrations decline, however, and despite maturation of complement synthesis to adult capacity, opsonophagocytosis of type III organisms is poor to nil.

During the course of septic shock caused by group B streptococci, complement components are consumed. Cairo and co-workers<sup>466</sup> found a significant association between low levels of total hemolytic complement and fatal outcome from neonatal sepsis related to a variety of bacterial pathogens, including group B streptococci. Recently, a critical role for C3 activation through the alternative pathway has been shown for potent group B streptococcus-induced TNF- $\alpha$  release.<sup>467</sup> This finding and the observation that complement-dependent uptake of capsular polysaccharide by marginal zone B cells appears necessary for an effective immune response to the capsular polysaccharide<sup>468</sup> may in part explain this observation. The  $\beta$  component of C protein also may bind human factor F, a negative regulator of complement activation, thereby evading complement attack.<sup>469</sup>

### Phagocyte Function

The role of neutrophil function in host defense against group B streptococci has been explored extensively.<sup>326</sup> Group B streptococcal antigens incubated in the absence of serum may enhance neutrophil adherence to endothelial cells and may impair the influx of neutrophils to sites of infection, such as the alveoli.<sup>470</sup> This enhanced adherence to endothelium could contribute to the pulmonary edema and hypertension observed in early-onset group B streptococcal infection.<sup>471</sup> With granulocyte depletion, there is significant attenuation of the pulmonary hypertension and hypoxemia characterizing the early phase of experimental infection. Chemiluminescence responses elicited by a type III group B streptococcal strain were significantly depressed for neutrophils from infants with group B streptococcal infection compared with values for neutrophils from healthy infants or adults.<sup>472</sup> "Stressed" infants with infections caused by organisms other than group B streptococci or those with noninfectious illnesses similarly had depressed chemiluminescence responses.

Smith and associates<sup>473</sup> examined the role of complement receptors CR1 and CR3 in the opsonic recognition of type Ia and type III group B streptococci by neutrophils from healthy neonates and adults. Selective blockade of CR3 or of both CR1 and CR3 inhibited killing for each serotype by neutrophils from neonates. These experiments indicated the importance of CR function to opsonization, phagocytosis, and killing of group B streptococci by neutrophils. Whether deficient CR function contributes to susceptibility of neonates to invasive infection is not known. Of interest, a role for CR3 also has been shown in nonopsonic recognition of group B streptococci by macrophages.<sup>474</sup>

Yang and co-workers<sup>475</sup> carried out selective blockade of neutrophil receptors in experiments with type III group B streptococci opsonized with immune globulin. Antibodies to neutrophil Fc receptor III (FcR III) inhibited phagocytosis of opsonized bacteria to an extent exceeding that of CR3. Noya and colleagues<sup>476</sup> demonstrated a substantial role for neutrophil FcR II in mediating ingestion of type III group B streptococci opsonized in complement-inactivated serum. When CR function was allowed, FcR II participation no longer was requisite for occurrence of phagocytosis. Participation by FcR and CR in phagocytosis of group B streptococci by peritoneal macrophages also has been reported.<sup>477</sup>

Christensen and co-workers<sup>363,365</sup> and others<sup>362</sup> have addressed the explanations for the profound neutropenia often observed in fulminant group B streptococcal infection in neonates. The nearly maximal proliferative rate of granulocytic stem cells in noninfected neonatal animals led to the suggestion that neutrophil transfusion might improve the survival of human neonates with group B streptococcal infection in whom neutrophil storage pool depletion was documented.<sup>362,466</sup> In experimental infection with type III group B streptococci, monoclonal IgM antibody to type III polysaccharide stimulated the release of neutrophils from storage pools into the bloodstream and improved neutrophil migration to the site of infection.<sup>478</sup> This facilitation of neutrophil function by type III-specific antibody improved survival in animals only if the antibody was administered when neutrophil reserves were intact (very early in infection).<sup>479</sup> Antibody recipients did not become neutropenic and did not experience depletion of their neutrophil reserves. These and similar *in vitro* and *in vivo* studies using commercial preparations of immune globulin for intravenous administration<sup>480-482</sup> emphasize the importance of IgG in facilitating the neutrophil inflammatory response.

Reticuloendothelial clearance of opsonized group B streptococci also is less efficient in experimental infection of young animals,<sup>483,484</sup> as are lung macrophage postphagocytic oxidative metabolic responses.<sup>301</sup> An age-related impairment in clearance of group B streptococci from the lungs has been reported for infant compared with adult rats and for preterm compared with term animals.<sup>300,485</sup> Animal age is a more important determinant of bacterial elimination from the lung than is amount of polysaccharide capsule, although encapsulated strains are ingested less efficiently and in fewer numbers in infant rats than in adult rats.<sup>486</sup>

### Other Factors Relating to Pathogenesis

Fibronectin is a high-molecular-weight glycoprotein that participates in adherence and functions as a nonspecific opsonin. The observation that septic neonates have significantly lower fibronectin levels than those of healthy age-matched controls stimulated evaluation of its possible role in the pathogenesis of group B streptococcal infection.<sup>487</sup> Soluble fibronectin binds poorly to group B streptococci in the absence of other opsonins.<sup>488</sup> Group B streptococci do adhere to immobilized fibronectin, however. Fibronectin also enhances ingestion by neutrophils, monocytes, or macrophages of group B streptococci opsonized with type-specific antibody<sup>489-491</sup> and may promote TNF- $\alpha$  production by macrophages.<sup>492</sup> It also has been shown that interaction of type III capsular polysaccharide with the lectin site of CR3 effectively triggers phagocytosis of type III organisms by

nonimmune serum. Use of this mechanism provides a potential explanation for the infrequency with which invasive infection develops in susceptible persons exposed to group B streptococci.<sup>493</sup>

It has been hypothesized that some persons may have a genetically based predisposition to infection with group B streptococci. Grubb and co-workers<sup>494</sup> identified a surplus of people possessing G3m(5) and a deficit of those with G1m(1) among 34 Swedish mothers of infants with group B streptococcal disease. Thom and colleagues<sup>495</sup> found deficits of G1m(1) and Km(1) and an increased incidence of G2m(23) among mothers of infected infants. The distribution of allotypic markers may influence responses to protein and polysaccharide antigens. For example, G2m(23) is a marker of IgG<sub>2</sub>, the subclass most often associated with brisk immune responses to polysaccharide antigens. Thus, there could be genetically determined explanations for the deficiency of IgG subclasses,<sup>496</sup> high IgM concentration with divergent ratio of IgG to IgM,<sup>497,498</sup> and the chronic colonization state without immunologic response<sup>499</sup> described among Swedish mothers of infants with group B streptococcal disease. However, in a study of U.S. women who delivered infants with invasive type III group B streptococcal disease, postpartum immunization with type III group B streptococcal polysaccharide elicited immune responses similar to those in control women.<sup>464</sup>

## **PATHOLOGY**

The morphologic features characteristic of early-onset neonatal infection are dependent on the type and duration of exposure to group B streptococci before or during birth. Intrauterine death has been attributed to group B streptococcal infection,<sup>293,500,501</sup> and it may be a relatively common cause of mid-gestational fetal loss in women who have experienced either vaginal hemorrhage or septic abortion.<sup>501,502</sup> Increasing evidence indicates that fetal membrane infection with group B streptococci may result in spontaneous abortion or premature rupture of membranes or both, as suggested by Hood and associates in 1961.<sup>503-505</sup> Becroft and colleagues<sup>506</sup> noted histologic changes consistent with congenital pneumonia in live-born neonates whose autopsy lung cultures yielded group B streptococci. Six of 10 placentas available for examination showed amnionitis; in each of the six cases, the infant had had pneumonia and died within 36 hours of birth. The evidence was sufficient in four of six stillborn infants to suggest that death was a direct result of group B streptococcal amnionitis and intrauterine pneumonia. deSa and Trevenen<sup>502</sup> documented pneumonitis with pulmonary interstitial and intra-alveolar inflammatory exudates in each of 15 infants weighing less than 1000 g with intrauterine group B streptococcal infection. Six infants were stillborn, and nine died within 6 hours of birth. Placental examination revealed chorioamnionitis. In a nonhuman primate model of infection, intra-amniotic inoculation of group B streptococci elicited fulminant early-onset neonatal infection.<sup>299</sup> Transmission electron microscopy of lung tissue revealed group B streptococci within membrane-bound vacuoles of alveolar epithelial cells and interstitial fibroblasts. The presence of organisms within tissue macrophages of the liver, spleen, and brain documents rapid dissemination to other viscera.

The finding of a high frequency of associated amnionitis and early death is not always so striking. However, it is clear that amnionitis in association with early-onset group B streptococcal sepsis (1) is more frequently detected when death occurs shortly after birth, (2) is a common finding when membranes have been ruptured 24 hours or more before delivery,<sup>295,502,503</sup> and (3) can be clinically silent in some women. It is obvious that group B streptococci can enter the amniotic cavity through ruptured or intact membranes,<sup>507</sup> thus allowing fetal aspiration of infected fluid and subsequent pulmonary lesions or bacteremia, *without* eliciting a local inflammatory response or maternal signs of amniotic fluid infection.

Among neonates with fatal early-onset group B streptococcal infection, pulmonary lesions represent the predominant pathologic feature. The association between pulmonary inflammation and hyaline membrane formation was first noted by Franciosi and co-workers.<sup>2</sup> Subsequently, autopsy findings in early-onset disease indicated "atypical" pulmonary hyaline membranes in a majority of the cases,<sup>2,294,295</sup> a finding that corresponds with radiographic features consistent with hyaline membrane disease in about 50% of neonates with early-onset sepsis.<sup>9</sup> Morphologically, the distribution of these membranes may be typical of those found in hyaline membrane disease, but in neonates who survive more than 20 hours, it may be less uniform. Group B streptococci frequently are found within these membranes, which in some patients are composed almost entirely of streptococci, rendering them basophilic in hematoxylin and eosin preparations.<sup>298</sup> Katzenstein and colleagues<sup>298</sup> postulated that invasion of alveolar pneumocytes and capillary endothelial cells by group B streptococci resulted in exudation of plasma proteins into the alveoli, deposition of fibrin, and hyaline membrane formation. Immune complex-mediated injury to the lung was proposed by Pinnas and associates<sup>508</sup> as a mechanism for the hyaline membrane formation in early-onset group B streptococcal pneumonia. These investigators demonstrated C3, IgG, and fibrin deposition in the lungs of infants with fatal early-onset group B streptococcal sepsis.

Histologic evidence for pneumonia is found in approximately 80% of patients with fatal early-onset group B streptococcal pneumonia diagnosed by chest radiography.<sup>294,508,509</sup> The radiographic pattern can be focal or extensive or lobular or bronchial, involving one or more lobes. The typical histologic features of congenital pneumonia (i.e., alveolar exudates composed of neutrophils, erythrocytes, and aspirated squamous cells, with edema and congestion) can be observed either independently or in association with hyaline membrane formation. In neonates with fulminant, rapidly fatal infection, the cellular inflammatory response is less pronounced. A consistent feature is an interstitial inflammatory exudate. Also noted is progressive atelectasis, which is prominent in infants surviving more than 20 hours. Group B streptococci have been detected in hyaline membranes, within the alveoli, or in the alveolar septa beneath the membranes in most neonates for whom the location has been specified. Pulmonary hemorrhage, ranging from focal interstitial to extensive intra-alveolar, has been a common finding at autopsy.

In central nervous system infection, age at onset predicts distinctive morphologic findings in the brain and meninges. In early-onset meningitis, little or no evidence of lepto-

Table 13-7 Features of Group B Streptococcal Disease in Neonates and Infants

Feature	Early-Onset (<7 days)	Late-Onset (≥7 days)	Late, Late-Onset
Median age at onset <sup>10</sup>	1 hour	27 days	>3 months
Incidence of prematurity	Increased	Not increased	Common
Maternal obstetric complications	Frequent (70%)	Uncommon	Varies
Common manifestations <sup>9, 10, 245, 516</sup>	Septicemia (25-40%)	Meningitis (30-40%)	Bacteremia without a focus (common)
	Meningitis (5-10%)	Bacteremia without focus (40-50%)	Bacteremia with a focus (occasional)
Serotypes isolated <sup>52, 222, 245</sup>	Pneumonia (35-55%) Ia, Ib, Ia/c (30%) II (30%) III (40% nonmeningeal; 80% meningeal isolates)	Osteoarthritis (5-10%) III (~75-80%)	Several
Mortality rate <sup>9, 10, 516, 517</sup>	5-10%	2-6%	Low

meningeal inflammation is seen in up to three quarters of reported cases,<sup>2,246,311</sup> although purulent meningitis may be observed occasionally. This lack of inflammatory response may be the result of rapidly progressive infection, with an interval of only a few hours from onset of clinical illness until death, or may reflect deficient host response to infection, or both mechanisms may be involved. Bacteria generally are found in large numbers, and perivascular inflammation, thrombosis in small vessels, and parenchymal hemorrhage frequently are noted.<sup>311</sup> In some preterm infants surviving septic shock caused by early-onset group B streptococcal infection, periventricular leukomalacia, a condition characterized by infarction of the white matter surrounding the lateral ventricles, develops.<sup>510</sup> Those infants with fatal late-onset meningitis almost always have diffuse purulent leptomeningitis, especially at the base of the brain, with or without perivascular inflammation and hemorrhage.<sup>2,511</sup> In infants with severe meningitis who survive, multiple areas of necrosis and abscess formation may be found throughout the brain by neuroimaging or at later autopsy.

This age-related inflammatory response in infants with group B streptococcal infection has a parallel in the infant rat model of meningitis.<sup>396</sup> In infant rats 5 to 10 days of age, numerous bacteria distributed in a perivascular pattern are present, and in some animals, organisms extend transmurally into vessel lumina. These animals generally have no evidence of acute inflammation or edema in the leptomeninges. By contrast, 11- to 15-day-old animals have leptomeningitis and cerebritis characterized by a pronounced infiltration of neutrophils and macrophages around meningeal vessels and in perivascular spaces within the cerebral cortex. Because host response to infection becomes more efficient within a few weeks after birth, the absence of inflammation in the brain and meninges of infant rats as well as of human neonates with early-onset group B streptococcal infection may relate to chemotactic defects,<sup>326</sup> exhaustion of neutrophil stores,<sup>365,512</sup> immaturity of the reticuloendothelial system,<sup>483</sup> or other deficits in the host response to infection.

## CLINICAL MANIFESTATIONS AND OUTCOME

### Early-Onset Infection

When the incidence of neonatal infection caused by group B streptococci rose dramatically in the 1970s,<sup>513</sup> a bimodal

distribution of cases according to age at onset of signs became apparent. Thus, two syndromes related to age were described in 1973 by Franciosi and associates<sup>2</sup> (acute and delayed) and by Baker and colleagues<sup>245</sup> (early and late). Early-onset infection almost always manifests itself within 24 hours of birth (an estimated 90% of cases; median age, 8 hours), but it may appear during the second 24 hours of life (an estimated 5% of cases) or at any time during the subsequent 5 days.<sup>9,245,514</sup> Premature infants often experience onset at or within 6 hours of birth; when onset is after the first 24 hours infants usually are term gestation.<sup>292,407</sup> Late-onset infections occur at 7 to 90 days of age (median age, 27 days).<sup>9</sup> Although this classification of syndromes by age at onset has been useful to enhance our understanding of the pathogenesis of infection, there is a continuum in age at onset. A few patients with early-onset disease may present at 5 or 6 days of age, and very late-onset infection occasionally affects 3- to 7-month-old infants, especially those with gestational age of less than 28 weeks.<sup>9,245</sup> Onset beyond 6 months of age may herald the presentation of human immunodeficiency virus (HIV) infection or other immune system abnormalities.<sup>515</sup>

Early-onset group B streptococcal infection often affects neonates whose mothers have obstetric complications associated with risk for neonatal sepsis (onset of labor before 37 weeks of gestation, prolonged interval at any gestation between rupture of membranes and delivery, rupture of membranes 18 or more hours before delivery, intrapartum fever, chorioamnionitis, early postpartum febrile morbidity, and twin births) (Table 13-7). A nearly threefold risk of early-onset group B streptococcal disease has occurred when six or more vaginal examinations are performed before delivery.<sup>518</sup> The incidence of infection correlates inversely with the degree of prematurity, and a contemporary report reveals that the group B streptococcus is the most frequent pathogen associated with early-onset sepsis in neonates of very low birth weight (less than 1500 g).<sup>519</sup> Early-onset group B streptococcal infection often develops in term neonates with no defined maternal risk factors other than colonization. In such cases, diagnosis and treatment often are delayed until the appearance of definite signs of sepsis (fever, tachypnea, apnea, hypotension), but more subtle signs usually precede these clinical manifestations. One recent report found that one third of healthy term neonates with early-onset group B streptococcal infection were identified solely on the basis of

evaluation for maternal intrapartum temperature exceeding 100.4° F.<sup>520</sup>

The three most common manifestations of early-onset infection are septicemia (signs of sepsis in association with bacteremia *without* a defined focus of infection), pneumonia, and meningitis. Septicemia without a focus occurs in 25% to 40%, pneumonia in 35% to 55%, and meningitis in 5% to 10% of cases.<sup>9,10,245,517,519</sup> Bacteremia often is detected in neonates with the latter two presentations. Irrespective of site of involvement, respiratory signs (apnea, grunting respirations, tachypnea, or cyanosis) are the initial clinical findings in more than 80% of neonates. Hypotension is an initial finding in approximately 25%. Infants with fetal asphyxia related to group B streptococcal infection in utero may have shock and respiratory failure at delivery.<sup>511,516</sup> Other associated signs include lethargy, poor feeding, hypothermia or fever, abdominal distention, pallor, tachycardia, and jaundice. Five percent to 10% of neonates with early-onset infection have meningitis.<sup>9,10,162,516,517</sup> Neonates with meningitis often have a clinical presentation identical to those without meningeal involvement. In one study, respiratory distress was the most common initial sign, and among 27 infants with early-onset meningitis, seizures were never a presenting feature.<sup>521</sup> Examination of CSF is the only means to exclude meningitis, a finding that requires modification of supportive and specific chemotherapy (see “Treatment” later on). Seizures occur during the first 24 hours of therapy in nearly 50% of infants with meningitis. Persistent seizures, semicoma, or coma is associated with a poor prognosis.<sup>245,522,523</sup>

Pulmonary involvement occurs in 35% to 55% of patients with early-onset infection, and virtually all of these infants have acute respiratory signs (grunting, tachypnea, apnea). Of 175 neonates with pulmonary involvement, 84% had respiratory signs in the first few hours of life (many at birth), and in an additional 11%, these signs developed within the first 24 hours of life.<sup>292,294,295,298,524</sup> Among 19 infants with congenital pneumonia at autopsy, 89% had 1-minute Apgar scores of 4 or less, indicating in utero onset of infection.<sup>292</sup> Radiographically, features consistent with and indistinguishable from those of hyaline membrane disease are present in more than one half of neonates with group B streptococcal bacteremia and pulmonary infection (Fig. 13-6). Treatment with surfactant improves gas exchange in a majority of these infants, although the response is slower than in noninfected infants, and repeated surfactant doses often are needed.<sup>525</sup> Infiltrates suggesting congenital pneumonia (Fig. 13-7) are present in one third. Increased vascular markings suggesting the diagnosis of transient tachypnea of the newborn or pulmonary edema can occur. Occasionally, respiratory distress is present in the absence of radiographic abnormalities, appearing as persistent fetal circulation.<sup>509,526</sup> Small pleural effusions and cardiomegaly also have been described.<sup>509,527</sup>

The case-fatality rate for the nearly 300 neonates with early-onset infection summarized by Anthony and Okada<sup>513</sup> in 1977 was 55%. More recent reports<sup>9,516,517</sup> suggest lower rates, ranging from 2% to 10%. Features associated with fatal outcome include a low 5-minute Apgar score, shock, neutropenia, pleural effusion, apnea, and delay in treatment after the onset of symptoms.<sup>10,516,527</sup> Fatal infection also occurs significantly more often among premature than among term neonates (Table 13-8). Pyati and colleagues<sup>530</sup> reported a fatality rate of 61% among 101 neonates who had

**Figure 13-6** Chest radiograph from an infant with early-onset group B streptococcal septicemia showing features consistent with respiratory distress syndrome of the newborn.

**Figure 13-7** Chest radiograph demonstrating right upper and lower lobe infiltrates as manifestations of early-onset group B streptococcal pneumonia in an infant.

early-onset group B streptococcal infection. However, infants with a birth weight in excess of 1500 g had a fatality rate of 14%. Recent data suggest a 15-fold increase when infants with a gestational age of 33 weeks or less are compared with term infants.<sup>22</sup> A contemporary case-fatality rate of 42% was reported for infants weighing less than 2500 g at birth. This was significantly higher than the case-fatality rate of 7% among infants who weighed 2500 grams or more at birth.<sup>162</sup>

### Late-Onset Infection

Late-onset group B streptococcal infection typically affects the term infant from 7 days to 90 days of age. Such infants frequently have an unremarkable early neonatal history, although late-onset disease may occur in premature infants.<sup>247,529</sup> One report found that group B streptococci accounted for 2% of late-onset sepsis episodes in very low birth weight neonates.<sup>531</sup> Late-onset disease has a lower fatality rate (2% to 6%) than that of early-onset disease,<sup>22,516,517,532</sup> and meningitis is a frequent clinical manifestation (occurring in an estimated 35% to 40% of cases). Serotype III strains are isolated from two thirds to three quarters of patients, irrespective of focus of infection.<sup>12</sup> An exception to the usual pattern for late-onset infection is in the neonatal intensive care unit setting, where prematurity can dominate as a risk factor and where clusters of nosocomially acquired disease among low-birth-weight infants may occur.<sup>219,517,531</sup> In these infants, the spectrum of clinical expression is similar to that in early-onset disease, and serotypes other than type III have been implicated.

The initial signs in infants with late-onset meningitis almost always include fever, irritability or lethargy or both, poor feeding, and tachypnea. Upper respiratory tract infection precedes late-onset meningitis in 20% to 30% of infants, suggesting that alteration of mucosal barriers might facilitate entry of group B streptococci into the bloodstream.<sup>2,3,245</sup> In contrast with early-onset infection, grunting respirations and apnea are less frequent initial findings, and their presence suggests a more rapidly progressive, fulminant infection. Apnea or hypotension is observed in less than 15% of patients, but there is a spectrum in clinical severity of illness at presentation. Some neonates with late-onset meningitis are clinically well a few hours before their initial hospital evaluation, when they are noted to have seizures, poor perfusion, neutropenia, and large numbers of gram-positive cocci in the CSF. Such patients often have a rapidly fatal course, or if they survive, they are left with devastating neurologic sequelae. Leukopenia or neutropenia at the time of admission has been correlated with fatal outcome in such infants.<sup>527</sup> Other admission findings associated with increased risk for fatal outcome or permanent neurologic sequelae include hypotension, coma or semicomatose status, status epilepticus, an absolute neutrophil count of less than 1000/mm<sup>3</sup>, a CSF protein level exceeding 300 mg/dL, and a high concentration of type III group B streptococcal antigen in CSF.<sup>245,513,527</sup> This last prognostic factor and the observation indicating

prolonged antigenuria in meningitis survivors who are left with neurologic abnormalities probably reflect a larger bacterial inoculum in the CSF than is found in that of survivors with a normal outcome. Subdural effusions, which usually are small, unilateral, and asymptomatic, are found in up to 20% of patients with late-onset meningitis. These are not associated with any permanent sequelae.<sup>9,516</sup> Subdural empyema as a complication is rare.<sup>533</sup>

The outcomes with meningeal infection are based on reports of infants cared for nearly 20 years ago. Whether or not the prognosis has improved must await additional data. Of greater than 200 neonates with early- or late-onset meningitis, one quarter died in the hospital as the direct result of meningitis.<sup>245,521-523</sup> A substantial number of survivors (25% to 50%) had permanent neurologic sequelae of variable severity. In three series assessing a total of 112 survivors at mean intervals ranging from 2 to 8 years after diagnosis, major neurologic sequelae were observed in 21% of children. The most serious of these included profound mental retardation, spastic quadriplegia, cortical blindness, deafness, uncontrolled seizures, hydrocephalus, and hypothalamic dysfunction with poor thermal regulation and central diabetes insipidus.<sup>521,523,534,535</sup> Mild or moderate sequelae persisted in 21% of survivors evaluated at a mean of 6 years after diagnosis.<sup>523</sup> These problems included profound unilateral sensorineural hearing loss, borderline mental retardation, spastic or flaccid monoparesis, and expressive or receptive speech and language delay. In a sibling-controlled follow-up study, Wald and co-workers<sup>535</sup> found that the psychometric performance did not differ significantly for children who had had group B streptococcal meningitis and their siblings. More postmeningitis children than control children had seizure disorders and hydrocephalus that required shunting procedures, but they were functioning in a manner comparable with that of their siblings. More subtle deficits such as delayed language development and mild hearing loss may not be detected by routine examination,<sup>523</sup> and all patients should undergo auditory brain-stem evoked response testing during convalescence as well as careful long-term neurologic and developmental assessments.

Bacteremia without a detectable focus of infection now is the most common clinical expression of late-onset group B streptococcal disease.<sup>536</sup> Osteomyelitis, septic arthritis, cellulitis, and adenitis are less frequent manifestations of late-onset disease. The infant with bacteremia without a focus typically has an uncomplicated perinatal course and presents

Table 13–9 Clinical Features of Group B Streptococcal Bone and Joint Infections<sup>a</sup>

Feature	Septic Arthritis without Osteomyelitis (20 Patients) <sup>a, 415, 544-549</sup>	Osteomyelitis (45 Patients) <sup>a, 541-544, 550-561</sup>

with nonspecific signs (fever, poor feeding, irritability, rhinorrhea) in either an inpatient or an outpatient setting. Diagnosis results from the practice of obtaining blood cultures in febrile infants in the first few weeks of life to exclude serious bacterial infection as an underlying cause. These infants are mildly ill, but failure to initiate antimicrobial therapy *before* the availability of blood culture findings can result in extension of infection to distant sites such as the central nervous system. Both transient and persistent bacteremia have been described in symptomatic and healthy patients.<sup>4,537,538</sup> Fatal outcome has not been reported among patients with late-onset bacteremia without a focus, and survivors recover without sequelae after treatment.

### Late, Late-Onset Infection

One report suggests that infections in infants older than 3 months of age account for 20% of cases of late-onset disease.<sup>517</sup> The terms *very late onset*, *late late-onset*, and *beyond early infancy* have been applied to disease in these infants. Most of these infants have a gestational age of less than 35 weeks. The need for prolonged hospitalization and its attendant monitoring, as well as the immature host status of these infants, probably contributes to infection beyond the interval for term neonates. Bacteremia without a focus is a common presentation. Occasionally a focus for infection, such as the central nervous system, intravascular catheter, or soft tissues, is identified (see Table 13-7). In the outpatient setting, infants older than 3 months of age are likely to have a temperature higher than 39° C and a white blood cell count exceeding 15,000/mm<sup>3</sup>.<sup>536</sup> When there are no other apparent risk factors, immune deficiency including HIV infection should be considered in the setting of a very late-onset infection.<sup>539,540</sup>

### Septic Arthritis and Osteomyelitis

Group B streptococcal bone and joint infection has an indolent onset and a good prognosis. Less than 20% of affected infants demonstrate poor feeding,<sup>541</sup> respiratory distress,<sup>542</sup> meconium aspiration,<sup>543</sup> or mild elevation of serum bilirubin levels during the early neonatal period.<sup>544</sup> Manipulations known to predispose neonates to bone and joint infection

caused by other pathogens (heel or needle puncture, umbilical vessel catheterization, exchange transfusion) have not been reported.

The clinical features of 20 infants with arthritis alone and 45 with osteomyelitis (with or without concomitant septic arthritis) related to group B streptococci are summarized in Table 13-9. The mean age at diagnosis of osteomyelitis (31 days) is greater than that for septic arthritis (20 days) or other manifestations of late-onset disease (27 days). In septic arthritis, the onset is acute (mean duration of clinical signs, 1.5 days), whereas in osteomyelitis, the course is often protracted (mean, 9 days). In some infants with osteomyelitis, failure to move the involved extremity since hospital discharge after birth, or shortly thereafter, may be noted; this lack of movement may persist for as long as 4 weeks before the diagnosis is made.<sup>550</sup>

Decreased motion of the involved extremity and evidence of pain with manipulation, such as lifting or diaper changing, are the most common signs of group B streptococcal bone or joint infection. Inflammatory signs (warmth or redness) occasionally are described<sup>556,557</sup>; a history of fever is reported in only 20% of infants. Lack of signs suggesting infection and the finding of pseudoparalysis has led to an initial diagnosis of Erb's palsy and to assessment for possible child abuse.<sup>541,550,561</sup> In several infants, findings on nerve conduction studies were consistent with brachial plexus neuropathy associated with group B streptococcal osteomyelitis of the proximal humerus,<sup>558,562</sup> and in one infant, sciatic nerve injury at the level of the pelvis caused footdrop as a result of iliac osteomyelitis.<sup>563</sup>

Signs frequently observed include fixed flexion of the involved extremity, mild swelling, evidence of pain with passive motion, decreased spontaneous movement, and, in a minority of infants, erythema and warmth. Lack of associated systemic involvement is the rule, although osteomyelitis in association with meningitis, peritonitis, and overwhelming sepsis with congestive heart failure has been reported.<sup>541,544,557,559,564</sup>

When infants with septic arthritis alone are compared with those with osteomyelitis, those with septic arthritis more often have lower extremity involvement, with the hip joint predominating.<sup>544,548</sup> By contrast, over one half of the reported infants with osteomyelitis have had exclusive

involvement of the humerus, and in those for whom the location was specified, the proximal humerus was affected in greater than 90%.<sup>541,544,550,554</sup> Osteomyelitis involving both proximal humeri has been described.<sup>559</sup> The next most common site of involvement is the femur, and small, flat, and vertebral bone infections occur occasionally.<sup>565,566</sup> Single bone involvement predominates for group B streptococcal osteomyelitis, although infection involving two adjacent bones or multiple nonadjacent bones has been described.<sup>542,551,559</sup> The rarity of multiple bone involvement contrasts with its common occurrence (estimated at 70%) in neonatal osteomyelitis caused by *S. aureus* or gram-negative enteric bacilli. Although most infants with humeral osteomyelitis have had concomitant infection in the shoulder joint, isolated septic arthritis of the shoulder joint has not been reported.

Impaired function after neonatal osteomyelitis caused by bacteria other than group B streptococci occurs in one fourth to one third of patients. By contrast, in 17 (90%) of 19 infants with group B streptococcal osteomyelitis evaluated 6 months to 4 years after diagnosis, no functional impairment of the affected extremity was found.<sup>4,543,544,546,550,556,558,559</sup> Residual shortening and limitation of motion of the humerus were noted in a patient who had overwhelming sepsis of acute onset, with congestive heart failure and osteomyelitis involving noncontiguous sites.<sup>544</sup> Growth disturbance can result as a consequence of subluxation of the hip joint.

Although both septic arthritis and osteomyelitis are considered manifestations of late-onset disease, osteomyelitis may represent a clinically silent early-onset bacteremia with secondary spread to a metaphysis and then late-onset expression of infection. An episode of asymptomatic bacteremia with a birth trauma-induced nidus in the proximal humerus could allow localization of bacteria to the bone. Because lytic lesions take more than 10 days to become radiographically visible, the presence of such lesions on radiographs obtained at hospital admission is suggestive of long-standing disease (Fig. 13-8). Also, non-type III strains are overrepresented among infants with osteomyelitis. These findings are consistent with the hypothesis that, in at least some patients, early-onset acquisition may have occurred.

### Cellulitis or Adenitis

The manifestation of late-onset group B streptococcal infection designated facial cellulitis,<sup>567</sup> submandibular cellulitis,<sup>568</sup> cellulitis/adenitis,<sup>569</sup> or lymphadenitis<sup>570</sup> has been reported in at least 25 infants.<sup>571-574</sup> Presenting signs include poor feeding, irritability, fever, and unilateral facial, preauricular, or submandibular swelling, usually but not always accompanied by erythema. The mean age at onset is 5 weeks (range, 2 to 11 weeks), and in contrast with all other patients with group B streptococcal infection, there is a striking male predominance (72%). The most common sites are the submandibular and parotid areas, and enlarged adjacent nodes become palpable within 2 days after onset of the soft tissue infection. Four of the five infants with facial or submandibular cellulitis described by Baker<sup>569</sup> had ipsilateral otitis media at the time of diagnosis. Less common sites of involvement with cellulitis are the face, preauricular or inguinal areas, scrotum, anterior neck region, and prepatellar spaces (Fig. 13-9).<sup>569,573,574</sup> In one patient, cellulitis of the

**Figure 13-8** Radiograph showing a lytic lesion (arrow) of the proximal humerus in an infant whose bone biopsy demonstrated osteomyelitis caused by type III group B streptococci.

neck occurred in association with an infected thyroglossal duct cyst.<sup>569</sup>

Bacteremia almost always is detected in these infants (92%), and cultures of soft tissue or lymph node aspirates have yielded group B streptococci in 83% of the children in whom aspiration was performed. These patients usually are not seriously ill, few have associated meningitis, and recovery within a few days of initiation of appropriate antimicrobial therapy is the rule. However, fulminant and fatal facial cellulitis has been described in a 7-hour-old neonate<sup>4</sup> and associated meningitis in two infants.<sup>575</sup>

### Unusual Manifestations of Infection

A number of uncommon clinical manifestations of early- and late-onset group B streptococcal infection have been recorded (Table 13-10). Peritonitis<sup>576</sup> and adrenal abscess<sup>577-579</sup> have been described as abdominal manifestations of early-

**Figure 13-9** Prepatellar bursitis of both knees in an infant who had abraded his knees on the bedsheets. Aspiration of purulent material from the prepatellar space yielded type III group B streptococci. The knee joints were not affected.

and late-onset infection. Adrenal abscess is thought to be the result of bacteremic seeding associated with adrenal hemorrhage and subsequent abscess formation. One neonate thought to have neuroblastoma underwent en bloc resection of a large mass with nephrectomy before the diagnosis of adrenal abscess was established.<sup>578</sup> Gallbladder distention is a nonspecific manifestation of early-onset sepsis that usually resolves with medical management.<sup>580</sup> Late-onset bacteremia can occur in association with jaundice, elevated levels of liver enzymes, and increased direct-reacting bilirubin fraction. Possibly, hemolysis and “toxic” hepatocellular damage contribute to the development of jaundice. Underlying liver disease, a known predisposing factor for development of group B streptococcal bacteremia in adults, was suggested as an explanation for group B streptococcal bacteremia in a 22-month-old child.<sup>628</sup>

Brain abscess rarely occurs in association with recurrence of group B streptococcal meningitis. One infant recovered after craniotomy and excision of a well-encapsulated frontal mass but had neurologic sequelae.<sup>581</sup> Sokol and colleagues<sup>583</sup> described a 5-week-old infant with a cerebellar cyst believed to represent an astrocytoma. This infant proved to have obstructive hydrocephalus and chronic group B streptococcal ventriculitis. Rarely, anterior fontanelle herniation may complicate severe meningitis. The presence of a noncystic doughy mass over the fontanelle indicates that brain herniation may have occurred, and head ultrasonography or computed tomography may be used for confirmation. This finding is a poor prognostic sign.<sup>582</sup> One patient with cervical myelopathy initially had absence of extremity movement but made a good recovery and was able to walk at age 3 years.<sup>585</sup> Another unusual complication of group B streptococcal meningitis is subdural empyema, which has been described in patients with both early- and late-onset

infections.<sup>533,534</sup> The diagnosis was established by needle aspiration of the subdural space at the time of hospital admission<sup>534</sup> or within the first 5 days of treatment. Irritability, vomiting, seizures, increasing head circumference, focal neurologic signs, a tense anterior fontanelle, or a combination of these prompted evaluation.<sup>533,629</sup> Sterilization of the subdural space was accomplished by drainage, open or closed, in conjunction with antimicrobial therapy. Basal ganglia and massive cerebral infarction also have been described.<sup>584</sup>

Cardiovascular manifestations of group B streptococcal infection are rare. However, endocarditis,<sup>219,564,589,590</sup> pericarditis,<sup>591</sup> myocarditis,<sup>543</sup> and mycotic aneurysm of the aorta<sup>592</sup> have been documented. Echocardiography has been useful in determining the nature of cardiac involvement, and this technique was employed successfully to delineate a 0.7-cm vegetation on the anterior leaflet of the mitral valve in a 4-week-old infant with endocarditis caused by a serotype III strain.<sup>564</sup> Paroxysmal atrial tachycardia may be a presenting feature of group B streptococcal bacteremia in the absence of focal infection of the heart.<sup>9</sup>

Group B streptococci are an uncommon cause of otitis media in the first few weeks of life (2% to 3% of cases).<sup>594</sup> However, otitis media is not infrequently associated with late-onset disease manifesting as meningitis or submandibular cellulitis.<sup>593,595,596</sup> The finding of acute mastoiditis at autopsy in one infant with otitis media and meningitis suggests that the middle ear may serve as a portal of entry in some patients.<sup>596</sup>

Conjunctivitis related to group B streptococci occurs with such rarity that no cases were identified among 302 neonates with ophthalmia neonatorum described by Armstrong and associates.<sup>597</sup> However, exudative conjunctivitis has been reported in association with early-onset bacteremia.<sup>597</sup> More severe ocular involvement is rare, but endophthalmitis has been noted in infants with bacteremia and meningitis.<sup>599,600</sup> As is the case for other agents producing endophthalmitis, high-grade bacteremia is a likely prelude to this unusual metastatic focus of group B streptococcal infection.

Supraglottitis was described in a 3-month-old infant with acute onset of stridor.<sup>604</sup> Swelling of the left aryepiglottic fold but not the epiglottis was noted at laryngoscopy. An infant with bacterial tracheitis had a similar presentation.<sup>607</sup> Although pulmonary infection caused by group B streptococci is common, pleural involvement is rare, but it has been reported as a complication of both early-onset<sup>606</sup> and late-onset<sup>605</sup> pneumonia. An interesting but as-yet inexplicable association is that of delayed development of right-sided diaphragmatic hernia and early-onset group B streptococcal sepsis.<sup>602,603,630,631</sup> In affected infants, the onset of respiratory distress invariably occurs at or within hours of birth, whereas the mean age at diagnosis of right-sided diaphragmatic hernia is 12 days (range, 3 to 35 days).<sup>602</sup> Ashcraft and associates<sup>602</sup> postulate that the insufficient diaphragmatic motion predisposes a neonate with peripartum exposure to group B streptococci to the development of pneumonia and that subsequent respiratory effort accounts for the ultimate herniation of viscera into the pleural space. This phenomenon should be remembered and considered in the infant with group B streptococcal infection whose condition continues to deteriorate despite appropriate management. Radiographic features include increased density in the right lower lung or

Table 13-10 Unusual Clinical Manifestations of Group B Streptococcal Infections

Site and Manifestation	Associated with Early- or Late-Onset Infection	Reference Nos.
<b>Abdomen</b>

Urinary tract infection	Both	517, 627

irregular aeration or both, followed by progression to elevation of right bowel gas and liver shadow.

In addition to cellulitis and adenitis, group B streptococci uncommonly can produce a variety of unusual skin and soft tissue manifestations. These include violaceous cellulitis,<sup>632</sup> perineal cellulitis and septicemia after circumcision,<sup>633</sup> scrotal ecchymosis as a sign of intraperitoneal hemorrhage,<sup>613</sup> purpura fulminans,<sup>620,621</sup> necrotizing fasciitis,<sup>615-617</sup> impetigo neonatorum,<sup>618,619</sup> omphalitis,<sup>511,622</sup> scalp abscess secondary to fetal scalp electrode,<sup>626</sup> abscess complicating cystic hygroma,<sup>608</sup> retropharyngeal cellulitis<sup>624,625</sup> and breast abscess.<sup>609</sup> In patients with impetiginous lesions and abscess formation, bacteremia is unusual, but it is a frequent accompaniment to omphalitis and necrotizing fasciitis.

Among infants with early-onset bacteremia, isolation of group B streptococci from the urine is frequent when this

body fluid is cultured, but primary urinary tract infection with these organisms is rare. An infant with severe bilateral ureterohydronephrosis and group B streptococci in his urine has been described.<sup>627</sup> The isolation of group B streptococci from a urine culture of a patient *without bacteremia* is an indication for evaluation for possible structural anomalies of the genitourinary tract.

Sudden death occurred in three infants ranging from 3 to 8 months of age. The deaths were attributed at the time of autopsy to group B streptococcal infection.<sup>500</sup>

### Relapse or Recurrence of Infection

Recurrent infection has been reported in an estimated 0.5% to 3% of infants<sup>572,581,612,633-640</sup> in whom signs developed either during treatment or after an interval of 3 to 101 days

after completion of antibiotic therapy. In one retrospective review, eight of nine infants were born at 25 to 36 weeks of gestation, and male infants predominated.<sup>639</sup> The first episode occurred at a mean age of 10 days (range, 1 to 27), and recurrence was noted at a mean age of 42 days (range, 23 to 68 days). In a recent report that included a set of fraternal twins, seven of eight infants were born before 37 weeks of gestation (mean 30 weeks), and each had a birth weight of less than 2500 g.<sup>641</sup> Each of the infections was late-onset. The mean age at initial presentation was 38 days (range, 13 to 112), and recurrence occurred at a mean age of 57 days (range, 34 to 130 days). Two separate episodes have been documented in several infants.<sup>637,640,642,643</sup> In some cases, circumstances that potentially predisposed the infant to relapse or reinfection were reported (maternal mastitis, protracted focal seizures in an infant with a brain abscess,<sup>581,644</sup> endocarditis with underlying congenital heart disease<sup>634</sup>). Identical isolates were recovered from the maternal genital and breast milk cultures, suggesting that breast-feeding might have been the source of repeated exposure both when signs of mastitis were noted and when the mother had no clinical features of mastitis.<sup>640,645</sup> Recurrent infection usually has a clinical expression similar to that of the initial episode, but some affected infants have had new sites of involvement with the relapse or recurrence (meninges, ventricular or subdural fluid, or both<sup>634,636,637</sup>; brain parenchyma<sup>581</sup>; and soft tissue<sup>572,612</sup>). In most patients, the second episode of group B streptococcal disease was treated in a similar manner with a  $\beta$ -lactam antibiotic, most often penicillin or ampicillin, but typically the duration was longer.<sup>641</sup>

One possible explanation for some early reports of relapse or recurrence was failure to administer penicillin G or ampicillin at an optimal dosage or for a sufficient duration. In two patients, penicillin-tolerant organisms were isolated at the time of the second infection<sup>581,634</sup>; isolates from the initial episode were not available for susceptibility testing. Because the finding of *in vitro* penicillin tolerance is not uncommon among group B streptococcal isolates (estimated at 4%<sup>645</sup>), the relationship between tolerance and relapse is unknown, and it is suggested that the phenomenon of penicillin tolerance may be one factor contributing to persistent mucosal carriage (see "Treatment" later on).<sup>646</sup>

Because infants who receive treatment for invasive infection frequently remain colonized with group B streptococci at mucous membrane sites, pharyngeal or gastrointestinal colonization may be the source for another episode of bacteremia. In addition, among infants recovering from invasive infection with type III strains, protective levels of antibody infrequently develop during convalescence. Moylett and colleagues<sup>641</sup> and others<sup>643</sup> used restriction endonuclease analysis to document that isolates from patients with recurrent episodes of group B streptococcal disease in an infant were identical and were derived from a single clone. Sets of isolates analyzed from first and second episodes and from maternal and infant colonizing and invasive strains were genotypically identical using pulsed-field gel electrophoresis.<sup>639,641</sup> Thus, recurrent infection in most infants results from reinvasion from persistently colonized mucous membrane sites or reexposure to a household carrier. However, a minority of infants encounter a new strain and have a second episode based on exposure other than maternal.

## Maternal Infections Caused by Group B Streptococci

In 1938, Fry<sup>1</sup> described three fatal cases of endocarditis in postpartum women. This finding was the first indication that the group B streptococcus was a human pathogen and could cause puerperal infection. For the next several decades, additional postpartum infections including septic abortion, bacteremia, chorioamnionitis, endometritis, pneumonia, and septic arthritis were recorded sporadically.<sup>503,647,648</sup> However, before 1970, group B streptococcal infection in the postpartum woman, as in the neonate, was uncommon.<sup>9</sup> The increase in neonatal infections during the past 4 decades has been paralleled by an increasing number of infections in adults.<sup>5,7,506</sup> It is now obvious that group B streptococci constitute a significant common cause of febrile morbidity in pregnant women.

Before institution of intrapartum antibiotic prophylaxis, group B streptococci accounted for 10% to 20% of blood culture isolates from febrile women on obstetric services.<sup>6,9</sup> These women have a clinical picture generally characterized by fever, malaise, moderate uterine tenderness with normal lochia, and occasionally chills. A detailed study of group B streptococcal infection in postpartum patients was reported by Faro.<sup>7</sup> Forty women with endometritis and endoparametritis related to group B streptococci were observed among 3106 women giving birth over a 12-month interval, an incidence of 1.3 per 1000 deliveries. The diagnosis was established by isolation of group B streptococci from the endometrium either alone (in 35% of the cases) or in addition to other organisms; one third of the women had concomitant bacteremia. In many (94%) of these women, infection developed after cesarean section. Fever characteristically developed early in the postpartum course (mean time to onset, 11.7 hours; range, 1 to 24 hours). Additional clinical features included chills, tachycardia, abdominal distention, and exquisite uterine, parametrial, or adnexal tenderness. Temperature of 38.5°C or higher correlated with an increased risk of concomitant bacteremia. Recovery was uniform after administration of one of a number of antimicrobial agents to which group B streptococci were susceptible. However, group B streptococcal septicemia developed in 6 (13.3%) of 45 infants delivered to these women, and fatal infection occurred in 3. Febrile morbidity in a mother can be the single early clue of bacteremic infection in her neonate,<sup>7,9</sup> and the infants of such women should be carefully evaluated.

The contemporary incidence of invasive disease in pregnant women is 0.2 to 0.3 per 1000 live births.<sup>22,162</sup> This incidence has declined significantly in association with implementation of recommendations for maternal antibiotic prophylaxis to prevent early-onset neonatal disease. Bacteremia is the primary manifestation of infection, accounting for 64% of cases in one series.<sup>22</sup> Bacteremia in association with chorioamnionitis or endometritis each occurred in 10% of cases, and septic abortion in 7%. Maternal infection carries a toll for the infant, both for clinical illness with survival (17%) and for spontaneous abortion, stillbirth, or fatal infection (occurring in 29% of infants born to mothers with invasive infection).<sup>22</sup> Most obstetric patients with group B streptococcal infection, even in the presence of bacteremia, demonstrate a rapid response

after initiation of appropriate therapy, but potentially fatal complications rarely occur, including meningitis,<sup>649</sup> ventriculoperitoneal shunt infection,<sup>650</sup> abdominal abscess,<sup>651</sup> endocarditis,<sup>13,652-654</sup> vertebral osteomyelitis,<sup>655</sup> epidural abscess,<sup>656</sup> and necrotizing fasciitis.<sup>657</sup>

Group B streptococcal bacteriuria during pregnancy is a risk factor for intrauterine or neonatal infection. Asymptomatic bacteriuria and cystitis or pyelonephritis occur in 6% to 8% of women during pregnancy. In those with asymptomatic bacteriuria, approximately 20% are caused by group B streptococci.<sup>658</sup> Pass and associates<sup>659</sup> observed three patterns of urinary tract infection among 20 patients: symptomatic lower urinary tract infection in the antenatal period; asymptomatic bacteriuria at delivery; and postpartum lower and upper tract infection. Eleven infants born to these women were colonized with group B streptococci, and early-onset sepsis developed in one. In the series reported by Moller and associates,<sup>504</sup> the 68 women with asymptomatic bacteriuria caused by group B streptococci had a significantly increased risk of delivery before 37 weeks of gestation compared with controls, but a causal relationship was not established. Among women with spontaneous abortion, the occurrence of group B streptococci in the urine has been significantly associated with fetal loss.<sup>660</sup> Women with group B streptococcal bacteriuria are those with heavy colonization, and both conditions are associated with enhanced risk for maternal and neonatal infection.<sup>154</sup>

## DIAGNOSIS

### Isolation and Identification of the Organism

The diagnosis of invasive group B streptococcal infection is established by isolation of the organism on culture of blood, CSF, or other specimen from the site of suppurative focus (e.g., bone, joint fluid, empyema fluid). Isolation of group B streptococci from surfaces such as the skin or umbilicus, or from mucous membranes, is of no clinical significance.

A selective approach to performing a lumbar puncture in the evaluation of neonates with possible sepsis has been advocated by some clinicians. Exclusion of meningeal infection by lumbar puncture always is indicated when either early- or late-onset group B streptococcal infection is suspected, however, because meningeal penetration occurs in 5% to 10% of cases<sup>9,10,162,516,517</sup> and early clinical features cannot distinguish between meningitis and bacteremia without meningitis. In many neonates with meningitis, group B streptococci are isolated from blood at initial evaluation, but the organism cannot be identified in a substantial minority (10% to 15%) of infants so affected. Wiswell and colleagues<sup>661</sup> found that if lumbar puncture was omitted as part of the early neonatal sepsis evaluation, the diagnosis of bacterial meningitis would have been missed or delayed in more than one third of infants. Infants with late-onset infection can have meningitis even when another site of infection, such as cellulitis, is apparent.<sup>575</sup> If lumbar puncture must be deferred initially because an infant is clinically unstable, penicillin G or ampicillin at the doses recommended for treatment of group B streptococcal meningitis (see "Treatment" later on) should be administered until meningeal involvement can be excluded.

### Antigen Detection Methods

The difficulty of clinically differentiating neonates with group B streptococcal infection from those infected with other agents or with noninfectious disorders 3 decades ago prompted the development of tests to provide a presumptive diagnosis. These techniques included countercurrent immunoelectrophoresis (CIE),<sup>662,663</sup> latex particle agglutination (LPA),<sup>664-666</sup> staphylococcal coagglutination (SCA),<sup>664,667,668</sup> and enzyme immunoassay.<sup>669</sup> Each was based on the detection of group B- or type-specific polysaccharide antigens in body fluids using hyperimmune polyclonal antisera or monoclonal antibodies. The methods all have the attributes of simplicity, rapidity, and the ability to detect antigen after antimicrobial therapy has been initiated.

Antigen tests are not a substitute for appropriately performed bacterial cultures and now are rarely used for the diagnosis of group B streptococcal infection. A positive result indicates the presence of group B streptococcal antigen and not necessarily the presence of viable organisms. The only specimens recommended for antigen detection testing are serum and CSF.<sup>670</sup> In neonates with meningitis, the reported sensitivity of CSF assays is 72% to 89%. Serum is less likely to have detectable antigen (estimated sensitivity is 30% to 40%). LPA is more sensitive than CIE.<sup>664,665</sup> False-positive results have been encountered for antigen testing of serum and CSF, and the estimated specificity of assays varies, ranging from 95% to 98%. These assays should not be employed to monitor treatment efficacy.

### Other Laboratory Tests

Elevation of levels of acute-phase reactants such as C-reactive protein may be observed acutely during group B streptococcal infection.<sup>671,672</sup> The usefulness of elevated serial C-reactive protein responses for detecting bacteremia was shown by Pourcyrus and colleagues.<sup>672</sup> Philip<sup>671</sup> suggests that C-reactive protein may not be a good indicator of neonatal infection during the first 12 hours after birth. However, the return to normal of the C-reactive protein level has been used to assist in minimizing antibiotic exposure in the nursery setting.<sup>673</sup> Levels of inflammatory cytokines such as interleukin-6 (IL-6) also are frequently elevated acutely during group B streptococcal sepsis. In one report, production of IL-6 was noted in all 16 neonates with bacteremic early- or late-onset group B streptococcal infection in samples collected within 48 hours of initiation of antimicrobial therapy.<sup>674</sup>

Abnormalities in the white blood cell count, including relative leukopenia, absolute neutropenia, leukocytosis, and a tendency for a decline in the total white blood cell count in the first 24 hours of life, are thought by some investigators to be useful in identifying neonates with group B streptococcal pneumonia.<sup>295,298,675,676</sup> In a study designed to determine the usefulness of the differential white blood cell count for distinguishing early-onset group B streptococcal infection from noninfectious causes of respiratory distress, Manroe and co-workers<sup>675</sup> found that each infected infant was identified by abnormalities in two or more of the following indices: (1) absolute neutrophil count indicating neutropenia or neutrophilia (87%), (2) elevation of the absolute immature neutrophil count (42%), and (3) abnormal ratio of immature neutrophils to the total number of neutrophils. The most useful index was the ratio of absolute immature

neutrophils to absolute total neutrophils, which was elevated (greater than 0.20) in 91% of infants with infection and in only 1 of 23 noninfected infants with respiratory disease.<sup>675</sup> Greenberg and Yoder<sup>677</sup> caution that repeat testing at 12 to 24 hours of age may enhance sensitivity in comparison with testing between 1 and 7 hours of age. Fatal early-onset group B streptococcal sepsis can occur with a normal leukocyte count, however.<sup>678</sup> In general, measurements of peripheral blood leukocytes or inflammatory mediators are nonspecific and should be employed as adjuncts to blood and CSF cultures.

### Differential Diagnosis

The clinical features in neonates with early-onset group B streptococcal infection mimic those in infants with sepsis caused by other etiologic agents and by some noninfectious illnesses. Radiographic findings characteristic of pneumonia are present in only one-third of neonates with early-onset group B streptococcal sepsis. At least one half of the neonates with proven bacteremia and pulmonary disease have radiographic abnormalities consistent with respiratory distress syndrome. Neonates with early-onset group B streptococcal pulmonary disease are more likely to have an interval after rupture of membranes of more than 12 hours before delivery, apnea and shock within the first 24 hours of life, a 1-minute Apgar score of 5 or less, and an unusually rapid progression of pulmonary disease than are neonates with noninfectious causes for respiratory distress.<sup>292</sup> Group B streptococcal infection also should be considered in a neonate with persistent fetal circulation associated with respiratory distress, neutropenia, and systemic hypotension.<sup>527</sup>

The differential diagnosis for late-onset group B streptococcal infection depends on the clinical presentation. For infants with meningitis, the characteristic CSF Gram stain findings can provide a presumptive diagnosis. When this is inconclusive or if partial treatment may have altered the CSF culture, other organisms, including viruses, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and nontypeable *Haemophilus influenzae*, must be considered. Fever usually is a presenting feature, and empirical therapy with broad-spectrum antibiotics customarily is employed until results of cultures permitting a specific diagnosis of bacteremia are available. The paucity of signs characteristic of group B streptococcal osteomyelitis and the occasional history that signs have been present since birth have caused its confusion with Erb's palsy and neuromuscular disorders. Nevertheless, the characteristic bone lesion in the affected metaphysis, the common finding of tenderness of the extremity when a careful examination is performed, and the isolation of the organism from blood, bone, or joint fluid usually provide a definitive diagnosis.<sup>550</sup> Finally, the lengthy list of uncommon manifestations of group B streptococcal infection between 1 week and 3 months of age and beyond indicates that the group B streptococcus should be suspected as an etiologic agent, irrespective of site of infection, for infants in this age group.

### TREATMENT

Group B streptococci have been a frequent cause of infection in neonates for more than 3 decades, resulting in increased

awareness of associated risk factors and need for prompt and aggressive therapy. Despite striking declines, however, death and permanent sequelae from these infections remain all-too-frequent outcomes. In addition, relapses or reinfections, although uncommon, occur in the face of optimal therapy by conventional standards. These facts should prompt efforts to develop improved treatment modalities.

### In Vitro Susceptibility

Uniform susceptibility of group B streptococci to penicillin G has continued for almost 50 years of usage.<sup>679-683</sup> In vitro susceptibility of these organisms to ampicillin, semisynthetic penicillins, vancomycin, teicoplanin, linezolid, quinopristin/dalfopristin, gatifloxacin, levofloxacin, and first-, second- (excluding cefoxitin), and third-generation cephalosporins also is the rule, although the degree of in vitro activity varies.<sup>682-690</sup> Ceftriaxone is the most active of the cephalosporins in vitro. Imipenem and meropenem are highly active.<sup>680,684</sup> Ciprofloxacin has moderate in vitro activity.<sup>686</sup> Resistance to erythromycin and clindamycin has increased dramatically. Contemporary data indicate that 20% to 30% of isolates are resistant to erythromycin and that 10% to 20% of isolates are resistant to clindamycin.<sup>682,683,690-692</sup> These rates of resistance have been reported from such geographically diverse areas as Turkey, France, Spain, and Taiwan, as well as North America.<sup>693-696</sup> The most frequently encountered macrolide resistance mechanisms in streptococci are ribosomal modification by a methylase encoded by an *erm* gene and drug efflux by a membrane-bound protein encoded by a *mef* gene.<sup>691</sup> The *erm*(A), *erm*(B), and *mef*(A) genes, either alone or in combination, are responsible for erythromycin resistance.<sup>681</sup> Erythromycin-resistant isolates that are constitutively resistant, inducibly resistant, or susceptible to clindamycin are described.<sup>697</sup> A higher proportion with resistance to erythromycin has been reported for serotype V strains than for other group B streptococcal serotypes.<sup>683,698</sup> Both tigecycline and telithromycin are very active in vitro against macrolide-resistant group B streptococci, but data are not yet available confirming their clinical effectiveness.<sup>699,700</sup> Tetracycline resistance has increased significantly; the percentage of resistant strains has increased from about 30% in 1957<sup>701</sup> to nearly 90%.<sup>685</sup> Resistance of group B streptococci to bacitracin, nalidixic acid, trimethoprim-sulfamethoxazole, metronidazole, and aminoglycosides is uniform.

Despite the in vitro resistance of most group B streptococcal strains to aminoglycosides, when one of these drugs (especially gentamicin) is combined with a penicillin, in vitro<sup>702-705</sup> and in vivo synergy<sup>703,706-708</sup> often is observed. The best combination to theoretically accelerate the killing of group B streptococci in vivo is penicillin, or ampicillin, plus gentamicin. By contrast, the rapid and predictable bactericidal effect of penicillin or ampicillin on group B streptococci in vitro is ablated by the addition of rifampin.<sup>709,710</sup> Although in vivo data are lacking, the in vitro antagonism of rifampin when combined with penicillins suggests that they should not be employed concurrently in the treatment of proven or suspected group B streptococcal disease.

Among the newer  $\beta$ -lactam antibiotics reputed to attain high concentrations of drug in the CSF, only cefotaxime,

**Table 13-11 Antimicrobial Regimens Recommended for Treatment of Group B Streptococcal Infections in Infants<sup>a</sup>**

Manifestation of Infection	Drug	Daily Dose (intravenous)	Duration
Bacteremia without meningitis	Ampicillin plus gentamicin	150-200 mg/kg plus 7.5 mg/kg	Initial treatment before culture results (48-72 hr)
	Penicillin G	200,000 units/kg	Complete a total treatment course of 10 days
Meningitis	Ampicillin plus gentamicin	300-400 mg/kg plus 7.5 mg/kg	Initial treatment (until cerebrospinal fluid is sterile)
	Penicillin G	500,000 units/kg	Complete a minimum total treatment course of 14 days <sup>b</sup>
Septic arthritis	Penicillin G	200,000 units/kg	2-3 wk
Osteomyelitis	Penicillin G	200,000 units/kg	3-4 wk
Endocarditis	Penicillin G	400,000 units/kg	4 wk <sup>c</sup>

<sup>a</sup>No modification of dose by postnatal age is recommended. Oral therapy is never indicated.

<sup>b</sup>Longer treatment (up to 4 wk) may be required for ventriculitis.

<sup>c</sup>In combination with gentamicin for the first 14 days.

ceftriaxone, meropenem, and imipenem achieve minimal bactericidal concentrations (MBCs) comparable with those of penicillin G and ampicillin (0.008 to 0.4 µg/mL, respectively).<sup>680,684,691,708</sup> Only a few infants have received treatment with these agents,<sup>711-713</sup> and limited data suggest that their efficacy is equivalent to that of penicillin G. Thus, no compelling reason exists to consider use of these alternative therapeutic agents.

Despite their uniform susceptibility to penicillin G, group B streptococci require higher concentrations for growth inhibition in vitro than are required for strains belonging to group A. The minimal inhibitory concentration (MIC) of penicillin G to group B streptococci is 4- to 10-fold greater (range, 0.003 to 0.4 µg/mL) than that for group A strains.<sup>679,685,702</sup> This observation, combined with that indicating the significant influence of inoculum size on in vitro susceptibility to penicillin G may have clinical relevance.<sup>679,714</sup> If the inoculum of group B streptococci is reduced from 10<sup>5</sup> to 10<sup>4</sup> colony-forming units (CFU)/mL, a twofold decrease in the concentration of penicillin G is sufficient to inhibit in vitro growth. Similarly, if the inoculum is increased from 10<sup>4</sup> to 10<sup>7</sup> CFU/mL, the MBC of ampicillin is increased from 0.06 to 3.9 µg/mL. Such in vitro findings may have in vivo correlates, because some infants with group B streptococcal meningitis have CSF bacterial concentrations of 10<sup>7</sup> to 10<sup>8</sup> CFU/mL.<sup>714</sup> At the initiation of therapy for meningitis, achievable CSF levels of penicillin G or ampicillin may be only 1/10 of serum levels. This inoculum effect also has been noted with cefotaxime and imipenem.<sup>685</sup> Therefore, the dose chosen to treat group B streptococcal meningitis may be crucial to the prompt sterilization of CSF.

Although group B streptococci are susceptible to penicillin G, in vitro tolerance among 4% to 6% of strains has been noted.<sup>581,634,645,715</sup> Defined as an MBC in excess of 16 to 32 times the MIC, tolerance in vitro corresponds with delayed bacterial killing, additive rather than synergistic effects when gentamicin is used in combination with penicillin G, and possibly an autolytic enzyme defect in such strains.<sup>716,717</sup> Detection of tolerance among group B streptococcal isolates, however, is highly dependent on choice of growth medium, growth phase of bacterial

inoculum, and quantitative definition of MBC employed for testing.<sup>685</sup> Although some infants with recurrence of group B streptococcal infection have had tolerant strains,<sup>583,634</sup> the clinical significance of this in vitro phenomenon is doubtful.

### Antimicrobial Therapy

Although other penicillins are equally active in vitro, penicillin G remains the drug of choice for the treatment of group B streptococcal infections. This recommendation is undisputed, yet suggestions for dosage have varied considerably. The recommended dosage of penicillin for treatment of meningitis is relatively high because of (1) the relatively high MIC of penicillin G for group B streptococci (median, 0.04 µg/mL) with respect to attainable levels of this drug in the CSF,<sup>718</sup> (2) the large initial inoculum in the CSF of some infants,<sup>9,714</sup> (3) reports of relapse in infants with meningitis treated for 14 days with 200,000 units/kg per day of penicillin G, and (4) the safety of higher doses of penicillin G in the newborn. To ensure rapid bactericidal effects, particularly in the CSF, we recommend penicillin G (500,000 units/kg per day) or ampicillin (300 to 400 mg/kg per day) for the treatment of group B streptococcal meningitis (Table 13-11). There is no evidence to suggest increased risk for adverse reactions to these drugs at these higher doses even in premature infants.

In the usual clinical setting, antimicrobial therapy will be initiated before definitive identification of the organism. Initial therapy should include ampicillin and an aminoglycoside appropriate for the treatment of early-onset neonatal pathogens including group B streptococci. Such a combination has been shown more effective than penicillin G or ampicillin alone for in vitro and in vivo killing of group B streptococci.<sup>702-704</sup> It is our practice to continue combination therapy until the isolate has been identified as group B streptococci and, in patients with meningitis, until a CSF specimen obtained 24 to 48 hours into therapy is sterile. Kim<sup>717</sup> suggested that MIC and MBC determinations be considered in the following clinical circumstances: (1) a poor bacteriologic response to antimicrobial therapy, (2) relapse or recurrence of infection without a discernible cause, and (3) infections manifested as meningitis or endocarditis.

If tolerance is demonstrated in one of these circumstances, the clinician has the choice of empirically continuing the combination of penicillin G or ampicillin and gentamicin, or of using penicillin G or ampicillin alone, or of employing cefotaxime. No data are available to indicate the best choice.<sup>719</sup>

For the infant with late-onset disease in whom the CSF Gram stain reveals gram-positive cocci in pairs or short chains, initial therapy should include ampicillin and gentamicin or cefotaxime, rather than penicillin G alone. The rationale for this recommendation rests on several observations. First, group B streptococci are a frequent cause of meningitis in infants from 1 to 8 weeks of age. In this setting, combination therapy may provide for added efficacy early in the course of infection. Second, meningitis caused by *Listeria monocytogenes* can produce a CSF Gram stain indistinguishable from that with meningitis caused by group B streptococci, especially to an inexperienced observer. Ampicillin and gentamicin are synergistic in vitro against most strains of *Listeria*. If pneumococcal meningitis is a consideration, cefotaxime in combination with vancomycin should be included in the empirical regimen pending culture confirmation. Because group B streptococcal meningitis occurs uncommonly beyond 8 weeks of age, no change is suggested from the use of conventional agents as the initial treatment of meningitis in term infants older than 2 months of age. For the premature infant remaining in the hospital since birth, empirical therapy can include vancomycin and an aminoglycoside. However, if meningitis is suspected, an additional agent should be added (i.e., either ampicillin or cefotaxime), because vancomycin achieves low CSF concentration and has a substantially higher MBC against group B streptococci than that of ampicillin.

Once the bacteriologic diagnosis of group B streptococcal infection is known and the CSF of patients with meningeal infections 24 to 48 hours into therapy is shown to be sterile, treatment can be completed with penicillin G alone. Although the total duration of treatment is arbitrary, good outcomes have been noted when parenteral therapy is given for 10 days for bacteremia without a focus or with soft tissue infection, 2 to 3 weeks for meningitis or pyarthrosis,<sup>544</sup> and 3 to 4 weeks for osteomyelitis<sup>550</sup> or endocarditis<sup>5,720</sup> (see Table 13-11). Limited evidence suggests that a somewhat shorter course of therapy (6 to 7 days) may suffice for uncomplicated bacteremia, but additional data are needed to support a change in the current recommendations.<sup>721</sup> In the management of infants with meningitis, failure to achieve sterility suggests the presence of an unsuspected suppurative focus (subdural empyema, brain abscess, ventriculitis, septic thrombophlebitis) or failure to administer an appropriate drug in sufficient dosage. At the completion of therapy (minimum 14 days), another lumbar puncture should be considered to determine whether the CSF findings are compatible with adequacy of treatment or are of sufficient concern to warrant further treatment or further diagnostic evaluation. For example, polymorphonuclear cells in excess of 30% of the total or a protein concentration in excess of 200 mg/dL would merit additional investigation. These findings also can be observed in patients with a fulminant course manifested by severe cerebritis, extensive parenchymal destruction with focal suppuration, or severe vasculitis, or all three.

Infants with septic arthritis should receive at least 2 weeks of parenteral therapy; those with bone involvement require

3 to 4 weeks of therapy to optimize the chance for an uncomplicated outcome. Drainage of the suppurative focus is an adjunct to antibiotic therapy. In infants with septic arthritis excluding the hip or shoulder, needle aspiration of the involved joint on one occasion usually achieves adequate drainage.<sup>4,544,545,550</sup> With hip or shoulder involvement, immediate open drainage is warranted. For many infants with osteomyelitis, some type of drainage procedure, whether closed or open, is required for diagnosis because most patients have sterile blood cultures. Such procedures must be performed before or early in the course of antimicrobial therapy to ensure the successful isolation of the infecting organism.

With recurrent infection, three points should be considered. First, appropriate antimicrobial therapy fails to eliminate mucous membrane colonization with group B streptococci in up to 50% of infants.<sup>722</sup> Second, community exposure of the infant may result in colonization with a new strain that subsequently invades the bloodstream. Systemic infection in neonates does not result in protective levels of type-specific antibodies.<sup>420</sup> Therefore, even in the absence of an underlying immunologic abnormality or an unsuspected suppurative focus, recurrent systemic infections do occur. In this event, an evaluation to exclude underlying immune abnormality (e.g., HIV infection or hypogammaglobulinemia) should be considered. Most infants, however, will have no defined abnormalities. Therapy in those infants with recurrent infection need not be extended beyond that recommended by site of infection. Finally, although it is logical to suggest that colonization be eliminated, an efficacious regimen has not been identified. Rifampin has uniform in vitro activity against group B streptococci, but this agent is bacteriostatic. One small prospective study revealed that administration of oral rifampin (20 mg/kg per day for 4 days) to infants after completion of parenteral therapy eliminated mucous membrane colonization in some subjects.<sup>723</sup> Further study is needed to identify a means to eliminate colonization in infants who have invasive disease.

## Supportive Management

Prompt, vigorous, and careful supportive therapy is important to the successful outcome of most group B streptococcal infections. In neonates with early-onset disease accompanied by respiratory distress, the need for ventilatory assistance should be anticipated before onset of apnea, because its appearance can herald a poor outcome.<sup>245,277</sup> The early treatment of shock, often not suspected during its initial phase, when systolic pressure is maintained by peripheral vasoconstriction, is crucial. Persistent metabolic acidosis and reasonably normal color are characteristic of this early phase. Any indication of poor peripheral perfusion after initial attempts to achieve adequate volume expansion merits placement of a central venous pressure monitoring device and treatment with appropriate inotropic agents. This concept applies also to patients with late-onset meningitis. Fluid management should include packed red blood cell transfusions if anemia is significant. In patients with meningitis, effective seizure control is required to achieve proper oxygenation, to decrease metabolic demands, to prevent additional cerebral edema, and to optimize cerebral blood flow. Attention to the details of urine output and

electrolyte balance and osmolality is necessary to detect and manage the early complications of meningitis, such as inappropriate secretion of antidiuretic hormone and increased intracranial pressure. Such intense and careful supportive management requires treatment in an intensive care unit of a tertiary care facility.

Extracorporeal membrane oxygenation (ECMO) has been used as rescue therapy for neonates with overwhelming early-onset group B streptococcal sepsis. Hocker and associates<sup>724</sup> reported a retrospective study that compared conventional treatment and ECMO for neonates with early-onset disease. A fatal outcome occurred in three (11%) of 28 of infants in the conventional treatment group and in nine (17%) of 53 infants placed on ECMO. If only hypotensive neonates were considered, 13 of 15 ECMO patients survived, compared with 11 of 18 of those who received conventional treatment ( $P = .06$ ). The authors concluded that neonates with suspected early-onset sepsis in whom acidosis or hypotension develops should be considered for early referral to an ECMO center. Commenting on these results, LeBlanc<sup>725</sup> emphasizes the difficulty of interpreting this study, citing the retrospective design and the fact that the most ill infants die before ECMO can be initiated. He also stressed that fatal complications of ECMO, such as brain hemorrhage, can occur. Until a prospective, controlled trial is performed, ECMO therapy should be considered controversial.

### Adjunctive Therapies

Despite prompt initiation of antimicrobial therapy and aggressive supportive care, death and neurologic morbidity can result from group B streptococcal infection. Adjunctive therapy directed toward improvement of neonatal host defenses against group B streptococci has received considerable investigative effort. Reports indicating increases in mortality rate for neutropenic neonates prompted clinical evaluation of granulocyte transfusions as adjunctive therapy for early-onset group B streptococcal sepsis.<sup>362,466,726,727</sup> In three trials, 13 infants with neutrophil storage pool depletion (documented by bone marrow aspiration) were assessed.<sup>362,466,726</sup> The results seemed promising, but the logistics of providing timely transfusion and the concern for adverse effects (graft-versus-host reaction, transmission of viral agents, pulmonary leukocyte sequestration) make this mode of therapy impractical.

Recombinant human cytokine molecules stimulatory for granulocyte progenitor cells, namely, granulocyte colony-stimulating factor (G-CSF) and GM-CSF, are widely available. G-CSF promotes proliferation of granulocyte progenitors in bone marrow, enhances chemotactic activities and superoxide anion production, and increases expression of neutrophil C3bi receptors. Because many of these attributes might improve the limited bone marrow neutrophil reserve and the defective neutrophil functions in human neonates, several investigators have evaluated the use of these agents as adjunctive therapy in experimental infection. Taken together, these studies suggest that G-CSF or GM-CSF might be useful as adjunctive agents in the treatment of group B streptococcal neonatal sepsis, possibly when they are used in combination with intravenous immune globulin (IGIV).<sup>728-731</sup> Any clinical recommendations must await evaluation of their safety and efficacy in controlled clinical trials.

Another proposed therapy is human immune globulin modified for intravenous use to provide type-specific antibodies for more efficient opsonization and phagocytosis of group B streptococci.<sup>732-738</sup> IGIV has been shown in an animal model<sup>739</sup> and in septic neonates<sup>740</sup> to improve complement activation and chemotaxis by neonatal sera and to hasten resolution of neutropenia. Administration of sufficient human type-specific antibodies against capsular polysaccharides to animals before lethal challenge with group B streptococci of the homologous serotype is protective.<sup>427,732-736</sup>

Despite the sound theoretical basis on which use of IGIV as adjunctive therapy is based, several concerns remain. First, commercially available preparations contain relatively low concentrations of protective antibodies (directed at either protein or polysaccharide surface antigens),<sup>735-738,740-745</sup> suggesting that large doses would be required and raising concern for reticuloendothelial system blockade.<sup>734,737</sup> Second, the *in vitro* functional activity of the currently licensed globulins varies by method of preparation and by lot.<sup>733,734,740-746</sup> Third, the increase in type-specific antibodies after infusion may be only transient.<sup>741,747</sup>

Development of hyperimmune group B streptococcal globulin or of human-human monoclonal antibodies would theoretically circumvent many of these potential problems. Raff and co-workers<sup>748</sup> developed a human IgM monoclonal antibody specific for the group B cell wall polysaccharide. This antibody reacted with all group B streptococcal serotypes and was evaluated for safety and pharmacokinetics in two neonatal nonhuman primates.<sup>749</sup> Both it and a hyperimmune globulin<sup>744</sup> prepared by vaccination of healthy adults with polysaccharides from type Ia, Ib, II, and III group B streptococci were protective against experimental challenge with type I, II, and III strains in doses as low as 4 to 20 mg/kg.<sup>750</sup>

At present, any application of these intriguing experimental findings to the clinical setting is unclear. Clinical trials provide some insights. A prospective, multicenter, placebo-controlled trial included 753 neonates with birth weights from 500 to 2000 g receiving empirical treatment for possible sepsis; in 12, the causative agent was group B streptococci. Administration of IGIV at a dose of 500 mg/kg within 12 hours of birth was well tolerated and resulted in a survival rate for infants with group B streptococcal sepsis similar to that for placebo recipients. Christensen and colleagues<sup>751</sup> administered either IGIV (750 mg/kg) or albumin to 22 neonates with severe, early-onset sepsis. All infants survived. Eleven patients had neutropenia, but in IGIV recipients, this abnormality resolved within 24 hours of infusion, whereas it persisted in albumin (control) recipients. Each of the IGIV recipients had a significant elevation of immature to total neutrophil ratios 1 hour after infusion when compared with controls. The IGIV was considered to stimulate release of neutrophils into the circulation from bone marrow storage pools. It can be concluded that administration of IGIV in a single dose ranging from 500 to 750 mg/kg in neonates with clinical sepsis is safe and may provide some hematologic and immunologic benefit.

### PROGNOSIS

Despite the extensive investigation of group B streptococcal disease, a relative paucity of information exists concerning

the prognosis for infants surviving invasive neonatal infection. Several reports have assessed sequelae among survivors of meningitis, but these reports do not reflect outcome for infants who received intensive supportive care subsequent to improvements in such care since the late 1980s. In 1977, Haslam and associates<sup>522</sup> reported major neurologic sequelae in 2 of 15 survivors of meningitis. No differences were evident between survivors and sibling controls in tests of hearing, speech, or adaptive skills. In a prospective assessment of 20 survivors of early-onset meningitis treated between 1974 and 1982, 14 (70%) were considered to be normal.<sup>521</sup> Major handicaps were found in 15%, and three had mild cognitive impairments. Similarly, 50% of children assessed at a mean age of 6 years after surviving meningitis during the 1970s were functioning normally.<sup>523</sup> Another 29% had severe sequelae, including global mental retardation, cortical blindness, and spasticity. Among the 21% with mild or moderate sequelae, deficits such as borderline mental retardation, spastic or flaccid monoparesis, or language delay still permitted function at or near age-expected norms. In a study of 74 children who survived early- or late-onset group B streptococcal meningitis, 9 (12%) had major neurologic sequelae when evaluated at 3 to 18 years of age.<sup>535</sup> When these 9 children were excluded, there were no significant differences, as rated by parents, between the children with meningitis and their siblings for academic achievement, measures of intelligence quotient, fine motor dexterity, or behavior difficulties. These investigators concluded that “children not identified early, after appropriate examination, as having serious sequelae can be expected to perform intellectually, socially, and academically in a manner similar to other family members.”<sup>11,535</sup>

Several clinical scoring systems exist for predicting a fatal outcome with neonatal group B streptococcal infection.<sup>523,527,752</sup> Payne and colleagues<sup>527</sup> described a score, derived from five variables, that, together with an initial blood pH less than 7.25, enabled prediction of outcome accurately in 93% of infants with early-onset group B streptococcal infection. These features were birth weight less than 2500 g, absolute neutrophil count less than 1500 cells per mm<sup>3</sup>, hypotension, apnea, and a pleural effusion seen on the initial chest radiograph.

A fatal outcome can be predicted with reasonable accuracy, but little information is available concerning the long-term prognosis for survivors of neonatal group B streptococcal sepsis. One group at potential risk for sequelae consists of preterm infants with septic shock, who could develop periventricular leukomalacia. Among these survivors, substantial neurodevelopmental sequelae have been identified at evaluation during the second year of life. The correlates of severity and duration of shock with periventricular leukomalacia and with long-term morbidity from group B streptococcal disease have not been assessed, however.

## PREVENTION

Theoretically, early- and late-onset group B streptococcal disease could be prevented if susceptible hosts were not exposed to the microorganism or if exposure occurred in the setting of protective immunity. Several approaches to prevention have been advocated; conceptually, these are

directed at either eliminating exposure or enhancing host resistance—that is, chemoprophylaxis or immunoprophylaxis. Both strategies have limitations with respect to implementation, could be targeted for the prevention of maternal as well as neonatal infections, and are theoretically achievable.<sup>19,24,406,753</sup>

## Chemoprophylaxis

### Historical Precedents

Chemoprophylaxis as a method for preventing early-onset group B streptococcal infection was first suggested by Franciosi and colleagues in 1973.<sup>2</sup> Because vertical transmission was documented to be the prelude to early-onset disease, investigators proposed oral penicillin treatment for colonized women late in pregnancy to interrupt maternal exposure of the neonate at delivery. Group B streptococcal carriers were identified with third-trimester vaginal cultures; culture-positive women received oral antimicrobial agents for 1 to 2 weeks. Approximately 20% to 30% remained colonized at the end of therapy, and in nearly 70%, group B streptococci were isolated from vaginal cultures at delivery.<sup>149,754,755</sup> A suggested mechanism for treatment failure was reinfection of women by colonized sexual partners.<sup>2</sup> When colonized pregnant women and their spouses received concurrent treatment, 70% of women and 40% of their husbands remained infected after treatment.<sup>149</sup> Somewhat better results were reported by Lewin and Amstey,<sup>756</sup> who administered penicillin intramuscularly to colonized women in their third trimester of pregnancy and their husbands: Only 18% of women remained colonized at delivery. One explanation for failure of antimicrobial therapy to eliminate group B streptococcal colonization is the inherent difficulty of eradicating a constituent of the bowel flora even when high doses of intravenous penicillin G or ampicillin are employed.<sup>149</sup>

The next method evaluated in the attempt to prevent early-onset group B streptococcal neonatal infection by interrupting perinatal exposure was use of intravenously administered antibiotic in women during labor. Yow and colleagues<sup>757</sup> gave intravenous ampicillin (500 mg) at hospital admission to 34 third-trimester women colonized with group B streptococci. Ampicillin uniformly interrupted vertical transmission to the neonates of women who received treatment, contrasting with an expected rate of approximately 50%. This observation was confirmed by others.<sup>169,758-760</sup>

The first documentation that intrapartum chemoprophylaxis was effective in preventing early-onset neonatal disease as well as group B streptococcal-associated maternal morbidity was reported by Boyer and Gotoff in 1986.<sup>760</sup> Women colonized with group B streptococci who had risk factors for early-onset infection (delivery at less than 37 weeks of gestation, membrane rupture at 12 hours before delivery or earlier, or intrapartum fever) were randomized to receive routine care or intrapartum intravenous ampicillin. Group B streptococcal sepsis developed in 5 of 79 neonates born to women in the routine care group (one death), whereas each of the 85 infants born to women in the ampicillin treatment group remained well ( $P = .024$ ). Intrapartum ampicillin chemoprophylaxis for group B streptococcal carriers also resulted in reduced maternal morbidity.<sup>761</sup>

These and other data<sup>758,762-764</sup> established the efficacy of intrapartum chemoprophylaxis in group B streptococcal carriers identified antenatally in the prevention of early-onset neonatal disease and group B streptococcus-associated maternal morbidity. The cost effectiveness of this prevention method also has been validated.<sup>765-769</sup>

### **Rapid Assays for Antenatal Detection of Group B Streptococci**

There are inherent difficulties in determining group B streptococcal colonization status at hospital admission even when assays can be processed 24 hours a day. Several methods using cervical or lower vaginal swab specimens have been evaluated to rapidly ascertain the colonization status at hospital admission. When secretions from vaginal swabs are immediately extracted and tested for group B streptococcal antigen by LPA, the sensitivity ranges from 15% to 28% for all culture-positive women and from 57% to 67% for heavily colonized women; the specificity ranges from 95% to 99%.<sup>763,770-772</sup> The sensitivity of enzyme immunoassays ranges from 12% to 44% for all colonized women and from 36% to 100% for heavily colonized women; the specificity is 95% to 99%.<sup>771,773-776</sup> Thus, these assays have limited sensitivity to detect group B streptococcal carriers, especially among women with a small inoculum of organisms. Although attack rates for early-onset disease are significantly higher in neonates born to heavily colonized women, risk does exist for those born to lightly colonized women (approximately 1.0%).<sup>217,247,763,773</sup> If commercially available latex assays are positive, the result is highly reliable. An optical immunoassay (Strep B OIA test, Biostar, Boulder, Colo.) is more sensitive for detecting light (13% to 67%) and heavy (42% to 100%) or overall (81%) colonization and outperforms enzyme immunoassays in direct comparisons.<sup>776-780</sup> Assays using a DNA hybridization methodology have shown variable sensitivity.<sup>781,782</sup> None of these rapid tests is sufficiently accurate for routine use in the intrapartum detection of maternal colonization with group B streptococci. A bulletin from the Food and Drug Administration (FDA) in 1996 provided guidelines stipulating that antigen tests "cannot be relied upon to exclude group B streptococcal colonization in a pregnant woman. Negative group B streptococcal antigen test results should be confirmed using selective broth culture which is more sensitive than antigen tests."

A recent study evaluated a new rapid polymerase chain reaction (PCR) assay as an alternative screening tool for rapid identification of colonized women at admission for delivery.<sup>783</sup> The sensitivity of both a rapid and a conventional PCR assay was 97%, and the negative predictive value was 99%. Both the specificity and the positive predictive value were 100%. The time required to obtain results by the rapid PCR assay was 30 to 45 minutes. The test has now been licensed by the FDA, and although its performance in nonresearch settings awaits further study, a cost-benefit analysis suggests that its widespread implementation would afford benefit over the current culture-based strategy.<sup>784</sup>

### **Intrapartum Antimicrobial Prophylaxis**

The rationale for offering intrapartum antibiotic prophylaxis (IAP) to women who are antenatal culture positive for group

B streptococci evolved from two concerns. First, selective intrapartum chemoprophylaxis based on clinically identifiable maternal risk factors fails to prevent 25% to 30% of cases and about 10% of deaths.<sup>10,760,785</sup> These cases represent term infants born to women with no risk factors for early-onset infant disease except vaginal or rectal colonization. The number of cases missed by selective chemoprophylaxis diminishes if maternal risk factors are expanded to include premature rupture of membranes at any gestational stage,<sup>195</sup> asymptomatic bacteriuria caused by group B streptococci,<sup>251,504,786</sup> nongestational diabetes mellitus,<sup>10,786</sup> maternal age younger than 20 years, and black race.<sup>10,250,406</sup> Second, the pregnant woman informed that she carries a potential pathogen for her newborn often desires prophylaxis in the absence of risk factors, especially when she is told that a culture-based prevention approach is more effective than a risk factor-based approach in preventing neonatal infection.<sup>23</sup> Thus, one approach to the prevention of early-onset group B streptococcal sepsis in neonates through intrapartum maternal chemoprophylaxis is to target all colonized women. Garland and Fliegner<sup>762</sup> identified Australian vaginal carriers of group B streptococci at 32 weeks of gestation and gave intravenous penicillin G during labor to all culture-positive women. From 1981 to 1988, no cases of early-onset disease occurred in neonates born to culture-positive women given IAP.

For the prevention of early-onset disease, intrapartum maternal chemoprophylaxis should be administered at least 4 hours before delivery. This interval allows sufficient time to achieve concentrations of penicillin, ampicillin, or cefazolin in the fetal blood (an estimated 30 minutes) and the amniotic fluid (approximately 2 to 4 hours)<sup>787-789</sup> that are bactericidal for group B streptococci. Also, when high doses of penicillin G (5 million units), ampicillin (2 g), or presumably cefazolin are given intravenously 4 or more hours before delivery, vertical transmission is interrupted<sup>790</sup> and infant disease prevented. Intrapartum chemoprophylaxis has no known efficacy in the prevention of late-onset infant infection.

In 1992, the ACOG<sup>791</sup> and the AAP<sup>792</sup> published separate documents regarding maternal intrapartum chemoprophylaxis for the prevention of early-onset group B streptococcal infection. Both documents concurred that selective IAP prevented early-onset group B streptococcal disease and reduced maternal puerperal morbidity. Both concurred that preterm labor at less than 37 weeks of gestation, preterm premature rupture of membranes at less than 37 weeks of gestation, rupture of membranes at any gestation beyond 18 hours, fever during labor, and previous delivery of a sibling with invasive group B streptococcal disease enhanced risk for early-onset neonatal disease.<sup>793,794</sup> Whereas the ACOG technical bulletin<sup>791</sup> was educational, the AAP guidelines<sup>792</sup> were more directive. The latter recommended that if culture screening was performed antenatally, culture specimens from both lower vaginal and anorectal sites should be obtained, and that culture-positive women with one or more risk factors and group B streptococcal colonization should be given intrapartum intravenous penicillin G or ampicillin. The ACOG proposed that culture screening could be avoided by providing treatment for all women with risk factors. Neither approach was adequately implemented, and invasive disease rates remained unacceptably high.

**Figure 13-10** Incidence of early-onset (dark bars) and late-onset (light bars) group B streptococcal disease from 1993 to 2002. Data for 1993 and 1996 reflect aggregate disease rates from the state of Maryland, as well as from three counties in California, eight in Georgia, and five in Tennessee, which represent approximately 190,000 births annually. Data for 1999 and 2002 are from the Active Bacterial Core Surveillance (ABCS) Emerging Infections Program Network, which represents 425,404 children younger than 1 year of age. (Adapted from Schuchat A. Group B *Streptococcus*. *Lancet* 353:51-56, 1999; and data from the CDC National Center for Infectious Diseases website on group B streptococcal infection [<http://www.cdc.gov/ncidod/dbmd/abcs/surreports/gbs02.pdf>].)

In 1996, consensus guidelines for the prevention of early-onset group B streptococcal disease were published by the CDC, the ACOG, and the AAP.<sup>19-21</sup> These guidelines recommended that obstetric care providers and hospitals adopt a policy for group B streptococcal infection prevention based on one of two strategies, one culture-based and the other risk factor-based, to identify women who require IAP.<sup>19-21</sup> The culture-based approach employed the results of lower vaginal and rectal cultures obtained at 35 to 37 weeks of gestation to determine candidates for prophylaxis. Most women prefer self-obtaining of cultures, and there is a high correlation of patient-collected and of nurse-collected samples for accuracy.<sup>795,796</sup> Furthermore, pregnant women place a high priority on knowing their group B streptococcal colonization status.<sup>797</sup> The risk factor-based strategy favored by the ACOG identified IAP recipients by factors known to increase the likelihood of neonatal group B streptococcal disease: labor onset or membrane rupture before 37 weeks of gestation, intrapartum fever, and rupture of membranes 18 or more hours before delivery. In both strategies, women with previous delivery of an infant with group B streptococcal disease or with group B streptococcal bacteriuria during the current pregnancy always received IAP. These strategies each result in the administration of IAP to an estimated 25% of pregnant women.<sup>19</sup>

In association with active efforts to promote IAP in the 1990s, the incidence of early-onset disease declined by 70% from 1.7 per 1000 live births to 0.5 per 1000 live births by 1999 (Fig. 13-10) and remains stable.<sup>24,798</sup> For the years 1998 to 1999, an estimated 3900 to 4500 early-onset infections

and 200 to 225 neonatal deaths were prevented annually by the use of IAP.<sup>22,24</sup> By contrast, the rate of late-onset disease has remained constant at 0.5 to 0.6 per 1000 live births throughout the 1990s and into the 21st century. The incidence of invasive group B streptococcal disease among pregnant girls and women declined significantly (21%) with implementation of IAP, from 0.29 per 1000 live births in 1993 to 0.23 in 1998.<sup>22,24</sup>

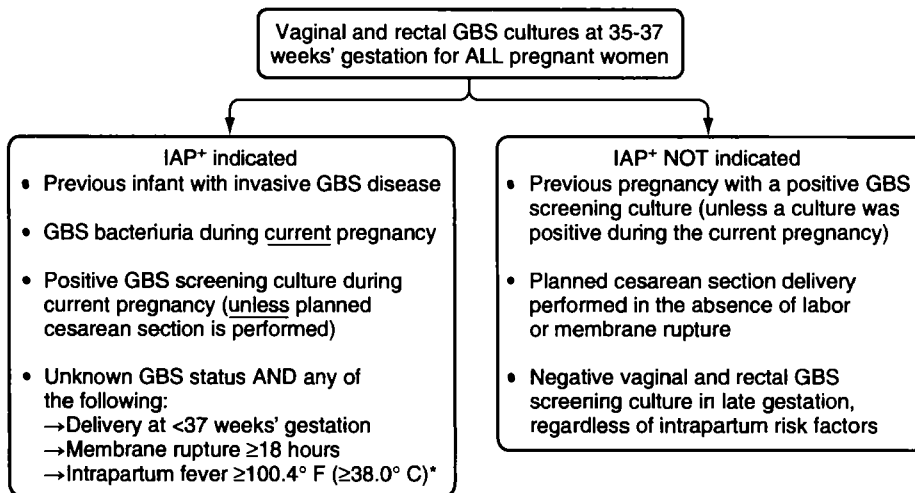

Surveys of physicians' practices have documented significant increases in the number of obstetric care providers who were screening at least 75% of pregnant women in their practices, and in the number of group B streptococcus-positive women who received IAP in the late 1990s.<sup>799-801</sup> Implementation of the consensus guidelines was associated with a reduction in the number and incidence of early-onset disease in a number of geographic regions in the United States and Canada.<sup>799,801-803</sup> By 1999, two thirds of U.S. hospitals in a multistate survey had a formal prevention policy, and a high number of individual practitioners had adopted policies.<sup>24,804</sup>

The proportion of disease theoretically prevented by the culture-based approach is higher (85% to 90%) than that using the risk factor-based approach (50% to 65%).<sup>19</sup> Group B streptococcal carriers without risk factors can be delivered of infants with early-onset disease, and approximately 45% of infants with early-onset disease are born to such women.<sup>785</sup> By 2002, it was evident that a further reduction in the incidence of early-onset disease could be accomplished only by adoption of universal culture screening. A direct comparison of the two methods in 5144 births demonstrated that culture screening was 50% more effective than a risk-based strategy in preventing early-onset disease in neonates.<sup>23</sup> Culture-based screening not only was more effective but was more often associated with administration of IAP more than 4 hours before delivery. The 2002 revised guidelines from the CDC for the prevention of perinatal group B streptococcal disease have been endorsed by the AAP and the Committee on Obstetric Practice of the ACOG.<sup>24,805,806</sup>

All pregnant women now should be screened in each pregnancy for group B streptococcal carriage at 35 to 37 weeks of gestation. The risk-based approach is not an acceptable alternative except in circumstances in which the culture results are not available before delivery. Culture specimens should be obtained from the lower vagina and the rectum using the same or two different swabs. These should be placed in a non-nutritive transport medium, incubated overnight in a selective broth medium, and subcultured onto 5% sheep blood agar medium for isolation of group B streptococci. At the time of labor or rupture of membranes, IAP should be given to all pregnant women identified as group B streptococcal carriers. The indications for IAP are shown in Figure 13-11. Delivery of a previous infant with invasive disease and group B streptococcal bacteriuria are always indications for IAP, and screening is not necessary for these women. If the results of culture are not known at the onset of labor, the risk factors listed in Figure 13-11 should be used to determine the need to institute IAP.

Planned cesarean section before rupture of membranes and onset of labor constitutes an exception to the need for IAP among women colonized with group B streptococci. These women are at low risk for having an infant with early-onset disease. Similarly, women documented to have negative

IAP<sup>+</sup> = Intrapartum antibiotic prophylaxis.

\*If chorioamnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS IAP.

**Figure 13-11** Revised recommendations for culture-based screening for maternal colonization with group B streptococci (GBS) and administration of intrapartum antibiotic prophylaxis (IAP). (Adapted from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC. MMWR Morb Mortal Wkly Rep 51[RR-11]:1-22, 2002.)

screening cultures for group B streptococci delivered at 37 weeks or later need not receive IAP routinely, even when a risk factor is present. Of course, therapeutic use of antibiotics in labor should be employed as is appropriate for maternal indications.

The current recommendations also include an algorithm for IAP for women with threatened preterm delivery.<sup>24</sup> If the results of screening cultures are not available and if onset of labor or rupture of membranes occurs before 37 weeks of gestation with a substantial risk for imminent preterm delivery, IAP should be provided pending culture results. For women who are culture positive, penicillin should be administered for a total of at least 48 hours, unless delivery occurs sooner. If tocolysis is successful, IAP should be reinitiated when labor that is likely to proceed to delivery occurs. If a negative culture result within the previous 4 weeks is on record, or if labor can be successfully arrested, IAP should not be initiated.

The recommended maternal intrapartum chemoprophylaxis regimen consists of penicillin G (5 million units initially and 2.5 million units every 4 hours thereafter until delivery).<sup>24</sup> Prophylaxis should be initiated as soon as possible, because penicillin given 4 or more hours before delivery prevents vertical transmission and early-onset disease more reliably than doses given at shorter intervals. Ampicillin administered as a 2-g intravenous loading dose and then 1 g every 4 hours until delivery is the alternative antimicrobial agent.<sup>24</sup>

Prophylaxis for penicillin-allergic women takes into account increasing resistance among group B streptococci to erythromycin and clindamycin. Women who are not at high risk for anaphylaxis should receive cefazolin, 2 g intravenously as an initial dose and then 1 g every 8 hours until delivery. When anaphylaxis to  $\beta$ -lactams is considered a risk, IAP can be based on the results of susceptibility testing for erythromycin and clindamycin, if available. Women with erythromycin- and clindamycin-susceptible isolates can be given either clindamycin (900 mg intravenously

every 8 hours) or erythromycin (500 mg intravenously every 6 hours until delivery). If susceptibility testing is not available or the results are not known, or when isolates are resistant to erythromycin and clindamycin, vancomycin 1 g intravenously every 12 hours until delivery is an alternative for women with immediate penicillin hypersensitivity.

The risk of anaphylaxis from administration of penicillin is low. Estimates range from 4 events per 10,000 to 4 per 100,000 recipients. There are reports of anaphylaxis associated with administration of a penicillin as IAP for the prevention of early-onset group B streptococcal infection.<sup>23,807-809</sup> No fatalities in association with IAP have been reported, and the risk of a fatal event is low, because the antimicrobials are administered in a hospital setting, in which intervention is readily available.

A number of residual problems, barriers to implementation, and missed opportunities remain that must be overcome to achieve the maximal benefit from IAP.<sup>810-812</sup> Procedural issues such as suboptimal culture techniques and collection of cultures earlier than 5 weeks before delivery constitute one set of barriers. Socioeconomic barriers also remain. Women who are not screened adequately are more likely to be in their teens. Blacks and Hispanics are more likely than whites to receive inadequate prenatal care and prenatal testing and are less likely to receive recommended prevention interventions. Increased awareness of perinatal group B streptococcal infection is needed. In one report, only 47% of women younger than 50 years of age reported ever having heard of group B streptococci.<sup>813</sup> Women with a high school education or less, low household income, or reporting black, Asian/Pacific Islander, or "other" race had lower awareness than that noted in other women. Efforts to raise awareness should target women from groups that traditionally are underserved in the health care system. Hospital infection control teams also can contribute to these efforts by spearheading educational efforts to effective implementation among hospital staff and laboratory personnel.<sup>814</sup>

### **Impact of Intrapartum Antibiotic Prophylaxis on Neonatal Sepsis**

The efficacy of IAP in preventing early-onset group B streptococcal infection has been shown in a number of observational studies and in countries other than the United States when guidelines have been implemented.<sup>23,518,815-817</sup> The impact of increased use of IAP on the occurrence of sepsis caused by organisms other than group B streptococci is a subject of ongoing evaluation. Concern has been raised that neonatal sepsis caused by organisms other than group B streptococci may be increasing while group B streptococcal sepsis is decreasing and that the organisms causing non-group B streptococcal sepsis are more likely to be ampicillin resistant.<sup>818</sup> Reports that document such increases have found that they are restricted to preterm or low-birth-weight infants.<sup>819</sup> Among multicenter studies of the incidence of neonatal sepsis, a significant increase in the rate of early-onset sepsis caused by *E. coli* has been observed, but only infants of very low birth weight were evaluated.<sup>820</sup> In another multisite surveillance of trends in incidence and antimicrobial resistance of early-onset sepsis, stable rates of sepsis caused by other organisms were found, but an increase in ampicillin-resistant *E. coli* was observed among preterm but not term infants.<sup>821</sup>

A relationship between neonatal death caused by ampicillin-resistant *E. coli* and prolonged antepartum exposure to ampicillin was noted by Terrone and colleagues.<sup>822</sup> The frequency with which ampicillin-resistant Enterobacteriaceae were isolated, however, was similar after exposure to ampicillin to that after exposure to penicillin in another report.<sup>823</sup> Repeat cultures at 6 weeks post partum revealed no increase in antibiotic resistance in either group B streptococci or *E. coli* from women who had received antibiotics in labor.<sup>824</sup> To date, no causal link has been demonstrated between IAP and increasing numbers of infections caused by *E. coli* or ampicillin-resistant gram-negative sepsis among low-birth-weight neonates.<sup>825</sup> Fluctuations in the incidence of non-group B streptococcal sepsis and in the annual incidence of ampicillin-resistant infections indicates that ongoing population-based surveillance will be needed to monitor these trends and to identify possible reasons for the increase in ampicillin-resistant *E. coli* infections in preterm neonates.<sup>826,827</sup>

### **Management of Neonates Born to Mothers Receiving Intrapartum Antimicrobial Prophylaxis**

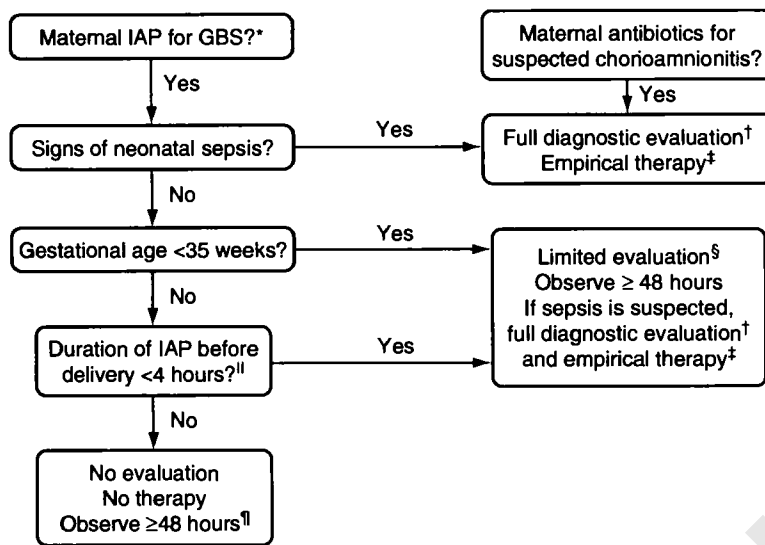

Management of the infant born to a mother given intrapartum chemoprophylaxis is based on the infant's clinical status and gestational age as well as the duration of maternal chemoprophylaxis before delivery (Fig. 13-12).<sup>24</sup> If a woman receives IAP for suspected chorioamnionitis, her infant should have a full diagnostic evaluation and empirical therapy pending culture results regardless of the clinical condition at birth, gestational age, or duration of IAP before birth. This approach is based on the infant's exposure to suspected established infection. If the infant has signs of infection at or shortly following birth, full diagnostic evaluation including a complete blood cell count and differential, blood culture, and chest radiograph (if the neonate has respiratory signs) is indicated. A lumbar puncture, if feasible, also should be performed. A minimum of 10% to 15% of infants with meningitis will have a negative blood culture.<sup>661</sup> If lumbar

puncture is deferred and therapy is continued for more than 48 hours because of suspected infection, CSF should be obtained for routine studies and culture. Empirical therapy for neonatal sepsis then is initiated. The duration of therapy is based on results of cultures and the infant's clinical course (see "Treatment" section). If the infant is healthy in appearance but has a gestational age of less than 35 weeks, a limited evaluation, including complete blood count and a blood culture, is performed without regard to the duration of maternal chemoprophylaxis. Empirical therapy need not be initiated unless signs of sepsis develop or the infant is very immature. Healthy-appearing infants with a gestational age of 35 weeks or more whose mothers received intravenous penicillin, ampicillin, or cefazolin less than 4 hours before delivery also should be evaluated and observed closely. If the infant is healthy, has a gestational age of 35 weeks or more, and has a mother given penicillin, ampicillin, or cefazolin 4 hours or more before delivery, then neither a diagnostic evaluation nor empirical antimicrobial therapy is recommended. The recommended observation interval for neonates undergoing a limited evaluation is 48 hours. The approach presented in Figure 13-12, however, is not an exclusive management pathway. Hospital discharge as early as 24 hours of age may be reasonable under certain circumstances, specifically when the infant is born after 4 or more hours of maternal  $\beta$ -lactam IAP, has a gestational age of 38 weeks or more, and is healthy-appearing. Other discharge criteria should be met, and the infant should be under the care of a person able to comply with instructions for home observation.<sup>24,828</sup> The risk of bacterial infection in healthy-appearing newborns is low. Outcomes among infants whose mothers receive IAP are better than among those whose mothers do not. Rehospitalization is uncommon among these infants.<sup>829</sup>

The influence of maternal IAP on the clinical spectrum of early-onset infection in term infants has been evaluated.<sup>829-831</sup> Exposure to antibiotics in labor does not change the clinical spectrum of disease or the onset of clinical signs of infection within 24 hours of birth for infants with early-onset group B streptococcal infection. Infants whose mothers have received IAP are less likely to be ill, to require assisted ventilation, or to have bacterial infection.<sup>829</sup> These infants are not more likely to undergo invasive procedures or to receive antibiotics.<sup>830</sup> The number of infants undergoing evaluation for sepsis has decreased in association with implementation of IAP guidelines, and among group B streptococcus-negative women, ordering of laboratory tests has diminished by almost 40%.<sup>800</sup>

### **Chemoprophylaxis for the Neonate**

Chemoprophylaxis for neonates at birth continues to be advocated by some investigators. Three decades ago, Steigman and associates<sup>832</sup> found no cases of early-onset group B streptococcal infection among 130,000 newborns who received a single intramuscular injection of penicillin G (50,000 units) at birth as prophylaxis for gonococcal infection. Neonates with possible in utero acquisition of infection (those ill at birth) did not receive prophylaxis and were excluded from the analysis. Pyati and co-workers<sup>833</sup> evaluated over 1000 neonates with birth weights of less than 2000 g in whom a blood culture was obtained before penicillin was administered. In these high-risk infants, penicillin prophylaxis at

- \* If no maternal IAP for GBS was administered despite an indication of being present, data are insufficient on which to recommend a single management strategy.
- † Includes complete blood cell (CBC) count and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.
- ‡ Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings, if obtained, and clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.
- § CBC with differential and blood culture.
- ¶ Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens.
- ¶¶ A healthy-appearing infant who was  $\geq 38$  weeks' gestation at delivery and whose mother received  $\geq 4$  hours of IAP before delivery may be discharged home after 24 hours IF other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

**Figure 13-12** Recommended management of newborn infants exposed to maternal intrapartum antibiotic prophylaxis (IAP) for group B streptococcal (GBS) infection. (Adapted from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC. *MMWR Morb Mortal Wkly Rep* 51[RR-11]:1-22, 2002.)

birth was not effective in preventing group B streptococcal bacteremia or in altering the mortality rate associated with infection.

A few centers employ a combined maternal and neonatal protocol that consists of a risk-based maternal IAP approach combined with a single dose of intramuscular penicillin given to all infants within 1 hour of birth.<sup>834,835</sup> This policy is based on uncontrolled observational studies showing declines in early-onset group B streptococcal disease coincident with a policy of universal administration of penicillin to all infants.<sup>836</sup> A 76% reduction in early-onset infection has been noted, to 0.47 per 1000 live births, when the infection rate for the 5 years from 1986 to 1994 was compared with that from 1994 to 1999.

A special circumstance merits consideration for infant chemoprophylaxis: the non-affected sibling in a twin or multiple birth with early-onset<sup>407,408</sup> or late-onset<sup>408</sup> group B streptococcal disease. In this situation, the infant sibling of a neonate with invasive infection has a 25-fold increased risk of developing group B streptococcal disease. At the time of diagnosis of group B streptococcal disease in one infant of a multiple birth, the other infant or infants should be clinically evaluated.<sup>408</sup> If any sign of infection is noted, culture samples of blood and CSF are obtained, and

empirical antimicrobial treatment is initiated and continued until cultures have been sterile for 48 hours. Obviously, if cultures are positive, a full course of treatment is recommended. If findings on the initial clinical evaluation are unremarkable, management should be individualized. The high incidence of infection in both twins and the poor outcome noted when the second twin was not evaluated until the onset of clinical signs of infection merit caution in this circumstance. Even when empirical therapy is given and invasive infection excluded, later onset is possible.<sup>837</sup>

### Immunoprophylaxis

The most promising and potentially lasting method for prevention of early- and late-onset infant infections as well as maternal infectious morbidity is immunoprophylaxis.<sup>406,753</sup> The underlying principle is that serum IgG directed against the type-specific capsular polysaccharide of group B streptococci, critical for protection against invasive group B streptococcal disease, is provided by passive or active immunization. Human sera containing sufficient amounts of type III-specific antibody has been demonstrated to be protective against lethal challenge in animal models of infection.<sup>838</sup> Studies of the other serotypes also

indicate the importance of type-specific antibody in protection.<sup>425-429,839,840</sup> Provision of protective levels of type-specific immunity to the newborn theoretically may be achieved through passive or active immunization of the mother. Passive immune therapy for the mother would require development of hyperimmune preparations of human immune globulin for intravenous use, but animal studies indicate the potential usefulness of such an approach.<sup>727,841</sup>

The first candidate group B streptococcal vaccine, a purified type III capsular polysaccharide, underwent initial testing in healthy adults in 1978.<sup>440</sup> Subsequently, type Ia and type II capsular polysaccharides were studied.<sup>842</sup> Although these vaccines were well tolerated and elicited primarily IgG class response within 2 weeks, the immunogenicity was variable. It was discovered that nearly 90% of adults had very low preimmunization serum concentrations of capsular polysaccharide-specific antibodies in association with presumed immunologic naïveté. These low levels predicted a poor immune response in many, so that only 40% and 60% developed significant type-specific antibody responses after immunization with type Ia and type III polysaccharides, respectively. By contrast, 88% of those immunized with type II polysaccharide responded.

These early trials verified the feasibility of immunization as an approach to prevent group B streptococcal disease and revealed the need to develop candidate vaccines with enhanced immunogenicity. The first study conducted in pregnant women was an encouragement to the ultimate potential success of a group B streptococcal vaccine program.<sup>464</sup> Among 25 pregnant responders to a type III group B streptococcal polysaccharide vaccine, 90% delivered infants with substantial levels of specific antibody to the type III capsular polysaccharide in cord sera that promoted functional activity *in vitro* throughout the first 3 months of life in most.

Development of the first group B streptococcal conjugate vaccine, type III polysaccharide-tetanus toxoid, was driven by the prominence of type III among infant early- and late-onset disease-causing isolates, and by its dominance as a cause of meningitis. The type III polysaccharide was linked covalently to monomeric tetanus toxoid by reductive amination coupling chemistry.<sup>843</sup> Group B streptococcal capsular polysaccharide-protein conjugate vaccines of all clinically important serotypes subsequently were produced and found to be immunogenic and protective in experimental animals.<sup>843-849</sup> In the first clinical evaluation of the type III conjugate, greater than fourfold rises were achieved in 90% of healthy nonpregnant women who received the conjugate vaccine.<sup>850</sup> The vaccine was well tolerated, and the antibodies, predominantly of the IgG class, were functional *in vitro* and protective in a murine model of infection.

Since 1996, conjugate vaccines to each of the clinically relevant group B streptococcal serotypes causing invasive disease have been developed and tested in nearly 500 healthy adults 18 to 50 years of age.<sup>850-853</sup> Systemic responses, such as low-grade fever, chills, headache, or myalgias, which were short-lived, have been observed in less than 2% of these volunteers. Immune responses to each of the conjugate vaccines, with the exception of type V, are dose dependent. Doses of 4 to 15 µg of the capsular polysaccharide component have elicited greater than fourfold increases in capsular

polysaccharide-specific IgG in 80% to 93% of recipients of type Ia, Ib, II, III and V conjugates at 8 weeks after immunization. Preliminary evaluation of a vaccine combining type II and type III capsular polysaccharide, each conjugated to tetanus toxoid, have shown no immune interference when compared with response following administration of the monovalent vaccine.<sup>854</sup>

As with the uncoupled purified polysaccharide, a phase I randomized placebo-controlled, double-blinded trial of type III capsular polysaccharide-tetanus toxoid conjugate vaccine has been conducted in 30 women at 30 to 32 weeks of gestation.<sup>855</sup> Immunization was well tolerated. Geometric mean concentrations of IgG antibody to type III capsular polysaccharide from immunized women were significantly increased from preimmunization values and correlated well with infant cord values. Sera from the infants of vaccinated women collected at 1 and 2 months of age promoted *in vitro* opsonization and killing of type III group B streptococci by neutrophils.

One alternate strategy for the preparation of group B streptococcal conjugate vaccines is to construct “designer” glycoconjugate vaccines with size-specific antigens and site-controlled coupling that optimizes the magnitude and specificity of the antipolysaccharide response.<sup>856</sup> An oligosaccharide-based tetanus toxoid conjugate vaccine against type III group B streptococci was synthesized to retain the antigenic specificity of the native polysaccharide and has been shown to be immunogenic in mice.<sup>857</sup> Conjugate size, polysaccharide size, and the degree of polysaccharide-protein cross-linking all are important considerations in optimizing immunogenicity of candidate vaccines.<sup>858</sup>

Use of proteins that are conserved across most group B streptococcal serotypes offers another vaccine development strategy. The C protein may be a promising alternative to tetanus toxoid as the protein component of a conjugate vaccine.<sup>840,847,859</sup> A type III polysaccharide-C protein conjugate vaccine theoretically could prevent a majority of systemic infections.<sup>12</sup> The group B streptococcal surface proteins Rib, Sip, and C5a peptidase each have been shown to elicit antibodies that are protective in experimental models of group B streptococcal infection.<sup>860-862</sup>

Because a majority of women have low concentrations of type-specific antibody in their sera, the most practical approach for future immunoprophylaxis is active immunization of all women of childbearing age, either before or later in pregnancy (i.e., early third trimester) or perhaps at the time of adolescent vaccinations.<sup>753</sup> Furthermore, in view of the substantial disease burden in nonpregnant adults, especially those with diabetes mellitus or age 65 or more years, targeted adult immunization is an attractive prevention strategy. Taken together, type Ia, type III, and type V group B streptococci now account for 75% to 85%, and five serotypes (Ia, Ib, II, III, and V), for nearly 100% of disease in infants and adults.<sup>12,162,863,864</sup> The production of a trivalent or a pentavalent conjugate is technically achievable. Physicians and their patients *and* pharmaceutical industry leaders must perceive this mode of prevention to be of high benefit and negligible risk, especially if pregnant women are to be the target population. The cost of developing suitable vaccines, although substantial, is considerably less than that of loss of life and of treating these infections and, for some infants, their lifelong sequelae.<sup>766,769</sup> If the prevention of group B

streptococcal disease is to become a reality, however, obstetricians, pediatricians, public health officials, parents, and legislators must join together as advocates for the pregnant woman, her neonate, and high-risk adults.

*Listeria monocytogenes* is a gram-positive, motile bacterium and a frequent veterinary pathogen that causes abortion and meningoencephalitis in sheep and cattle. Infection in a wide variety of other mammals is recognized. Uncommon in humans, listeriosis has potential for significant morbidity and mortality and occurs most frequently in the neonatal period, during pregnancy, and in elderly or immunosuppressed patients. Nyfeldt described "*Listerella hominis*" as the cause of human infectious mononucleosis in 1929,<sup>1</sup> but later descriptions indicate that human disease parallels that found in animals, with sepsis and meningoencephalitis occurring most commonly.

Murray and co-workers provided the first adequate description of the organism in 1926.<sup>2</sup> An epizootic among laboratory rabbits and guinea pigs provided an isolate, subsequently named *Bacterium monocytogenes*. The clinical characteristics were of dramatic wasting, lack of appetite, and lethargy leading to death. The greatest incidence and

mortality rates were for newborn animals that had recently been weaned. Later, Pirie isolated the organism from South African gerbils and called it *Listerella hepatolytica*, in honor of Lord Lister.<sup>3</sup> Pirie subsequently revised the name to *Listeria monocytogenes*, the currently accepted species name.<sup>4</sup>

## THE ORGANISM

### Morphology

The morphology of *L. monocytogenes* varies with the age of the culture. In clinical specimens, Gram stains typically demonstrate short intracellular and extracellular gram-positive rods. Over-decolorized direct examinations may lead to a misdiagnosis of *Haemophilus influenzae* meningitis.<sup>5</sup> On primary culture, early bacterial growth may have a slightly pointed coccoid morphology with short chains occasionally seen. Older cultures may be gram variable.

### Motility

All strains of *L. monocytogenes* are motile, distinguishing the organism from *Erysipelothrix* and most species of *Corynebacterium*. A characteristic tumbling motility is seen in hanging drop preparations of primary cultures grown at room temperature.<sup>6</sup> Tubes of semi-solid motility medium produce a distinctive umbrella pattern at room temperature when inoculated with the stab technique. Electron microscopic studies and protein electrophoresis have demonstrated that *L. monocytogenes* fails to express flagellar protein at 37° C.<sup>7</sup>

### Culture and Identification

*L. monocytogenes* grows well on common media, including brain-heart infusion, trypticase soy, and thioglycollate broths. Primary isolation from normally sterile sites can be made on blood agar. Growth occurs between 4° C and 37° C, with fastest growth rates occurring between 30° C and 37° C. Selective media, such as Oxford, modified Oxford, or PALCAM agar, should be used for isolation from contaminated specimens, and they have largely replaced cold-enrichment techniques.<sup>8,9</sup>

After 48 hours at 37° C on 5% sheep blood agar, colonies are 0.2 to 1.5 mm in diameter. Narrow zones of  $\beta$ -hemolysis may often be visualized only by moving the colony. *Listeria seeligeri* and *Listeria ivanovii* are also  $\beta$ -hemolytic but non-pathogenic in humans. Speciation is aided by performance of the CAMP test using *Staphylococcus aureus* for *L. monocytogenes* and *L. seeligeri* and *Rhodococcus equi* for *L. ivanovii*.<sup>10</sup>

Discrimination between *Listeria* species is aided by sugar fermentation patterns. *L. monocytogenes* produces acid from L-rhamnose and  $\alpha$ -methyl-D-mannoside but not from

xylose. *L. ivanovii* and *L. seeligeri* produce acid from D-xylose only. Automated systems, commercial biochemical strips, and DNA probes are available to aid in the identification for clinical microbiology laboratories.

### Antigenic Structure and Typing Systems

Thirteen serotypes of *Listeria* have been described and are distinguished on the basis of somatic (O) and flagellar (H) antigens.<sup>11,12</sup> Serotypes 1/2a, 1/2b, and 4b are responsible for most animal and human disease. Determining serotypes has no impact on clinical management but has a public health role in epidemiologic investigations. A commercial kit for serotyping *Listeria* has become available (Denka Seiken, Tokyo, Japan).

Before the advent of molecular methods, phage typing with an international bacteriophage set was used for epidemiologic investigations.<sup>13,14</sup> It proved useful in tracing sources of foodborne outbreaks of *Listeria* when serotyping failed to discriminate between epidemic and nonepidemic strains.<sup>14,15</sup> Some strains remained nontypeable, however, and phage typing has largely been replaced by molecular methods.

Molecular typing methods have provided investigators with new levels of discriminatory power. Multilocus enzyme electrophoresis (MLEE), although not directly DNA based, has proved reliable in distinguishing strains based on electrophoretic mobility of enzymes.<sup>16</sup> MLEE is limited, however, by the failure of many nucleotide and amino acid changes to alter net enzyme charge and hence electrophoretic mobility.<sup>17,18</sup>

Analysis of *Listeria* DNA and RNA is now the gold standard for strain typing.<sup>19,20</sup> One approach is generating restriction endonuclease and the creation of microrestriction patterns by using high-frequency-cutting enzymes. The technique has been used successfully in epidemiologic investigations, but its complex results can make strain comparison difficult. Ribotyping simplifies this by examining only DNA fragments from the ribosomal genes.<sup>17</sup> The automation of ribotyping into commercially available systems (RiboPrinter, Qualicon, Wilmington, Del) has enabled rapid identification of disease clusters and immediate typing of *Listeria* detected in food processing centers.

DNA macrorestriction pattern analysis using pulsed-field gel electrophoresis (PFGE) has become the method adopted by the World Health Organization (WHO) for standardizing international typing.<sup>12</sup> It is a highly discriminating and reproducible method—even for serotype 4b, which is poorly typed by most other methods. The Centers for Disease Control and Prevention (CDC) in the United States have created PulseNet, a network of laboratories using standardized PFGE protocols to subtype foodborne bacterial pathogens. Using the Internet for reporting and comparing PFGE patterns, laboratories are able to identify regional or national clusters that could be missed with localized reporting.

DNA amplification-based typing methods such as random amplification of polymorphic DNA (RAPD) have been shown to have a high degree of discriminatory power. The primary drawback is the lack of standardization. The combination of DNA amplification with automated sequencing provides ultimate discrimination—to the nucleotide level—but is not available on a widespread basis.

### Virulence Factors

Foodborne outbreaks of *L. monocytogenes* infections have precipitated an intense interest in organism-specific virulence factors to determine the pathogenesis of infection. As the steps are characterized, *L. monocytogenes* has become a paradigm for intracellular parasitism. A review of virulence factors summarizes the progress made.<sup>21,22</sup>

Entry into host cells occurs by engulfment within a phagosome and involves several key bacterial proteins. The internalin (InI) family of bacterial surface proteins mediate attachment to mammalian cells.<sup>23,24</sup> InIA, an 80-kDa protein, promotes internalization of bacteria by normally nonphagocytic intestinal epithelial cells. Its glycoprotein receptor, E-cadherin, is present on the surface of host cells known to be potential targets for *Listeria*: intestinal epithelial cells, brain microvascular endothelial cells, hepatocytes, and epithelial cells lining the choroid plexus and placental chorionic villi. Lecuit and colleagues<sup>25</sup> identified a proline residue in E-cadherin that mediates species specificity—the first potential molecular explanation of bacterial-host species specificity. InIB, a 67-kDa protein, has two receptors, Met and gC1q-R (a cellular ligand for the C1q complement fraction) that confer a tropism for hepatocytes and brain microvascular epithelial cells. A third protein, invasion-associated protein (iap or p60), with a molecular mass of 60 kDa, is secreted by invasive *Listeria* strains and is a major antigen in the protective response against *L. monocytogenes*.<sup>26,27</sup>

Invasive strains of *L. monocytogenes* produce listeriolysin O (LLO), a sulfhydryl-activated hemolysin similar to streptolysin O. Nonhemolytic mutants display a loss of virulence in animal models.<sup>28</sup> Listeriolysin O (*hly* gene) lyses phagosomes, releasing *Listeria* into the cytosol, where it begins intracellular growth.<sup>29,30</sup> Once in the cytosol, the bacterial surface protein ActA—product of the *actA* gene—triggers polymerization of host cell actin, enabling intracellular movement and cell-to-cell spread.<sup>30-32</sup>

*L. monocytogenes* also produces phospholipase C (*plcA* gene) and a lecithinase (*plcB* gene), which contribute to lysis of the primary phagosome and secondary phagosomes formed during cell-to-cell spread. Mutations of the *plcA* and *plcB* genes reduce virulence.<sup>24,34</sup> A metalloprotease encoded by the gene *mpl* converts lecithinase into its active form.<sup>35</sup>

The regulatory gene, *prfA* (positive regulatory factor A), controls expression of *hly* and *plcB* through PrfA, its protein product.<sup>36</sup> PrfA is the main switch of a regulon containing most of the virulence genes in *Listeria*. It promotes expression of certain genes (*hly*, *plcB*) and downregulates others (the motility-associated genes *motA* and *flaA*),<sup>37</sup> implying a global regulatory role.<sup>38</sup> PrfA/*prfA*-induced regulation is influenced by the bacteria's physicochemical environment. Thermoregulation is one example. PrfA-dependent transcription is minimal below 30°C (environmental temperature) but is induced at 37°C (body temperature of mammals).<sup>39,40</sup>

Other putative virulence factors include stress response mediators; a set of conserved proteins that upregulate after exposure to thermal stress, acidic pH, toxic molecules, and various stimuli that threaten survival.<sup>41,42</sup> They may play a role in repair and removal of damaged bacterial proteins, enabling adaptation to hostile conditions. In animal models, acid-adapted *Listeria* have enhanced survival in low gastric pH, resulting in higher bacterial loads in the intestine and

mesenteric lymph nodes after oral infection.<sup>43,44</sup> The monocytosis initially observed in animals infected with *L. monocytogenes* has been partially explained. A phospholipid, monocytosis-producing agent (MPA) that produces monocytosis in rabbits, has been isolated.<sup>45</sup> Monocyte production is stimulated by an endogenous mediator induced by MPA.<sup>46</sup>

## EPIDEMIOLOGY AND TRANSMISSION

### Natural Reservoir and Human Transmission

*Listeria* species are ubiquitous in nature and can be isolated from diverse environmental sources including a variety of foods, soil, water, and feces of humans and animals. The natural habitat of the organism is in decaying plant matter.<sup>47</sup> Spoiled silage appears to be a source of infection for ruminant animals.<sup>48</sup> Fecal carriage of *L. monocytogenes* in animals probably plays a key role in the organism's persistence by providing an enrichment cycle through ingestion of contaminated silage.

Although direct transmission of *L. monocytogenes* to humans and veterinarians from infected animals has been described,<sup>49-50</sup> almost all human cases of infection are acquired through ingestion of contaminated food.<sup>51,52</sup> In the early and mid-1980s, large outbreaks of *L. monocytogenes* infection occurred in pregnant women and immunocompromised hosts. The first outbreak, reported from Canada,<sup>15</sup> suggested indirect transmission from an animal reservoir. In this outbreak, *Listeria*-contaminated sheep manure was used to fertilize cabbage, which was placed in cold storage over the winter; clinical disease developed in pregnant women and immunocompromised patients who subsequently consumed the cabbage. Large outbreaks caused by contaminated dairy products were first reported in the 1950s and continue to occur in North America and Europe.<sup>53-55</sup> The relative resistance of *Listeria* to high temperatures and its ability to multiply at low temperatures provide opportunities for heavy contamination of dairy products if pasteurization has been done improperly.<sup>54,56</sup> In recent years, outbreaks have been more commonly associated with prepared meat products, including deli meats, pâté, and hot dogs,<sup>57-61</sup> and occasionally seafood.<sup>62</sup>

Whether outbreaks are related to a high inoculum of *L. monocytogenes* in food or enhanced virulence of the epidemic strain is unknown. Host susceptibility appears to be constant in the population, although Schwartz and associates<sup>63</sup> have proposed that other gastrointestinal pathogens might be a predisposing factor in translocation of *L. monocytogenes* from the intestine and development of disseminated disease.

The improved ability to culture *L. monocytogenes* with selective media has offered the opportunity to examine food eaten by patients who have developed sporadic cases of listeriosis.<sup>64</sup> However, proof that most cases of sporadic listeriosis are caused by ingestion of contaminated foodstuffs was not confirmed until studies in the United States by the Listeriosis Study Group at the CDC clearly demonstrated this relationship.<sup>65,66</sup> These studies implicated undercooked chicken and soft cheeses as significant sources of sporadic disease. The conclusion is supported by sampling surveys carried out by regulatory agencies. A review of foodborne listeriosis has been published.<sup>54,67</sup>

### Occurrence

*L. monocytogenes* causes an estimated 2500 serious illnesses and 500 deaths annually in the United States. Active surveillance programs in several countries have suggested an annual incidence of 0.4 to 0.7 cases per 100,000 people.<sup>68,69</sup> Slightly lower figures have been reported from Australia,<sup>70</sup> England,<sup>71</sup> and Denmark.<sup>72</sup> However, these studies relied on passive reporting programs. *L. monocytogenes* may cause symptomatic gastroenteritis, a nonreportable condition. Fecal carriage of listeriosis is uncommon but may be as high as 26% in household contacts of patients with listeriosis.<sup>73</sup> In the Canadian outbreak, fecal surveys demonstrated carriage rate in approximately 5% of family contacts.<sup>15</sup> During another outbreak carriage rates in the community were approximately 8%.<sup>74</sup>

The distribution of serovars causing disease may not be uniform. In the United States, serovars 4b and 1/2 account for 95% of strains, with serotype 4b being the most common overall. In Canada, serovar 1/2b occurred in 42% of clinical isolates.<sup>75</sup> In Spain and Germany, serovar 4b was predominant.<sup>76,77</sup> The significance of these geographic differences is unknown.

The incidence in the United States for neonatal listeriosis is estimated at 13 per 100,000 livebirths. This represents approximately one third of the total caseload in humans.<sup>68</sup> Two forms of neonatal listeriosis can occur: perinatal and nonperinatal listeriosis. The incidence of perinatal disease reported from other countries is similar.<sup>76-78</sup> However, the true incidence is probably much higher because abortion and stillbirth due to *Listeria* are largely unrecognized unless bacterial cultures are obtained from tissue. Epidemics of foodborne listeriosis have disproportionately involved perinatal cases. It is possible that lower inocula are needed to infect pregnant women compared with the general population. No differences in carriage rates between pregnant women and nonpregnant individuals have been found in fecal and vaginal specimens.<sup>79</sup> Fecal carriage may lead to vaginal colonization and be responsible for the development of late-onset infection in infants born of healthy mothers.

Two thirds of cases of listeriosis occur in immunocompromised adults, in whom sepsis and meningitis are the most frequent presenting illnesses.<sup>69</sup> Louria and co-workers<sup>80</sup> initially described this infection in patients with malignancies, but many other conditions have been reported in association with invasive listeriosis.<sup>81,82</sup> Susceptibility in laboratory animals is increased by the administration of corticosteroids,<sup>83</sup> cyclosporine,<sup>84</sup> and prostaglandins,<sup>85</sup> and the human experience parallels these studies. Renal transplantation appears to be a particularly significant risk factor, and a nosocomial outbreak has been reported in this population.<sup>86</sup> Hemochromatosis with increased iron stores may also predispose to infection. Patients with HIV infection have a 400- to 1000-fold increased risk of acquiring invasive listeriosis.<sup>87</sup> Alcoholism, diabetes, and cirrhosis also contribute to infection, although community-acquired listeriosis may occur spontaneously in patients with no underlying predisposing conditions.<sup>88</sup> Animal studies<sup>89</sup> and one outbreak of human listeriosis<sup>90</sup> suggest that decreased gastric acidity may also predispose to invasive infection in patients with immunosuppressive conditions.

**Figure 14-1** Cellular invasion by *Listeria monocytogenes*. Attachment of *L. monocytogenes* to the surface of cell membrane (a) is determined by a family of bacterial surface proteins, including internalins (IntA and IntB). Once internalized (b) within a vacuole (c), listeriolysin O (LLO) can lyse the vacuole membrane, liberating the bacteria into the cytoplasm. Bacterial surface protein ActA induces polymerization of cellular actin, which concentrates at one end of the bacterium. This "rocket tail" (d) provides propulsion for the organism to move through the cytoplasm and into adjacent cells, where the intracellular process will begin again.

## Nosocomial Transmission

Although most large outbreaks of listeriosis have occurred in the community, case clusters of nosocomial listeriosis in neonates and adults have been described.<sup>91-97</sup> Person-to-person transmission caused by poor infection-control techniques is likely responsible for most of these small clusters. Often, the patient with the index case presents with early-onset infection, and subsequent cases have typical late-onset listeriosis. Multiple cases of early-onset disease may suggest the possibility of foodborne disease in the community. Nosocomial infection among adults in the Boston outbreak<sup>90</sup> was probably related to ingestion of contaminated food in the hospital environment or within 2 weeks of hospitalization. Clear-cut nosocomial infection has been demonstrated in a neonatal outbreak in Costa Rica.<sup>98</sup> In that outbreak, the index case had early-onset disease and was bathed with mineral oil that became contaminated with the epidemic isolate. Subsequent bathing of other infants with the same oil led to late-onset disease in those infants.

## PATHOGENESIS

### Host Response in Normal Adults

#### Innate Immune Response

The pathogenesis of listeriosis in humans remains poorly understood. Most of the hypothetical evidence is derived from observations made on animal models of infection. Given that food is the most common source of outbreak and sporadic cases, the gastrointestinal tract is thought to be the usual portal of entry into the host. Although *L. monocytogenes* is probably ingested frequently through contaminated food sources, the incidence of clinical disease in humans is relatively low.<sup>69</sup> This suggests the organism has relatively low virulence, a concept supported by the high concentration of organisms required to cause infection in animal models.

Translocation of *Listeria* across the intestinal mucosa occurs very rapidly and without histologic evidence of inflammation in the bowel wall. The organism is transported to the liver within minutes of ingestion. This rapid process appears

to be independent of the known listerial virulence factors, because mutant strains lacking these factors arrive at the liver at roughly the same time as their parent wild strains.<sup>22</sup>

In the liver, the first stage of the battle between bacteria and host occurs.<sup>99</sup> Within hours of ingestion, macrophages of the liver (Kupffer cells) and spleen capture and destroy most of the inoculum. Over the next 3 days, a nonspecific, T cell-independent phase of host resistance, called innate resistance is operative. Since the 1960s, it was known that *L. monocytogenes* could survive within Kupffer cells that line the hepatic sinusoids. In the late 1980s, it was also appreciated that *Listeria* could infect nonphagocytic cells (i.e., epithelial, hepatocellular, and fibroblast cell lines), providing the organism with an intracellular environment temporarily sheltered from more hostile host defense.<sup>100-102</sup>

Although proteins on the surface of *Listeria*, such as InIA, InIB, and p60, may identify important factors associated with entrance into the cell in vitro,<sup>24,26,103</sup> they do not fully explain intracellular spread and multiplication of the organism in vivo.<sup>104</sup> During the early course of infection, *L. monocytogenes* resides within a vacuole (for nonphagocytic cells) or a phagosome (in monocyte/macrophage-derived cells) (Fig. 14-1). Lysis of the phagosome or vacuole is mediated by LLO and non-LLO-derived proteins.<sup>30,105-108</sup>

Bacteria-derived phospholipase C, a metalloprotease-mediated lysin and other virulence factors may also contribute to escape of *L. monocytogenes* from vacuoles and phagosomes.<sup>22,109,110</sup>

Release of *L. monocytogenes* from intracellular vacuoles precipitates intracellular growth and actin polymerization.<sup>31,111</sup>

Actin polymerization is important in the cell-to-cell transfer of *L. monocytogenes* and is mediated by ActA product of the *actA* gene.<sup>35</sup> A surface protein, ActA causes host-cell actin to assemble into filaments around the bacterium. After 2 or 3 hours, the actin filaments polarize at one end of the organism. This "rocket tail" provides propulsive force for the organism to move through the cytoplasm. When the bacterium reaches the cell membrane, it forms a filipod that is ingested by adjacent cells. In the process, the organism avoids exposure to the extracellular environment. In addition to hepatocytes, enterocytes, and phagocytic cells, *Listeria* can grow and spread in fibroblasts, epithelial cells, vascular endothelial cells, and renal tubular epithelial cells.<sup>111</sup> The

**Figure 14-2** Interferon and cytokine production. Blood monocytes and tissue macrophages produce a variety of cytokines after ingestion of live *Listeria*. Interleukin (IL)-12 causes activation of natural killer (NK) cells, which release high concentrations of interferon- $\gamma$  (IFN- $\gamma$ ). Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is produced in high concentrations by monocytes and macrophages after ingestion of *Listeria*. TNF- $\alpha$  leads to priming of polymorphonuclear leukocytes (PMNs) and activation of other macrophage cells, with increased production of superoxide ( $O_2^-$ ), nitric oxide (NO), and TNF- $\alpha$ . Macrophage-produced IL-1 leads to proliferation of T cells that produce immunomodulating proteins such as IL-2, macrophage colony-stimulating factor (M-CSF), and IFN- $\gamma$ .

intracytoplasmic environment provides abundant growth conditions and a protected environment for this organism to survive.<sup>100,112</sup>

Between 3 and 4 days after infection begins, there is normally a decrease in viable bacteria in the monocyte-macrophage phagocytic system. This heralds the onset of the T cell-dependent stage of anti-*Listeria* defense, called acquired resistance.<sup>113</sup> Development of acquired anti-*Listeria* activity is seen by day 5 of infection and can be demonstrated by adoptive transfer of resistance using immune T cells. At this stage, the number of activated macrophages in infected tissue rapidly increases (Fig. 14-2).

### Cellular Response

For adult animals, the process leading to acquired immunity to *Listeria* has been partially elucidated, and the sequence of cell-to-cell interaction resulting in cytolytic activity is becoming clear. In adult immunocompetent animals, *Listeria* are phagocytosed by “professional” phagocytes (i.e., macrophages and monocytes) and by “nonprofessional” phagocytic cells (e.g., fibroblasts, hepatocytes) (see Fig. 14-1). Once ingested, partial degradation of *Listeria* occurs and transfer of the *Listeria* protein antigen fragments to the macrophage cell surface takes place.<sup>114</sup>

Peptides resulting from digestion of *Listeria* in the cytoplasm are actively processed by the endoplasmic reticulum, where the peptides bind to major histocompatibility complex (MHC) class I molecules (Fig. 14-3).<sup>11</sup> The *Listeria*-peptide-MHC complex is transported to the cell surface, where it can be recognized by cytolytic T lymphocytes (i.e., CD8 phenotype).

Bacterial peptides that are digested within phagosomes are transported to the plasma membrane, where they attach

to MHC class II molecules. CD4 T lymphocytes recognize specific antigens that are presented by MHC class II membrane receptors.<sup>115</sup> Development of T helper ( $T_H$ ) subset during an immune response is pivotal because *L. monocytogenes* infection is most effectively controlled through this immune response.<sup>115</sup> *L. monocytogenes* induction of  $T_H1$  development in vitro is mediated by macrophage-produced interleukin-12 (IL-12). Cells with  $T_H1$  phenotype secrete IL-2 and interferon- $\gamma$  (IFN- $\gamma$ ) during primary infection.<sup>116,117</sup> Although a small number of  $T_H2$  cells may develop during *Listeria* infection, they play little role in the clearance of *Listeria*.<sup>118</sup>

In the presence of *Listeria* antigens and IL-2, T cells divide, producing *Listeria*-specific clones. In vitro evidence demonstrates that *L. monocytogenes*-immune CD8 T cells are cytolytic for *Listeria*-infected macrophages and hepatocytes (see Fig. 14-3).<sup>119,120</sup> A robust CD8 T cell response is induced during *L. monocytogenes* infection. *Listeria*-specific CD8 T cells confer protective immunity to naive animals. However, such T cells lose antibacterial activity within days.<sup>121</sup> Neutrophils and monocytes that migrate to the site of primary infection may participate in the lysis of infected cells and, more importantly, play a role in the elimination of bacteria that are released to the surrounding tissue. By this stage of infection, phagocytic cells have been primed or activated by IFN- $\gamma$  or cytokines, making them more effective killers.<sup>121-127</sup>

### Roles of Toll-like Proteins, Interferon, and Cytokines

Toll-like receptors (TLRs) are conserved primitive membrane proteins found in cells that have been identified as key to initiation of innate immunity.<sup>128</sup> Ten TLRs have been identified. TLR-2 and TLR-6 are heterodimers for gram-positive peptidoglycan. Surface TLRs stimulate an innate immune

**Figure 14-3** Activation of cytolytic cell mechanisms. Within an antigen-presenting cell, organisms killed and digested within a phagosome release bacterial peptides that are transported to the plasma membrane, where they attach to major histocompatibility complex (MHC) class II molecules. CD4 T lymphocytes recognize specific antigens that are presented by MHC class II receptors. CD4 T lymphocytes differentiate predominantly into  $T_H1$  cells through stimulation by interleukin-12 (IL-12). Such cells secrete high concentrations of IL-2 and interferon- $\gamma$  (IFN- $\gamma$ ) during primary infection. Bacterial peptides may also come from proteolytic digestion of intracytoplasmic organisms. Such peptides are processed by the endoplasmic reticulum, where they bind to MHC class I receptors. The bacterial-peptide-MHC I complex is transported to the cell membrane, where it is recognized by cytolytic T lymphocytes (CTLs, CD8 phenotype). Such cells cause lysis of *Listeria*-infected cells, which are recognized by the presence of *listerial* peptides on their surface. Lysis of *Listeria*-infected cells leaves the organism exposed to phagocytosis and killing by activated phagocytic cells, polymorphonuclear leukocytes, and monocytes.

response through a signal pathway involving intracellular kinases and transcription factors. The first intracellular adapter molecule in this cascade is myeloid differentiation antigen 88 (MyD88), which functions as a critical first adapter protein of several TLRs, including TLR-2 and TLR-6.<sup>129</sup> The role of the TLR and the TLR pathway in innate immunity to *Listeria* has become clear over the past 5 years. TLR-2-deficient mice show partial impairment in their resistance to *Listeria*.<sup>130</sup> However, MyD88 has an even more critical role in early clearance of *Listeria* and cytokine signaling.<sup>130,131</sup>

In mature immunocompetent animals, *Listeria* infection induces circulating IFN- $\gamma$  and IFN- $\alpha/\beta$  on the second or third day in the acquired phase of immunity. Cytokines such as macrophage colony-stimulating factor (M-CSF)<sup>118</sup> and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) also appear during the first 5 days and have been implicated as mediators of listerial clearance.<sup>126,132-137</sup> However, peak immunity to *Listeria* is expressed about the sixth day of infection, which coincides with maximal  $T_H1$  cell synthesis of IFN- $\gamma$ .<sup>138-139</sup> A role for endogenous IFN- $\gamma$  in resolution of *L. monocytogenes* infection has been shown.<sup>140,141</sup> Adult animals treated with monoclonal antibody directed against IFN- $\gamma$  do not develop activated macrophages, and clearance of *Listeria* from liver and spleen is decreased.<sup>140</sup>

There is clear evidence that the cytokine cascade involving various interleukins, interferon, and TNF- $\alpha$  is essential for host response to listerial infection. MyD88-initiated signaling pathways are required for IL-1, IL-12, and IL-18 and for TNF induction in monocytes and other early responsive cells.<sup>130,142-145</sup> All of these interleukins and cytokines are involved in an early response to *Listeria* infection through activation of resident macrophage cells, circulating monocytes, and polymorphonuclear leukocytes (PMNs). Early activation through the innate immune system leads to removal of 90% of the bacterial burden in the liver within 6 hours of infection in animal models.<sup>145</sup>

TNF is a key cytokine to enhance antibacterial or anti-parasitic resistance mechanisms (see Fig. 14-2).<sup>147-150</sup> Many cell types produce TNF, including natural killer (NK) cells<sup>151</sup>; however, monocytes and macrophages are probably the most abundant source. Endotoxins (lipopolysaccharides) and other agents, including mitogens, viruses, protozoa, and cytokines such as M-CSF, IL-1, IL-2, and IFN- $\gamma$  have been identified as inducers of TNF.<sup>152-155</sup> When administered before infection, TNF-inducing agents enhanced resistance of the host to bacterial infection.<sup>157</sup>

Endogenously produced TNF during sublethal *Listeria* infection in adult animals appears to function as an inducer

of resistance.<sup>132-135</sup> Injection of mice with anti-TNF immunoglobulin results in a striking proliferation of bacteria during the first 2 or 3 days of infection; however, administration of anti-TNF immunoglobulin on day 5 of infection has virtually no effect on *Listeria* replication in the spleen and liver.<sup>126,127,134</sup> These results suggest that TNF-dependent mechanisms limit intracellular infection early in the course of infection. Localized production of TNF is demonstrated in supernatants of organ homogenates from the liver or spleen.<sup>158</sup>

IL-12 participates in the differentiation of T<sub>H</sub>1 cells, IFN- $\gamma$  production, and NK cell activation.<sup>115,137,159</sup> In the absence of T<sub>H</sub>1 activation, animals are more susceptible to *L. monocytogenes* infection.<sup>115,159</sup> IL-1, IL-12, and IL-18, molecules whose receptor signaling require MyD88, are all required for normal host defense against *Listeria*.<sup>131,160</sup>

## Host Response in the Neonate

### Cell Activation

In newborn animals, susceptibility to *Listeria* appears to be associated with delayed activation of macrophages.<sup>161,162</sup> Studies on the afferent and efferent arms of the immune system in fetal and newborn mice have shown that macrophage-T lymphocyte interaction and macrophage activation are impaired.<sup>101,156,163-167</sup> A perinatal rhesus monkey model of human listeriosis has also been established.<sup>168</sup> In the model, animals exposed to *L. monocytogenes* at the beginning of the third trimester had increased risk of stillbirth delivery and showed pathology similar to humans. Antibody and *Listeria*-induced cell proliferation was increased in mothers after delivery of stillborn rhesus monkey infants. The relevance of animal studies to human infection remains to be determined; however, Issekutz and co-workers<sup>169</sup> reported similar immunologic findings among mothers and infants surviving natural *Listeria* infection.

Functional capacity of monocytic and macrophage cells is decreased in newborn animals. Chemotaxis, phagocytosis, and killing of *Candida albicans*, for example, is markedly impaired in neonatal rhesus monkey alveolar macrophages compared with those in juveniles and adults.<sup>170</sup>

NK cells also appear to be important in early response to *L. monocytogenes* infection. The proportion of mononuclear cells expressing NK cell phenotype and NK cell activity is decreased at birth, particularly in premature infants.<sup>171,172</sup> NK cell phenotype and function increase rapidly in the weeks after birth.

### Toll-like Proteins, Interferon, and Cytokines in Newborns

In adult animals and adult derived cells, *Listeria* infection induces production of IL-12 and IL-18, which mediates T<sub>H</sub>1 differentiation, NK cell activation, and IFN- $\gamma$  production.<sup>103</sup> The major cellular source of IL-12 and IL-18 are monocytes, macrophages, and dendritic cells. After lipopolysaccharide stimulation, IL-12 messenger RNA (mRNA) expression and protein production in cord blood mononuclear cells is also greatly decreased compared with adult cells.<sup>173</sup> The half-life of IL-12 p40 mRNA is shortened in activated cord blood cells compared with adult cells.<sup>174</sup> However, cord blood mononuclear cells from humans are capable of responding in vitro to exogenous IL-12 in high concentrations.

In adult animals, interferon and agents that induce or augment interferon production confer protection against lethal listeriosis.<sup>175,176</sup> Synthesis of interferon, IL-2 and IL-4, all of which modulate the immune response and macrophage activation, is deficient in newborns.<sup>167,177-179</sup> Although production of these factors may be defective, newborn animals do respond to exogenous interferon; pretreatment with interferon or its inducers<sup>180</sup> protects against subsequent infection.

The ontogeny of cytokine-related host defense mechanisms has not been studied in depth. TNF is decreased among newborn rats infected with *L. monocytogenes*.<sup>158</sup> In one study on *L. monocytogenes*-infected newborn rats, TNF was detected only among animals older than 8 days. The age at which TNF is measurable corresponds to the approximate age at which increased resistance to *L. monocytogenes* is seen. The study showed that IFN- $\gamma$  might enhance resistance to *L. monocytogenes* in newborn animals by permitting them to respond to exogenous TNF- $\gamma$ .

The pattern of delayed or diminished cytokine response in human newborns is similar to the response in animals deficient in TLR protein. This possibility has been explored in human newborns. However, TLR-2 and TLR-4 expressions are normal on mononuclear and PMN cells of newborns.<sup>143</sup> TLRs require membrane-associated proteins to initiate intracellular messenger activation and cytokine secretion. Chief among these proteins is MyD88, an intracellular myeloid differentiating antigen needed for intracellular signaling of all TLR proteins. Yan and colleagues<sup>143</sup> reported diminished TNF secretion in newborn monocytes associated with significantly diminished intracellular MyD88 protein.

### Serum Factors

Opsonic activity of newborn serum for *Listeria* is minimal.<sup>181,182</sup> *Listeria* is opsonized primarily by IgM together with the classic complement pathway. Because newborn serum has negligible amounts of IgM and low concentrations of the classic complement pathway, its poor opsonic activity may contribute to the severity of infection in newborns. Adult serum may also contain specific antibodies to inhibit *L. monocytogenes* invasion of brain microvascular endothelial cells.<sup>183</sup> The inhibitory antibody, which is absent in newborn cord serum, reacts with the *Listeria* surface protein InlB, described earlier as a key virulence factor.

## PATHOLOGY

In tissues, human listeriosis is characterized by miliary granulomas and focal necroses or by suppuration. The term *listerioma* has been coined for *Listeria*-associated granulomas. In the newborn, *Listeria* infection of organs produces multiple, tiny nodules that can be visualized on gross examination.<sup>184</sup> Massive involvement of the liver is typical, reflecting the abundance of internalin receptors on hepatocytes. Often, as in miliary tuberculosis, the liver is seeded with grayish yellow nodules. Analogous findings are observed in the spleen, adrenal glands, lungs, esophagus, posterior pharyngeal wall, and tonsils. Subepithelial granulomas often undergo necrosis. Focal granulomas may also be detected in the lymph nodes, thymus, bone marrow, myocardium, testes, and skeletal muscles. The intestinal tract is affected to a variable degree, with a preference for the lymphatic structures of the small

**Figure 14-4** Cutaneous listeriosis. Notice the numerous gram-positive rods that extend from the dermis into the epidermis above.

intestine and appendix. Cutaneous lesions of neonatal listeriosis were first described by Reiss,<sup>185</sup> and occur most commonly on the back and lumbar region (Fig. 14-4).

In listeriosis of the central nervous system (CNS), granuloma formation is typical.<sup>186</sup> A characteristic histologic picture is seen in *Listeria* encephalitis, consisting of cerebral tissue necrosis with a loosening of the reticulum and an infiltration of leukocytes and lymphocytes leading to abscess formation.

Suppurative inflammation is the second form of tissue reaction to listeriosis. It is predominantly found in the meninges, the conjunctiva, and the epithelial linings of the middle ear and nasal sinuses. In meningitis, the subarachnoid space becomes filled with thick purulent exudate.

The histologic changes in human listeriosis are the same as those observed in animals. The organisms cause necrosis, followed by a proliferation of reticuloendothelial cells, resulting in the development of granulomas. The granuloma's center is necrotic, and the periphery contains an abundance of chronic inflammatory cells. *Listeria* are present in variable numbers within these necrotic foci and can be demonstrated with a Gram stain or Levaditi silver impregnation. Similar changes are found in all affected organs, independent of the age of the infected individual.

The gross and microscopic appearance of the placenta in listeriosis, although not pathognomonic, is sufficiently distinct to enable a presumptive diagnosis by the experienced pathologist (Fig. 14-5). *Listeria* placentitis is characterized grossly by multiple, minute, white or gray necrotic areas within the villous parenchyma and decidua; the largest tend to occur in basal villi and the decidua basalis.<sup>187-189</sup> These necrotic foci are macroabscesses identical to those described in other fetal organs.<sup>184</sup> Typically, localized collections of PMNs are found between the villous trophoblast and stroma, and inflamed or necrotic chorionic villi are enmeshed in intervillous inflammatory material and fibrin. Chorioamnionitis, deciduitis, villitis, and funisitis (in order of frequency) are seen. Cord lesions may be confined to superficial foci. Gram-positive

**Figure 14-5** *Listeria* placentitis. Notice the microabscess between the necrotic villous trophoblast and the stroma (arrows). Chorionic villi are enmeshed by intervillous and inflammatory material.

rods are usually demonstrable within the necrotic centers of villous and decidual microabscesses, the membranes, and the umbilical cord. An immunohistochemical stain using polyclonal antibody directed at LLO has also been used.<sup>190</sup>

## CLINICAL MANIFESTATIONS

The clinical features of listeriosis have considerable variability and may mimic other infections or other disease states. Based on the most common clinical manifestations, four or more clinical groups may be distinguished.

### Listeriosis during Pregnancy

The predilection of *Listeria* for the fetoplacental unit and intrauterine infection is well documented.<sup>191-195</sup> Maternal listeriosis can be transmitted to the fetus by an ascending and transplacental route. Although early gestational listeriosis is associated with septic abortion, most clinically identified cases of perinatal listeriosis occur after the fifth month of pregnancy, with stillbirth or premature delivery of a septic infant the result.

Maternal influenza-like illness with fever and chills, fatigue, headache, and muscle pains often precedes delivery by 2 to 14 days. Although symptoms in the mother may subside before delivery, infection and fever precipitating delivery are common. Blood cultured from such women can yield *Listeria* at the same time or after these initial symptoms appear. Premature labor in mothers with listeriosis is common; length of gestation is less than 35 weeks in approximately 70%. The mortality rate, including stillbirth and abortion, is 40% to 50%. Early treatment of *Listeria* sepsis in pregnancy can prevent infection and sequelae in the fetus and newborn.<sup>196,197</sup> At the time of delivery, maternal symptoms of infection may be pronounced; however, symptoms in the mother usually subside with or without antibiotic treatment soon after delivery.

The pathogenesis of fetal listeriosis is not clear. Because the heaviest foci for neonatal infection are lung and gut, the fetus is probably infected by swallowing contaminated amniotic fluid and by the transplacental hematogenous route. Although ascending pathway from the lower genital tract may occur, infection through the transplacental route is favored by most experts. *L. monocytogenes* chorioamnionitis diagnosed by transabdominal amniocentesis before membrane rupture has been reported and supports a blood-borne route of infection.<sup>184,193,197-199</sup> Placental chorionic vascular thrombi can be associated with maternal coagulopathy. Emboli originating from *Listeria*-infected placental vessels have been described as a cause of congenital stroke in an infant.<sup>190</sup>

Susceptibility to *L. monocytogenes* is markedly increased in pregnant animals.<sup>167,200,201</sup> Immunoregulation during pregnancy is poorly understood. The fetoplacental unit must survive in the potentially hostile maternal immunologic environment throughout gestation. Evidence supports the hypothesis that the placenta and the immediately adjacent tissue constitute an immunologically privileged site, with local uterine immune response being suppressed.<sup>195,202,203</sup> Such regulation may be necessary to protect the fetus from immunologic rejection by the mother. However, if infection in this area occurs, bacterial proliferation may be overwhelming because of slow cell-mediated immune response.

### Early-Onset Neonatal Listeriosis

The first descriptions of neonatal listeriosis were published in the 1930s by Burn.<sup>204-206</sup> Since then, it has become recognized

Table 14-1 Clinical and Laboratory Findings of Early-Onset and Late-Onset Neonatal Listeriosis

Feature	Early Onset <sup>a</sup>	Late Onset <sup>b</sup>
Mortality (%)	25	15
Median age in days (range)	1 (0-6)	14 (7-35)
Male (%)	60	67
Preterm (%)	65	20
Respiratory involvement (%)	50	10
Meningitis (%)	25	95
Blood isolate (%)	75	20
Maternal perinatal illness (%)	50	0

<sup>a</sup>Data from references 77, 82, 191, 199, 207-211.

<sup>b</sup>Data from references 69, 207, 211-213, 287.

that neonatal infection is the most common clinical form of human listeriosis. Infection in the neonatal period is usually divided into two clinical groups defined by age: early-onset and late-onset listeriosis.

Some clinical and laboratory manifestations of early-onset neonatal listeriosis are outlined in Table 14-1, which is compiled from clinical cases published since 1970 in which early and late forms of the disease could be differentiated.<sup>69,77,82,191,199,207-213</sup> Classically, early-onset neonatal listeriosis develops within 1 or 2 days of life. However, in one outbreak involving 10 infants with nosocomially acquired listeriosis, an atypical clinical picture was described.<sup>98</sup> Nine of these infants were bathed with *L. monocytogenes*-contaminated mineral oil shortly after birth. Clinical features of infection developed 4 to 8 days later and were similar to those seen in late-onset infection (insidious onset of illness with fever and meningitis was common).

Evidence of preceding maternal illness is often described in infants with early-onset disease. Although some maternal symptoms are vague and nonspecific (e.g., malaise, myalgia), others are sufficiently distinctive (e.g., fever, chills) to alert physicians to the risk of prenatally acquired listeriosis. Blood cultures may be positive for *Listeria* from such mothers.

Although early-onset disease may occur in infants up to 7 days old, most cases are clinically apparent at delivery and demonstrate meconium staining, cyanosis, apnea, respiratory distress, and pneumonia. Meconium-stained amniotic fluid is a common feature in such infants and may occur at any gestational age. Pneumonia is also common, but radiographic features are nonspecific (i.e., peribronchial to widespread infiltration). In long-standing infection, a coarse, mottled, or nodular pattern has been described. Assisted ventilation is frequently necessary in such infants. Persistent hypoxia despite ventilator assistance is seen in severely affected infants.

In severe infection, a granulomatous rash—granulomatosis infantisepticum—has been described (Fig. 14-6). Slightly elevated pale patches (1 to 2 mm in diameter) with a bright erythematous base are seen. Biopsy of these areas demonstrates leukocytic infiltrates with multiple bacteria present (see Fig. 14-4).

Laboratory features are nonspecific; a leukocytosis with presence of immature cells may be seen, or if infection is severe, neutropenia may occur. Thrombocytopenia may also occur.<sup>191,208</sup> Many of the infants are anemic, perhaps attributable to hemolysin produced by the organism. These

**Figure 14-6** Rash of neonatal *Listeria monocytogenes* infection. Areas of small, elevated, pale pustules are surrounded by a deep red erythematous base on the abdomen of a premature neonate (horizontal bar  $\approx$  1 cm long).

**Figure 14-7** Short, gram-positive intracellular organisms with variable lengths and rounded ends are arranged irregularly.

laboratory and clinical features fail to distinguish listeriosis from early-onset group B streptococcal or other bacterial infection. The association of early-onset listeriosis with prematurity and maternal infection suggests the presence of intrauterine infection. The frequent presence of chorioamnionitis in the absence of ruptured membranes<sup>77,211</sup> supports the hypothesis of *Listeria* infection occurring by a transplacental route, which differs from the pathogenesis of group B streptococcal infection.

#### **Late-Onset Neonatal Listeriosis**

Neonatal listerial infection that occurs after 7 days of life is called *late-onset infection*. Although there is some overlap between early- and late-onset forms of listeriosis, the clinical patterns are usually distinct. Common clinical and laboratory features of late-onset neonatal listeriosis are shown in Table 14-1. By far the most common form of *Listeria* infection over this period is meningitis, which is present in 94% of late-onset cases. In many centers, *Listeria* ranks second only to streptococcus group B as a cause of bacterial meningitis in this age group, causing approximately 20% of such infections.<sup>207</sup>

Clinical features do not distinguish listerial meningitis in this age group from other causes. A striking predominance of male infants has been observed in most series. Fever and irritability are predominant clinical features. Often, infants do not appear excessively ill and may therefore elude diagnosis for several days. Other clinical forms of disease at this age are less common but include *Listeria*-induced colitis with associated diarrhea, and sepsis without meningitis.<sup>214,215</sup>

Laboratory features of late-onset infection are non-specific as well. Cell counts in cerebrospinal fluid are usually high, with a predominance of neutrophils and band forms. Occasionally, in long-standing disease, a high number of monocytes may be seen. Gram stain of cerebrospinal fluid may not always suggest a diagnosis, because the organism may be rare or the morphology is atypical. Variable decolorization during staining may result in organisms appearing as gram-negative rods or gram-positive cocci. The appearance of organisms as illustrated in Figure 14-7 is characteristic of listeriosis in the early phase of severe meningitis.

Mortality of late-onset newborn infection is generally low unless diagnosis is delayed by more than 3 or 4 days after onset. Long-term sequelae and morbidity are uncommon.

### Central Nervous System Infection

Acute or subacute bacterial meningitis accounts for two thirds of adult cases of listeriosis. Rhombencephalitis with ataxia, cranial nerve palsies, and multiple microabscesses on magnetic resonance imaging or computed tomography appears to be a distinct *Listeria* syndrome in humans, as it is in ruminants ("circling disease").<sup>186</sup> Survival of *Listeria* in the CNS is probably helped through cell-to-cell spread of the organism.<sup>216</sup> Morbidity and mortality rates are high for patients with CNS infection.<sup>82</sup>

### Bacteremia

In immunocompromised patients, bacteremia is the most common manifestation of *Listeria* infection, with meningitis second in frequency.<sup>68</sup> Clinical signs are indistinguishable from bacteremia due to other organisms and typically include fever and myalgias after a prodromal illness of nausea and diarrhea. The risk of invasive listeriosis in patients with a malignancy, HIV infection, or after organ transplantation, may be 1000 times the risk in otherwise healthy persons.<sup>77,217</sup> During the bacteremic phase, an accompanying conjunctivitis is sometimes observed. Anton's eye test<sup>218</sup> resulted from a laboratory accident in which a technician accidentally contaminated his face.

### Other Clinical Forms of Infection

Increasingly, a febrile gastroenteritis syndrome similar to salmonellosis has been described in adults and children. Processed meats have been repeatedly implicated,<sup>219</sup> but other outbreaks have involved contaminated shrimp salad,<sup>220</sup> rice salad,<sup>221</sup> and chocolate milk.<sup>215</sup> Only a few patients developed invasive disease (i.e., sepsis) in these outbreaks, and the level of *Listeria* contamination appeared to be very high.<sup>222</sup>

Papular cutaneous lesions are often observed in newborns when listeriosis is disseminated. These are to be distinguished from the primary skin lesions caused by *Listeria* as observed in adults,<sup>223,224</sup> which are the result of direct contact, such as the handling of a cow's placenta after abortion by a veterinarian or farmer.<sup>50</sup> Other unusual forms of listeriosis, such as endocarditis,<sup>225</sup> endophthalmitis,<sup>226,227</sup> liver abscesses,<sup>228</sup> peritonitis,<sup>229,230</sup> osteomyelitis, and septic arthritis,<sup>231</sup> have been described in adults but are rare in infants.

## DIAGNOSIS

The clinical signs and symptoms of listeriosis overlap considerably with other illnesses, making a specific diagnosis difficult, if not impossible, when patients are first seen.

### Serology

The agglutination reaction (Widal's test) demonstrates antibodies against O and H antigens of the various *Listeria*

serovars. Unfortunately, because of the antigenic complexity of *L. monocytogenes*, no agreement has been reached on the interpretation of agglutination reactions for diagnostic purposes.

Attempts to demonstrate complement-fixing *Listeria* antibodies date back to the 1930s.<sup>232</sup> In one study, serum samples collected from 32 mothers with perinatal *Listeria* infection were compared with 128 samples from matched controls.<sup>233</sup> The sensitivity and specificity of the complement fixation test were found to be 78% and 91%, respectively; however, the positive predictive value was only 75%. A titer of 1:8 or more is accepted as significant.<sup>233,234</sup>

Detection of antibodies to LLO has also been used to diagnose human listeriosis.<sup>235</sup> Purified LLO incorporated into nitrocellulose filters is tested with serial dilutions of sera. Absorbed anti-LLO is identified using enzyme-labeled anti-human IgG. Sensitivity and specificity of the test is over 90%, and during a febrile gastroenteritis outbreak, it correlated well with clinical illness.<sup>215</sup> Although these results are impressive, the technique is not available commercially. A precipitin test,<sup>236</sup> indirect hemagglutination reaction,<sup>237</sup> and antigen fixation test<sup>238</sup> have also been described, showing apparent success but remaining unavailable on a widespread basis.

### Isolation of the Organism

Cultivation of *L. monocytogenes* is the gold standard of diagnosis. Culture of venous blood, ascitic and other fluids, cervical material, urine, placenta, amniotic fluid, lochia and meconium, and tissues at biopsy or autopsy offers the best chances for identifying *Listeria* in persons with disease. Culture of the stool is not done routinely, because feces are positive for *Listeria* in 1% to 5% of healthy women.<sup>73,239</sup> In an outbreak setting, stool culture with selective media may recover organisms for comparative typing.

Microscopic diagnosis may be attempted by use of Gram stain only in specimens that normally do not contain bacteria: cerebrospinal fluid, meconium, and tissue smears. The finding of short, sometimes coccoid, gram-positive rods, strongly supports a suspicion of listeriosis and is indicative of this infection in meconium smears. Occasionally, *L. monocytogenes* may appear gram-variable or even predominantly coccoid. With long-standing disease or when the patient has received antibiotics, *Listeria* may appear gram-negative and be confused with *H. influenzae* when observed in the cerebrospinal fluid. In other instances, *Listeria* has been mistaken for pneumococci and corynebacteria.

### Molecular Detection

Polymerase chain reaction (PCR)-based methods are used to detect *Listeria* in clinical samples such as cerebrospinal fluid<sup>240</sup> and endophthalmitis.<sup>241</sup> Spurred by the food industry's demand for rapid *Listeria* detection, techniques such as real-time PCR<sup>242</sup> and amplification with sequencing of *Listeria* 16S ribosomal RNA genes<sup>243</sup> are being reported in the literature. Although few clinical laboratories use these methods, the increasing availability of PCR technology is already changing this pattern.

## PROGNOSIS

Neonatal listeriosis accounts for the largest recognizable group of infections caused by *L. monocytogenes*. Fetal loss with early gestational infection is a recognized complication of maternal infection. In late-gestational maternal infection, sparing of the fetus has been reported,<sup>244</sup> but it is probably uncommon unless antepartum antibiotic treatment has been given to the mother.<sup>245,246</sup>

Although fetal or neonatal infection with *L. monocytogenes* is known to have a high fatality rate, the long-term morbidity is unclear. Rotheberg and associates<sup>247</sup> found an increased incidence of developmental delay assessed at a mean age of 29.5 months among small (<1250 g at birth), *Listeria*-infected infants who required assisted ventilation. Naeye,<sup>248</sup> studying children 4 to 7 years after they recovered from early-onset listeriosis, found increased neurodevelopmental handicaps. Others have reported hydrocephalus.<sup>249</sup>

In contrast, Evans and co-workers<sup>250</sup> found no evidence of neurodevelopmental sequelae in six of eight survivors studied at a mean age of 15 months and again at 32 months. The two infants with neurodevelopmental sequelae had severe acute perinatal sepsis with meningitis. Both had spastic diplegia. The investigators concluded that long-term sequelae after neonatal early-onset listeriosis was uncommon. If meningitis does not occur, the outcome may be generally good. The prognosis for infants with late-onset neonatal sepsis and meningitis has not been studied extensively.

## THERAPY

*Listeria* remains susceptible to antibiotics commonly used in its treatment.<sup>251,252</sup> However, the high mortality rate and risk of relapse<sup>253,254</sup> have prompted a search for newer therapeutic regimens, including quinolones,<sup>255</sup> trimethoprim-sulfamethoxazole,<sup>256,257</sup> and rifampin.<sup>258</sup> Transferable plasmid-mediated antibiotic resistance has been reported<sup>259</sup> conferring resistance to chloramphenicol, tetracycline, and erythromycin.

## In Vitro Studies

Conflicting reports of in vitro activity of antibiotics against clinical isolates of *L. monocytogenes* probably reflect a variable pattern of susceptibility for strains and differences in laboratory technique. Several large in vitro studies of antibiotic susceptibility of clinical isolates of *L. monocytogenes* have been reported using broth dilution susceptibility methods.<sup>260-262</sup> Most studies found that the strains represented a homogeneous population susceptible to ampicillin, penicillin, erythromycin, and tetracycline. In vitro results, however, are greatly influenced by methodology: inoculum size, media, and definition of end points. Since 1988, several strains have been isolated showing various degrees of relative resistance to non- $\beta$ -lactam antibiotics such as tetracycline and gentamicin.<sup>261,262</sup> The minimal bactericidal concentration of antibiotics is often much higher than levels attainable clinically. Most antibiotics tested are bacteriostatic but not bactericidal. Although bacteriostatic antibiotics have been used in the past, bactericidal antibiotics have a potential advantage for patients with impaired host defense mechanisms.<sup>263</sup>

Studies with cephalosporin antibiotics using in vitro and in vivo models have been consistently disappointing.<sup>264</sup> The organism is uniformly resistant to cephalosporin antibiotics.<sup>265</sup> Cephalosporins may be incorporated into media to inhibit other bacteria while permitting growth of *Listeria*.<sup>201</sup> Activity of newer fluoroquinolones against *L. monocytogenes* is promising.<sup>266,267</sup> For example, moxifloxacin was found to have bactericidal activity for *Listeria* and was the most effective antibiotic tested for eradication of the organism from the intracellular compartment.<sup>266</sup>

## In Vivo Studies

Several combinations of antibiotics<sup>249,267-269</sup> or altered methods of preparation such as liposome-entrapment<sup>270</sup> have been compared for their bactericidal activity against *L. monocytogenes* in vivo. Animal models appear to provide the only practical way to assess therapeutic regimens, because large clinical studies in humans are not available. Murine models employing normal adults,<sup>257,270,271</sup> cortisone-treated adults,<sup>272</sup> immunodeficient adults,<sup>273-275</sup> or animals infected by inhalation of aerosolized *Listeria*<sup>257</sup> have been reported. A rabbit model using animals injected intracisternally with *Listeria* has also been described.<sup>276</sup> The model most analogous to neonatal disease was described by Hawkins and colleagues.<sup>277</sup> In their study, neonatal rats were injected intraperitoneally with bacteria and then randomized to begin antibiotic regimens 2 days later.

Interpretation of in vivo models is difficult because conflicting results have been reported. In addition to variability accounted for by technique (e.g., route of injection, bacterial strain, inoculum size), consideration should also be given to the pharmacokinetics for each antibiotic in the various animal species. For example, animal species differ widely in their metabolism of rifampin,<sup>276-278</sup> and the half-life of ampicillin is much longer in human neonates than in most of the adult animal models in which it has been assessed. In one study involving adult mice infected with a virulent strain of *L. monocytogenes*, no synergy was demonstrated using a combination of ampicillin and gentamicin.<sup>279</sup> However, in the in vivo model of neonatal listeriosis described by Hawkins and associates, the combination of ampicillin with gentamicin gave significantly better eradication of organisms in spleen compared with ampicillin alone.<sup>277</sup> Similarly, the combination trimethoprim-sulfamethoxazole was found to be superior to either drug alone.<sup>277</sup> Reports of efficacy of other antibiotics in vivo are conflicting. Rifampin has been found by some authors to be highly effective in eradicating organisms,<sup>257,278</sup> whereas others have found it to be ineffective.<sup>280</sup> Sensitivity of individual strains to rifampin may account for the widely discrepant results. Rifampin resistance may develop in vivo when it is used as monotherapy. The use of ciprofloxacin in animal models has not suggested any therapeutic advantage over ampicillin.<sup>272,281</sup>

## Clinical Reports

There have been no prospective clinical trials reported for human infection with *L. monocytogenes*. Anecdotal reports of single cases or reviews of outbreaks support the conclusions drawn from in vivo models. In one review of clinical management of 119 cases of listeriosis from three centers in

the United States, excellent therapeutic results were seen for patients treated empirically with penicillin or ampicillin; all had a reduction of fever and clinical improvement. However, patients treated initially with cephalosporins had persistent fever and infection.<sup>281</sup> In the largest assessment of treatment regimens during a single outbreak,<sup>282</sup> a lower mortality was reported for children given ampicillin (16% of 57 children) compared with those treated with chloramphenicol, tetracycline, or streptomycin (33% of 82 children). As summarized by McLauchlin,<sup>253</sup> there have been several reports of treatment failure and recurrent human listeriosis. In some cases, weeks or months elapse between episodes. Patients have been treated with bacteriostatic (e.g., erythromycin) or  $\beta$ -lactam antibiotics during initial treatment. Nevertheless, in the absence of controlled clinical trials, a definitive recommendation for treatment cannot be made.

## Suggested Management

### *Listeriosis during Pregnancy*

If amnionitis is present, initial treatment should be given by the intravenous route to ensure adequate tissue levels (ampicillin, 4 to 6 g/day divided into four equal doses plus an aminoglycoside). If amnionitis is not present or if acute symptoms of amnionitis have subsided, oral antibiotics are probably adequate (amoxicillin, 1 to 2 g/day divided into three equal doses). In both situations, treatment should continue for 14 days. If the patient has a significant allergy to ampicillin, therapeutic options are limited. Erythromycin may be given. The estolate form of this drug should be avoided because there is increased liver toxicity during pregnancy. Trimethoprim-sulfamethoxazole should not be used because premature delivery of the infant may occur as a consequence of infection, in which case the drug may be toxic to the infant.

### *Early-Onset Neonatal Listeriosis*

Ampicillin in combination with an aminoglycoside is the preferred management for early-onset infection. For infants with body weight less than 2000 g, 100 mg/kg/day (divided into two equal doses) should be administered for the first week of life. For infants with body weight of more than 2000 g, 150 mg/kg/day (divided into three equal doses) should be administered for the first week of life. For the second week of life, the appropriate dosages are 150 mg/kg/day and 200 mg/kg/day for infants weighing less than and more than 2000 g, respectively. Aminoglycoside doses vary with the agent chosen. For gentamicin, the suggested dosages are for full-term infants 5 mg/kg/day (divided into two equal doses) for the first week of life and 7.5 mg/kg/day (divided into three equal doses) for the second week of life. Fourteen days of treatment is recommended for early-onset neonatal sepsis due to *L. monocytogenes*; however, a longer course of treatment should be given in the uncommon event of early-onset neonatal listeriosis with meningitis.

### *Late-Onset Neonatal Listeriosis*

Meningitis commonly coexists with late-onset listeriosis. Delayed eradication of the organism may be seen in such cases. Ampicillin (200 to 400 mg/kg/day divided into four to six equal doses) in combination with an aminoglycoside is

recommended. Lumbar punctures should be repeated daily until the organism has been cleared. In the event of delayed clearance (>2 days), further investigations are indicated and should include computed tomography or cranial ultrasound evaluation to assess for the presence of cerebritis or intracranial hemorrhage. If the organism remains present in the cerebrospinal fluid after several days, the addition of moxifloxacin, rifampin, or use of trimethoprim-sulfamethoxazole may be considered if the organism is sensitive in vitro. Experience with these antibiotics and with this organism in neonates is limited.<sup>283</sup> Cephalosporin antibiotics have no role in treatment because *Listeria* organisms are uniformly resistant. Length of treatment is variable. If prompt clinical improvement and sterilization of cerebrospinal fluid occur, 10 to 14 days of treatment is probably adequate. However, if response is slow, treatment for as long as 21 days may be considered.

## PREVENTION AND OUTBREAK MANAGEMENT

Foodborne outbreaks of listeriosis are unpredictable and may occur in a wide geographic area. Reporting of sporadic cases of listeriosis to public health authorities may be the only method of distinguishing sporadic from epidemic disease. The epidemic threshold is unknown and may be determined only in retrospect. Studies suggesting that sporadic listeriosis is also a foodborne pathogen have important public health implications.<sup>284</sup>

Sampling of foodstuffs associated with sporadic cases of listeriosis is not warranted. Case-control studies to determine potential vehicles of transmission in outbreaks may help define the source, and environmental sampling may be an important part of such outbreak investigations. Strains of *Listeria* from clinical and environmental isolates should be forwarded to a reference laboratory for appropriate epidemiologic typing. At a minimum, serotyping, phage typing, and multifocus enzyme electrophoresis typing should be performed to characterize the epidemic strain.

During an outbreak of listeriosis, pregnant women presenting with sepsis syndrome or a flulike illness should be empirically treated with ampicillin and an aminoglycoside after appropriate cultures of blood, rectum, and vagina have been obtained. Amniocentesis for diagnosis of chorioamnionitis may be appropriate.<sup>198</sup> If membranes have ruptured and contamination is suspected, use of selective media may enhance the isolation of *Listeria* from these patients.

Identification of early- or late-onset listeriosis in a newborn nursery should prompt appropriate epidemiologic and clinical history taking from the mother and postpartum cultures of the rectum and vagina. Infection-control precautions with gowning, gloves, and careful hand washing can prevent nosocomial transmission between infected infants and is consistent with current procedures for all forms of neonatal sepsis.

The recognition that sporadic cases of listeriosis are primarily foodborne has also prompted publication of preventive guidelines by the CDC (Table 14-2).<sup>285</sup> Guidelines for preventing listeriosis are similar to those for preventing other foodborne illnesses and include thorough cooking of

**Table 14-2 Dietary Recommendations for Preventing Foodborne Listeriosis**

**For All Persons**

1. Thoroughly cook raw food from animal sources (e.g., beef, pork, poultry).
2. Thoroughly wash raw vegetables before eating.
3. Keep uncooked meats separate from vegetables, cooked foods, and ready-to-eat foods.
4. Avoid consumption of raw (unpasteurized) milk or foods made from raw milk.
5. Wash hands, knives, and cutting boards after handling uncooked foods.

**Additional Recommendations for Persons at High Risk<sup>a</sup>**

1. Avoid soft cheeses (e.g., Mexican-style feta, Brie, Camembert, blue-veined cheeses). There is no need to avoid hard cheeses, cream cheese, cottage cheese, or yogurt.
2. Leftover foods or ready-to-eat foods (e.g., hot dogs) should be reheated until steaming hot before eating.
3. Although the risk for listeriosis associated with foods from delicatessen counters is relatively low, pregnant women and immunosuppressed persons may choose to avoid these foods or to thoroughly reheat cold cuts before eating them.

<sup>a</sup>Persons immunocompromised by illness or medications, pregnant women, and the elderly.

From Centers for Disease Control. Update: foodborne listeriosis—United States, 1988-1990. MMWR Morb Mortal Wkly Rep 41:251, 1992.

raw food from animals and thorough washing of vegetables and utensils. Persons at high risk, such as pregnant women, should also avoid soft cheeses and prepared salads, meats, and cheeses from deli counters. Thoroughly heating leftover foods until steaming hot has also been recommended.<sup>61</sup> Following these guidelines may be difficult for all pregnant women, and their effectiveness in reducing sporadic cases of perinatal listeriosis will be difficult to ascertain. However, a decrease in the rates of listeriosis in some geographic areas in the United States has been temporally associated with the publication of these guidelines and industry efforts directed at removing foodborne pathogens from the food chain.<sup>285,286,287</sup>

Early Localized Disease	
Early Disseminated and Late Disease	
<b>Prognosis</b>	<b>493</b>
<b>Prevention</b>	<b>494</b>

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne illness in the United States. Although, in retrospect, a form of the illness had been recognized in Scandinavia in the early 1900s, modern awareness of Lyme disease began after a cluster of cases of “juvenile rheumatoid arthritis” in children living on one small street was reported by their parents in the mid-1970s. Investigation of this unexplained “epidemic” of arthritis led to the description of “Lyme arthritis” in 1976 and, ultimately, to the discovery of its bacterial etiology.<sup>1-3</sup> Both the reported incidence of Lyme disease and its geographic range have increased dramatically in recent years.<sup>4</sup>

Several spirochetes are known to cause transplacental infections in a variety of animals and in humans.<sup>5-11</sup> *Treponema pallidum* is the spirochete that has been the most thoroughly investigated with respect to transplacental transmission in humans.<sup>5</sup> Infection of the mother with *T. pallidum* during pregnancy frequently is associated with transplacental infection, resulting in congenital syphilis in the offspring. Congenital syphilis often is associated with clinically significant neurologic disease such as hydrocephalus, cerebral palsy, deafness, blindness, convulsive disorders, and mental retardation.<sup>5</sup> Adverse fetal outcomes also have been documented in gestational infections with *Leptospira canicola*, the etiologic agent of leptospirosis, and with other *Borrelia* species including *Borrelia recurrentis*, the etiologic agent of relapsing fever.<sup>6-10</sup> Because *B. burgdorferi* is a spirochete, whether it too can cause congenital infection naturally is of considerable interest.

## EPIDEMIOLOGY AND TRANSMISSION

*B. burgdorferi* is transmitted by ticks of the ixodid species. In the United States, in both the Northeast and the upper Midwest, the usual vector is *Ixodes scapularis* (the black-legged tick), commonly called the deer tick, whereas *Ixodes pacificus* (the Western black-legged tick) is the usual vector on the Pacific Coast.<sup>12</sup> In Europe, the most important vector for the spirochete is *Ixodes ricinus*, which commonly feeds on sheep and cattle.

The life cycle of *I. scapularis* consists of three stages—larva, nymph, and adult—that develop during a 2-year period.<sup>12</sup> Ticks feed once during each stage of the life cycle. The larvae emerge in the early summer from eggs laid in the spring by the adult female tick. More than 95% of the larvae are born uninfected with *B. burgdorferi*, because transovarial transmission rarely occurs. The larvae feed on a wide variety of small mammals, such as the white-footed mouse, which are natural reservoirs for *B. burgdorferi*. Larvae become infected by feeding on animals that are infected with the spirochete. The tick emerges the following spring in the nymphal stage. It is this stage of the tick that is most likely to transmit infections to humans,<sup>13</sup> presumably because it is active at times during which humans are most likely to be in tick-infested areas and because it is very small and difficult to see. Consequently, it is more likely to be able to feed for a relatively long time, which increases the likelihood of transmission. If the nymphal tick is not infected with *B. burgdorferi*, it may subsequently become infected if it feeds on an infected animal in this stage of its development. The nymphs molt in the late summer or early fall and re-emerge as adults. If the adult is infected, it also may transmit *B. burgdorferi* to humans. The adult deer tick may spend the winter on an animal host, a favorite being white-tailed deer (hence its name, the deer tick). In the spring the females lay their eggs and die, thereby completing the 2-year life cycle.

A number of factors are associated with the risk of transmission of *B. burgdorferi* from infected ticks to humans. The proportion of infected ticks varies greatly, both by geographic area and by the stage of the tick in its life cycle. *I. pacificus* often feeds on lizards, which are not a competent reservoir for *B. burgdorferi*. Consequently, less than 5% of these ticks are infected with *B. burgdorferi*, so Lyme disease is rare in the Pacific states. By contrast, *I. scapularis* feeds on small mammals that are competent reservoirs for *B. burgdorferi*. As a result, in highly endemic areas the rates of infection for different stages of deer ticks are, approximately, 2% for larvae, 15% to 30% for nymphs, and 30% to 50% for adults.

*B. burgdorferi* is transmitted when an infected tick inoculates saliva into the blood vessels of the skin of its host. The risk of transmission of *B. burgdorferi* from infected deer ticks has been shown to be related to the duration of feeding.

\*See references 75, 76, 80, 83, 85, 87, 88, 93, 96, 98, 101, 115, 121-124, 134, 140, 143.

**Figure 15-1** Worldwide geographic distribution of reported Lyme disease.

It takes hours for the mouth parts of ticks to implant in the host, and much longer (days) for the tick to become fully engorged from feeding. *B. burgdorferi* is found primarily in the midgut of the tick, but as the tick feeds and becomes engorged, the bacteria migrate to the salivary glands, from which they can be transmitted. Experiments with animals have shown that infected nymph-stage ticks must feed for 48 hours or longer and infected adult ticks must feed for 72 hours or longer before the risk of transmission of *B. burgdorferi* becomes substantial.<sup>14-16</sup> Results of a study of transmission of Lyme disease to humans are consistent with these experimental results.<sup>13</sup> Among persons bitten by nymphal stage ticks for which the duration of feeding could be estimated, the risk of Lyme disease was zero among persons bitten by nymphs that had fed for less than 72 hours but was 25% among persons bitten by nymphs that had fed for 72 hours or more. Approximately 75% of persons who recognize that they have been bitten by a deer tick remove the tick within 48 hours after it has begun to feed.<sup>17</sup> This may explain why only a small proportion of persons who recognize that they have been bitten by deer ticks subsequently develop Lyme disease. Indeed, the risk of Lyme disease probably is greater from *unrecognized* bites, because in such instances the tick is able to feed for a longer time.

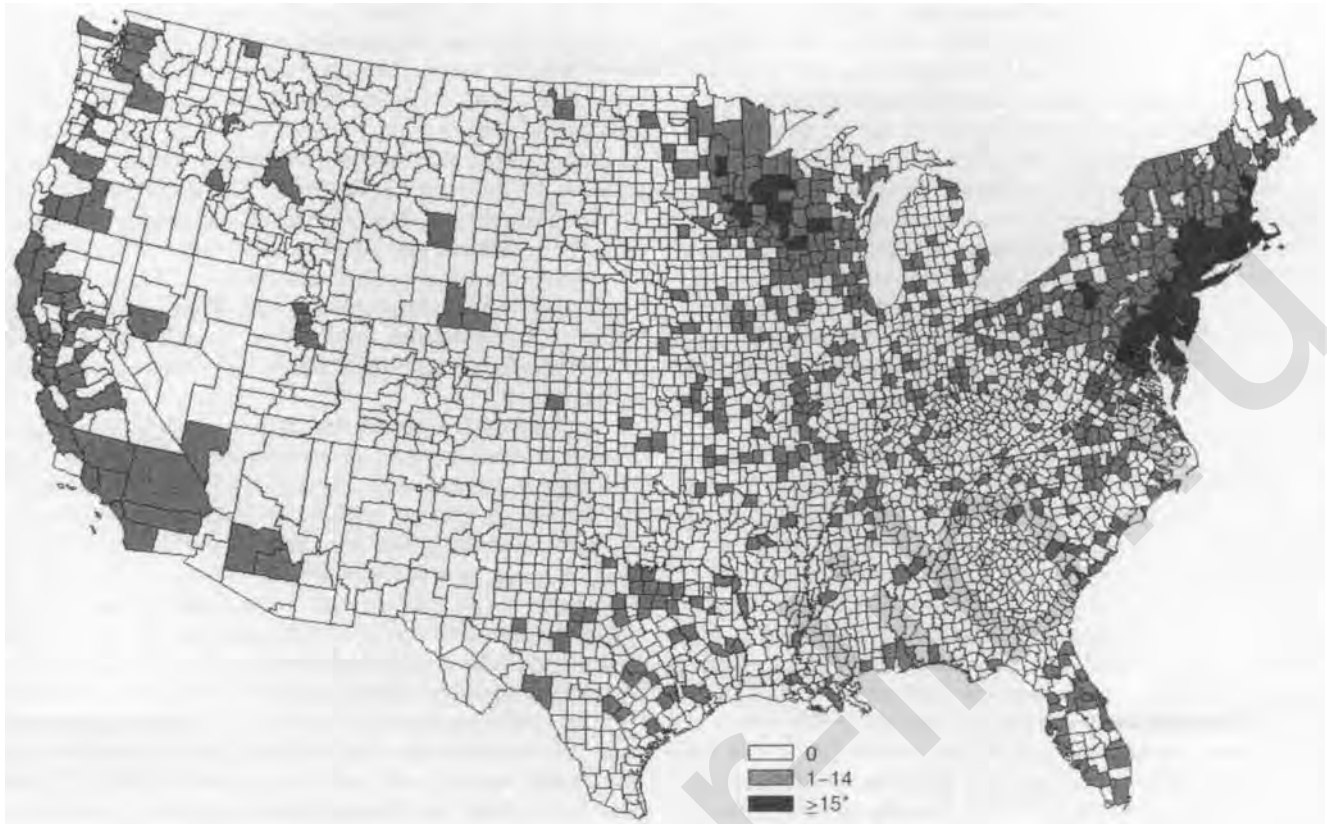

Substantial evidence indicates that the risk of Lyme disease after a recognized deer tick bite, even in hyperendemic areas, is only 1% to 3%.<sup>13,18,19</sup> Unfortunately, the expertise to identify the species, stage, and degree of engorgement of a tick, and

thereby to assess the degree of risk, is rarely available to persons who are bitten. Many “ticks” submitted for identification by physicians turned out actually to be spiders, lice, scabs, or dirt, none of which can transmit Lyme disease. In addition, estimates by patients of the duration for which the tick fed are unreliable.<sup>20</sup>

Lyme disease occurs throughout the world (Fig. 15-1). In the United States, most cases occur in a few highly endemic areas—southern New England, New York, New Jersey, Pennsylvania, Minnesota, and Wisconsin (Fig. 15-2).<sup>21</sup> In Europe, most cases occur in the Scandinavian countries and in central Europe (especially in Germany, Austria, and Switzerland), although cases have been reported from throughout the region.

Although an increase in frequency and an expansion of the geographic distribution of Lyme disease in the United States have occurred in recent years, the incidence of Lyme disease even in endemic areas varies substantially, both from region to region and within local areas. Information about the incidence of the disease is complicated by reliance, in most instances, on passive reporting of cases as well as by the high frequency of misdiagnosis of the disease. Furthermore, studies have indicated that some patients in whom serologic evidence of recent infection with *B. burgdorferi* develops are asymptomatic.<sup>22,23</sup>

A total of 17,730 cases of Lyme disease were reported to the Centers for Disease Control and Prevention (CDC) by 44 states and the District of Columbia in 2000 (a 9% increase

**Figure 15-2** Number of cases of Lyme disease, by county: United States, 2000. (From MMWR Morb Mortal Wkly Rep 5:31, 2002 [available at <http://www.cdc.gov/mmwr/PDF/wk/mm5102.pdf>].)

from 1999).<sup>21</sup> Approximately 90% of the reported cases occurred in just 124 counties (see Fig. 15-2).

## MICROBIOLOGY

The spirochetal bacterium *B. burgdorferi* is a fastidious, microaerophilic organism that in vitro must be grown on special media. It is a slow-growing bacterium with a cell membrane that is covered by flagella and a loosely associated outer membrane. Major antigens of the bacteria include the outer-surface lipoproteins OspA, OspB, and OspC (highly charged basic proteins of molecular masses of about 31, 34, and 23 kDa, respectively), as well as the 41-kDa flagellar protein. The organism is more properly classified as the *Borrelia burgdorferi* sensu lato ["in the broad sense"] species complex, which has been subclassified into several genospecies, among which the major ones that cause human diseases are *Borrelia burgdorferi* sensu stricto ["in the strict sense"], *Borrelia garinii*, and *Borrelia afzelii*. In the United States only *B. burgdorferi* sensu stricto has been isolated from humans. By contrast, substantial variability exists in the species of *B. burgdorferi* isolated from humans in Europe, most of which are either *B. garinii* or *B. afzelii*. The complete genome of the organism has been sequenced.<sup>24</sup> The biology of *B. burgdorferi* is complex, as might be expected in view of the complicated life cycle of this vector-borne bacterium, part of which is spent in ticks (with a primitive immune system) and part of which is spent in mammals, which have a highly

evolved immune system. The reader is referred to other sources for detailed discussion of the biology of this organism.<sup>25</sup>

## PATHOGENESIS AND PATHOLOGY

In approximately 90% of patients in the United States, Lyme disease begins with the characteristic expanding skin lesion, erythema migrans, at the site of the tick bite.<sup>26,27</sup> The spirochete subsequently disseminates by means of the bloodstream, producing the malaise, fatigue, headache, arthralgia, myalgia, fever, and regional lymphadenopathy that may be associated with early Lyme disease, as well as the clinical manifestations of early disseminated and, ultimately, of late Lyme disease. The spirochete's ability to spread through skin and other tissues may be facilitated by the binding of human plasminogen and its activators to the surface of the organism.<sup>28</sup> During dissemination, *B. burgdorferi* attaches to certain host integrins,<sup>29,30</sup> matrix glycosaminoglycans,<sup>31</sup> and extracellular matrix proteins,<sup>32</sup> which may explain the organism's particular tissue tropisms (e.g., collagen fibrils in the extracellular matrix in the heart, nervous system, and joints).<sup>31</sup> In addition, the sequences of OspC vary considerably among strains, and only a few groups of sequences are associated with disseminated disease.<sup>33</sup>

Studies in mice have clearly demonstrated the importance of inflammatory innate immune responses in controlling early disseminated Lyme disease.<sup>34,35</sup> In humans with erythema

migrans, infiltrates of macrophages and T cells produce both inflammatory and anti-inflammatory cytokines.<sup>36</sup> In addition, evidence suggests that in disseminated infections, adaptive T cell and B cell responses in lymph nodes produce antibodies against many components of the spirochete.<sup>37,38</sup>

A nonhuman primate animal model of neuroborreliosis has been developed to help elucidate the spread of *B. burgdorferi* within the nervous system.<sup>39</sup> In immunosuppressed monkeys with an exceptionally large spirochetal burden, *B. burgdorferi* infiltrated the leptomeninges, motor and sensory nerve roots, and dorsal root ganglia, but not the brain parenchyma.<sup>40</sup> *B. burgdorferi* also infiltrated the perineurium (the connective tissue sheath surrounding each bundle of peripheral nerve fibers) in the peripheral nervous system of these monkeys.

A C3H mouse model of Lyme carditis has been developed in which cardiac infiltrates of macrophages and T cells produce inflammatory cytokines.<sup>41</sup> In these mice, the killing of spirochetes through cellular immune mechanisms appears to be the dominant factor in the resolution of cardiac disease.<sup>42</sup>

Synovial tissue from patients with Lyme arthritis typically shows synovial hypertrophy, vascular proliferation, and a marked mononuclear cell infiltrate. Sometimes pseudolymphoid follicles are present that are reminiscent of peripheral lymph nodes.<sup>43</sup> During the attack of Lyme arthritis, innate immune responses to *B. burgdorferi* lipoprotein, as well as marked adaptive immune responses to many spirochetal proteins, are found.<sup>38,44,45</sup> A *Borrelia*-specific, inflammatory T<sub>H</sub>1 response can be seen in the joint fluid; however, anti-inflammatory (T<sub>H</sub>2) cytokines also may be present.<sup>46,47</sup> In addition, patients with Lyme arthritis typically have higher *Borrelia*-specific antibody titers than those in patients with other manifestation of Lyme disease.<sup>38,48</sup>

Investigations of Lyme arthritis in inbred strains of mice have demonstrated that severe, acute arthritis develops in certain strains of mice that are infected with *B. burgdorferi* but not in other strains.<sup>49</sup> The components of the immune response that account for these differences have yet to be identified. Effective innate immune responses, however, appear to be important in resistance to arthritis produced by infection with *B. burgdorferi*.<sup>34,35</sup> About 10% of adult patients with Lyme arthritis, particularly those with HLA-DRB1\* 0401 or related alleles, will develop a chronic, antibiotic treatment-resistant, autoimmune arthritis.<sup>50-52</sup>

Several spirochetes have demonstrated the ability to cause transplacental infections in a variety of animals and in humans.<sup>5-11</sup> Transplacental transmission of *B. burgdorferi* has been documented in several animal studies, including case reports, case series, and transmission studies. *B. burgdorferi* has been cultured from fetal tissues of a coyote and a white-footed mouse, as well as from the blood of a newborn calf.<sup>53-55</sup> The presence of *B. burgdorferi* in fetal tissues of a white-footed mouse and a house mouse also has been demonstrated by polymerase chain reaction (PCR) assay.<sup>56</sup> Serologic evaluations also have been used to document in utero fetal infection with *B. burgdorferi* in an aborted calf, a newborn foal, and four beagle pups.<sup>54,55,57</sup> Several animal studies have linked infection with *B. burgdorferi* during pregnancy with fetal wastage and reproductive failure in cows and beagles.<sup>55,57</sup> Infection with *B. burgdorferi* during pregnancy also has been associated with reproductive failure and severe fetal infection in horses,<sup>58</sup> as well as with increased fetal loss in mice.<sup>59</sup>

In animal experiments, transplacental transmission of *B. burgdorferi* was documented by PCR assay in 19 of 40 pups born to female beagles that had been intradermally inoculated with this spirochete multiple times during pregnancy.<sup>57</sup> Only 4 of the 19 pups had culture-positive tissues, and none of the pups had any evidence of inflammation. In other studies, however, female rats inoculated with *B. burgdorferi* intraperitoneally at 4 days of gestation and pregnant hamsters infected by tick bite just before gestation showed no evidence by culture of transplacental transmission of *B. burgdorferi* to their offspring.<sup>60,61</sup> In another study, offspring of naturally infected white-footed mice were unable to transmit *B. burgdorferi* to spirochete-free deer ticks allowed to feed on them.<sup>62</sup>

Transplacental transmission of *B. burgdorferi* in humans has been demonstrated in association with adverse fetal outcome in several case reports. The first was a report by Schlesinger and co-workers in 1985<sup>63</sup> that described a 28-year-old woman with untreated Lyme disease during the first trimester of pregnancy, who gave birth, at 35 weeks of gestation, to an infant with widespread cardiovascular abnormalities. This infant died during the first week of life, and postmortem examination showed spirochetes morphologically compatible with *B. burgdorferi* in the infant's spleen, kidneys, and bone marrow, but not in the heart. In contrast with the mononuclear cell infiltrate and proliferation of fibroblasts usually seen with congenital syphilis,<sup>64</sup> there was no evidence of inflammation, necrosis, or granuloma formation in the infant's heart or other organs. In 1987, MacDonald and co-workers<sup>65</sup> described a 24-year-old woman with untreated Lyme disease in the first trimester of pregnancy who gave birth at term to a 2500-g stillborn infant. *B. burgdorferi* was cultured from the liver, and spirochetes were seen in the heart, adrenal glands, liver, brain, and placenta with both immunofluorescence and silver staining techniques. No evidence of inflammation was seen, however, and no abnormalities were noted except for a small ventricular septal defect. Weber and co-workers in 1988<sup>66</sup> described a 37-year-old woman who received penicillin orally for 1 week for erythema migrans during the first trimester of pregnancy. She subsequently gave birth to a 3400-g infant at term who died at 23 hours of age, of what was believed to be "perinatal brain damage." *B. burgdorferi* was identified in the newborn's brain using immunochromogenic staining with monoclonal antibodies. No significant inflammation or other abnormalities, however, were found in any organ, including the brain, on postmortem examination. In 1997, Trevisan and co-workers<sup>67</sup> described an otherwise healthy child who presented with multiple annular, erythematous lesions, fever, and generalized lymphadenopathy at 3 weeks of age. These clinical abnormalities recurred throughout the first 3 years of life despite oral therapy with amoxicillin and josamycin. A skin biopsy revealed spirochetes by silver stain and was positive for *B. burgdorferi* by PCR assay. In addition, serologic studies were positive for infection with *B. burgdorferi*. The patient's mother had no history of either a tick bite or Lyme disease, but she had been involved in outdoor activities in an endemic area and had a weakly positive serologic test for Lyme disease.

Several case reports have described pregnant women with either erythema migrans or neuroborreliosis who received appropriate antimicrobial therapy at different stages of their pregnancies.<sup>68-72</sup> In none of these reports was there an

association between Lyme disease in the mother and an adverse outcome of the pregnancy.

Transplacental transmission of *B. burgdorferi* also has been investigated in a study of 60 placentas from asymptomatic women who lived in an area endemic for Lyme disease and whose results on serologic testing by enzyme-linked immunosorbent assay (ELISA) were either positive or equivocal for antibodies to *B. burgdorferi*.<sup>73</sup> All 60 placentas were examined with a Warthin-Starry silver stain for evidence of infection with *B. burgdorferi*; 3 (5%) were positive for spirochetes. PCR assays for *B. burgdorferi* nucleotide sequences were performed on 2 of these 3 placentas and were positive in both. The women from whom these 3 placentas were obtained all had equivocal results on ELISAs and negative results on Western blot analysis for Lyme disease as well as negative results on serologic tests for syphilis. In addition, none of these women had a history of either a tick bite or a clinical course consistent with Lyme disease. All of these pregnancies had entirely normal outcomes.

In addition to the individual case reports, several published case series have assessed the relationship between Lyme disease in pregnant women and fetal outcomes. Two of these case studies were conducted by the CDC. The first was a retrospective investigation conducted in 19 women with Lyme disease during pregnancy who were identified by the investigators without knowing the fetal outcomes.<sup>74</sup> The adverse outcomes included prematurity, cortical blindness, intrauterine fetal death, syndactyly, and a generalized neonatal rash. Infection with *B. burgdorferi* could not be directly implicated as the cause of any of these outcomes, however. The second case series included 17 women who acquired Lyme disease during pregnancy and were evaluated prospectively.<sup>75</sup> One woman had a spontaneous abortion with no evidence of an infection with *B. burgdorferi* on either stains or cultures of the fetal tissue, one woman had an infant with isolated syndactyly, and 15 women were delivered of normal infants with no clinical or serologic evidence of infection with *B. burgdorferi*.

In 1999, Maraspin and co-workers<sup>76</sup> reported a series of 105 women with erythema migrans during pregnancy. Ninety-three (88.6%) of the 105 women had healthy infants delivered at term, 2 (1.9%) pregnancies ended with a miscarriage, and 6 (5.7%) ended with a preterm birth. One of the preterm infants had cardiac abnormalities, and 2 died shortly after birth. Four (3.8%) babies born at term had congenital anomalies (1 with syndactyly and 3 with urologic abnormalities). As with a previous study, infection with *B. burgdorferi* could not be directly implicated as the cause of any of these adverse outcomes.

Several epidemiologic studies of Lyme disease during pregnancy also have been conducted. In the first, Williams and co-workers<sup>77</sup> examined 421 serum specimens obtained from cord blood and found no association between the presence of IgG antibodies to *B. burgdorferi* and congenital malformations. In another study, Nadal and co-workers<sup>78</sup> investigated outcomes in 1434 infants of 1416 women for the presence of antibodies to *B. burgdorferi* at the time of delivery. Twelve (0.85%) of the women were found to be seropositive, but only 1 woman had a history consistent with Lyme disease during pregnancy. Of the infants born to the 12 seropositive women, 2 had transient hyperbilirubinemia; 1 had transient hypotonia; 1 was post term and small for

gestational age, with evidence of chronic placental insufficiency; 1 had transient macrocephaly; and 1 had transient supraventricular extra beats. The infant born to the woman with a clinical history of Lyme disease during pregnancy had a ventricular septal defect. At follow-up evaluations approximately 9 to 17 months later, all of the children except for the child with the cardiac defect were entirely well, and none had serologic evidence of infection with *B. burgdorferi*.

In 1994, Gerber and Zalneraitis<sup>79</sup> surveyed neurologists in areas of the United States in which Lyme disease was endemic at that time to determine how many had seen a child with clinically significant neurologic disease whose mother had been diagnosed as having Lyme disease during pregnancy. None of the 162 pediatric and 37 adult neurologists who responded to the survey had ever seen a child whose mother had been diagnosed with Lyme disease during pregnancy. The investigators concluded that congenital neuroborreliosis was either not occurring or occurring at an extremely low frequency in areas endemic for Lyme disease. In a retrospective case-control study carried out in an area endemic for Lyme disease, 796 "case" children with congenital cardiac anomalies were compared with 704 "control" children without cardiac defects with respect to Lyme disease in their mothers either during or before the pregnancy.<sup>80</sup> No association was found between congenital heart defects and either a tick bite or Lyme disease in the mothers either within 3 months of conception or during pregnancy.

Investigators in New York performed two studies of the relationship between Lyme disease in pregnant women and adverse outcomes of the pregnancies. The first was an unselected, prospective, population-based investigation in an area endemic for Lyme disease in which approximately 2000 women in Westchester County, New York, were evaluated for clinical and serologic evidence of Lyme disease at the first prenatal visit and again at delivery.<sup>81</sup> Of these women, 11 (0.7%) were seropositive and 79 (4%) reported at the first prenatal visit that they had had Lyme disease sometime in the past. One woman with an untreated influenza-like illness in the second trimester had a negative result on serologic testing for Lyme disease at the prenatal visit but a positive result at delivery. In addition, during the study period, clinical Lyme disease was diagnosed in 15 pregnant women. No association was found between exposure of the mother to *B. burgdorferi* either before conception or during pregnancy and fetal death, prematurity, or congenital malformations. In the second study, the researchers compared 5000 infants, half from an area in which Lyme disease was endemic and half from an area without Lyme disease, who served as controls. The researchers found no significant difference in the overall incidence of congenital malformations between the two groups.<sup>82</sup> Although there was a statistically significant higher rate of cardiac malformations in the endemic area compared with that in the control area, no relationship was noted between a cardiac malformation and either a clinical history or serologic evidence of Lyme disease. The researchers concluded from the findings of these two studies that a pregnant woman with a past infection with *B. burgdorferi*, either treated or untreated, did not have an increased risk of early fetal loss or of having a low-birth-weight infant or an infant with congenital malformations.<sup>82</sup>

Two reports have documented the presence of *B. burgdorferi* in cow's milk. In 1988, Burgess<sup>55</sup> cultured *B. burgdorferi* from

1 of 3 samples of colostrum from cows but from none of 44 samples of cow's milk. Lischer and co-workers<sup>83</sup> used a PCR assay to identify nucleotide sequences of *B. burgdorferi* in the milk of a cow with clinical Lyme disease. In a similar investigation of human milk, Schmidt and co-workers<sup>84</sup> examined breast milk from two lactating women with erythema migrans and from three lactating women with no clinical evidence of Lyme disease. The breast milk samples from both women with erythema migrans tested positive for *B. burgdorferi* by PCR assay, whereas the breast milk samples from all three healthy women tested negative. No other reports have corroborated these findings in human milk, however, and transmission of Lyme disease through breast-feeding has never been documented.

## CLINICAL MANIFESTATIONS

The clinical manifestations of Lyme disease depend on the stage of the illness—early localized disease, early disseminated disease, or late disease.<sup>4,85</sup> Erythema migrans, the manifestation of *early localized Lyme disease*, appears at the site of the tick bite, 3 to 30 days (typically 7 to 10 days) after the bite. Erythema migrans is found in about 90% of patients with objective evidence of infection with *B. burgdorferi*.<sup>26,27,86</sup> Erythema migrans begins as a red macule or papule and expands for days to weeks to form a large, annular, erythematous lesion that is at least 5 cm and as much as 70 cm in diameter (median, 15 cm). This rash may be uniformly erythematous, or it may appear as a target lesion with a variable degree of central clearing. It can vary greatly in shape and, occasionally, may have vesicular or necrotic areas in the center. Erythema migrans is usually asymptomatic but may be pruritic or painful, and it may be accompanied by systemic findings such as fever, malaise, headache, regional lymphadenopathy, stiff neck, myalgia, or arthralgia.

The most common manifestation of *early disseminated Lyme disease* in the United States is multiple erythema migrans. The secondary skin lesions, which usually appear from 3 to 5 weeks after the tick bite, consist of multiple annular erythematous lesions similar to, but usually smaller than, the primary lesion. Other common manifestations of early disseminated Lyme disease are cranial nerve palsies, especially facial nerve palsy, and meningitis. Systemic symptoms such as fever, myalgia, arthralgia, headache, and fatigue also are common in this stage of Lyme disease. Carditis, which usually is manifested by various degrees of heart block, is a rare manifestation of early disseminated disease.<sup>27</sup>

The most common manifestation of *late Lyme disease*, which occurs weeks to months after the initial infection, is arthritis. The arthritis is usually monoarticular or oligoarticular and affects the large joints, particularly the knee. Although the affected joint often is swollen and tender, the intense pain associated with a septic arthritis usually is not present; not infrequently, the swollen joint is only mildly symptomatic. Encephalitis, encephalopathy, and polyneuropathy also are manifestations of late Lyme disease, but they are rare.

The clinical manifestations of Lyme disease also may depend on which subspecies of *B. burgdorferi* is causing the infection.<sup>26</sup> The differences in subspecies found in Europe and in North America may account for differences in the

frequencies of certain clinical manifestations of Lyme disease in these areas. For example, neurologic manifestations of Lyme disease are more common in Europe, whereas rheumatologic manifestations are more common in North America. In addition, certain skin and soft tissue manifestations of Lyme disease, such as acrodermatitis chronica atrophicans and lymphocytomas, occur in Europe but are extremely rare in the United States.

*Ixodes* ticks may transmit other pathogens in addition to *B. burgdorferi*, including *Babesia*, *Ehrlichia*, other *Borrelia* species, and viruses. These agents may be transmitted either separately from or simultaneously with *B. burgdorferi*. The frequency with which co-infection occurs is unknown, however, and its impact on both the clinical presentation and the response to treatment of Lyme disease is not well established.

## DIAGNOSIS

The CDC clinical case definition for Lyme disease initially was intended for epidemiologic surveillance purposes.<sup>87</sup> When used in conjunction with CDC and Food and Drug Administration (FDA) guidelines for diagnostic tests,<sup>87-89</sup> however, this case definition has been widely accepted as a means to standardize the clinical diagnosis of Lyme disease (Table 15-1).

**Table 15-1 CDC Lyme Disease Case Definition for Public Health Surveillance Purposes**

Erythema migrans
Single primary red macule or papule, expanding over days to weeks to large round lesion $\geq 5$ -cm diameter (physician-confirmed), $\pm$ central clearing, $\pm$ secondary lesions, $\pm$ systemic symptoms (fever, fatigue, headache, mild neck stiffness, arthralgia, myalgia)
PLUS
Known exposure $\leq 30$ days before onset to an endemic area (in which $\geq 2$ confirmed cases have been acquired, or in which <i>B. burgdorferi</i> -infected tick vectors are established)
OR
One or more late manifestations without other etiology:
1. Musculoskeletal
–Recurrent brief episodes of monoarticular or pauciarticular arthritis with objective joint swelling, $\pm$ chronic arthritis
2. Neurologic
–Lymphocytic meningitis, facial palsy, other cranial neuritis, radiculoneuropathy, encephalomyelitis (confirmed by CSF <i>B. burgdorferi</i> antibody $>$ serum <i>B. burgdorferi</i> antibody)
3. Cardiovascular
–Acute second- or third-degree atrioventricular conduction defects, lasting days to weeks, $\pm$ myocarditis
PLUS
Laboratory confirmation by either:
1. Isolation of <i>B. burgdorferi</i> from patient specimen
2. Diagnostic levels of <i>B. burgdorferi</i> IgM or IgG antibodies in serum or CSF (initial ELISA or IFA screen followed by Western blot of positive or equivocal results)

CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assay.

Adapted from Centers for Disease Control and Prevention. MMWR Morb Mortal Wkly Rep 46(RR):20–21, 1997.

For patients in locations endemic for Lyme disease who present with the characteristic lesion of erythema migrans, the diagnosis of Lyme disease should be based on the clinical presentation alone. In such situations, laboratory testing is neither necessary nor recommended. With the exception of erythema migrans, however, the clinical manifestations of Lyme disease are nonspecific. Therefore, for patients who do not have erythema migrans, the diagnosis of Lyme disease should be based on clinical findings supported by results of laboratory tests. These laboratory tests may consist of either direct identification of *B. burgdorferi* in the patient or demonstration of a serologic response to the organism.

Methods for identifying the presence of *B. burgdorferi* in a patient (e.g., culture, histopathologic examination, antigen detection) generally have poor sensitivity and/or specificity and may require invasive procedures (such as a biopsy of the skin) to obtain an appropriate specimen for testing. Isolation of *B. burgdorferi* from a symptomatic patient should be considered diagnostic of Lyme disease. *B. burgdorferi* has been isolated from blood, skin biopsies, cerebrospinal fluid (CSF), myocardial biopsies, and the synovium of patients with Lyme disease. The medium in which *B. burgdorferi* is cultured is expensive, however, and it can take as long as 6 weeks for the spirochete to grow in culture. The best chance of culturing *B. burgdorferi* from a patient is when erythema migrans is present,<sup>90</sup> although at this stage of the disease, the diagnosis should be largely clinical. During the later stages of Lyme disease, culture is much less sensitive. In addition, it is necessary for patients to undergo an invasive procedure, such as a biopsy, to obtain appropriate tissue or fluid for culture. Therefore, culture is indicated only in rare circumstances.

*B. burgdorferi* has been identified with silver stains (Warthin-Starry or modified Dieterle) and with immunohistochemical stains (with monoclonal or polyclonal antibodies) in skin, synovial, and myocardial biopsies. *B. burgdorferi* can be confused with normal tissue structures, however, or it may be missed, because it often is present in low concentrations. Considerable training and experience are needed for skill in identifying spirochetes in tissues. Therefore, direct detection of *B. burgdorferi* in tissue is of limited practical value.

Attempts have been made to develop antigen-based diagnostic tests for Lyme disease, but no convincing data indicating the accuracy of any of these tests are available. All of these tests should be considered experimental until additional studies confirm their validity and reproducibility. Assays to detect *B. burgdorferi* antigens in CSF or urine, including the Lyme urine antigen test (LUAT) based on the procedure of Hyde and colleagues,<sup>91,92</sup> have both poor specificity and poor sensitivity and therefore are not recommended.<sup>93</sup>

Tests that use PCR techniques to identify *B. burgdorferi* may be helpful. However, results of such tests may be positive for some time after the spirochetes are no longer viable. In addition, the risk of false-positive results on PCR assays is great, especially when they are performed in commercial laboratories. If a PCR test is done, it should be performed in a reference laboratory that meets the highest standards of quality control for diagnostic PCR assays.<sup>92</sup> Because of its limited availability, expense, and insufficient evidence of its value in the management of most patients, PCR is at present reserved for special situations.<sup>94</sup> Use of PCR assay may be appropriate in testing of specimens such as synovial tissue or

fluid from patients with persistent arthritis after a course of appropriate antibiotic therapy for late Lyme disease; samples of abnormal CSF from patients who are seropositive for antibodies to *B. burgdorferi* and have a neurologic illness that is compatible with, but not typical of, Lyme disease; and skin biopsy specimens from patients who have a localized rash that is consistent with erythema migrans but have no history of possible exposure or either residence in, or travel to, areas where Lyme disease is endemic.<sup>94</sup> Currently there is insufficient evidence of the accuracy, predictive value, or clinical significance of a PCR test of urine for *B. burgdorferi*, and its use for decisions regarding the management of patients has been strongly discouraged.<sup>94</sup>

Because of the limitations of laboratory tests designed to identify directly the presence of *B. burgdorferi* in a patient, the confirmation of Lyme disease in patients without erythema migrans usually is based on the demonstration of antibodies to *B. burgdorferi* in the serum. The normal antibody response to acute infection with *B. burgdorferi* is well described.<sup>95</sup> Specific immunoglobulin M (IgM) antibodies appear first, usually 3 to 4 weeks after the infection begins. These antibodies peak after 6 to 8 weeks and subsequently decline. However, a prolonged elevation of IgM antibodies sometimes is seen even after effective antimicrobial treatment.<sup>96</sup> Consequently, the results of serologic tests for specific IgM antibodies should not be used as the sole indicator of the timing of an infection. Specific IgG antibodies usually appear 6 to 8 weeks after the onset of the infection. These antibodies peak in 4 to 6 months. The IgG antibody titer may decline after treatment, but even after the patient is clinically cured, these antibodies usually remain detectable for many years.<sup>97,98</sup>

The immunofluorescent antibody test was the initial serologic test for diagnosing Lyme disease. It requires subjective interpretation and is time-consuming to perform, however, and has largely been replaced by ELISA. The ELISA method may give false-positive results because of cross-reactive antibodies in patients with other spirochetal infections (e.g., syphilis, leptospirosis, relapsing fever), certain viral infections (e.g., varicella), and certain autoimmune diseases (e.g., systemic lupus erythematosus). Unlike patients with syphilis, those with Lyme disease do not have positive results on nontreponemal tests for syphilis such as the Venereal Disease Research Laboratory (VDRL) test or rapid plasma reagin (RPR) determination. In addition, antibodies directed against bacteria in the normal oral flora may cross-react with antigens of *B. burgdorferi* to produce a false-positive ELISA result.

The first-generation ELISA method uses either whole cells of *B. burgdorferi* or the supernatant of sonicated spirochetes as the antigen. To improve the specificity of the ELISA, new assays have been developed that use less complex fractions of the spirochetes, such as the bacterial membrane, or purified native or recombinant proteins, alone or in combination.<sup>94</sup>

Immunoblot (Western blot) analysis for serum antibodies to *B. burgdorferi* also is used as a serologic test for Lyme disease. Although some investigators have suggested that the immunoblot is both more sensitive and more specific than the ELISA, there is still some debate about its interpretation. The immunoblot is most useful for validating a positive or equivocal ELISA result, especially in patients with a low clinical likelihood of having Lyme disease. For serologic

testing for Lyme disease, it is recommended that a sensitive ELISA be performed, and, if results are either positive or equivocal, that a Western blot analysis be done to confirm the specificity of the result.<sup>88</sup> Specimens that give a negative result on a sensitive ELISA do not require immunoblot testing.

One reason for the poor sensitivity of serologic tests for Lyme disease is that erythema migrans, which is the clinical finding that usually brings patients to medical attention, usually appears within 2 to 3 weeks of onset of infection with *B. burgdorferi*. Antibodies to *B. burgdorferi* often are not detected at this early stage of the disease. The antibody response to *B. burgdorferi* also may be abrogated in patients with early Lyme disease who receive prompt treatment with effective antimicrobial agent; in these patients, antibodies against *B. burgdorferi* may never develop, at least as a result of that exposure. Most patients with early, disseminated Lyme disease and virtually all patients with late Lyme disease, however, have serum antibodies to *B. burgdorferi*. Seropositivity may persist for years even after successful antimicrobial therapy. Ongoing seropositivity, even persistence of IgM, is not necessarily a marker of active infection. Likewise, serologic tests should not be used to assess the adequacy of antimicrobial therapy.

Unfortunately, serologic tests for Lyme disease have not been adequately standardized. Both the accuracy and the reproducibility of currently available serologic tests, especially widely used, commercially produced kits, are poor.<sup>99-103</sup> Use of these commercial diagnostic test kits for Lyme disease will result in a high rate of misdiagnosis. Moreover, as with any diagnostic test, the predictive value of serologic tests for Lyme disease depends primarily on the probability that the patient has Lyme disease based on the clinical and epidemiologic history and the physical examination (the "pretest probability" of Lyme disease). Use of serologic tests to "rule out" Lyme disease in patients with a low probability of the illness will result in a very high proportion of test results that are falsely positive.<sup>104</sup> Therefore, antibody tests for Lyme disease should *not* be used as screening tests.<sup>89,104,105</sup> With few exceptions, the probability that a patient has Lyme disease will be very low in areas in which Lyme disease is rare. Even in areas with a high prevalence of Lyme disease, patients with *only* nonspecific signs and symptoms, such as fatigue, headache, and arthralgia, are not likely to have Lyme disease.<sup>104,105</sup> Although such nonspecific symptoms are common in patients with Lyme disease, they are almost always accompanied by more specific objective findings such as erythema migrans, facial nerve palsy, or arthritis. Even when more accurate tests performed by reference laboratories are available, clinicians should order serologic tests for Lyme disease selectively, reserving them for patients from populations with a relatively high prevalence of Lyme disease who have specific objective clinical findings that are suggestive of Lyme disease, so that the predictive value of a positive result is high.<sup>104-106</sup>

Clinicians should realize that even though a symptomatic patient has a positive result on serologic testing for antibodies to *B. burgdorferi*, Lyme disease may not be the cause of that patient's symptoms. In addition to the possibility that it is a falsely positive result (a common occurrence), the patient may have been infected with *B. burgdorferi* previously, and the patient's symptoms may be unrelated to that previous infection. As noted earlier, once serum antibodies to *B. burgdorferi* do develop, they may persist for many years

despite adequate treatment and clinical cure of the illness.<sup>97,98</sup> In addition, because symptoms never develop in some people who become infected with *B. burgdorferi*, in endemic areas there will be a background rate of seropositivity among patients who have never had clinically apparent Lyme disease.

The diagnosis of an infection of the central nervous system with *B. burgdorferi* is made by demonstrating the presence of inflammation in the CSF as well as *Borrelia*-specific intrathecal antibodies.<sup>92,107</sup> Most patients with typical cases of Lyme neuroborreliosis have antibodies to *B. burgdorferi* in serum, and testing for the presence of antibodies in the CSF usually is not necessary.<sup>94</sup> In some instances, however, examination of the CSF for antibodies to *B. burgdorferi* may be indicated. Because antibodies to *B. burgdorferi* may be present in the CSF as the result of passive transit through a leaky blood-brain barrier, detection of antibodies in the CSF is not proof of infection of the CNS by the organism. Better evidence of CNS disease is the demonstration of intrathecal production of antibodies. This is accomplished by simultaneously measuring the antibodies in the serum and CSF by ELISA and calculating the "CSF index."<sup>94</sup> As noted previously, a PCR test of the CSF may be helpful in confirming the diagnosis of CNS Lyme disease.<sup>92,94</sup>

A lymphoproliferative assay that assesses the cell-mediated immune response to *B. burgdorferi* has been developed and used as a diagnostic test for Lyme disease. This assay has not been standardized, however, and is not approved by the FDA. The indications for this lymphoproliferative assay are few, if any.<sup>94</sup>

The diagnosis of Lyme disease in a pregnant woman should be made in accordance with the currently accepted CDC case definition (see Table 15-1). There is no indication for routine prenatal serologic screening of asymptomatic healthy women. Serosurveys have demonstrated that the seroprevalence rates among pregnant women were comparable with those in the general population<sup>81,82,108</sup> and that asymptomatic seroconversion during pregnancy was unusual.<sup>81</sup>

## MANAGEMENT AND TREATMENT

Pediatricians are sometimes confronted with the challenge of how to manage a baby born to a woman who was diagnosed with Lyme disease during her pregnancy. The difficulty arises because of the paucity of evidence that congenital Lyme disease is a clinical problem. In addition, for reasons cited earlier, the diagnosis in the mother often is not accurate. First, parents should be reassured that there is no evidence that the child is at increased risk of any problem from maternal Lyme disease. Next, an attempt should be made to ascertain the accuracy of the diagnosis in the mother; if the mother did not have objective signs of Lyme disease (e.g., erythema migrans) or if the diagnosis was based on nonspecific symptoms (e.g., fatigue, myalgia) and a positive serology, it is likely that the diagnosis is not accurate. There is no reason to order serologic tests for Lyme disease in infants who are asymptomatic (even if diagnosis of Lyme disease in the mother is accurate). If such tests are ordered, it is important to remember that if the mother did have Lyme disease and is seropositive, the infant may have passively acquired antibodies from the mother and so may remain seropositive for many months even in the absence of infection.

**Table 15–2 Antimicrobial Treatment of Lyme Disease**

**Early Disease**

**Localized Erythema Migrans**

Doxycycline, 2-4 mg/kg/day divided bid (maximum: 100 mg/dose) for 10-21 days (do not use in children < 8 years of age), or amoxicillin, 50 mg/kg/day divided tid (maximum: 500 mg/dose) for 14-21 days. The preferred alternative agent for those who cannot take either amoxicillin or doxycycline is cefuroxime axetil, 30 mg/kg/day divided bid (maximum: 500 mg/dose) for 14-21 days. Erythromycin or azithromycin are less effective alternatives for patients who cannot take the other recommended agents.

**Early Disseminated Disease**

**Multiple Erythema Migrans**

Treat as for localized erythema migrans but for 21 days

**Neurologic Disease**

**1. Isolated seventh nerve or other cranial nerve palsy**

Treat as for localized erythema migrans but for 21-28 days

**2. Meningitis (with or without encephalitis or radiculoneuritis)**

Ceftriaxone: 75-100 mg/kg once daily (maximum: 2 g/dose) for 14-28 days

Alternatives include penicillin G, 200,000-400,000 units/kg/day (maximum: 18-24 million units/day) divided q4h or cefotaxime 150 mg/kg/day (maximum: 2 g/dose) divided q8h for 14-28 days

**Carditis**

**1. First- or second-degree heart block**

Treat as for localized erythema migrans

**2. Third-degree heart block or other evidence of severe carditis**

Treat as for meningitis

**Late Disease**

**Arthritis**

Doxycycline, 2-4 mg/kg/day divided bid (maximum: 100 mg/dose) for 28 days (do not use in children <8 years of age), or amoxicillin, 50 mg/kg/day divided tid (maximum: 500 mg/dose) for 28 days. The preferred alternative agent for those who cannot take either amoxicillin or doxycycline is cefuroxime axetil, 30 mg/kg/day divided bid (maximum: 500 mg /dose) for 28 days. For recurrent or persistent arthritis for which oral treatment has failed, either a second course of one of the orally administered agents for 28 days or a course of parenteral treatment for 14-28 days (as for meningitis) is indicated.

**Neurologic Disease**

As for meningitis above for 14-28 days

Because of the high frequency of false-positive test results, a positive test for IgM antibodies against *B. burgdorferi* in an asymptomatic child should be interpreted with a high degree of skepticism.

The choice of antibiotic and the duration of treatment for Lyme disease depend on the stage of the disease that is being treated (Table 15-2). In general, pregnant women should receive the same treatment as for other patients, except that use of doxycycline is not recommended during pregnancy.

**Early Localized Disease**

Doxycycline is the drug of choice for children 8 years of age and older with early localized Lyme disease.<sup>109</sup> Exposure to the sun should be avoided by persons who are taking doxycycline, because a rash develops in sun-exposed areas 20% to

30% of the time. Use of sunscreen may decrease this risk. Amoxicillin is recommended for children younger than 8 years of age, for pregnant women, and for patients who cannot tolerate doxycycline. For patients allergic to penicillin, alternative drugs are cefuroxime axetil, erythromycin, and azithromycin. Erythromycin and azithromycin may be less effective than other agents. Most experts recommend a 14- to 21-day course of therapy for early localized Lyme disease, although evidence indicates that 10 days of doxycycline constitutes adequate treatment in adults with uncomplicated infection.<sup>110</sup> A prompt clinical response to treatment is usual, with resolution of the erythema migrans within several days of initiating therapy. Occasionally, a Jarisch-Herxheimer reaction, which usually consists of an elevated temperature and worsening myalgia, develops shortly after antimicrobial treatment is initiated. These reactions typically last 1 to 2 days and do not constitute an indication to discontinue antimicrobial therapy, and symptoms respond to nonsteroidal anti-inflammatory agents. Appropriate treatment of erythema migrans almost always prevents development of the later stages of Lyme disease.

**Early Disseminated and Late Disease**

Multiple erythema migrans and initial episodes of arthritis should be treated with orally administered antimicrobial agents. If peripheral facial nerve palsy is the only neurologic manifestation of Lyme disease, the patient can be given an oral regimen of antimicrobials. If the facial nerve palsy is accompanied by clinical evidence of central nervous system involvement (e.g., severe headache, nuchal rigidity), a lumbar puncture should be performed. If there is pleocytosis, parenterally administered antimicrobials should be prescribed. Meningitis and recurrent or persistent arthritis also should be treated with parenterally administered antimicrobial agents. Some experts, however, will prescribe a second course of an orally administered antimicrobial agent for recurrent or persistent arthritis before using a parenterally administered agent. Nonsteroidal anti-inflammatory agents are a useful adjunct to antimicrobial therapy for patients with arthritis. Although mild carditis is usually treated orally with either doxycycline or amoxicillin, most experts recommend parenterally administered therapy for severe carditis. Other neurologic manifestations of late Lyme disease (e.g., encephalitis, encephalopathy, polyneuropathy) should be treated with antimicrobials administered parenterally.

The optimal duration of antimicrobial therapy for the various stages of Lyme disease is not well established, but there is no evidence that children with any manifestation of Lyme disease benefit from prolonged (longer than 4 weeks) courses of either orally or parenterally administered antimicrobial agents. Lyme disease, like other infections, may trigger a fibromyalgia syndrome that does not respond to additional courses of antimicrobials but may be managed with symptomatic therapy.

**PROGNOSIS**

Attempts to determine the potential impact of gestational Lyme disease on the outcome of the pregnancy have been limited for several reasons.<sup>111</sup> First, the prevalence of Lyme

disease among pregnant women, even in highly endemic areas, is low, making it difficult to perform studies with sufficient statistical power. Second, diagnoses of gestational Lyme disease that are based on seropositivity, a history of a tick bite, or even a retrospective clinical history are often unreliable. Finally, because of increased awareness and concern about Lyme disease, it is difficult to find women with suspected gestational Lyme disease who did not receive antimicrobial treatment.

Despite these limitations, it is clear that *B. burgdorferi* can cross the placenta, presumably during a period of spirochetemia. The frequency and clinical significance of transplacental transmission of *B. burgdorferi* are unclear, however. Although a temporal relationship between Lyme disease during pregnancy and adverse outcomes has been documented, a causal relationship has not been established. The claims for the existence of a congenital Lyme disease syndrome are undermined by the absence of an inflammatory response in fetal tissue, absence of a fetal immunologic response, and lack of a consistent clinical outcome in affected pregnancies. An analysis of the current data indicates that there is no evidence of increased risk of abnormal outcomes with Lyme disease during pregnancy.

It is difficult to conduct high-quality studies of clinical outcome in persons with Lyme disease. On the basis of the available data, the long-term prognosis for adults or children who receive appropriate antimicrobial therapy for Lyme disease, regardless of the stage of the disease, appears to be excellent.<sup>11,12</sup> The most common reason for a lack of response to appropriate antimicrobial therapy for Lyme disease is misdiagnosis (i.e., the patient actually does not have Lyme disease). In approximately 10% of adults and less than 5% of children with Lyme arthritis, inflammatory joint disease develops that typically affects one knee for months to years and does not respond to antimicrobial therapy. An increased frequency of certain HLA-DR4 alleles has been noted among these patients, and recent findings suggest that an autoimmune process is involved.<sup>52</sup>

Nonspecific symptoms (such as fatigue, arthralgia, or myalgia) may persist for several weeks, even in patients with successfully treated early Lyme disease; their presence should not be regarded as an indication for additional treatment with antimicrobials. These symptoms usually respond to nonsteroidal anti-inflammatory agents. Within 6 months of completion of the initial course of antimicrobial therapy, these vague, nonspecific symptoms usually resolve without additional antimicrobial therapy. For those unusual patients who have symptoms persisting longer than 6 months after the completion of antimicrobial therapy, an attempt should be made to determine whether these symptoms are the result of a postinfectious phenomenon or have another etiology.

Klempner and co-workers recently reported the results of two controlled trials of antibiotic treatment for adult patients with chronic musculoskeletal pain, neurocognitive symptoms, or both that persisted after antibiotic treatment for Lyme disease.<sup>13</sup> One study included patients who were seropositive for IgG antibodies to *B. burgdorferi* at the time of enrollment; the other study included patients who were seronegative. In both studies, patients were randomly assigned to receive either ceftriaxone administered intravenously for 30 days, followed by doxycycline orally for 60 days, or matching regimens with placebos administered intravenously and orally in a double-

blind manner. No significant differences were noted in the outcomes of patients in the antibiotic treatment group compared with those in the placebo group among either the seropositive or the seronegative patients. These findings support earlier recommendations that such patients are best managed with symptomatic treatment, rather than with prolonged courses of antibiotic therapy, which have been associated with serious adverse side effects.

## PREVENTION

Reducing the risk of tick bites is one obvious strategy to prevent Lyme disease. In endemic areas, clearing brush and trees, removing leaf litter and woodpiles, and keeping grass mowed may reduce exposure to ticks. Application of pesticides to residential properties is effective in suppressing populations of ticks but may be harmful both to other wildlife and to people. Erecting fences to exclude deer from residential yards and maintaining tick-free pets also may reduce exposure to ticks.

Tick and insect repellents that contain *n,n*-diethylmetatoluamide (DEET) applied to the skin provide additional protection, but most preparations require reapplication every 1 to 2 hours for maximum effectiveness. Serious neurologic complications in children from either frequent or excessive application of DEET-containing repellents have been reported, but they are rare and the risk is low when these products are used according to instructions on the label. Use of products with concentrations of DEET greater than 30% is not necessary and increases the risk of adverse effects. DEET should be applied sparingly only to exposed skin, but not to a child's face, hands, or skin that is either irritated or abraded. After the child returns indoors, skin that was treated should be washed with soap and water. Permethrin (a synthetic pyrethroid) is available in a spray for application to clothing only and is particularly effective because it kills ticks on contact.

Because most persons (approximately 75%) who recognize that they were bitten by a tick remove the tick within 48 hours,<sup>17</sup> the risk of Lyme disease from recognized deer tick bites is low—approximately 1% to 3% in areas with a high incidence of Lyme disease. Indeed, the risk of Lyme disease probably is higher from unrecognized bites (because in those cases the tick will feed for a longer time). A recent study of antimicrobial prophylaxis following tick bites among adults found that a single, 200-mg dose of doxycycline was 87% effective in preventing Lyme disease, although the 95% confidence interval around this estimate of efficacy was wide (the lower bound was 25% or less, depending on the method used).<sup>13</sup> In that study, the only persons in whom Lyme disease developed had been bitten by nymph-stage ticks that were at least partially engorged; the risk of Lyme disease in this group was 9.9% (among recipients of placebo), whereas it was zero for bites by all larval and adult deer ticks. Unfortunately, the expertise to identify the species, stage and degree of engorgement of a tick, and thereby to assess the degree of risk, is rarely available to persons who are bitten. Consequently, routine use of antimicrobial agents to prevent Lyme disease in persons who are bitten by a deer tick, even in highly endemic areas, generally is not recommended because the overall risk of Lyme disease is low. Only doxy-

cycline (which is not recommended for children younger than 8 years of age) has been shown to be effective in prophylaxis of Lyme disease.<sup>19</sup> In the unusual instance in which doxycycline prophylaxis is used (e.g., in a nonpregnant patient older than 8 years of age who removes a fully engorged nymph-stage deer tick in an endemic area), only a single dose of doxycycline (200 mg) should be prescribed, and it should be taken with food to minimize nausea.

There is no evidence that pregnant women are at increased risk of Lyme disease after a deer tick bite. Moreover, the only drug that has been shown to be effective in preventing Lyme disease after a tick bite—doxycycline—is not recommended for use during pregnancy because of its possible effect on the developing fetus. Consequently, antimicrobial prophylaxis is not recommended for pregnant women.

Serologic testing for Lyme disease after a recognized tick bite also is not recommended. Antibodies to *B. burgdorferi* that are present at the time that the tick is removed likely would be due either to a false-positive test result or to an earlier infection with *B. burgdorferi*, rather than to a new infection from the recent bite. Likewise, in this setting the predictive value of a positive result is very low.

Ascertainment of whether the tick is infected, using tests such as the PCR assay, is also not recommended. Although testing ticks with a PCR assay may provide important epidemiologic information, the predictive values for infection of humans of either a positive or a negative PCR test result is unknown. The result may be positive even if only very few organisms are present, and it provides no information about the duration of feeding, a key determinant of the risk of transmission. In addition, the problems of both false-positive results due to contamination with amplification products and false-negative results due to inhibition of PCR by substances in the sample (such as blood) limit the test's validity.

People should be taught to inspect themselves and their children's bodies and clothing daily after possible exposure to ixodid ticks. An attached tick should be grasped with medium-tipped tweezers as close to the skin as possible and removed by gently pulling the tick straight out. If some of the mouth parts remain embedded in the skin, they should be left alone, because they usually are extruded eventually; additional attempts to remove them often result in unnecessary damage to tissue and may increase the risk of local bacterial infection.

Mycoplasmas are prokaryotes of the class Mollicutes and represent the smallest known free-living organisms. Notably, they lack a cell wall and are bound by a cell membrane. Many of the biologic properties of mycoplasmas are due to the absence of a rigid cell wall, including resistance to  $\beta$ -lactam antibiotics and marked pleomorphism among individual cells. The mycoplasmal cell membrane contains phospholipids, glycolipids, sterols, and various proteins. Their small size of 150 to 350 nm is more on the order of viruses than of bacteria. Mycoplasmas are able to grow in cell-free media and possess both RNA and DNA. The entire genomes of many of the *Mycoplasma* species have been sequenced and have been found to be among the smallest of prokaryotic genomes, with the *Mycoplasma genitalium* genome consisting of only 580,070 DNA base pairs. The elimination of genes related to synthesis of amino acids, fatty acid metabolism, and cholesterol necessitates a parasitic dependence on their host for exogenous nutrients, such as nucleic acid precursors, amino acids, fatty acids, and sterols. In mammals, *Mycoplasma* species most commonly colonize mucosal surfaces, such as those of the respiratory and genital tracts. At least 16 different species of Mollicutes colonize the mucosa of humans.

*Ureaplasma urealyticum* and *Mycoplasma hominis* are the mycoplasmas most commonly isolated from the genital tract of females and are associated with maternal and fetal infection. Therefore, this chapter focuses on these two species in the maternal-fetal/neonatal and very young infant populations. Mycoplasmal illnesses in other populations, such as immunocompromised older children and nonpregnant adults, are not discussed. *Mycoplasma pneumoniae*, *M. genitalium*, and *Mycoplasma fermentans* are mentioned briefly.

## **UREAPLASMA UREALYTICUM AND MYCOPLASMA HOMINIS: COLONIZATION AND DISEASES OF THE URINARY AND REPRODUCTIVE TRACTS IN ADULTS**

### **Colonization**

*U. urealyticum* and *M. hominis* are commensal organisms in the lower female genital tract. Colonization of the female lower urogenital tract by *U. urealyticum* and *M. hominis* generally occurs as a result of sexual activity. In fact, sexual contact is the major mode of transmission of these organisms, and colonization increases dramatically with increasing numbers of sexual partners.<sup>1,2,28</sup>

In the asymptomatic female, these mycoplasmas may be found throughout the lower urogenital tract, including the external cervical os, vagina, labia, and urethra.<sup>30,31</sup> The vagina yields the largest number of organisms, followed by the periurethral area and the cervix.<sup>31</sup> *U. urealyticum* is isolated less often from urine than from the cervix, but *M. hominis* is present both in the urine and the cervix with approximately the same frequency. In the asymptomatic adult male, mycoplasmas also have been isolated from urine, semen, and the distal urethra.<sup>33</sup>

*U. urealyticum* can be isolated from the vagina of 40% to 80% of sexually active, asymptomatic women; *M. hominis* is found in 21% to 70%. Both microorganisms can be found concurrently in 31% to 60% of women.<sup>6,7</sup> In males, colonization with each is less prevalent. In women, colonization has been linked to younger age, lower socioeconomic status, multiple sexual partners, black ethnicity, oral contraceptive use, and recent antimicrobial therapy.<sup>28,35</sup> Additionally, mycoplasmas are prevalent in the lower genital tract of pregnant women.<sup>6,36,37</sup> When genital mycoplasmas are present at the first prenatal visit, usually they persist throughout the pregnancy. Studies of postmenopausal women suggest that this population is infrequently colonized with genital mycoplasmas.<sup>38</sup>

### **Urinary Tract**

Three disease associations have been established for *U. urealyticum* and *M. hominis* in the urinary tract. These are

urethritis in men caused by *U. urealyticum*, urinary calculi from *U. urealyticum*, and pyelonephritis due to *M. hominis*.<sup>53</sup>

Intraurethral inoculation of human volunteers and non-human primates with *U. urealyticum* produces urethritis.<sup>53</sup> Serologic studies and antimicrobial treatment trials also support a causative role of this organism in urethritis.<sup>53</sup> The common presence of ureaplasmas in the urethra of asymptomatic men suggests either that only certain serovars of ureaplasmas are pathogenic or that predisposing factors, such as lack of mucosal immunity, must exist in those persons in whom symptomatic infection develops. Alternatively, disease may develop only on initial exposure to ureaplasmas. *U. urealyticum* also has been implicated in urethrostatis and epididymitis.<sup>9</sup>

*U. urealyticum* has been shown to have a limited role in the production of urinary calculi. *U. urealyticum* produces urease, which splits urea into ammonia and carbon dioxide, and has been demonstrated to induce crystallization of struvite and calcium phosphates in artificial urine in vitro, demonstrating the capacity of *U. urealyticum* to induce stone formation.<sup>39,40</sup> Renal calculi have been induced experimentally by inoculation of pure cultures of *U. urealyticum* directly into the bladder and renal pelvis of rats. *U. urealyticum* has been isolated from stones recovered by surgery in 6 of 15 patients. In 4 of these 6, no other urease-producing organisms were isolated either in the stone or in urine sampled from the renal pelvis. *Proteus mirabilis* is the most common cause of similar stones in humans. The frequency with which *U. urealyticum* reaches the kidney, the predisposing factors that allow this to occur, and the relative frequency of renal calculi induced by this organism compared with that of calculi induced by other organisms are not known.

Even with the high incidence of *M. hominis* in the lower urogenital tract, this organism has been isolated from the upper urinary tract only in patients with symptoms of acute infection.<sup>41</sup> In one study, *M. hominis* was recovered from samples of ureteral urine collected during surgery from 7 of 80 patients (4 in pure culture) with acute pyelonephritis, and in a second study from 3 of 18 patients with acute exacerbation of chronic pyelonephritis. *M. hominis* was not found in the upper urinary tract of 22 patients with chronic pyelonephritis without acute exacerbation, or from 60 patients with noninfectious urinary tract disease.

### Reproductive Tract

*M. hominis* is considered an etiologic agent of pelvic inflammatory disease.<sup>42,43,49,50</sup> Inoculation of *M. hominis* into fallopian tubes of primates induces parametritis and salpingitis within 3 days,<sup>51</sup> whereas inoculation of human fallopian tube explants produces ciliostasis.<sup>52</sup> The organism has been isolated in pure cultures from the fallopian tubes of approximately 8% of women with salpingitis diagnosed by laparoscopy, but not in any women without salpingitis.<sup>42</sup> The organism also can be isolated from the endometrium. A role for this organism in cases of pelvic inflammatory disease not associated with either *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is supported by significant increases in specific antibodies to *M. hominis*.<sup>49</sup> *U. urealyticum* is not considered to be a cause of pelvic inflammatory disease.<sup>9</sup>

## CHORIOAMNIONITIS, CLINICAL AMNIONITIS, AND MATERNAL SEPTICEMIA

### Histologic Chorioamnionitis

Isolation of *U. urealyticum*, but not *M. hominis*, from the chorioamnion uniformly has shown a significant association with histologic chorioamnionitis.<sup>3,5,10-14</sup> Studies in which extensive culture for other agents was performed reported that women whose amniotic membranes contained *U. urealyticum* were more likely to have histologic evidence of chorioamnionitis than were women without *U. urealyticum*, even after adjusting for duration of labor, premature rupture of membranes, duration of membrane rupture, and the presence of other bacteria.<sup>11</sup> *U. urealyticum* in the chorioamnion was found to be significantly associated with histologic chorioamnionitis in the presence of intact membranes when delivery was by cesarean section.<sup>15</sup> In some cases, *U. urealyticum* was the only organism isolated. Case reports<sup>5,17,18</sup> indicate that *U. urealyticum* can persist in the amniotic fluid for as long as 7 weeks in the presence of an intense inflammatory response and in the absence of ruptured membranes or labor and can be isolated as a single microorganism when cultures for multiple agents are performed. These findings demonstrate that ureaplasmas can produce histologic evidence of chorioamnionitis.

### Infection of the Amniotic Fluid and Clinical Amnionitis

Although *U. urealyticum* and *M. hominis* can invade the amniotic fluid as early as 16 to 20 weeks of gestation in the presence of intact membranes and in the absence of other microorganisms, these infections tend to be clinically silent and chronic (Fig. 16-1).<sup>5,17</sup> *U. urealyticum* and *M. hominis* have been isolated more frequently from the chorioamnion than from the amniotic fluid. Isolation of organisms from the chorioamnion or amniotic fluid has been significantly associated with histologic evidence of chorioamnionitis but not with clinical amnionitis.<sup>15</sup> Ureaplasmas can be detected in the amniotic fluid in up to 50% of both asymptomatic and symptomatic persons.<sup>8</sup> These reports indicate that the role of *U. urealyticum* in clinical amnionitis is not clear.

In an investigation by Yoon and colleagues,<sup>57</sup> amniocentesis was performed in 154 patients with preterm premature rupture of membranes. Amniotic fluid was cultured for aerobic and anaerobic bacteria and for mycoplasmas. Polymerase chain reaction (PCR) assay for *U. urealyticum* also was performed on the fluid. These investigators found that amniotic fluid culture for mycoplasmas missed 42% of cases identified as positive by *U. urealyticum* PCR assay. Patients with a negative result on amniotic fluid culture for *U. urealyticum* but a positive result on PCR assay had a significantly shorter interval from amniocentesis to delivery, higher amniotic fluid interleukin-6 (IL-6) concentrations, and higher white blood cell counts compared with patients with no detection of *U. urealyticum* by culture or PCR assay. Subsequently, in a similar investigation by Yoon and colleagues<sup>58</sup> in 257 patients with preterm labor and intact membranes, significant findings were similar, except that the prevalence of *U. urealyticum* was lower.

**Figure 16-1** **A**, Section of placenta at 24 weeks of gestation showing extensive inflammation in the amnion and chorion (25 $\times$ ). *Ureaplasma urealyticum* was isolated from the amniotic fluid 7 weeks before delivery and from multiple fetal organs at postmortem examination. **B**, Adjacent section of placenta stained with rabbit anti-*U. urealyticum* serovar 1 serum and reacted with fluorescein-labeled goat anti-rabbit immunoglobulin G (IgG) (750 $\times$ ). **C**, Photomicrograph of the umbilical cord from the same case as in **A** and **B** demonstrates extensive inflammation (25 $\times$ ). **D**, Photomicrograph of lung tissue shows histologic evidence of pneumonia (50 $\times$ ).

The detection of *M. hominis* does not correlate with clinical symptoms. *M. hominis* commonly invades the chorioamnion and amniotic fluid, but such invasion rarely occurs in the absence of other organisms, particularly ureaplasmas. Thus, it is unclear whether this organism alone is a cause of histologic chorioamnionitis or clinical amnionitis.<sup>15</sup>

### Postpartum and Postabortal Fever

*M. hominis*<sup>64-67</sup> and *U. urealyticum*<sup>68,69</sup> have been isolated from blood cultures from women with postpartum fever and septic abortion. Serologic investigations indicate that *M. hominis* is a common cause of postpartum fever, as demonstrated by a fourfold or greater rise in mycoplasmacidal antibody titer.<sup>70</sup> In a study at Boston City Hospital,<sup>71</sup> blood was obtained from 327 women shortly after vaginal delivery. Ten of these 327 women had blood cultures that grew *M. hominis*; 15 grew *U. urealyticum*; and in 1 woman, both *M. hominis* and *U. urealyticum* were isolated. The frequency of mycoplasma isolation was inversely related to the interval between delivery and the time at which the blood was obtained for culture. Twenty women whose blood culture grew mycoplasmas at the time of delivery were re-evaluated with a

second culture 1 or more days later; in only 1 of these women was a positive result obtained on the second blood culture. Pathogenic bacteria were cultured from the blood of 16 of these 327 women, including 4 of the 11 women with *M. hominis*, but none from the women with *U. urealyticum*.

In a prospective study of 620 blood cultures from febrile obstetric patients,<sup>73</sup> *U. urealyticum* was the second and *M. hominis* the third most common microorganism isolated. All specimens were obtained during febrile postpartum or postabortal episodes. Mycoplasmas were isolated on a number of occasions from blood drawn more than 2 days after the procedure. Endometritis or histologically documented chorioamnionitis was present in one half of the patients, and fever persisted after delivery or abortion in many of the cases despite administration of antimicrobial agents directed at organisms other than mycoplasmas. Fever resolved after tetracycline therapy.

It has been shown that colonization of the chorioamnion with ureaplasmas in women with intact membranes undergoing cesarean delivery is a significant and independent predictor of ensuing endometritis.<sup>74</sup> Endometritis occurred in 28% of women with ureaplasmas isolated from the chorioamnion at cesarean delivery, compared with only 8.4%

if the culture result was negative, and 8.8% if only bacteria but no ureaplasmas were isolated.

Roberts and associates<sup>75</sup> found ureaplasmas to be the most common microorganism isolated from postcesarean wound infections. Of 47 cultures with a positive result from 939 wounds, ureaplasmas were recovered from 29. Additionally, one third of the cultures positive for ureaplasmas yielded no other microorganisms. Additionally, *M. hominis* has been recovered from the joint fluid of women post partum. These women had been febrile during the immediate postpartum period, and signs of arthritis developed 7 days to 3 weeks after delivery.<sup>76</sup> Cases of postpartum pneumonia with isolation of *M. hominis* from pleural fluid and cases of *M. hominis* wound infections after cesarean section also have been reported.<sup>77-80</sup>

Andrews and co-workers<sup>61</sup> performed a randomized, double-blind, placebo-controlled trial in 597 women to compare rates of postcesarean endometritis after prophylaxis with cefotetan versus cefotetan plus doxycycline and azithromycin. The frequency of postcesarean endometritis and wound infection was significantly lower in the group that received cefotetan plus doxycycline and azithromycin. The investigators concluded that this extended-spectrum antibiotic prophylaxis regimen, with activity against mycoplasmas, reduced the frequency of postcesarean endometritis and wound infection. *Mycoplasma* cultures were not obtained in this investigation, however, so it is not clear that the improved outcome was due to the addition of doxycycline and azithromycin prophylaxis aimed specifically at *Mycoplasma* infections.

## ADVERSE PREGNANCY OUTCOME

### Fetal Loss

Although studies have found the presence of *U. urealyticum* and *M. hominis* in the genital tract to be significantly associated with spontaneous abortion and early pregnancy loss,<sup>62</sup> their actual role in these events remains uncertain. Both organisms have been isolated from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, in some cases in the presence of an inflammatory response and in the absence of other organisms.<sup>5,13,81,82</sup> In these cases, however, it was not clear whether death of the fetus occurred before these organisms "invaded." *U. urealyticum* has been found more frequently in the products of early abortions and midtrimester fetal losses than in products of induced abortions.<sup>83,84</sup> Furthermore, *U. urealyticum* has been isolated more frequently from the placentas of aborted fetuses than from controls.<sup>10,13</sup>

Although rates of isolation of ureaplasmas from the lower genital tract of habitual aborters are not different from those of normal controls, ureaplasmas are isolated more frequently from the endometrium of habitual aborters.<sup>83,84</sup> When only those patients with a positive result on cervical culture are considered, no higher endometrial colonization rates are found, however.<sup>85</sup> Antibody titers to *U. urealyticum* are higher in mothers with a history of fetal loss.<sup>86</sup> Those epidemiologic studies are difficult to interpret, however, because the comparability of the various groups of women is uncertain and the role of other potential infectious agents was not always taken into account.

Isolation of *U. urealyticum* from amniotic fluid in pure culture from women with intact membranes and subsequent fetal loss in the presence of histologic chorioamnionitis has been reported.<sup>5,18,87</sup> Berg and associates<sup>60</sup> performed a retrospective analysis of 2718 amniocentesis specimens obtained for genetic indications and cultured for *U. urealyticum* and *M. hominis*. Of the 2718 patients, 49 (1.8%) patients were found to be positive for one or both organisms. Of 43 evaluable patients, 35 were given oral erythromycin at the discretion of the physician caring for the patient. Rates of midtrimester loss were 11.4% and 44.4% ( $P = .04$ ) in the treated and untreated groups, respectively. This study demonstrated that treatment of amniotic mycoplasmal colonization with erythromycin may decrease midtrimester losses. Prospective controlled trials are necessary to validate this hypothesis, however.

### Preterm Birth

Multiple studies involving almost 12,000 patients have been conducted to evaluate the association of cervical ureaplasma infection with prematurity.<sup>4,88</sup> The evidence suggests no consistent relationship between the presence of *U. urealyticum* in the lower genital tract of the mother and prematurity or low birth weight in the infant.

At least six prospective studies have evaluated the role of ureaplasma infection of the amniotic fluid in etiology of prematurity. Three of these studies investigated the outcome of pregnancy when ureaplasmas were detected at the time of genetic amniocentesis between 12 and 20 weeks of gestation, when membranes were intact and when labor had not begun.<sup>5,87,89</sup> In an investigation by Cassell and colleagues,<sup>5</sup> two infants with *U. urealyticum* isolated from amniotic fluid were born preterm; both infants died, and both had evidence of pneumonia. *U. urealyticum* was isolated in pure culture at postmortem examination in both cases. In a study by Gray and associates,<sup>87</sup> 7 of 10 patients from whom ureaplasmas were isolated by culture of the amniotic fluid subsequently aborted within 4 to 7 weeks after amniocentesis and at less than 25 weeks of gestation. The 3 remaining infants were born at less than 37 weeks of gestation; 2 of these died. Histologic evidence of chorioamnionitis was present in all 10 placentas, and histologic evidence of pneumonia was present in all 8 fetuses. Placentas grew *U. urealyticum*, but results were negative for cultures of all other microorganisms in 6 of 7 evaluated at delivery and from 4 of the 6 fetal lungs that were evaluated. The third and largest investigation by Gerber and co-workers<sup>89</sup> utilized PCR assay and detected *U. urealyticum* in 29 of 254 (11.4%) amniotic fluid specimens. As might be expected, a higher percentage of *U. urealyticum*-positive amniotic fluid samples were found in this study that used PCR than in previous investigations that relied solely on culture. Subsequent preterm labor occurred in 17 (58.6%) *U. urealyticum*-positive women, compared with 10 (4.4%) of those whose cultures were *U. urealyticum* negative ( $P < .0001$ ). Preterm birth occurred in 7 (24.1%) *U. urealyticum*-positive women compared with 1 (0.4%) *U. urealyticum*-negative woman ( $P < .0001$ ). Of note, *U. urealyticum*-positive women did have a higher prevalence of preterm labor in a prior pregnancy (20.7%) than that in the *U. urealyticum*-negative women (2.7%;  $P < .0008$ ).

In contrast with the foregoing studies, in the remaining three studies culture of amniotic fluid was performed on women hospitalized with preterm labor and intact membranes. *U. urealyticum* in the amniotic fluid was not consistently associated with preterm birth in these studies.<sup>90-92</sup> It must be noted that in these later studies of women with preterm labor, the mean gestation was 31.5 weeks, compared with 12 to 20 weeks of gestation in the previous studies of women with no labor.

A significant relationship between isolation of *U. urealyticum* from the chorioamnion and preterm birth has been documented in three of six prospective studies.<sup>10-12,16,93,94</sup> In most patients in these investigations, however, membrane rupture had occurred, which could have led to intrapartum microbial invasion of the chorioamnion, potentially confounding the results even if the duration of membrane rupture is taken into account.

As noted previously, Berg and associates<sup>60</sup> performed a retrospective analysis of 2718 genetic amniocentesis specimens cultured for *U. urealyticum* and *M. hominis*. Of the 2718 specimens, 49 (1.8%) were found to be positive for either organism. Of 43 evaluable patients in this study, 35 received treatment with oral erythromycin. Preterm delivery rates were similar in the treated and untreated groups at 19.4% and 20%, respectively. The investigators speculated that the lack of a treatment effect may have been due to recolonization with mycoplasmas.

The sum of the evidence suggests that the risk of preterm labor and delivery is increased when ureaplasmas are detected at amniocentesis between 12 to 20 weeks of gestation in women with intact membranes before onset of labor. Otherwise, the association between preterm birth and ureaplasmas is uncertain.

### TRANSMISSION OF UREAPLASMA UREALYTICUM AND MYCOPLASMA HOMINIS TO THE FETUS AND NEWBORN

*U. urealyticum* and *M. hominis* can be transmitted to a fetus from an infected female either in utero or at the time of delivery by passage through a colonized birth canal. The isolation of *U. urealyticum* in pure culture from the chorioamnion, amniotic fluid, and internal fetal organs in the presence of funisitis and pneumonia<sup>5</sup> and a specific immunoglobulin M (IgM) response<sup>95</sup> can be taken as evidence that fetal infection can occur in utero. Investigators<sup>21,26</sup> also have found that *U. urealyticum* and *M. hominis* can be isolated from endotracheal specimens collected within 30 minutes to 24 hours after birth from infants who were delivered by cesarean section with intact membranes. It is thought that the acquisition of *U. urealyticum* and *M. hominis* can occur in utero either by an ascending route secondary to colonization of the mother's genital tract or transplacentally from the mother's blood. Each of these organisms has been isolated from maternal and umbilical cord blood at the time of delivery.<sup>72,73</sup>

The rate of vertical transmission of *U. urealyticum* and *M. hominis* ranges from 18% to 88%.<sup>47,96-99</sup> Chua and colleagues<sup>99</sup> prospectively investigated the transmission and colonization of *U. urealyticum* and *M. hominis* from mothers to term and preterm newborns delivered by the vaginal route.

The rates of maternal cervical colonization with *U. urealyticum* and *M. hominis* were 57.5% and 15.8%, respectively, whereas the rates for isolation of *U. urealyticum* and *M. hominis* from nasopharyngeal secretions of the newborns were 50.8% and 6.6%, respectively. The vertical transmission rates were 88.4% for *U. urealyticum* and 42.1% for *M. hominis*. Maternal transmission was not associated with gestational age. In preterm neonates, the isolation of mycoplasmas was not associated with gestational age or birth weight. There was a tendency for *U. urealyticum* to persist in preterm newborns, especially in those with birth weight less than 2 kg. Colonization of full-term infants appears to be relatively transient, with a sharp drop in isolation rates after 3 months of age.<sup>100</sup> In premature infants with ureaplasma infection, persistence of the organism in the lower respiratory tract and cerebrospinal fluid (CSF) has been documented for weeks to months.<sup>19,21</sup>

### PERINATAL UREAPLASMA UREALYTICUM AND MYCOPLASMA HOMINIS INFECTION

A number of prospective studies based on direct culture of the affected site indicate that both *U. urealyticum* and *M. hominis* can cause invasive disease in infants, particularly in infants born prematurely. It must be noted, however, that the presence of mycoplasmas in the chorioamnion or amniotic fluid does not necessarily result in infection of the fetus. Similarly, the isolation of mycoplasmas from surface cultures (e.g., eyes, ears, nose, throat, gastric aspirates, vagina) is not necessarily indicative of invasive disease.

#### Pneumonia

Case reports,<sup>17,27,29,87</sup> retrospective studies,<sup>103</sup> and prospective studies<sup>5,13,17</sup> indicate an association of *U. urealyticum* with congenital and neonatal pneumonia. The organism has been isolated from affected lungs in the absence of other pathogens, such as chlamydiae, viruses, fungi, and bacteria, in the presence of chorioamnionitis and funisitis<sup>5</sup> and has been demonstrated within fetal membranes by immunofluorescence<sup>5</sup> and in lung lesions by electron and immunofluorescent microscopy.<sup>95</sup> A specific IgM response has been demonstrated in some cases of neonatal pneumonia.<sup>95</sup>

In a study of 98 infants,<sup>21</sup> respiratory distress syndrome, the need for assisted ventilation, severe respiratory insufficiency, and death were significantly more common among those born at less than 34 weeks of gestation from whom *U. urealyticum* was recovered from endotracheal aspirates at delivery than among those with a negative culture result. In another series of 292 infants with birth weights of less than 2500 g who were studied by follow-up evaluation for 4 weeks after birth, isolation of *U. urealyticum* from the endotracheal aspirate within a week of birth (mean age, 1.3 days) was significantly associated with radiographic pneumonia, whereas no such association was found for uninfected infants.<sup>34</sup> *U. urealyticum* was the most common organism isolated (15% of infants) among these 292 patients, and it was isolated in pure culture in 71%.

Conversely, other investigators have found a possibly protective effect associated with the isolation of *U. urealyticum* from preterm infants. Hannaford and co-workers,<sup>105</sup> in a prospective consecutive investigation of 143 ventilated new-

borns born at than 28 weeks of gestation, isolated *U. urealyticum* from endotracheal aspirates of 39 (27%) infants. Respiratory distress syndrome occurred significantly less often in infants from whom *U. urealyticum* was isolated than in infants from whom it was not isolated ( $P = .002$ ). In addition, a trend for lower mortality rates in the first 28 days of life was identified among *U. urealyticum*-positive infants. Berger and associates<sup>106</sup> also found an apparently protective effect of *U. urealyticum* isolated from the amniotic cavity at the time of delivery against hyaline membrane disease in infants with a mean gestational age of 29 to 30 weeks, although nonsignificant. Again, no increase in acute morbidity or mortality was found to be associated with *U. urealyticum* isolation.

The baboon model of prematurity has been employed to investigate the pathogenicity of *U. urealyticum*. At age 140 days, baboons demonstrate physiologic and pathologic characteristics similar to those of human neonates of 30 to 32 weeks of gestation (e.g., they have hyaline membrane disease).<sup>108</sup> Endotracheal inoculation of premature baboons with *U. urealyticum* isolated from human infants results in histologic pulmonary lesions, including acute bronchiolitis with epithelial ulceration and polymorphonuclear infiltration, that are indistinguishable from those of hyaline membrane disease.<sup>32</sup>

Yoder and colleagues<sup>181</sup> performed an investigation in premature baboons that offers explanation for the divergent findings in human studies of *U. urealyticum* and respiratory status in preterm infants. Premature baboon infants were delivered 48 to 72 hours after maternal intra-amniotic inoculation with *U. urealyticum*. Two distinct patterns of disease were observed in the baboon infants. Baboons with persistent *U. urealyticum* tracheal colonization manifested worse lung function and prolonged elevated tracheal cytokines. Conversely, colonized baboons that subsequently cleared *U. urealyticum* from tracheal cultures demonstrated improved lung function compared with unexposed control animals.

In addition, pneumonia with persistent pulmonary hypertension has been described in newborn infants with *U. urealyticum* isolated from the lower respiratory tract.<sup>27,29</sup> Although cases of ureaplasma pneumonia have been documented in full-term infants, pneumonia due to this agent is thought to occur much less frequently than in premature neonates. Case reports indicate that *M. hominis* can be a cause of pneumonia in newborns, but it has not been implicated as a common etiologic agent in prospective studies. These mycoplasmas are not thought to be a significant cause of acute respiratory disease in otherwise healthy infants after the first month of life.<sup>59</sup>

## Chronic Lung Disease

*U. urealyticum* frequently colonizes the neonatal respiratory tract. Although a majority of the investigations support a significant association between ureaplasmas and chronic lung disease (CLD) in preterm infants, its role in causation of CLD remains uncertain. CLD is most often defined as a requirement for supplemental oxygen at 28 days of age or at 36 weeks of postconceptional age. Presence of concurrent chest radiographic changes compatible with CLD sometimes is included in this definition.

Wang and co-workers,<sup>109</sup> in a meta-analysis of 17 investigations published before 1995, explored the association

between *U. urealyticum* and CLD. The studies in this analysis included preterm and term neonates. CLD was defined as a requirement for oxygen at 28 to 30 days of age, and diagnosis of *Ureaplasma* colonization required the recovery of *U. urealyticum* from a respiratory or surface specimen. The estimates of relative risk exceeded 1 in all of the investigations; however, the lower confidence interval included 1 in 7 (41%). The meta-analysis concluded that the relative risk for the development of CLD in colonized infants was 1.72 (95% confidence interval 1.5 to 1.96) times that for noncolonized infants. In the analysis, investigations that focused on extremely premature, very low birth weight (VLBW) neonates did not identify a significantly different relative risk from that for investigations that included all neonates. Also, the relative risk did not differ significantly between those studies in which only endotracheal aspirates were used to define colonization and other studies.

Subsequent to this meta-analysis, the association of *U. urealyticum* with chronic pulmonary disease, including bronchopulmonary dysplasia (or CLD), has been confirmed in multiple studies<sup>101,102,104-106,110-115</sup> but not in others.<sup>116-122</sup> Perzigian and colleagues<sup>102</sup> prospectively investigated a cohort of 105 VLBW (less than 1500 g) infants; in 22 (21%), results of tracheal aspirate cultures were positive for *U. urealyticum* at birth. At 28 days, *U. urealyticum*-positive patients were significantly more likely to have CLD than were *U. urealyticum*-negative patients, despite routine use of exogenous surfactant. The *U. urealyticum*-positive infants also required significantly longer duration of oxygen therapy and of mechanical ventilation. No significant differences were found for CLD at 36 weeks or for duration of hospitalization, however.

Because the relationship of neither *Ureaplasma* species nor the concentration of ureaplasmas with the development of CLD had yet been investigated, a prospective study was designed to look for such an association. In 175 VLBW infants, endotracheal aspirates were obtained at birth for quantitative culture; the results were analyzed for correlation with the development of CLD.<sup>120</sup> Ureaplasmas were isolated from 66 (38%) of the 175 infants. No statistically significant associations were identified between the development of CLD and the *Ureaplasma* species isolated (*U. urealyticum* or *Ureaplasma parvum*) or the concentration of ureaplasmas in the lower respiratory tract secretions.

Because the observed disparities in these studies might be explained in part by the variable persistence of *Ureaplasma* colonization of the infant respiratory tract, a prospective longitudinal study was performed to investigate this possibility. In 125 VLBW infants, culture and PCR assay were used to frequently sample for *U. urealyticum* in the respiratory tract over the course of their neonatal intensive care unit stay. It was found that the pattern of colonization was predictive for the development of CLD.<sup>104</sup> In this study, 40 (32%) of 125 infants had at least one specimen positive for *U. urealyticum*; however, only 18 (45%) of the 40 had persistent colonization throughout their hospitalization. Only persistent *U. urealyticum* colonization was associated with a significantly increased risk of development of CLD, both at 28 days of age and at 36 weeks after conception. Neither early transient colonization nor late acquisition of *U. urealyticum* was associated with CLD. The study by Yoder and colleagues<sup>181</sup> in premature baboons similarly found that the pattern of

tracheal colonization was important in the manifestations of respiratory disease.

Inadequate detection of *U. urealyticum* in neonates can be another confounding factor in CLD research. False-negative results for isolation of *U. urealyticum* from respiratory specimens could weaken the association with CLD. Utilizing in situ hybridization (ISH) for *U. urealyticum* on lung autopsy tissue from 7 infants with positive cultures and 7 infants with negative cultures for *U. urealyticum* from the lower respiratory tract, Benstein and co-workers<sup>101</sup> found all 7 culture-positive infants were positive for *U. urealyticum* by ISH; 2 of the culture negative were positive by ISH. The ISH results had a 100% correlation with the presence of histopathologic evidence of bronchopulmonary dysplasia at autopsy of these 14 infants.

Although properly conducted antimicrobial agent trials showing reduction in CLD incidence and severity in neonates with *U. urealyticum* would support a causal role for this microorganism, failure of amelioration with effective therapy does not necessarily indicate that *U. urealyticum* does not have some role in the development of CLD. Small trials of therapy with erythromycin or clarithromycin have failed to provide evidence that therapy, predicted by in vitro testing to be effective, decreases CLD severity or produces clinical improvement in neonates with *U. urealyticum*.<sup>106,121,123-127</sup> Only two randomized, controlled trials have been conducted, together involving a total of 37 VLBW infants with *U. urealyticum* isolated from their respiratory tract; each failed to demonstrate a reduction in the incidence of CLD after 7 to 10 days of erythromycin therapy.<sup>123</sup> In one of these trials, erythromycin treatment significantly reduced the isolation of *U. urealyticum* from the respiratory tract, but it did not significantly alter required length of time with supplemental oxygen.<sup>121</sup> A large, definitive, well-controlled trial is needed, perhaps with more prolonged antimicrobial therapy.

Debate over the concept that initiating therapy after birth may be too late to influence the outcome of an inflammatory process with possible onset in utero was partially addressed in the Overview of Role of Antibiotics in the Curtailment of Labour and Early Delivery (ORACLE) I and ORACLE II prenatal trials (erythromycin or amoxicillin-clavulanic acid, or both, in a randomized double-blind, placebo-controlled design) involving a combined total of 11,121 women with preterm, prelabor rupture of fetal membranes or spontaneous preterm labor.<sup>128,129</sup> One of the primary outcomes of these trials was CLD, defined as the need for daily supplementary oxygen at age 36 weeks after conception; the other primary outcomes were neonatal death and major cerebral abnormality. ORACLE I and ORACLE II revealed no statistically significant reduction in any primary outcome. *U. urealyticum* colonization was not specifically addressed in these trials, however, so the results should not be generalized to directly address *U. urealyticum* and CLD.

To investigate for the presence of a long-term detrimental effect of perinatal *U. urealyticum* infection, a cohort of 40 preterm infants was prospectively followed for 12 months.<sup>130</sup> In 22 (55%), *U. urealyticum* was present in samples obtained from the trachea and/or blood at birth. The infants with perinatal *U. urealyticum* required significantly more days of hospitalization than the number of days for infants without *U. urealyticum*. The difference was attributed to an increase in respiratory tract disease among the infants with perinatal

*U. urealyticum*. In addition, CLD was associated with significantly more admissions in the infants with perinatal *U. urealyticum* than in those without it. Syrogiannopoulos and associates<sup>47</sup> monitored 108 full-term infants during the first 3 months of life. These researchers were unable to demonstrate an increased risk of lower respiratory illness during this period of observation in the 51 of 108 infants with persistent pharyngeal *Ureaplasma* colonization over that in the infants who were not pharyngeally colonized at 3 months of life.

Although *U. urealyticum* has not been definitively shown to cause CLD, investigations have identified possible pathogenic mechanisms through which it may contribute to CLD. *U. urealyticum* has been hypothesized to induce lung injury through immunopathogenic mechanisms involving the release of pulmonary cytokines and chemokines after exposure to this microorganism either in utero or postnatally. It also has been proposed that *U. urealyticum* infection potentiates oxygen-induced lung injury.<sup>101,104</sup>

Although much effort has been expended to define the role of *U. urealyticum* in CLD, no clear conclusions can be made at present, although a majority of the investigations seem to indicate a significant association. Novel strategies need to be instituted to further explore the link between these entities.

## Bloodstream Infections

Ureaplasmas have been isolated from blood cultures from neonates.<sup>19,23,26,72,73,107,131,132</sup> Case reports also have described the isolation of ureaplasmas from the bloodstream of neonates with pneumonia.<sup>21,29</sup> Cassell and associates<sup>26</sup> found that 26% of preterm infants with endotracheal aspirates that grew *U. urealyticum* also had a positive result on blood cultures for this organism, suggesting that bacteremia with ureaplasmas can be common in preterm infants. Cases of *M. hominis* bacteremia with systemic symptoms accompanied by an antibody response also have been reported.<sup>56,133</sup>

Not all investigations have been successful in recovering mycoplasmas from the blood of infants.<sup>22-24</sup> Mycoplasmas were not isolated from blood cultures obtained within 30 minutes of birth from 146 preterm infants in Israel.<sup>23</sup> In addition, investigators did not isolate mycoplasmas from the 191 blood cultures in a prospective study of older infants hospitalized for possible sepsis.<sup>24</sup> The frequency of clinical signs of infection in infants with *U. urealyticum* or *M. hominis* bacteremia is not clear.

## Central Nervous System Infections

In general, the clinical significance of recovering *U. urealyticum* or *M. hominis* from a central nervous system (CNS) specimen from a neonate remains uncertain. In some situations, an association with a disease process appears plausible, whereas in others, no corresponding disease state is apparent. Multiple cases of *M. hominis* CNS infection (meningitis, brain abscess) have been described in full-term and preterm infants.<sup>25,54,134-142</sup> *U. urealyticum* also has been isolated from the CSF of infants with suspected sepsis and meningitis.<sup>19-22,28,48,143</sup>

In a prospective trial in 100 mostly premature infants, *U. urealyticum* was isolated from the CSF of 8 and *M. hominis* from the CSF of 5 who were undergoing investigation for

**Figure 16-2** A 37-week-gestation newborn who had hypothermia, hypotonia, and lethargy noted at age 3 days. Computed tomography showed decreased attenuation predominantly of the supratentorial white matter symmetrically with punctate early-calcified lesions. Examination of the cerebrospinal fluid (CSF) demonstrated mononuclear pleocytosis, and *Mycoplasma hominis* was isolated. CSF culture was sterile after 5 days of doxycycline treatment, but the infant had spastic quadriplegia at 6 months of age.

suspected sepsis or treatment of hydrocephalus.<sup>19</sup> Of the 8 neonates with *U. urealyticum*, 6 had severe intraventricular hemorrhage, 3 had hydrocephalus, and 4 had ureaplasmas isolated several times in the CSF. *Ureaplasma* infection was significantly associated with severe intraventricular hemorrhage ( $P < .001$ ). *U. urealyticum* was isolated from the respiratory tract of 4 of the 8 infants with CSF infections. Five infants received treatment with erythromycin or doxycycline. Three *Ureaplasma*-infected infants died. All 5 of the neonates from whom *M. hominis* was isolated from the CSF were being investigated for suspected sepsis; prominent neurologic signs and CSF pleocytosis were noted in only 1. This infant received doxycycline treatment and improved but had substantial neurologic sequelae (Fig. 16-2).<sup>19</sup> No *M. hominis*-infected infants died. A subsequent study by the same group of investigators in 318 infants isolated *U. urealyticum* from the CSF of 5 and *M. hominis* from 9. Spontaneous clearance of the organisms was documented in 5 of the infants, and 12 infants had a good outcome.<sup>145</sup>

Shaw and colleagues<sup>144</sup> performed a prospective study of 135 preterm infants undergoing lumbar puncture and found *U. urealyticum* in the CSF of 1 neonate and *M. hominis* in none. Ureaplasmas continued to be isolated from this 1 infant over the course of 16 weeks, despite treatment with erythromycin. The organism maintained in vitro susceptibility to erythromycin. Doxycycline treatment was associated with the disappearance of the organism.

In a prospective study by Ollikainen and co-workers,<sup>21</sup> *U. urealyticum* was isolated from the CSF of four of six infants born at less than 34 weeks of gestation. None had pleocytosis or hypoglycorrhachia in the CSF. Three had the organism also isolated from blood, and one from a tracheal sample. One died and had a postmortem brain culture positive for *U. urealyticum*. None had intracranial hemorrhage.

Valencia and associates<sup>22</sup> isolated *M. hominis* from 9 and *U. urealyticum* from 1 of 69 consecutive infants in whom CSF was cultured within the first 3 months of life for suspected sepsis. The CSF indices, except for bloody specimens, were considered to be within normal limits for newborns. Only 1 of the infants whose CSF culture grew *M. hominis* had clinical signs compatible with systemic infection. The other infants were healthy but were evaluated secondary to maternal fever and prolonged rupture of membranes. All 10 infants received ampicillin and gentamicin, antimicrobial agents without good activity against these organisms, and had a good clinical outcome.

In cultures of CSF from 920 infants in a neonatal intensive care unit, *U. urealyticum* was isolated from 2 (0.2%) and *M. hominis* from none.<sup>124</sup> Likitnukul and colleagues<sup>24</sup> and Mardh<sup>25</sup> failed to recover mycoplasmas from CSF of infants in prospective investigations. The study by Likitnukul's group involved infants who had been previously discharged from the hospital and had returned because of suspected sepsis. No mycoplasmas were recovered from the CSF of 47 preterm infants cultured within the first week of life by Israeli and co-workers.<sup>23</sup> The reason for the frequent isolation of mycoplasmas in some studies but not in others remains uncertain. Possible technical reasons are discussed by Waites<sup>148</sup> and Heggie<sup>149</sup> and their colleagues.

The question of whether mycoplasmas are linked to abnormalities on CNS imaging also has been investigated, although in an indirect manner. Perzigian and associates<sup>102</sup> prospectively investigated a cohort of 105 VLBW infants in whom 22 (21%) results of tracheal aspirate culture were positive for *U. urealyticum* at birth. No differences were found between the groups for intraventricular hemorrhage or cystic periventricular leukomalacia. Similarly, in a study of 464 VLBW infants, Dammann and co-workers<sup>150</sup> addressed the question of whether *U. urealyticum* or *M. hominis* cultured from the placenta was associated with an increased risk of ultrasonographic cerebral white matter echolucency as a measure of white matter damage. The cranial ultrasound studies were performed up to a median of 22 days of life. Culture results were as follows: 139 of 464 (30%) were positive for *U. urealyticum*, 27 (6%) were positive for *M. hominis*, and 21 (5%) were positive for both. It was found that with a positive result on culture for *U. urealyticum*, the infants were not at increased risk of cerebral white matter damage. The presence of *M. hominis* was associated with a trend toward an increased risk of echolucency ( $P = .08$ ).

The clinical findings in newborns with *U. urealyticum* and *M. hominis* isolated from the CSF are variable. *U. urealyticum* and *M. hominis* may produce abnormal CSF indices with pleocytosis, or an inflammatory reaction in CSF may be absent.<sup>19,21,22,25</sup> In some infants, mycoplasmas are cleared spontaneously from the CSF, whereas in others, the organisms have been shown to persist for weeks to months even after appropriate treatment.<sup>44,59,139,146,147</sup>

### Other Sites of Infection in the Neonate

*M. hominis* also has been isolated from the pericardial fluid,<sup>55</sup> subcutaneous abscesses,<sup>151,152,154</sup> and the submandibular lymph node of neonates.<sup>153</sup> *U. urealyticum* and *M. hominis* have been isolated from the urine, but the clinical significance was uncertain.<sup>24</sup>

**Figure 16-3** A, *Mycoplasma hominis* (original magnification 100 $\times$ ). B, *Ureaplasma urealyticum* (original magnification 1000 $\times$ ). (From Klein JO. Mycoplasmas, genitourinary tract infection, and reproductive failure. Hosp Pract 6:127-133, 1971, with permission.)

## OTHER MYCOPLASMAS

The role of other mycoplasmas, such as *M. genitalium*, *M. fermentans*, and *M. pneumoniae*, in maternal/fetal and neonatal infections is not thought to be prominent, although investigations are limited. *M. genitalium* was not isolated by culture of the chorioamnion of 609 women or by culture or PCR assay of 232 amniotic fluid samples tested.<sup>155</sup> To evaluate the impact of *M. genitalium* on the outcome of pregnancy, cervical samples from 1014 women were assayed by PCR techniques for the presence of *M. genitalium*.<sup>156</sup> Among those women, *M. genitalium* was isolated in 6.2%, but its isolation was not significantly associated with adverse outcomes of pregnancy (preterm delivery, small for gestational age, spontaneous abortion, stillbirth). Taylor-Robinson<sup>157</sup> recently reviewed disease associations with *M. genitalium*.

*M. fermentans* was detected in amniotic fluid collected at the time of cesarean section from 4 of 232 women with intact membranes.<sup>155</sup> Placental tissue also was PCR assay positive for *M. fermentans* in 3 women. Villitis and chorioamnionitis were present in two of the four positive specimens, and no other organisms were detected.

## DIAGNOSIS

Culture and PCR assay both are appropriate methods for the diagnosis of *Mycoplasma* and *Ureaplasma* infections. Culture of *U. urealyticum* and *M. hominis*, however, requires special handling with techniques and media generally not available outside major medical centers or reference laboratories. Detailed laboratory techniques for culture and identification of mycoplasmas and ureaplasmas have been reviewed by others.<sup>59,160</sup>

Ureaplasmas and mycoplasmas are extremely susceptible to adverse environmental conditions. Accordingly, correct methods of collecting, processing, and transporting specimens are important for reliable and interpretable culture results. A specific ureaplasma transport medium, such as Shepard's 10B broth,<sup>161,162</sup> for *U. urealyticum* and *M. hominis* should be available for direct inoculation of clinical specimens and swabs at the time of collection. If specimens are allowed to sit at room temperature and are not inoculated into appropriate media, the recovery of these organisms is unlikely. Only calcium alginate- or Dacron-tipped swabs with plastic or wire shafts should be utilized for sampling of mucosal surfaces. Blood should be collected free of anticoagulants and immediately inoculated into the transport medium in a 1:5 to 1:10 ratio.<sup>59</sup> Specimens should be refrigerated at 4 $^{\circ}$  C and protected from drying in a sealed container until transported to the laboratory. If transport to a suitable laboratory is not possible within 6 to 12 hours after collection, the specimen in appropriate transport medium should be stored at -70 $^{\circ}$  C and shipped frozen on dry ice. Ureaplasmas and mycoplasmas are stable for long periods when kept frozen at -70 $^{\circ}$  C in a protein-containing support medium such as Shepard's 10B. Storage at -20 $^{\circ}$  C is less reliable and will result in a significant loss in number of organisms in a relatively short time.<sup>59</sup> Before collecting a clinical sample for culture, it is appropriate to arrange processing of samples with the microbiology laboratory.

*U. urealyticum* and *M. hominis* grow within 2 to 5 days. Broth cultures are incubated at 37 $^{\circ}$  C under atmospheric conditions; agar plates are incubated under 95% nitrogen and 5% carbon dioxide. Colonies of *U. urealyticum* can be identified on A8 agar by urease production. The colonies often are amorphous. Colonies of other mycoplasmas are urease negative and have a typical "fried egg" appearance (Fig. 16-3).

PCR assays for the detection of *U. urealyticum* and *M. hominis*<sup>63,118,163,164</sup> have been developed. These assays appear to have greater sensitivity than culture in most studies.<sup>57,58,104,165,166</sup> A combination of PCR assay and culture should give the most reliable results.

Although enzyme-linked immunosorbent assays (ELISAs) have been developed to detect *U. urealyticum*- and *M. hominis*-specific antibodies in sera, serologic testing is not recommended for the routine diagnosis of *U. urealyticum* and *M. hominis* infections. The use of these assays is limited to the research setting.

Owing to the fastidiousness and slow growth of *M. genitalium* and *M. fermentans*, PCR assay, in situ hybridization, and/or immunohistochemistry are recommended for detection of these mycoplasmas.<sup>155,158,159</sup>

## TREATMENT OF NEONATAL INFECTIONS

A positive result on culture or PCR assay for *U. urealyticum* or *M. hominis* from a normally sterile site, particularly in the absence of other microorganisms, is justification to consider treatment for infants with evidence of infectious inflammation. On the basis of the current understanding of these organisms, however, the isolation of *U. urealyticum* or *M. hominis* in the absence of disease generally does not warrant treatment.

Formulation of guidelines for treatment when these organisms are isolated from a maternal/fetal or neonatal specimen is difficult, in view of the following considerations as reviewed in this chapter:

- Causation has not been clearly established for many of the conditions associated with *U. urealyticum* and *M. hominis* (all maternal/fetal and neonatal associations, except postpartum and postabortal fever).
- Organisms often are present (in CSF, bloodstream, respiratory tract, amniotic fluid, or lower genital tract, for example) with little or no adverse clinical outcome.
- Organisms often are spontaneously cleared (from CSF, bloodstream, or respiratory tract, for example) without treatment.
- No definitive controlled trials have been performed for many sites of infection (e.g., CSF, bloodstream, amniotic fluid, lung in acute pneumonia).
- Small randomized, controlled trials have not shown benefit of treatment for CLD.
- Evidence that treatment can be useful comes from uncontrolled case reports for which the outcome without treatment is not known.
- Comparative clinical trials among antimicrobials have not been performed to assess their relative efficacy.
- Often the clinical indication for culture or PCR assay has resolved before the positive result is reported.

Treatment may be warranted in some situations, so decisions must be made on a case-by-case basis, to ensure full consideration of the risk-benefit ratio related to disease and treatment. The relative contribution of *U. urealyticum* and *M. hominis* infection to morbidity and mortality is difficult to establish, because most cases have been reported in VLBW preterm infants with multiple complications or in infants with clinical problems that probably contribute to

the poor outcome. An authoritative reference states that antimicrobial therapy for *U. urealyticum* cannot be recommended for pregnant women to prevent preterm delivery or in preterm infants to prevent pulmonary disease, because trials of antimicrobial therapy for these indications generally have not demonstrated efficacy.<sup>167</sup> It also suggests that definitive efficacy of antimicrobial agents in the treatment of CNS *U. urealyticum* infections in infants is lacking.<sup>167</sup>

The treatment of some non-neonatal *U. urealyticum* and *M. hominis* infections is better established. For instance, *U. urealyticum* urethritis and *M. hominis* pyelonephritis, pelvic inflammatory disease, postabortal fever, and postpartum fever, as well as infections with either organism in immunocompromised patients (especially those with hypogammaglobulinemia), generally are considered to warrant treatment.

Erythromycin generally has been considered the antimicrobial agent of choice for neonatal ureaplasma infections (not involving the CNS), although clinical superiority over other agents has not been investigated.<sup>175</sup> Erythromycin has been employed in most clinical trials in infants with *U. urealyticum*.<sup>121,123-127</sup> Other agents with in vitro activity against *U. urealyticum* and variable clinical experience include clarithromycin, azithromycin, doxycycline, and chloramphenicol.<sup>106,171,172,174,176</sup> Resistance to macrolides, doxycycline, and chloramphenicol has been reported.<sup>168,173,175</sup> The in vitro activities of newer agents, such as quinolones and ketolides, against *Ureaplasma* have been reported; clinical experience is lacking.<sup>175,177-180</sup>

*M. hominis* is resistant to erythromycin, as well as to other macrolides and azolides.<sup>171,172,174,175</sup> Doxycycline is the drug of choice for treatment of *M. hominis* infections, although resistance has been reported.<sup>46,53,139,169,170</sup> Clindamycin and chloramphenicol also are generally active in vitro against *M. hominis*.<sup>175</sup> The in vitro activity of newer antimicrobials against *M. hominis* has been reported; clinical experience is lacking, however.<sup>175,177-180</sup>

Antimicrobial susceptibility testing should be considered when it is deemed necessary to treat a *U. urealyticum* or *M. hominis* infection in a neonate, especially for the persistent isolation of either organism from a normally sterile site, because resistance to commonly used antibiotics is not rare. Some tetracycline-resistant strains of *U. urealyticum* can be erythromycin resistant, but high-level erythromycin resistance in *U. urealyticum* is uncommon.<sup>175</sup> Penetration of the blood-brain barrier by antimicrobials should be considered in treating a CNS infection, as should the safety and pharmacokinetics of antimicrobials in newborns in making treatment decisions.

Staphylococcal disease has been recognized in neonates for hundreds of years, identified at least as early as 1773, when pemphigus neonatorum was described.<sup>1</sup> Outbreaks of staphylococcal disease in nurseries were first noted in the late 1920s<sup>2</sup> and continue to occur sporadically today, although fortunately with less frequency than in the past.<sup>3</sup>

Up through the 1970s, staphylococcal disease in newborn infants was caused most often by *Staphylococcus aureus*.<sup>4</sup> In the past 3 decades, however, coagulase-negative staphylococci (CoNS) have assumed an equally important role, especially in premature infants in neonatal intensive care units (NICUs).<sup>5-14</sup> Indeed, in some NICUs, CoNS are responsible for almost half of all cases of serious bacterial disease.<sup>12-21</sup>

In recent years, management of staphylococcal disease in infants has become more complicated, reflecting the increasing incidence of methicillin resistance and the threat of vancomycin resistance among isolates of *S. aureus* and

CoNS. Antibiotic-resistant isolates are particularly troublesome when they are responsible for epidemics in NICUs.<sup>22-31</sup>

This chapter summarizes current information about the medical aspects of *S. aureus* and CoNS, with a focus on the diseases these organisms produce in young infants.

**EPIDEMIOLOGY AND TRANSMISSION*****Staphylococcus aureus***

Many factors are involved in the transmission of staphylococci among newborns, including nursery design, density of infant population, and obstetric and nursery practices. Other factors important in transmission include biologic properties of the organism and undefined host factors. The difficulty of isolating and investigating each variable in the epidemiologic equation accounts for the disagreement among various workers about which factors predominate in transmission and prevention of staphylococcal disease. Of note, a particular factor that is critical in one epidemic may not operate under different circumstances.

Quantitative studies demonstrate that very small numbers of *S. aureus* are capable of initiating colonization in the newborn. Fewer than 10 bacteria can initiate umbilical colonization in 50% of newborns, and approximately 250 organisms achieve a similar effect on the nasal mucosa.<sup>32</sup> These findings provide a plausible explanation for the challenge of defining any factor in the environment (e.g., fomites, hands, clothes) as a potential source of infection.

Most evidence indicates that the initial and perhaps major source of infection is medical and nursing personnel.<sup>32,33</sup> The *S. aureus* strain common among medical attendants is far more likely than a maternal strain to colonize a given infant.<sup>3</sup> Data collected by Wolinsky and colleagues suggest that in 85% of cases, infant colonization with *S. aureus* results from an attendant's touch.<sup>34</sup> In one group of 37 infants handled by a study nurse for 10 minutes through the window of an isolette, 20 infants (54%) acquired the nurse's strain of *S. aureus*.<sup>35</sup> Of note, the disseminating capacity of attendants varies.<sup>36</sup> Persons with overt lesions or disease often are highly infectious, but asymptomatic carriers can be infectious as well,<sup>37</sup> and carriage on the skin, in the anterior nares, and in the perineal area is relevant.<sup>36,38</sup>

Colonization of the newborn umbilicus, nares, and skin takes place early in life. By the fifth day in the nursery, the colonization rate among nursery inhabitants may be as high as 90%.<sup>39-41</sup> The incidence of colonization is higher in males than in females,<sup>42</sup> suggesting that genetic factors may be important, although studies of twins argue against this hypothesis.<sup>43</sup> The umbilicus or rectum usually is colonized before the nares are.<sup>44,45</sup> During the next 4 to 8 weeks in the infant's life, the likelihood of colonization of the umbilicus

falls off rapidly and approaches zero and then stabilizes at approximately 20% for the balance of the first year of life.<sup>40,41</sup>

Despite the high rate of colonization during the newborn period, the incidence of disease in neonates is generally low, except when epidemic strains are involved. In one epidemic, the disease rate in infants and family members who were colonized with a virulent hospital strain of *S. aureus* approached 70%, whereas colonization with nonepidemic strains was associated with a disease rate of 3%.<sup>46</sup> Epidemics of staphylococcal disease resulting from colonization that occurs in well-infant nurseries usually are not revealed by infections in the nursery. Skin disease typically appears 1 to 3 weeks after hospital discharge, and breast abscesses and pneumonia may not develop until 2 weeks to 2 months of age. In NICUs, disease becomes apparent in the unit because of prolonged hospital stays.

Shortly after the introduction of methicillin in 1960, methicillin-resistant *S. aureus* (MRSA) emerged as an important nosocomial pathogen.<sup>47</sup> For MRSA, resistance is mediated through the *mecA* gene, which codes for an altered penicillin-binding protein (called PBP2a or PBP2') that has a dramatically reduced affinity for  $\beta$ -lactam antibiotics.<sup>48</sup> Beyond possessing *mecA*, MRSA isolates frequently harbor other antibiotic resistance determinants as well, further limiting treatment options. Risk factors for infection with MRSA include treatment with antimicrobials, prolonged hospitalization, and stay within an intensive care unit.<sup>49</sup> Fortunately, although MRSA has become endemic in many adult hospitals, most infant nurseries have been unaffected by these organisms.<sup>22-31,50-54</sup> In a recent survey of neonatologists practicing in NICUs, 70% reported no cases of MRSA infection.<sup>55</sup> The incidence of MRSA infection in neonates is likely to increase over time, however.

Since the mid-1990s, infection with community-acquired MRSA (CA-MRSA) isolates has been reported increasingly in patients without hospital contact or traditional risk factors for MRSA.<sup>56</sup> Several features of CA-MRSA isolates differentiate them from health care-associated MRSA.<sup>57</sup> CA-MRSA strains typically have a distinct antibiotic susceptibility profile, with retained susceptibility to multiple classes of antimicrobials. CA-MRSA strains frequently cause skin and soft tissue infections, as with methicillin-sensitive *S. aureus* (MSSA). Several cases of invasive disease, bacteremia, and death caused by CA-MRSA have been reported, however.<sup>58</sup> These isolates appear to be readily transmitted between family members and close contacts,<sup>57</sup> but transmission in a health care setting has been limited to date. Health care transmission of CA-MRSA has been reported as the cause of infection among a cohort of postpartum women, although no infants were affected in this instance.<sup>59</sup> Unfortunately, unlike health care-associated MRSA, isolates of CA-MRSA are particularly well adapted to survive in the community, and introduction into and transmission within hospitals are likely to increase in the near future.

When clusters of staphylococcal disease associated with hospital exposure occur, temporal clustering of cases suggests the possibility of an outbreak caused by a single strain.<sup>60</sup> It is clear that strain identity as determined by phenotypic methods (i.e., phage types, antibiograms, and even plasmid profiles) may not be precise enough to identify *S. aureus* strains for epidemiologic investigatory purposes. In these situations, strain identity requires characterization based on a molecular technique, such as pulsed-field gel electrophoresis (PFGE).

PFGE generally is considered the most discriminating molecular typing approach for evaluating strains present during local outbreaks.<sup>61</sup> The performance of PFGE requires time and specialized equipment, however, and this technique is not universally available for routine clinical applications. Additionally, PFGE relies on examination of banding patterns on a gel and may not be useful for comparisons of strains between laboratories<sup>62</sup> or of strains responsible for outbreaks that are separated in time. Multilocus sequence typing (MLST) is a sequence-based typing system that utilizes the sequence of seven housekeeping genes to evaluate the genetic relatedness of strains of staphylococci.<sup>63</sup> The discriminatory power of this approach is less than that of PFGE, so the usefulness for the evaluation of local outbreaks is less.<sup>64</sup> Nevertheless, MLST allows the user to compare sequences from isolates of various locations through a central database (<http://www.mlst.net>). Additional molecular approaches that have been applied to strain evaluation for epidemiologic purposes include staphylococcal protein A typing (*spa* typing),<sup>65</sup> random amplification of polymorphic DNA (RAPD),<sup>66</sup> repetitive element-based polymerase chain reaction (PCR) (rep-PCR)<sup>67</sup> and multilocus restriction fragment typing (MLRFT).<sup>64</sup>

### Coagulase-Negative Staphylococci

CoNS are common inhabitants of human skin and mucous membrane sites.<sup>68</sup> *S. epidermidis* is the species found most commonly as a member of the normal flora of the nasal mucosa and the umbilicus of the newborn.<sup>69</sup> Colonization occurs early and at many sites. With sensitive culture techniques, the nose, umbilicus, and chest skin are colonized with CoNS in up to 83% of neonates by 4 days of age.<sup>70</sup> In one study, rates of colonization with *S. epidermidis* among 63 infants in a NICU were as follows: nose, 89%; throat, 84%; umbilicus, 90%; and stool, 86%. Comparable percentages for *S. aureus* were 17%, 17%, 21%, and 10%, respectively.<sup>69</sup>

In other studies in which isolates were characterized by species, biotype, antibiotic susceptibility pattern, and the capacity to form biofilms (using an assay for slime), colonization rates were 50% to 80% by 4 to 7 days after admission to the NICU.<sup>71-73</sup> After 2 weeks in the unit, 75% to 100% of infants were colonized with CoNS at some mucosal site. In one study, biofilm-forming strains selectively colonized infants over a 4-week period, with nearly 90% of infants eventually harboring a single predominant *S. epidermidis* biotype.<sup>72</sup> Although most infants acquire CoNS from environmental sources, including hospital personnel, a small percentage are colonized by vertical transmission.<sup>74,75</sup> The ubiquity of these organisms and their tolerance to both drying and temperature changes offer an explanation for the high prevalence of colonization among infants.

Ecologic relationships between the microbial flora of various body sites have been well studied, and factors that reduce colonization at one site with one organism tend to increase colonization at that site with others.<sup>71</sup> Current nursery practices that decrease colonization with *S. aureus* contribute to the increased presence of CoNS in neonates. These practices include the extensive use of antimicrobial agents and the use of skin and umbilical cleansing techniques. Furthermore, isolates of *S. epidermidis* and other CoNS resistant to multiple antibiotic agents are becoming

increasingly common.<sup>71</sup> In a study involving premature neonates, D'Angio and associates demonstrated that the incidence of strains resistant to multiple antibiotics rose from 32% to 82% by the end of the first week of life.<sup>72</sup>

The observation that CoNS are important nosocomial pathogens among newborns, especially low-birth-weight infants in NICUs, is explained by the prevalence of colonization with these organisms at multiple sites and the widespread use of invasive therapeutic modalities. Examples of invasive treatments include endotracheal intubation; mechanical ventilation; placement of umbilical catheters, central venous catheters, chest tubes, and ventriculoperitoneal shunts; and the use of feeding tubes.<sup>10,11,16,17,20,21</sup> In this setting, CoNS account for greater than 50% of bloodstream isolates obtained from neonates with late-onset sepsis.<sup>12,13</sup>

An inverse relationship exists between the rate of infection with CoNS and both birth weight and gestational age. Additional factors that appear to be associated with CoNS bacteremia among very low birth weight (VLBW) neonates include respiratory distress syndrome, bronchopulmonary dysplasia, patent ductus arteriosus, severe intraventricular hemorrhage, and necrotizing enterocolitis.<sup>14</sup>

Certain nutritional factors are associated with the development of late-onset sepsis, including delayed initiation of enteral feeding, prolonged period to reach full enteral feeding status, delayed reattainment of birth weight, and prolonged parenteral hyperalimentation.<sup>13</sup> Administration of intralipids through a Teflon catheter has been shown in a case-control study to be associated with an increased risk of bacteremia due to CoNS.<sup>76</sup> The significant pathogenic factors include capacity of the organism to form biofilms, lipid infusion, and presence of the Teflon catheter, all of which interfere with neutrophil and macrophage function. Whether lipids infused through catheters made of other materials are associated with a similar risk remains to be determined.

Considered together, the clinical and experimental data suggest that CoNS have not become more virulent over time. Rather, these ubiquitous organisms have become more common pathogens because therapeutic approaches have become increasingly invasive and because premature infants, with compromised immunity, are surviving for longer periods of time.

## MICROBIOLOGY

Staphylococci are members of the family Micrococcaceae and are nonmotile, non-spore-forming bacteria that are catalase negative. Species of staphylococci are defined by DNA-DNA hybridization studies and are separated into two large groups on the basis of ability to produce the extracellular enzyme coagulase. Organisms that produce coagulase are known as coagulase-positive staphylococci, or *S. aureus*,<sup>77</sup> and organisms that produce no coagulase are referred to as CoNS. The presence of coagulase can be evaluated either by assessing broth medium for secreted enzyme, which reacts with coagulase-reacting factor in plasma and results in formation of a fibrin clot, or by testing for cell-bound enzyme, which results in clumping when a suspension of organisms is incubated with plasma.

Staphylococci grow best in an aerobic environment but are capable of growing under anaerobic conditions as well.

They grow readily on most routine laboratory media and usually are isolated from clinical specimens using sheep blood agar. Gram staining reveals gram-positive cocci that range from 0.7 to 1.2  $\mu\text{m}$  in diameter and are usually visible in irregular grapelike clusters (Fig. 17-1A). Growth in liquid culture often results in a predominance of single cocci, pairs, tetrads, and chains of three or four cells. Of note, dying organisms and bacteria in stationary phase or ingested by phagocytes may appear to be gram-negative. Growth on blood agar results in round, convex, shiny opaque colonies that are 1 to 2 mm in diameter after 24 hours of incubation. Colonies of *S. aureus* often are deep yellow or golden and typically are surrounded by a zone of  $\beta$ -hemolysis (see Fig. 17-1B). By contrast, colonies of CoNS usually are chalk-white, often lacking surrounding hemolysis.

## *Staphylococcus aureus*

For clinical purposes, many of the key characteristics of *S. aureus* can be determined by simple procedures performed with commercial rapid identification kits and automated systems.<sup>77</sup> *S. aureus* strains can be subdivided by their capacity to be lysed by certain bacteriophages.<sup>78</sup> Historically, phage typing and serologic typing were the most common systems for differentiating strains of *S. aureus* for epidemiologic purposes.<sup>79</sup> However, in recent years molecular approaches have become the standard for defining strain identity in a patient with multiple isolates or in a possible outbreak involving multiple patients.<sup>80-82</sup>

Studies of the subcellular structure of *S. aureus* have generated an increasing body of information. Of particular interest is knowledge about the chemical composition, biosynthesis, and antigenicity of the staphylococcal cell wall, which is made up of two major components, peptidoglycan and teichoic acid.<sup>83</sup> *S. aureus* peptidoglycan is composed of chains of acetylglucosamine, acetylmuramic acid, alanine, glutamic acid, and lysine or diaminopimelic acid, with pentaglycine bridges that cross-link these chains.<sup>84</sup> Studies on the inhibition of peptidoglycan biosynthesis have led to a recognition of the mode of action of several antibiotics and staphylolytic enzymes.<sup>85</sup> Four penicillin-binding proteins called PBP1, PBP2, PBP3, and PBP4 play an important role in peptidoglycan biosynthesis and are inactivated by  $\beta$ -lactams.<sup>86</sup> (PBP2a is present in isolates of MRSA and is resistant to  $\beta$ -lactams.) Teichoic acid is a polymer of ribitol phosphate that is held in the cell wall by covalent attachment to the insoluble peptidoglycan. Staphylococcal teichoic acid is antigenic, and antibodies to this substance cause agglutination of isolated staphylococcal cell walls.<sup>87</sup> Antibodies to teichoic acid enhance opsonophagocytic killing of nonencapsulated strains of *S. aureus* but have little effect on encapsulated isolates.<sup>88,89</sup> By way of contrast, antibodies to peptidoglycan play a key role in the opsonization of *S. aureus*.<sup>90-93</sup> Of note, antibodies to both teichoic acid and peptidoglycan are widespread in the population.<sup>93</sup>

In addition to peptidoglycan and teichoic acid, other components of the *S. aureus* cell wall include group antigen known as protein A and a number of other surface-exposed proteins. Similar to the situation with other gram-positive bacteria, many *S. aureus* proteins anchored in the cell wall possess a carboxy-terminal LPXTG motif, which serves as a sorting signal for a membrane enzyme called sortase (SrtA).<sup>94,95</sup>

**Figure 17-1** **A**, Gram stain of *Staphylococcus aureus* showing characteristic clusters. **B**, Blood agar plate showing growth of *S. aureus* with zone of  $\beta$ -hemolysis surrounding colonies.

This enzyme cleaves polypeptides between the threonine and the glycine of the LPXTG motif and catalyzes formation of an amide bond between the carboxy group of threonine and the amino group of peptidoglycan cross-bridges.<sup>96</sup> Sortase is encoded by *srtA* and is a 206-amino-acid protein with a putative amino-terminal membrane-spanning domain and a carboxy-terminal catalytic domain that is presumably translocated across the cytoplasmic membrane.<sup>96</sup> Of interest,

BLAST searches using the *srtA* gene as a query have identified a second sortase gene called *srtB*.<sup>97</sup> Existing evidence indicates that the *srtA* and *srtB* gene products do not have redundant functions, raising the possibility that they catalyze similar reactions using different protein substrates.

*S. aureus* produces a capsular layer external to the cell wall. The staphylococcal capsule has aroused interest both because of its role in pathogenesis<sup>98,99</sup> and because of its

ability to stimulate antibody production. Although the thick mucoid capsule produced by the prototype Smith strain is uncommon, most *S. aureus* strains produce a microcapsule.<sup>100,101</sup>

Nucleotide sequencing of the whole genome for several isolates of *S. aureus* established that the genome is 2.8 to 2.9 megabases in size, with approximately 2600 to 2700 open reading frames and an overall guanine:cytosine content of approximately 33%.<sup>102,103</sup> Much of the *S. aureus* genome appears to have been acquired by lateral gene transfer. Most antibiotic resistance genes are carried on mobile genetic elements, including a unique resistance island. Pathogenicity islands belonging to at least three different classes have been identified, including toxic shock syndrome toxin islands, exotoxin islands, and enterotoxin islands. Of interest, the exotoxin and enterotoxin islands are closely linked to other gene clusters encoding putative virulence factors.

### Coagulase-Negative Staphylococci

CoNS are a heterogeneous group of organisms that have been divided into 32 species.<sup>77</sup> The following 15 species of CoNS are found as members of the normal human flora: *S. epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus saprophyticus*, *Staphylococcus capitis*, *Staphylococcus warnerii*, *Staphylococcus hominis*, *Staphylococcus xylosus*, *Staphylococcus cohnii*, *Staphylococcus simulans*, *Staphylococcus auricularis*, *Staphylococcus saccharolyticus*, *Staphylococcus caprae*, *Staphylococcus pasteurii*, *Staphylococcus lugdunensis*, and *Staphylococcus schleiferi*.<sup>77,104</sup> Among these species, several occupy very specific niches on the skin. For example, *S. capitis* is most abundant on the head, where sebaceous glands are plentiful. *S. auricularis* has a striking predilection for the external auditory canal. *S. hominis* and *S. haemolyticus* are most common in the axillae and the pubic area, where apocrine glands are numerous.

Speciation of CoNS is accomplished on the basis of a series of biochemical characteristics. In recent years, species identification has been simplified by the introduction of commercially available miniaturized kits.<sup>77</sup> Differentiation of two strains belonging to the same species (subspeciation) represents a more difficult problem, however. Biotyping and antibiotic susceptibility patterns together have been used for this purpose with some success.<sup>105</sup> Phage typing is another method that has been useful at times.<sup>105-107</sup> Analogous to the situation with *S. aureus*, more powerful techniques for distinguishing strains of a given species include PFGE, random amplification of a polymorphic DNA, rep-PCR assay, and MLRFT.<sup>108</sup>

The composition of CoNS is similar to the makeup of *S. aureus*, except that the teichoic acid contains glycerol in place of ribose and the cell wall lacks protein A. Determination of the genome of *S. epidermidis* strain ATCC 12228 (a commensal isolate not associated with disease) revealed a genome approximately 2.5 megabases in size with 2419 open reading frames, greater than 10% smaller than the published genomes of *S. aureus* isolates.<sup>109</sup> In comparison with the available *S. aureus* genomes, ATCC 12228 contains fewer antibiotic resistance genes and lacks pathogenicity islands and a capsule locus. A homologue of the *S. aureus* *srtA* gene is present, along with nine proteins predicted to contain an LPXTG motif.

## PATHOGENESIS OF DISEASE

### Role of the Organisms

#### *Staphylococcus aureus*

*S. aureus* has a diverse array of cellular and extracellular virulence proteins.<sup>110</sup> With the possible exception of toxic shock syndrome, staphylococcal scalded skin syndrome, and staphylococcal toxin-mediated enteritis, the pathogenesis of staphylococcal disease is dependent on the coordinated activity of multiple virulence factors (rather than a single predominant factor). The pathogenic process begins with colonization of host skin or mucosal surfaces and involves bacterial attachment to host cells or extracellular matrix. To persist, the organism produces molecules that resist phagocytosis and interfere with the function of specific anti-staphylococcal antibodies. Ultimately, the organism expresses specific factors that attack host cells and others that degrade components of the extracellular matrix, contributing to persistence and facilitating spread.

*S. aureus* produces a number of adhesive factors referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules), including clumping factor (ClfA), fibrinogen-binding protein (Fbp), fibronectin-binding protein A (FnbpA), fibronectin-binding protein B (FnbpB), collagen-binding protein (Cna), elastin-binding protein (EbpS), laminin receptor, bone sialoprotein-binding protein (Bbp), IsdA (which binds fibronectin and fibrinogen), and SdrC-D-E (which bind fibronectin), among others.<sup>111-116</sup> In addition, *S. aureus* is capable of binding to vitronectin<sup>117</sup> and thrombospondins,<sup>118</sup> although the specific genes and proteins responsible for these activities have not yet been identified. Studies suggest that the *S. aureus* MSCRAMMs and these additional adhesive activities play an important role in colonizing host tissues and binding to foreign objects such as catheters and prosthetic devices.<sup>119-121</sup> In the case of *S. aureus* Fnbp-mediated binding to fibronectin, the major binding sites on fibronectin reside in the amino-terminal type 1 module and toward the carboxy terminus. Proteins encoded by the *icaA-D* genes mediate interbacterial interactions and promote biofilm formation.

Bacterial survival during infection is dependent on the ability of the organism to circumvent host defenses. Staphylococci have developed several strategies for this purpose. Protein A is a surface-associated protein that binds to the Fc portion of IgG antibodies, presumably blocking opsonization and providing the organism with a protective cover.<sup>122,123</sup> *S. aureus* V8 protease is a serine protease that is capable of cleaving and inactivating IgG antibodies in vitro, leading to speculation that this protein functions to block the action of antibodies during natural infection. It is possible that V8 and other proteases also function to degrade antimicrobial peptides such as the neutrophil defensins and the platelet microbicidal proteins.<sup>124,125</sup> Catalase counteracts the toxic effects of oxygen free radicals produced by phagocytes and promotes survival inside and around neutrophils. The staphylococcal enterotoxins (SEA, SEB, SEC, SED, SEE, and SEH), toxic shock syndrome toxin 1 (TSST-1), and exfoliative (epidermolytic) toxins (ETA, ETB, ETC, and ETD) all have superantigen properties, binding to major histocompatibility complex class II proteins and activating specific subsets of T cells through the variable regions of T cell receptor  $\beta$

chains (V $\beta$  chains).<sup>126,127</sup> This relatively nonspecific stimulation of lymphocyte populations results in activation of nearly 30% of circulating lymphocytes, possibly serving to prevent the host from elaborating antibodies to other staphylococcal antigens. The mature pyrogenic toxin superantigens are small, nonglycosylated proteins with molecular masses ranging from 20,000 to 30,000 daltons. Leukocidin,  $\beta$ -hemolysin, and  $\gamma$ -hemolysin are *S. aureus* extracellular proteins that have leukocytolytic activity<sup>128-132</sup> and may enable the organism to circumvent neutrophil infiltration and phagocytosis. Pantone-Valentine leukocidin (PV leukocidin) causes lysis of rabbit and human phagocytes and is associated with an often lethal necrotizing pneumonia in patients. In addition, more than 90% of clinical isolates of *S. aureus* express a polysaccharide microcapsule, with 11 different known capsular types.<sup>133</sup> Although the role of the capsule in pathogenesis is unclear, more than 75% of human isolates express either the type 5 or the type 8 polysaccharide.<sup>134</sup> One hypothesis is that the capsule prevents the interaction of antibodies with the bacterial surface. In response to an infection, the host can produce a variety of fatty acids and other lipid molecules that act as surfactants to disrupt the bacterial membrane, especially when an abscess is formed. Virtually all strains of *S. aureus* express lipases and are lipolytic,<sup>50</sup> potentially counteracting the effects of host lipids.

A number of *S. aureus* factors have been postulated to promote tissue invasion. Perhaps the best-studied is  $\alpha$ -toxin (also referred to as  $\alpha$ -hemolysin), which forms heptamers in the membranes of a variety of cell types, creating pores.<sup>135,136</sup> Pore formation is associated with release of nitric oxide from endothelial cells and appears to stimulate apoptosis in lymphocytes.<sup>137,138</sup> On the basis of comparison of wild-type and mutant strains,  $\alpha$ -toxin has been implicated in virulence in animal models of keratitis and mastitis.<sup>139,140</sup>  $\beta$ -Hemolysin is an enzyme with sphingomyelinase activity and acts on the membrane of red blood cells in vitro and potentially other cells during natural infection.<sup>141</sup>  $\delta$ -Hemolysin is a 26-amino-acid peptide that potentiates the activity of  $\beta$ -hemolysin in vitro, causing membrane damage by a detergent-like action and enhancing hemolysis.<sup>142</sup> Additional proteins that may facilitate tissue invasion include hyaluronidase and hyaluronate lyase,<sup>143</sup> enzymes that digest hyaluronic acid, which is a straight-chain polymer found in skin, bone, synovial fluid, umbilical cord, and vitreous humor.<sup>144</sup> Of note, individual isolates of *S. aureus* have been shown to produce multiple electrophoretic forms of these enzymes, suggesting that families exist.

Of interest, many of the *S. aureus* cell wall-associated adhesive factors that facilitate the initial stages of infection are selectively produced during the exponential phase of in vitro growth.<sup>145</sup> It is noteworthy that these proteins can be anchored to the cell only while the cell wall is being assembled. By contrast, almost all *S. aureus* extracellular proteins presumed to participate in evasion of the immune system and to spread to adjacent tissues are synthesized predominantly in the postexponential phase of growth.<sup>145,146</sup> A notable exception is enterotoxin A, which is produced constitutively.<sup>147</sup> This differential expression of specific sets of virulence determinants probably is fundamental to the pathogenic process and is under control of the accessory gene regulator (*agr*) locus, the staphylococcal accessory gene regulator (*sar*) locus, and a catabolite repression system,

with influence from the *sae*, the *srr* (also referred to as *srh*), and the *arl* two-component systems.<sup>148-150</sup> The *agr* locus responds to cell density (mediating quorum sensing) and is activated in midexponential phase. The *sae* system appears to respond to both cell density and environmental conditions.<sup>151,152</sup> The *arl* system serves to downregulate overall exoprotein synthesis, presumably by downregulating *agr*.<sup>153</sup> The *srr* system inhibits *agr* activation and in turn is downregulated by *agr*.<sup>154</sup> Of note, this system is especially important under microaerobic conditions and is a prerequisite for normal growth in the absence of oxygen.

*S. aureus* is capable of existing harmlessly as a commensal on the skin or a mucous membrane and also is able to produce disease in the blood and a variety of tissue sites. This versatility probably is a reflection of the capacity to regulate gene expression in response to environmental signals, in large part through the *agr*, the *sar*, the *sae*, the *srr*, and the *arl* loci.<sup>148</sup>

### Coagulase-Negative Staphylococci

Until recently, the pathogenic potential of CoNS received little attention. With the emergence of these organisms as prominent pathogens, investigation has intensified in an effort to identify important virulence factors and develop new approaches to treatment and prevention. Attention has centered primarily on *S. epidermidis*, the species most commonly associated with clinical disease, usually in association with central intravascular catheters. Other species that have been examined, although to a lesser extent, include *S. lugdunensis*, *S. schleiferi*, and *S. saprophyticus*.

In CoNS infections involving indwelling catheters and other prosthetic devices, bacterial adherence to the foreign body is an important step in the pathogenic process (Fig. 17-2). Early evidence suggested that nonspecific factors, including long-range electromagnetic forces and surface hydrophobicity, promote initial attachment.<sup>155</sup> More recent studies have demonstrated that a polysaccharide capsular adhesin composed of *N*-acetylglucosamine also is involved in adherence.<sup>156,157</sup> This material is referred to as PIA or PS/A and is encoded by the *ica* locus. It promotes adherence to plastic polymers and functions as an antiphagocytic capsule, preventing C3 deposition and phagocytosis. A second factor suggested to promote attachment to plastic surfaces is AtlE, which shows significant homology with the major autolysin of *S. aureus*.<sup>158</sup> AtlE contains two bacteriologically active domains, including a 60-kDa amidase and a 52-kDa glucosaminidase domain, generated by proteolytic processing.<sup>158</sup> The 60-kDa domain is located on the bacterial surface and is a prerequisite for AtlE-related adhesion. Of note, AtlE also has vitronectin-binding activity,<sup>158</sup> suggesting that this protein plays a role in bacterial attachment both to a naked plastic surface early in infection and to plasma protein-coated surfaces later in infection. SSP-1 and SSP-2 are antigenically

**Figure 17-2** Schematic model of the phases involved in *Streptococcus epidermidis* biofilm formation.

**Figure 17-3** Scanning electron micrograph showing the presence of a *Streptococcus epidermidis* biofilm on an explanted intravascular catheter. The biofilm is characterized by multilayered cell clusters embedded in an extracellular polysaccharide. (From von Eiff C, Peters G, Heilmann C. Pathogenesis of infections due to coagulase-negative staphylococci. *Lancet Infect Dis* 2:677-685, 2002.)

related proteins that also contribute to binding to plastic. These proteins were identified in *S. epidermidis* strain 354 and form fiber-like structures on the surface of the organism.<sup>159,160</sup>

A variety of *S. epidermidis* factors promote attachment to host extracellular matrix proteins that may coat catheters and other foreign bodies (see Fig. 17-2). For example, AtlE mediates binding to vitronectin and is essential for full virulence in an intravascular catheter-associated infection model in rats.<sup>158,161</sup> Similarly, the Fbe protein mediates bacterial binding to fibrinogen, promoting interaction with the fibrinogen  $\beta$  chain.<sup>162,163</sup> Fbe is a member of the serine-aspartic acid-repeat-containing (Sdr) family of cell wall-anchored surface proteins. Other members of the family include SdrG, SdrE, and SdrH.<sup>164</sup> SdrG is 95% identical to Fbe and shares the capacity to bind to the fibrinogen  $\beta$ -chain. Recent evidence indicates that *S. epidermidis* cell wall teichoic acid facilitates adherence to fibronectin, perhaps serving as a bridging molecule between bacteria and fibronectin-coated surfaces.<sup>165</sup>

After initial attachment to a biomaterial, organisms multiply and form complex multilayered aggregates that involve intercellular adhesion and are referred to as biofilms (Fig. 17-3; see also Fig. 17-2). In recent work, Mack and colleagues found that a *S. epidermidis* mutant with a transposon in the *ica* locus was unable to form multilayered cell clusters.<sup>166</sup> Expression of the poly-*N*-acetylglucosamine adhesin is subject to reversible on and off switching, referred to as *phase variation* and resulting, at least in some cases, from reversible insertion and excision of an insertion sequence element in the *ica* operon.<sup>167</sup> Phase variation may be important in allowing for release of planktonic (free-floating) cells from mature biofilms. Of note, an *ica* mutant was less virulent than the wild-type strain in both a mouse model of subcutaneous foreign body infection and a rat

model of central venous catheter-associated infection.<sup>168,169</sup> A second factor important for *S. epidermidis* intercellular adhesion and biofilm formation is a 140-kDa extracellular protein referred to as accumulation-associated protein (AAP).<sup>170</sup> Elimination of expression of AAP has no effect on initial adhesion to glass and polystyrene surfaces but disrupts bacterial accumulation. Consistent with this result, antibody against AAP almost completely blocks accumulation.<sup>171</sup> Of interest, expression of this protein is found only in bacteria grown under sessile conditions (attached to a surface).<sup>171</sup>

Historically, isolates of CoNS were often described as elaborating “slime” and “slime-associated antigen,” terms that we now realize refer to biofilms and the presence of abundant quantities of poly-*N*-acetylglucosamine. In a hospital-wide survey, Ishak and colleagues noted slime production in 13 of 14 clinically significant bloodstream isolates of *S. epidermidis*, compared with only 3 of 13 blood culture contaminants and 4 of 27 skin isolates.<sup>172</sup> Studies in infants have revealed similar results. For example, in independent studies, Hall and co-workers and Gruskay and associates detected slime production by 82% of isolates from infants with invasive disease.<sup>173,174</sup> CoNS biofilm formation presumably provides a nonspecific physical barrier to cellular and humoral defense mechanisms. In addition, biofilm-associated polysaccharide inhibits neutrophil chemotaxis and phagocytosis and suppresses lymphocyte blastogenesis.<sup>175,176</sup> CoNS biofilm-associated polysaccharide also is capable of inhibiting the antimicrobial action of both vancomycin and teichoplanin.<sup>177</sup> Relevant to the issue of treatment, formation of biofilms makes eradication of CoNS infection more difficult.<sup>178,179</sup> With regard to regulation of CoNS biofilm formation, it is interesting that homologues of the *S. aureus agr* and *sar* loci have been identified in

*S. epidermidis* and that a *S. epidermidis agr* knockout mutant is deficient in biofilm formation.<sup>180-182</sup>

Recent work indicates that CoNS produce a variety of exoproteins, including urease, lipase/esterase, fibrinolysin, DNase, and a number of proteases.<sup>183</sup> In addition, selected isolates produce delta-like toxin, an extracellular hemolysin that is similar in size, biologic properties, and antigenicity to the enteropathic  $\delta$ -toxin of *S. aureus*. Studies by Scheifele and colleagues suggest that delta-like toxin may play a role in the pathogenesis of necrotizing enterocolitis.<sup>184,185</sup>

Selected strains of CoNS produce a polysaccharide capsule. By analogy with other encapsulated pathogens, it is possible that capsule plays a role in the pathogenesis of disease. Among fresh clinical isolates, however, capsular material is present in fewer than 10%.<sup>186,187</sup> Further studies are needed to establish the precise relationship between capsule production and disease.

### Role of the Host

Even under the most ideal conditions, infants in the hospital are surrounded by staphylococci. Physical barriers such as the skin and mucous membranes represent a major defense against staphylococcal disease. Bacteremic disease most often develops when organisms colonizing the skin gain access to the bloodstream through the portal created by an intravascular catheter. Other routes for entry into the bloodstream include the intestinal tract after injury to the epithelial barrier, the respiratory tract in patients receiving mechanical ventilation, the umbilicus when the umbilical cord is still in place, and occasionally the circumcision site. Localized disease occurs when colonizing organisms are implanted into deeper tissues, often related to a break in skin or mucous membrane integrity and sometimes during placement of a foreign body. On occasion, a foreign body becomes contaminated after placement, with organisms from the hands of medical personnel, from contaminated disinfectants, or from the patient.

As with other pathogenic bacteria, the presence of intact neutrophil phagocytic function is probably the single most important factor involved in controlling replication and spread of staphylococci.<sup>188</sup> Effective phagocytosis requires sufficient numbers of cells along with the ability to sense and migrate toward a site of infection and then ingest and kill microorganisms. In term infants, the peripheral neutrophil count is higher than in adults, but there is little capacity to respond to infection with an outpouring of additional cells. As a result, the number of neutrophils at a site of infection is relatively low in infants compared with that in adults.<sup>189</sup> In addition, neutrophils from newborns exhibit relatively diminished motility toward chemoattractants compared with that in cells from older children and adults.<sup>190</sup> Potential mechanisms for this diminished chemotaxis include decreased circulating levels of fibronectin,<sup>191</sup> abnormal polymerization of actin,<sup>192</sup> and decreased production of chemotactic factors such as C5a and interleukin-8 (IL-8).<sup>193,194</sup> Neutrophils from young infants also exhibit decreased migration across endothelium, possibly because of impaired capacity to up-regulate endothelial cell expression of the CR3 receptor.<sup>195,196</sup> Beyond decreases in neutrophil number, chemotaxis, and transepithelial migration, the capacity for neutrophil adherence and phagocytosis is reduced in neonates, largely

owing to deficiencies in opsonins, including complement, specific antibody, and fibronectin. Phagocytic killing appears to be intact in normal newborns but may be compromised in stressed infants, at least in part because of reduced production of hydroxyl radicals.<sup>188,197,198</sup>

Specific antibody is less important than complement in opsonization of *S. aureus* and plays a limited role in defense against neonatal staphylococcal disease, the possible exception being antibody directed against leukocidin and other toxins.<sup>199-201</sup> For example, in general, there is no correlation between antibody titers against *S. aureus* and the likelihood of asymptomatic carriage versus clinical disease.<sup>202,203</sup> Consistent with this information, an attempt many years ago to protect the newborn from staphylococcal disease by immunizing the mother near term was unsuccessful.<sup>204</sup>

In most cases of neonatal staphylococcal disease, the role of T cells is unclear. T cells are centrally involved, however, in the immune response to several *S. aureus* toxins, including TSST-1, the staphylococcal enterotoxins, and the staphylococcal exfoliative toxins (ETA, ETB, ETC, and ETD). All of these toxins appear to function as superantigens, interacting with major histocompatibility complex class II proteins on the surface of T cells and activating specific subsets of cells through the variable regions of T cell receptor  $\beta$ -chains. The consequence of this T cell activation is proliferation of a large proportion of T cells and release of a number of cytokines, including tumor necrosis factors TNF- $\alpha$  and TNF- $\beta$ , interleukins IL-1 and IL-2, and interferon- $\gamma$ .<sup>205</sup> These molecules are major contributors to the systemic manifestations of staphylococcal scalded skin syndrome, toxic shock syndrome, and food poisoning.

### **PATHOLOGY**

The most characteristic pathologic lesion associated with *S. aureus* infection is a local abscess, consisting of necrotic tissue, fibrin, and a large number of live and dead neutrophils. Similarly, CoNS infection is characterized by infiltration of neutrophils, usually with moderate necrosis. Other pathologic findings are described next in the sections on clinical manifestations.

### **CLINICAL MANIFESTATIONS**

#### **Bullous Impetigo and Staphylococcal Scalded Skin Syndrome**

*S. aureus* produces a spectrum of clinical skin diseases as a result of the elaboration of exfoliative (epidermolytic) toxins (ETs). The most serious of these is staphylococcal scalded skin syndrome (SSSS), also known as *Ritter's disease* after the physician who first described the condition among orphans in 1878. When the disease is localized, it is referred to most frequently as *bullous impetigo*.<sup>206</sup>

Large epidemiologic surveys have found that between 4% and 6.2% of *S. aureus* isolates produce ETs.<sup>207-210</sup> Neonates, children younger than 5 years of age, and adults with renal insufficiency or immunocompromise are the most susceptible to SSSS, the generalized form of staphylococcal ET-related disease.<sup>211</sup> When occurring in neonates, the illness usually

**Figure 17-4** Photomicrograph of a skin biopsy from a patient with staphylococcal scalded skin syndrome, stained with hematoxylin and eosin. The histologic appearance is characterized by epidermal splitting at the granular layer of the epidermis. Magnification is approximately 200x. (From Hardwick N, Parry CM, Sharpe GR. Staphylococcal scalded skin syndrome in an adult. Influence of immune and renal factors. *Br J Dermatol* 132:468-471, 1995.)

develops between days 3 and 16 of life, but both intrauterine and congenital infections have been reported.<sup>211-213</sup> Outbreaks of SSSS have been reported to occur both in the normal newborn nursery<sup>208,214</sup> and among premature infants in NICUs.<sup>60</sup> Rates of both bullous impetigo and SSSS appear to be increasing, and some authors have postulated that this increase may be due to a reduction in the application of triple dye to the umbilical cord, a procedure traditionally used to reduce early colonization with *S. aureus*.<sup>215</sup>

Localized infection of the upper respiratory tract, inner ear, conjunctiva, or umbilical stump,<sup>216</sup> or, rarely, a more invasive site, is the initial step in both bullous impetigo and SSSS. Blister formation results from the elaboration of ETs by *S. aureus*. Four ETs, designated ETA, ETB, ETC, and ETD, have now been described.<sup>127</sup> These toxins are secreted extracellularly by staphylococci and are subsequently absorbed into the systemic circulation, where they ultimately reach the epidermis without significant binding to other organs.<sup>217</sup> Recently, the molecular mechanism of action of these toxins has been elucidated, revealing that they act as glutamic acid-specific serine proteases that target desmoglein-1, a transmembrane glycoprotein of desmosomes.<sup>211,218,219</sup>

The characteristic histologic feature of SSSS is intraepidermal cleavage through the granular layer, without evidence of epidermal necrosis or inflammatory cell infiltrate (Fig. 17-4).<sup>220</sup> This appearance is distinct from that in toxic epidermal necrolysis, characterized by a subepidermal split and full-thickness necrosis of the epidermis.

The clinical spectrum of staphylococcal ET-related disease varies from a few localized blisters to diffuse exfoliation covering greater than 90% of the body surface area (Fig. 17-5). When localized blisters are present, as in bullous impetigo, they occur primarily in the perineal and periumbilical regions. The bullae are fragile and thin-roofed and rupture easily to release fluid that may be thin and amber-colored or purulent. For SSSS, the illness may begin with fever, lethargy, poor feeding, and an erythematous rash that rapidly

becomes bullous and may involve the entire skin surface and spare the mucous membranes.<sup>206</sup>

The diagnoses of bullous impetigo and SSSS are made primarily on the basis of clinical presentation. A biopsy of the lesion showing the characteristic histologic features is the most useful test, but biopsies are rarely performed.<sup>221,222</sup> Attempts to isolate *S. aureus* from patient specimens may not be clinically useful, because the confirmatory tests to determine toxin production by a specific strain are available only at specialized centers. Isolating *S. aureus* from a patient specimen without confirmation of ET production is neither sensitive nor specific for SSSS.<sup>222</sup> Currently, rapid serologic tests are under development to provide more rapid confirmation of the diagnosis of SSSS.<sup>223</sup> Considerations in the differential diagnosis in infants with blistering skin disease include drug-induced toxic epidermal necrolysis, epidermolysis bullosa, bullous mastocytosis, herpetic lesions, and neonatal pemphigus.<sup>224</sup>

Treatment of bullous impetigo and SSSS generally involves systemic antibiotics targeted at *S. aureus*, together with appropriate local management of skin lesions. Oral antibiotics may be appropriate for bullous impetigo, but topical antibiotics are often ineffective owing to unpredictable absorption through the damaged skin.<sup>206,221</sup>

The prognosis for infants with bullous impetigo or SSSS is good, with a mortality rate from the latter of less than 5%.<sup>210</sup> Prevention of SSSS generally involves strict isolation of affected patients and relatively simple measures such as appropriate hand hygiene and cleansing of equipment that comes in contact with the patient to prevent cross-contamination.

### Mastitis and Breast Abscess

Mastitis and breast abscesses are common problems among nursing mothers. The usual time to occurrence is between 2 weeks and 2 months post partum. The causative organism

A

B

**Figure 17-5** Generalized staphylococcal scalded skin syndrome in a previously well newborn infant. **A** and **B**, The characteristic well-demarcated erythematous superficial exfoliation, with areas of skin sparing, can be seen. (From Ladhani S, Joannou CL, Lochrie DP, et al. Clinical, microbial, and biochemical aspects of the exfoliative toxins causing staphylococcal scalded-skin syndrome. *Clin Microbiol Rev* 12:224-242, 1999.)

most frequently is *S. aureus* and originates from the mother's skin or the infant's nasopharynx,<sup>225-228</sup> generally gaining access to the interstitial tissues of the breast through a crack in the skin or nipple.<sup>226,227</sup> In addition to nipple breakdown, milk stasis secondary to incomplete emptying of the breasts has been proposed as a risk factor for breast infection among nursing mothers.<sup>226,229-231</sup>

Clinically, mastitis manifests as focal redness, warmth, tenderness, and induration of the breast. A breast abscess is diagnosed when the inflammatory findings are complemented by a fluctuant mass. Ultrasound examination is useful in confirming the diagnosis of breast abscess.<sup>226,232,233</sup> In addition to the focal findings, systemic signs of infection such as fever may be present. Culture of the milk or abscess fluid most frequently yields *S. aureus* as the causative organism.<sup>226,227,234,235</sup> Of note, however, staphylococci can be recovered from the milk of 25% to 50% of normal lactating women.<sup>236-239</sup>

The recommended therapy for mastitis involves systemic antibiotics and emptying the breast of milk.<sup>225,226,240,241</sup> Breast-feeding may be continued during the course of maternal therapy, with no adverse effects on the mother or the infant.<sup>227</sup> In the case of abscess formation, antibiotic treatment should be accompanied by needle aspiration or incision and drainage. Progression from mastitis to abscess formation may result from a delay in antibiotic therapy. Despite appropriate treatment, both mastitis and breast abscesses have relatively high rates of recurrence in the same or subsequent lactation periods.<sup>242</sup>

In neonates, breast disease usually occurs between the 10th and the 14th days of life. The disease can progress rapidly and involve the breast plus the surrounding subcutaneous tissue down to the abdomen and up to the shoulder and the back (Fig. 17-6). The extensive involvement is associated with systemic signs and symptoms of infection and a considerable amount of pus. Diagnosis can be made by Gram stain and culture of milk expressed from the infant's breast. Collections of pus should be incised, drained, and examined by Gram stain and culture.

Neonatal breast abscess can affect subsequent breast development and result in a decrease in breast size in adult life.<sup>243</sup> In one series of cases in which follow-up histories were obtained, a decrease in breast size was noted in two of six individuals who were examined at the ages of 8 and 15 years, respectively.<sup>244</sup>

## Omphalitis

Omphalitis in the newborn is uncommon in resource-rich areas of the world but continues to be a significant cause of death and morbidity in resource-limited settings.<sup>245</sup> Risk factors for the development of this infection include home delivery, low birth weight, and factors associated with neonatal sepsis, such as chorioamnionitis, preterm labor, and rupture of membranes for greater than 8 hours.<sup>246</sup>

Neonatal omphalitis occurs along a spectrum of severity ranging from an unhealthy-appearing umbilical stump with purulent discharge to severe abdominal wall inflammation associated with necrotizing fasciitis. In a recent study by Sawardekar,<sup>246</sup> neonatal omphalitis was separated into four grades according to the level of severity: (1) funisitis/umbilical discharge: an unhealthy-appearing umbilical cord with purulent malodorous discharge; (2) omphalitis with abdominal wall cellulitis: periumbilical erythema and tenderness in addition to an unhealthy-appearing cord with discharge; (3) omphalitis with systemic sepsis: the findings of grade 2 with the addition of systemic signs of infection; and (4) omphalitis with necrotizing fasciitis: umbilical necrosis with periumbilical ecchymosis, crepitus bullae, and evidence of involvement of superficial and deep fascia, in addition to the signs and symptoms of overwhelming sepsis and shock.

The laboratory findings in neonatal omphalitis vary with the extent of the illness. When signs of systemic sepsis are present, a causative organism is isolated from the blood in approximately 60% of cases.<sup>246</sup> In addition, cultures of the umbilicus often yield a pathogen, most commonly *S. aureus*.<sup>246,247</sup> Infection is polymicrobial in approximately 10% of cases.<sup>246</sup>

**Figure 17-6** A and B, Left breast abscess in a 12-day-old infant. The abscess extends toward the right side of chest and up over the arm. The infant responded well to incision and drainage and antibiotic treatment.

Treatment of omphalitis is directed by the extent of the infection. When an infant presents with an unhealthy-appearing cord but evidence of cellulitis or systemic infection is lacking, local cord care may be sufficient. If cellulitis is present, the addition of systemic antibiotics is advisable. Constitutional symptoms should trigger an evaluation for sepsis and administration of parenteral antimicrobial therapy.<sup>248</sup> Signs of necrotizing fasciitis represent a critical situation and warrant prompt surgical consultation and intensive medical support. Empirical therapy in this circumstance should be directed at a polymicrobial infection with coverage for gram-positive, gram-negative, and anaerobic organisms.<sup>247,248</sup> Despite aggressive support, the mortality rate for neonatal omphalitis with necrotizing fasciitis remains high.<sup>246,247</sup>

### Eye, Ear, Nose, and Throat Infections

One of the common sites of staphylococcal infection is the conjunctiva. Purulent staphylococcal conjunctivitis cannot be distinguished clinically from conjunctivitis caused by other organisms. The disease responds to local, nonspecific treatment and results in no residual damage, unlike gonococcal ophthalmitis.

Ethmoiditis with concomitant periorbital cellulitis is a serious infection that can evolve from *S. aureus* colonization of the nasopharynx. The periorbital tissues become red, edematous, and swollen. Disease progresses rapidly and leads to proptosis and limitation of eye movement. A variety of organisms other than staphylococci can cause this infection, which is dangerous because it is sometimes complicated by retrobulbar abscess and cavernous sinus infection and thrombosis. Intense parenteral treatment with antibiotics is required early.

Careful studies have suggested that staphylococci are occasionally true middle ear pathogens, *S. epidermidis* being the species most frequently encountered. Staphylococci are recovered from middle ear fluid in roughly 3% of premature infants with otitis media and can result in recurrent purulent or serous otitis.<sup>249</sup>

Neonatal suppurative parotitis is an uncommon infection among newborns, occurring with an incidence of 13.8/10,000 admissions.<sup>250</sup> Premature neonates and males appear to be at highest risk for suppurative parotitis,<sup>251,252</sup> which most frequently is caused by *S. aureus*.<sup>251-253</sup> Diagnosis of suppurative parotitis relies on the clinical findings of parotid swelling and purulent exudate from Stensen's duct on compression of the parotid gland, as well as growth of a pathogenic bacterium from culture of the pus.<sup>254</sup> Laboratory findings are most frequently nonspecific.<sup>252</sup> Antibiotic therapy without drainage is sufficient treatment in most cases of neonatal suppurative parotitis.<sup>250,252</sup> The lack of clinical improvement within 24 to 48 hours should prompt further evaluation for an intraparotid abscess that may require surgical drainage.

### Cervical Adenitis

In the newborn, *S. aureus* cervical adenitis can be another manifestation of nursery colonization. At least two outbreaks of cervical adenitis resulting from nursery infection have been described in England. One outbreak involving 25 infants had an attack rate of 1.9%, and another involving 9 infants

had an attack rate of 5.6%.<sup>255,256</sup> As with other manifestations of nursery-associated *S. aureus* disease, illness usually appears after discharge from the hospital. The mean incubation periods in the two epidemics in England were 86 and 72 days, respectively. Because of the delay in onset of disease, confirmation of a nursery as the source of the infection may be difficult and necessitates careful epidemiologic investigation.

Although the disease may be mild, serious complications occasionally have been reported. Dissection of the infection along the fascial sheaths of the neck into the thorax can result in secondary pneumonia and pyothorax.<sup>257</sup>

To guide treatment of *S. aureus* cervical adenitis, it is wise to obtain material for smear and culture by performing needle aspiration of the infected lymph node.<sup>258,259</sup>

### Toxic Shock Syndrome

Toxic shock syndrome (TSS) is caused by pyrogenic toxin superantigens produced by *S. aureus*. These superantigens include TSST-1 and several enterotoxins, most commonly staphylococcal enterotoxin serotype B or C.<sup>260,261</sup> Before the 1980s, TSS occurred most commonly in menstruating women, particularly in those who used tampons.<sup>262</sup> More recently, disease has been recognized in persons with focal infection or surgical wound infection due to *S. aureus*, including MRSA. The disease is characterized by sudden onset of fever, diarrhea, shock, hyperemia of the mucous membranes, and a diffuse macular erythematous rash, followed by desquamation of the hands and feet.

Although this condition was first described in children,<sup>263</sup> it is uncommon in pediatric patients and occurs only rarely in young infants.<sup>264</sup> Several probable cases of TSS have been reported in newborns,<sup>265,266</sup> and recently an even more convincing case was described, with the infant fulfilling the Centers for Disease Control and Prevention (CDC) diagnostic criteria for TSS.<sup>267</sup> That infant presented with respiratory distress, hypotension, and fever and had laboratory evidence of renal insufficiency, hepatitis, coagulopathy, and muscular dysfunction. A diffuse macular erythroderma with mucous membrane involvement developed by day 4 of his illness, and generalized desquamation, most notably of the hands and feet, occurred subsequently. Other laboratory features included leukopenia, thrombocytopenia, and an elevated C-reactive protein level. Results of blood cultures were negative. The infant recovered with intensive support and administration of vancomycin and netilmicin.

Fluid loss and shock constitute a common cause of death in TSS; accordingly, replacement of fluid and electrolytes should be a management priority. Antibiotic therapy should be aimed at eliminating the toxin-producing organism. Intravenous immunoglobulin (IGIV) has been shown to be effective in reducing the mortality rate in adults with streptococcal TSS,<sup>268</sup> but efficacy of this intervention in staphylococcal TSS remains unknown.

### Neonatal Toxic Shock Syndrome-like Exanthematous Disease

In 1997, researchers in Japan described a new neonatal exanthematous disease<sup>269</sup> that was later termed neonatal toxic shock syndrome-like exanthematous disease (NTED).<sup>270</sup>

**Figure 17-7** Typical exanthem in a full-term infant with neonatal toxic shock syndrome–like exanthematous disease (NTED). (From Takahashi N, Nishida H, Kato H, et al. Exanthematous disease induced by toxic shock syndrome toxin 1 in the early neonatal period. *Lancet* 351:1614-1619, 1998.)

Since the time of the first description, surveys in Japan have shown that up to 70% of Japanese hospitals have reported a similar illness in neonates.<sup>271</sup> Of interest, to date only three cases of probable NTED had been reported from countries other than Japan.<sup>265,266</sup>

The pathophysiology of NTED begins with colonization with MRSA, a common occurrence among Japanese newborns.<sup>272</sup> Typically, the colonizing strain of MRSA produces TSST-1,<sup>272</sup> and the symptoms of the disease are related to the overactivation of TSST-1–reactive T cells.<sup>270</sup> NTED does not develop in all infants who are colonized with TSST-1–producing MRSA, suggesting that protection from this illness may be mediated by the transplacental transfer of maternal antibody directed against TSST-1.<sup>271</sup>

The clinical criteria proposed for the diagnosis of NTED include erythema plus at least one of the following: thrombocytopenia, a low-positive serum C-reactive protein value, and fever.<sup>269,270</sup> In the initial description of the illness, fever occurred very early in the neonatal period, on the second or third day of life. Fever was absent from most preterm infants who were affected. With the resolution of fever came the development of a diffuse exanthem (Fig. 17-7), appearing on postnatal days 2 to 5 in full-term infants. The macular rash spread from the trunk to involve the face and extremities, including the palms and soles, often becoming confluent. Occasionally, petechiae were seen, but desquamation was absent. Abnormal laboratory studies in this condition include an elevated white blood cell count, low platelet count, and a C-reactive protein measurement that is above the upper limit of normal but usually below 50 mg/L. Hyperbilirubinemia requiring intervention is seen in both term and preterm infants with NTED. The most common site of colonization with MRSA is the umbilicus.<sup>271</sup>

Despite the apparently similar pathogenesis of NTED and TSS, these two entities can be easily differentiated by the absence of shock, desquamating rash, or multiple organ

involvement in infants with NTED.<sup>270</sup> In most full-term infants, NTED resolves spontaneously without any specific treatment. By contrast, in preterm infants, NTED has been associated with serious illness, including symptomatic patent ductus arteriosus, mucosal damage, apnea, and death.<sup>269,270</sup>

## Pneumonia

The incidence of *S. aureus* pneumonia in infants younger than 6 months of age is directly related to outbreaks of severe *S. aureus* disease in nurseries. In the late 1950s and early 1960s, many nurseries throughout the United States harbored virulent staphylococci (phage type 80/81). A sharp rise in the incidence of *S. aureus* pneumonia was noted during that period.<sup>273-275</sup> Over the years, *S. aureus* pneumonia has diminished in frequency, but the isolated cases that occur are still serious and should be cause for grave concern.<sup>276</sup> Recently, neonatal *S. aureus* pneumonia resulting from intrafamilial spread of virulent strains has been reported.<sup>277,278</sup>

*S. aureus* pneumonia can be secondary to a primary distant site of staphylococcal infection that results in bacteremia and seeding of the lung.<sup>279</sup> Most cases of *S. aureus* pneumonia in infants, however, occur in the setting of viral upper respiratory tract infection, with contiguous spread of bacteria from the upper respiratory tract to the alveoli, often resulting in microabscesses that rupture and produce empyema. The occlusion of terminal bronchioles leads to formation of pneumatoceles. The course of *S. aureus* pneumonia in infants typically is fulminant. In older series, mortality rates as high as 12% to 15% have been reported.<sup>273,274</sup> Because *S. aureus* pneumonia can be associated with either primary or secondary bacteremia, the possibility of distant metastatic staphylococcal lesions must be considered.

The clinical course of *S. aureus* pneumonia in infants is usually characterized by viral upper respiratory symptoms followed by rapid onset of tachypnea, dyspnea, and

tachycardia. Patients typically appear restless and acutely ill. Most but not all patients have fever. Ileus and abdominal distention are common. Early radiologic examination reveals extensive pulmonary infiltrates, pneumothorax, and pleural effusion.

*S. aureus* pneumonia in infants almost always is associated with empyema, and needle aspiration of the pleural cavity is the most reliable way to establish a microbiologic diagnosis.<sup>276</sup> Ultimately, the empyema must be drained by continuous closed underwater suction, which should be continued until the pleural space is evacuated and the lung is re-expanded. In general, a bactericidal drug such as oxacillin or another semisynthetic penicillinase-resistant penicillin is indicated in this disease. The duration of therapy usually is 3 weeks but depends on the clinical condition of the infant and the ancillary laboratory data. Supportive therapy includes blood transfusion if significant anemia is present, supplemental oxygen, and appropriate fluids.

After the patient recovers from the acute infection, residual pulmonary abnormalities such as pneumatoceles are relatively common. Pneumatoceles are most common with staphylococcal pneumonia, but they also are occasionally seen with acute pyogenic lung infections caused by *Streptococcus pneumoniae*, *Streptococcus pyogenes*, or *Haemophilus influenzae*. They may persist for many months and usually require no therapy. The long-term prognosis for complete recovery is excellent, even after extensive bilateral lung disease.<sup>280-282</sup>

Pneumonia due to CoNS has also been described. In general, this diagnosis is assigned when CoNS are isolated from the blood of an infant with respiratory distress and a pulmonary infiltrate. The largest series was reported by Hall and colleagues, who identified 12 infants with hospital-acquired pneumonia among a total of 27 infants with CoNS bacteremia.<sup>18</sup> These authors noted an association between the presence of an endotracheal tube and development of pneumonia. Nine of their 12 patients were intubated at the time of the positive blood culture and pulmonary infiltrate, and the remaining 3 had been intubated previously.

## Osteomyelitis

In interepidemic periods, *S. aureus* osteomyelitis is uncommon in neonates.<sup>18</sup> During nursery epidemics of *S. aureus* disease, however, osteomyelitis can occur secondary to skin infections and bacteremia.<sup>283</sup> Other factors that influence the pathogenesis of neonatal osteomyelitis include fetal monitoring<sup>284</sup> and manipulations related to the routine care of sick neonates, such as repeated heel punctures<sup>285-287</sup> and insertion of umbilical<sup>288,289</sup> and peripheral<sup>290</sup> intravascular catheters. Neonatal osteomyelitis is a different disease from the bone infection that is seen in older children.<sup>290-295</sup> For example, although the long, tubular bones are the most frequent sites of infection, membranous bones such as the scapula and maxilla also are frequently involved,<sup>292,293,296</sup> often with a relatively subtle clinical presentation.<sup>297</sup> Multifocal disease also is more common in neonates,<sup>297-299</sup> and an aggressive search for clinically silent sites may be necessary to identify all involved areas.<sup>297</sup> As in older infants and children, newborn infants develop bone infections at the metaphysis; however, because the cortex is thin and the periosteum strips easily in the bones of neonates, the sequestra that develop in

older children usually are not seen.<sup>300,301</sup> Greater contiguous spread of the infection is possible because the bones of neonates have larger intraosseous vascular spaces. Secondary joint involvement occurs relatively often,<sup>297-299</sup> and the hip and shoulder are particularly vulnerable because in these joints the synovial capsule reaches beyond the metaphysis.

The signs and symptoms of neonatal osteomyelitis include redness, swelling, and reduced movement of the involved extremity, but these findings are not always present. In some cases, the infant is afebrile, and the white blood cell count is normal.<sup>298</sup> In an infant who is inexplicably irritable, the loss of function as manifested by pseudoparalysis is sometimes the only manifestation of disease. Osteomyelitis of the vertebrae can be particularly difficult to diagnose and should be suspected in an irritable infant who is uncomfortable lying supine or has pain on palpation. The diagnostic problem is exaggerated with vertebral osteomyelitis, because roentgenographic evidence of disease may not become visible until 2 or 3 weeks after infection. Radioisotope studies may be helpful in these cases.<sup>302</sup> Rupture through the cortex of a vertebra can result in epidural abscess with attendant cord compression.<sup>303</sup> Typical signs of sepsis such as lethargy, poor perfusion, apnea and bradycardia, feeding intolerance, and temperature instability can be present, especially in premature infants.<sup>299</sup> In infants, roentgenographic evidence of bone destruction and new bone formation can be evident as early as 7 days after infection,<sup>293</sup> earlier than in older children. Roentgenograms sometimes reveal soft tissue changes around the site of a bone infection before changes are visible in the bone itself. The earliest changes usually are seen with radionuclide imaging. In some cases, evidence of bone infection is present as early as 16 hours after the appearance of clinical signs.<sup>304,305</sup>

Organisms can be obtained from the blood early in the course of disease in about 50% of cases.<sup>293</sup> Because optimal antibiotic therapy depends on isolation of the etiologic agent, a vigorous attempt should be made to recover the organism from the blood and from the lesion itself by needle aspiration or bone biopsy. This approach is especially important in the era of MRSA, which has been reported as a cause of bone and joint infections in NICUs, primarily among preterm neonates.<sup>289,299</sup> Because sequestra seldom occur in neonates and the bone infection is not localized, early operative intervention is not indicated. If signs of localized collections of pus are present, these must be evacuated.

In cases of osteomyelitis, antibiotic therapy should be parenteral and continued for 4 to 6 weeks. Regimens combining parenteral and oral antibiotics that are common for the management of osteomyelitis in older infants and children are not suitable for treatment for neonates.<sup>306,307</sup> In the newborn, serum levels are unpredictable when anti-staphylococcal antimicrobial agents are administered orally.<sup>308</sup> Following the sedimentation rate is a reasonable method for assessing the course of disease. If there is concomitant joint involvement, however, values may remain abnormal for a prolonged time.<sup>309</sup> Measurement of serum C-reactive protein is an alternative approach to monitoring response to therapy.

Despite early intensive therapy, neonatal osteomyelitis can result in severe long-term sequelae. In a study of 40 neonates followed for 7 months to 11 years after infection, the prognosis of neonatal osteomyelitis was correlated with both appropriate surgical measures and perinatal risk factors.<sup>310</sup>

Thirteen of 21 infants with sequelae had one or more of the following risk factors: low birth weight, low gestational age, catheterization of a large vessel, and respiratory distress syndrome. In neonates without such risk factors, however, the prognosis for acute osteomyelitis after adequate therapy is excellent unless the epiphysis of the bone is completely destroyed. Of interest, partially destroyed epiphyses of neonates show a remarkable ability to regenerate.<sup>311</sup> Chronic disease that results in draining sinuses is rarely observed, although permanent sequelae are possible if a joint is involved.

Neonatal osteomyelitis due to CoNS is unusual but has been reported at the site of a scalp clip.<sup>284</sup> In addition, osteomyelitis involving the sternum has been reported on occasion in neonates who have undergone sternotomy for intrathoracic surgery.<sup>312</sup>

### Septic Arthritis

Septic arthritis in the neonate can be secondary either to osteomyelitis or to a distant focus of infection. Some cases have been associated with femoral venipuncture.<sup>313</sup> *S. aureus* is the most common cause of this disease throughout infancy, including during the neonatal period. The disease typically is difficult to diagnose, because the only indication in an infant may be irritability and crying with movement. Some edema or discoloration surrounding the affected joint is sometimes evident. Occasionally, localized abnormalities are not detected when the infant is examined initially but are noted several days later. Roentgenograms can be normal or show soft tissue swelling or capsular distention.<sup>314</sup>

To facilitate appropriate treatment, it is important to establish an etiologic diagnosis. Joint fluid should be aspirated for Gram stain and culture. Blood specimens for culture also should be collected, because they will sometimes yield an organism even when the joint fluid culture is sterile. Analysis of joint fluid usually reveals a white blood cell count greater than 50,000/mm<sup>3</sup>, with a predominance of polymorphonuclear leukocytes, and a depressed glucose concentration.

Although satisfactory treatment in many cases consists only of repeated needle aspirations of purulent material in combination with antibiotic therapy, open drainage is advisable in infants to prevent destructive debilitating disease, particularly if the hip joint is involved. The femoral head may disappear within 4 days after onset of symptoms because of the extreme susceptibility of the articular cartilage to the ravages of *S. aureus*.<sup>314</sup>

In most cases, patients should receive treatment with a parenteral antibiotic for 3 to 4 weeks, provided that there is no evidence of osteomyelitis. If concomitant osteomyelitis is present, treatment should be continued for 4 to 6 weeks. In infants with delayed response to treatment, the possibility of a collection of pus should be explored, because even high concentrations of antibiotic may lack activity in the presence of pus. There is no evidence that instillation of antibiotics into the joint space itself hastens recovery.

### Septicemia

CoNS and *S. aureus* are well-recognized causes of septicemia in the newborn period.<sup>315,316</sup> Among patients in the NICU, CoNS cause between 40% and 60% of all bacteremic episodes.<sup>14,317-319</sup> Septicemia is the most common manifestation

of neonatal infection with CoNS and usually occurs in the setting of a central intravascular catheter. With *S. aureus*, septicemia often is associated with a focal site of infection and is more common when a virulent strain is present in the nursery.

The signs and symptoms associated with staphylococcal septicemia usually are nonspecific and include disturbances of temperature regulation, respiration, circulation, gastrointestinal function, and central nervous system activity. Hypothermia is more common than fever and often is observed as the initial sign. Respiratory distress frequently manifests as episodes of apnea and bradycardia, particularly in infants who weigh less than 1500 g. Other abnormalities related to respiration include tachypnea, retractions, and cyanosis. In 20% to 30% of infants, gastrointestinal abnormalities develop, including poor feeding, regurgitation, abdominal distention, diarrhea, and bloody stools. Evidence of poor perfusion can include mottling, poor capillary refill, and metabolic acidosis. In some infants, lethargy, irritability, or poor suck may be noted.

In infants who have septicemia with a focal site of infection, persistent bacteremia often is observed. Thus, when blood culture results remain positive after more than 72 hours of appropriate antibiotic therapy, a search for focal infection is advisable. The most common examples of such infection include skin or soft tissue infection, osteomyelitis, septic arthritis, endocarditis, and meningitis.

Of interest, Patrick and co-workers recently described a group of 13 low-birth-weight infants with persistent CoNS bacteremia who had no indwelling central intravascular catheter and lacked evidence of focal infection.<sup>320</sup> These infants had positive blood culture results for 6 to 25 days despite appropriate antibiotic therapy. Abdominal distention and thrombocytopenia were especially common findings. Although the bacteremia eventually cleared and no infants died, the explanation for the delayed response to therapy was elusive.

The diagnosis of staphylococcal septicemia is established by isolating organisms from the blood. To facilitate interpretation of positive results of cultures, especially those growing CoNS, multiple culture specimens should be obtained if at all possible. Recovery of the same strain (as defined by speciation, antibiotic susceptibility profile, and possibly molecular analysis) from two or more cultures provides strong evidence for true infection. On the other hand, when a single culture specimen is collected and CoNS is recovered, assessment of the likelihood of true infection is often difficult. At least one study suggests that quantitative blood cultures may be useful in this situation.<sup>321</sup> In that study, peripheral blood cultures yielding more than 50 colony-forming units per milliliter (CFU/mL) occurred exclusively in infants with proven septicemia. By contrast, low colony counts were observed with both septicemia and culture contamination. Infants with septicemia were significantly more likely to have a central catheter or an abnormal hematologic value (white blood cell count more than 20,000/mm<sup>3</sup> or less than 5000/mm<sup>3</sup>, immature-to-total neutrophil ratio more than 0.12, or platelet count less than 150,000/mm<sup>3</sup>), regardless of the magnitude of bacteremia. Infants who lacked these clinical features were more likely to have culture contamination. Several other studies have corroborated the usefulness of an elevated immature-to-total neutrophil ratio in identifying infants with CoNS septicemia.<sup>7,20,320</sup>

In an era of increasing methicillin resistance among staphylococci, the use of vancomycin is increasingly necessary for the treatment of both *S. aureus* and CoNS bacteremia. In a study by Krediet and co-workers, the *mecA* gene was identified in 78% of bloodstream isolates of CoNS from infants in the NICU.<sup>322</sup> Combination antibiotic therapy is sometimes necessary in infants who have persistent bacteremia. The addition of rifampin has been shown in selected patients to facilitate sterilization of the bloodstream.<sup>323,324</sup>

The decision to remove an indwelling catheter from a neonate with bacteremia often is difficult, especially when securing further intravascular access may be challenging but necessary for the delivery of life-sustaining therapies. Delayed removal of a central catheter in the setting of bacteremia may be associated with an increased risk of infection-related complications, including prolonged bacteremia and end-organ damage, however.<sup>325</sup> For infants with CoNS bacteremia, successful treatment of bacteremia may be possible with the central venous catheter in situ.<sup>325</sup> However, if bacteremia persists for longer than 4 days, the chance for subsequent clearance is reduced<sup>326</sup> and the risk of end-organ damage may be increased.<sup>325,327</sup> The presence of a ventricular reservoir or ventriculoperitoneal shunt increases the chance of the development of meningitis in the setting of prolonged catheter-related bacteremia. Thus, prompt removal of an indwelling central venous catheter should be considered in infants with central nervous system hardware.<sup>326</sup>

## Endocarditis

Historically, infective endocarditis (IE) in the neonatal period has been a rare clinical diagnosis. Autopsy studies from the 1970s, however, revealed unsuspected IE in 0.2% to 3% of neonates who came to autopsy.<sup>328,329</sup> Nonbacterial thrombotic endocarditis is a condition that may predispose the patient to IE and was found in up to 10% of neonatal autopsies.<sup>328,330</sup> In the 1990s several authors described series of neonates with IE,<sup>331-334</sup> with incidence ranging from 0.07% of admissions to the NICU<sup>334</sup> to 4.3% of patients of the same gestational age.<sup>333</sup> The increased reporting of IE may be due to either improved diagnostic capabilities or to a true increase in incidence reflecting the increasing use of invasive techniques in the care of sick neonates.<sup>335</sup>

In older children with IE,  $\alpha$ -hemolytic streptococci are the organisms recovered most frequently. By contrast, in neonates staphylococcal species appear to account for a majority of the cases of IE.<sup>335</sup> Historically, *S. aureus* has been the predominant bacterial pathogen among neonates with IE,<sup>335</sup> but more recent reports indicate that CoNS may be most common now.<sup>331-334</sup>

Most case reports of IE in the neonatal period involve infants with normal hearts who are receiving intensive medical care related to prematurity or serious congenital anomalies. These infants often have indwelling catheters and are at risk for bacteremia complicating invasive procedures. The initial step in the development of IE may be the formation of nonbacterial thrombotic endocarditis. In animal models, injury to the endocardium and subsequent thrombus formation can be induced by brief insertion of an intravascular catheter into the right atrium.<sup>336-338</sup> The finding of a catheter that has migrated to the right atrium is frequently reported as a preceding event in infants with

IE.<sup>328,331</sup> Other factors that may lead to thrombus formation include hypoxia, respiratory distress syndrome of prematurity, and disseminated intravascular coagulation.<sup>335</sup> Bacterial colonization of the thrombus may occur as a consequence of transient bacteremia that develops during procedures that traumatize the skin or mucous membranes.

The signs and symptoms of IE in neonates often are nonspecific and similar to those of other conditions such as sepsis or congenital heart disease, including poor feeding, tachycardia, and respiratory distress.<sup>335</sup> While a new or changing cardiac murmur may raise the suspicion of IE, this finding may be absent.<sup>331</sup> Traditional manifestations of IE in older children and adults, such as hepatosplenomegaly, petechiae, skin abscesses, arthritis, and central nervous system abnormalities, are less common in neonates. Classic findings in IE in adults, such as Osler nodes and Roth spots, have not been described in neonates,<sup>335</sup> and only one case in the literature describes Janeway lesions in this age group.<sup>339</sup> Fever frequently is absent in neonates with IE, although temperature instability may be observed.<sup>334</sup>

The diagnosis of IE should be considered in any neonate with bacteremia that persists despite catheter removal and appropriate antimicrobial therapy. In the presence of IE, the yield of a single blood culture has been reported to be between 77% and 97%. When three blood cultures are obtained, the yield approaches 100%.<sup>340-342</sup> Additional laboratory abnormalities that are frequently reported in neonates with IE include thrombocytopenia,<sup>331-334</sup> neutropenia or neutrophilia,<sup>332,334</sup> and an elevated C-reactive protein.<sup>331,332,334</sup> The thin chest wall and often normal cardiac anatomy of neonates with IE make echocardiography a highly sensitive tool for diagnosis of IE in this age group. The limitations of this technique include the inability to detect lesions less than 2 mm in diameter and to differentiate between vegetations and other masses such as thrombi.<sup>332</sup> Additional studies that should be included in the evaluation of a neonate with suspected IE are listed in Table 17-1.

**Table 17-1 Appropriate Laboratory Evaluation and Diagnostic Tests for Neonates with Suspected Endocarditis**

1. Cultures:
  - Blood (at least two)
  - Urine
  - Cerebrospinal fluid
  - Other usually sterile body fluids, if available
2. Complete blood count including white blood cell differential
3. Erythrocyte sedimentation rate (micromethod may be used)<sup>a</sup>
4. Coagulation profile:
  - Prothrombin time
  - Partial thromboplastin time
  - Fibrinogen
  - Fibrin split products
5. Rheumatoid factor (of uncertain value in neonate)
6. Urinalysis
7. Chest radiograph
8. Echocardiogram
9. Ultrasound examination of great vessels and abdomen, including renal vessels
10. Computed tomography of head (if indicated)

<sup>a</sup>Data from Adler SM, Denton RL. The erythrocyte sedimentation rate in the newborn period. *Pediatrics* 86:942, 1986.

Traditional classification systems for the diagnosis of IE in adults, such as the von Reyn classification<sup>343</sup> and the Duke criteria,<sup>344</sup> may have reduced sensitivity when applied to children and have not been studied in neonates.<sup>345</sup> A suggested set of criteria for the diagnosis of IE in neonates has been proposed but has not been studied prospectively.<sup>332</sup>

The choice of antimicrobial therapy for the treatment of neonatal IE should be based on the susceptibility of the infecting organism. A bactericidal agent should be used when possible. The addition of a second agent, such as an aminoglycoside or rifampin, should be considered if the patient fails to improve on monotherapy. A course of parenteral therapy that continues for at least 4 to 6 weeks from the first negative blood culture result is indicated in neonates with IE.<sup>335</sup>

Historically, the prognosis for neonates with IE has been grave. A number of series published in recent years report disease-specific survival rates ranging from 40% to greater than 85%.<sup>331-334,342,346,347</sup> Survival of neonates with IE is likely to be improved with early diagnosis and aggressive management.<sup>335</sup>

### Central Nervous System Infections

*S. aureus* and CoNS have long been recognized as causes of meningitis and ventriculitis, particularly in patients with intraventricular shunts or ventriculostomy catheters.<sup>348-350</sup> Before the extensive use of shunts and catheters to divert the flow of cerebrospinal fluid in patients with congenital or acquired obstructions, most staphylococcal infections of the central nervous system involved the dura and venous sinuses and were sequelae of infections near the face. In recent years, several authors have reported the development of neonatal staphylococcal meningitis in the absence of an intraventricular foreign body or a contiguous site of infection. In affected patients, meningitis appears to develop as a sequela of bacteremia.<sup>320,351</sup> In a recent series examining neonatal meningitis in VLBW infants, CoNS were the most frequently isolated organisms.<sup>352</sup> This change may be a consequence of the increased survival of VLBW infants and the resultant increased incidence of nosocomial infections including bacteremia with CoNS.

Neonatal staphylococcal meningitis typically is associated with nonspecific signs and symptoms, including lethargy, hypotonia, temperature instability, increased oxygen requirement, apnea and bradycardia, and feeding intolerance.<sup>352</sup> Among patients with a shunt or catheter, examination of the cerebrospinal fluid most often reveals a mild pleocytosis, typically with an elevated protein and sometimes with a slightly depressed glucose; however, occasionally, the cerebrospinal fluid is completely normal. Gruskay and associates described 10 infants with *S. epidermidis* bacteremia and meningitis who had unremarkable cerebrospinal fluid cell counts and normal glucose and protein levels; the mean cerebrospinal fluid white blood cell count was 6/mm<sup>3</sup>, with a range of 0 to 14/mm<sup>3</sup>, and the mean glucose and protein values were 2.8 mmol/L and 1.15 g/L, respectively.<sup>351</sup> The lack of cerebrospinal fluid pleocytosis during episodes of CoNS meningitis has been demonstrated by other investigators as well, especially among infants before 33 weeks of postconceptional age.<sup>352</sup> Although the pathogenesis of neonatal meningitis appears to involve preceding bacteremia, a concurrent positive blood culture may be found in only about half of infants with meningitis.<sup>353,354</sup>

Traditionally, management of staphylococcal meningitis in an infant with a shunt or catheter involves removal of the contaminated foreign body and administration of appropriate antibiotic therapy. Recently, however, several investigators have advocated simply externalizing the distal end of the shunt, administering both intravenous and intraventricular antibiotics (usually for 7 to 10 days after sterilization of the cerebrospinal fluid), and then replacing the distal catheter.<sup>355,356</sup> This approach can be effective in some patients but is less likely to succeed if the infecting organism elaborates polysaccharide and forms biofilms.<sup>179,357</sup> For *S. aureus*, oxacillin or nafcillin generally is recommended, unless the organism is methicillin resistant. For CoNS, vancomycin usually is the antibiotic of choice. In cases refractory to initial treatment, combination therapy with rifampin or gentamicin may be useful, especially if the intraventricular shunt or catheter cannot be removed.<sup>358</sup>

Diffuse glomerulonephritis can develop in patients with a ventriculoatrial shunt and CoNS bacteremia.<sup>359</sup> The renal disease results from immune-complex deposition in the renal parenchyma, rather than from direct bacterial embolization to the kidney. Improvement in renal function occurs after removal of the shunt.

Despite the frequent absence of significant neurologic and cerebrospinal fluid abnormalities, staphylococcal meningitis can have a significant detrimental effect on neurodevelopmental outcome, especially among VLBW infants. In a study by Doctor and associates, the presence of meningitis in VLBW infants was associated with higher rates of major neurologic abnormalities and cognitive impairment at 20 months of corrected age, compared with control infants admitted to the same NICU without meningitis.<sup>352</sup>

Abscesses in the central nervous system are infrequent in neonates and most often are secondary to infection with gram-negative bacilli.<sup>360</sup> Staphylococcal brain abscesses can occur in neonates and young infants, however, especially in the setting of prolonged bacteremia.<sup>361</sup> Additional risk factors for the development of brain abscesses in infants and children include the presence of congenital heart disease; head trauma; ventriculoperitoneal shunting; preceding ear, nose, or throat infection; sepsis; and meningitis.<sup>362,363</sup> A polymicrobial brain abscess including *S. aureus* has been reported as a complication of fetal scalp electrode monitoring.<sup>364</sup>

The signs and symptoms of abscesses of the central nervous system may be variable, depending on the location of the lesion and the identity of the infecting organism. In published studies of infants with brain abscesses, the most frequent presenting complaints include lethargy, irritability, poor feeding, respiratory symptoms, vomiting, a bulging fontanelle or splayed sutures, focal neurologic deficits, and seizures.<sup>360,365-367</sup> Fever is present in some infants<sup>366</sup> but is not a consistent finding.

Imaging of the brain with computed tomography (CT) or magnetic resonance imaging (MRI) is critical to establishing the diagnosis of a brain abscess.<sup>361</sup> Cerebrospinal fluid studies typically are unrevealing, and culture of the cerebrospinal fluid often is negative. In patients with a suspected brain abscess, lumbar puncture generally should be avoided until a CT or MRI study is performed and reveals no midline shift or mass.<sup>361</sup>

The treatment of brain abscesses in infancy and childhood typically involves both surgical and medical manage-

ment, although in some cases, medical management alone is sufficient.<sup>363,365</sup> Despite appropriate treatment, the outcome for infants with brain abscesses often is poor, with death and disability occurring in a majority of the cases.<sup>363,368</sup>

### Enteric Infections

*S. aureus* is a common colonizer of the gastrointestinal tract of newborns, present in up to 93% of asymptomatic infants.<sup>369</sup> The prevalence of colonization is not surprising, considering that large numbers of *S. aureus* can be recovered from samples of breast milk expressed from normal breasts of lactating and nonlactating women.<sup>238</sup>

On rare occasions, *S. aureus* may be associated with enterocolitis in the newborn infant. The first case was reported in 1947 and involved an infant whose mother suffered from staphylococcal mastitis.<sup>370</sup> Since that time, additional reports have emerged describing *S. aureus* enterocolitis in neonates. A number of etiologic factors have been implicated in the development of staphylococcal enterocolitis, including prior broad-spectrum antibiotic usage, gastrointestinal foreign bodies (feeding tubes), gastrointestinal surgery, influenza virus A infection, and possibly starvation.<sup>371</sup> The pathophysiology of *S. aureus* enterocolitis may be secondary to the elaboration of toxins and the capacity of some isolates to invade intestinal epithelium, resembling invasion by *Shigella* spp.<sup>371</sup>

Infants with staphylococcal enterocolitis often present with systemic signs of infection, including lethargy, cyanosis, and bradycardia, associated with frequent watery, sometimes green-hued diarrhea that may contain blood or mucus. Typical laboratory features include leukocytosis, thrombocytopenia, acidosis, disseminated intravascular coagulation, and an elevated C-reactive protein level. Stool cultures have yielded growth of *S. aureus* in all reported cases, and blood cultures are positive in a subset of patients. Treatment of staphylococcal enterocolitis with oral vancomycin has been successful in resolving symptoms in affected neonates, although colonic stenosis after severe MRSA enterocolitis has been reported.<sup>372</sup>

The role of CoNS in neonatal enteric disease has been the subject of much debate. An association between necrotizing enterocolitis and CoNS was first suggested by Fabia and associates in 1983.<sup>373</sup> In 1986, Gruskay and colleagues described a series of 19 newborns with *S. epidermidis* bacteremia and associated acute enterocolitis.<sup>374</sup> In this series, the diagnosis of enterocolitis was assigned in infants who had blood and mucus in their stools, signs and symptoms of gastrointestinal distress, and abnormalities on the abdominal radiograph. Pneumatosis intestinalis developed in only one infant, and none had portal venous or free intraperitoneal air. Furthermore, none of these patients experienced prolonged feeding intolerance, and none required surgery. An association between necrotizing enterocolitis and delta-like toxin produced by CoNS was proposed by Scheifele and co-workers, who found toxin production in the stools of CoNS-colonized infants with NEC more frequently than in control infants who were similarly colonized.<sup>184</sup> Several authors have reported cases of necrotizing enterocolitis associated with CoNS bacteremia, but a causal function for CoNS remains to be established.<sup>10,20,375-377</sup>

## ANTIBIOTIC TREATMENT

### *Staphylococcus aureus*

The therapeutic approach to *S. aureus* infection is influenced by the special biologic properties of this organism, including the ability to persist under adverse conditions, the tendency to form deep-seated abscesses, and the capacity for resistance to a variety of antibiotics. In general, therapy consists of a sound antimicrobial regimen, in some cases coupled with surgery. Aside from superficial skin lesions, staphylococcal infection in the newborn is a serious disease. Accordingly, in general, infants should be hospitalized and receive parenteral antibiotic therapy.

Approximately 95% of *S. aureus* isolates produce  $\beta$ -lactamase, a serine protease that hydrolyzes the  $\beta$ -lactam ring and confers resistance to penicillin. In addition, an increasing percentage of isolates contain the *mecA* gene, which encodes PBP2a (also referred to as PBP2') and confers resistance to methicillin and all other penicillinase-resistant penicillins (oxacillin, nafcillin, dicloxacillin, and cloxacillin) and cephalosporins.<sup>48</sup> Methicillin resistance is defined as a methicillin minimum inhibitory concentration (MIC) greater than 8  $\mu\text{g}/\text{mL}$  or an oxacillin MIC greater than 4  $\mu\text{g}/\text{mL}$ , and as noted earlier, isolates are referred to as methicillin-resistant *S. aureus* (MRSA) or sometimes oxacillin-resistant *S. aureus* (ORSA). The presence of the *mecA* gene can be detected by DNA probes or PCR assays directed at *mecA* or by a latex agglutination reaction specific for the PBP2a protein. The *mecA* gene is contained on a 21- to 67-kilobase genetic element that harbors a variety of other antibiotic resistance genes, accounting for the fact that MRSA isolates are typically resistant to multiple antibiotics.<sup>48</sup> This genetic element is integrated into the *S. aureus* chromosome and is called the staphylococcal cassette chromosome *mec* (SCC*mec*). At least four different variations of SCC*mec* exist, designated type I to type IV SCC*mec*.<sup>48</sup> Type IV SCC*mec* is being recognized with increasing frequency and is a smaller element that usually lacks resistance genes for aminoglycosides, tetracyclines, trimethoprim-sulfamethoxazole, and clindamycin. Occasional isolates of *S. aureus* display borderline resistance to methicillin, with a methicillin MIC less than 8  $\mu\text{g}/\text{mL}$  and no *mecA* gene. In these isolates, resistance is a consequence of hyperproduction of  $\beta$ -lactamase and can be overcome by use of high doses of penicillinase-resistant penicillins.<sup>378</sup>

In recent years, isolates with intermediate susceptibility to vancomycin have been identified with increasing frequency (MIC of 8 to 16  $\mu\text{g}/\text{mL}$ ), in almost all cases having evolved from strains that are methicillin resistant.<sup>379</sup> These isolates are referred to as VISA, for vancomycin-intermediate *S. aureus*, or GISA, for glycopeptide-intermediate *S. aureus* (reflecting intermediate resistance to other antibiotics in the same class as that of vancomycin). They lack the *vanA*, *vanB*, *vanC*, *vanD*, *vanE*, and *vanG* genes associated with vancomycin resistance in enterococci. Biochemical studies have revealed increased rates of cell wall synthesis, increased quantities of cell wall precursors, and a disorganized, thickened cell wall with an increased number of vancomycin-binding sites.<sup>380,381</sup> The precise mechanism of reduced susceptibility is unclear, but it appears that "affinity trapping" may prevent vancomycin from reaching the cytoplasmic membrane, where nascent peptidoglycan synthesis occurs and where

vancomycin exerts its antibiotic effect. In 2002, the first documented infections due to high-level vancomycin-resistant *S. aureus* were reported.<sup>382,383</sup> The original isolate was recovered from a catheter exit site in an adult diabetic patient undergoing chronic dialysis and had a vancomycin MIC of 1024 µg/mL.<sup>382,384</sup> Additional susceptibility testing revealed resistance to teichoplanin (a glycopeptide antibiotic, in the same class as that of vancomycin), oxacillin (MIC greater than 128 µg/mL), aminoglycosides, fluoroquinolones, macrolides, rifampin, and tetracycline, but susceptibility to chloramphenicol, linezolid, quinupristin-dalfopristin, and trimethoprim-sulfamethoxazole. Using a PCR assay, vancomycin resistance was identified as *vanA* mediated.<sup>385</sup> Further analyses suggested that *vanA* was acquired from a co-isolate of *Enterococcus faecalis* through interspecies transfer of Tn1546, a 10.8-kb transposon that contains *vanA* and the associated resistance gene cluster (*vanR*, *vanS*, *vanH*, *vanX*, *vanY*, and *vanZ*).<sup>385</sup> Analysis of another isolate, recovered from a foot ulcer in an adult male, demonstrated a vancomycin MIC of 32 µg/mL and the presence of *vanA*. This isolate was susceptible to chloramphenicol, linezolid, minocycline, quinupristin-dalfopristin, and trimethoprim-sulfamethoxazole. Of interest, additional testing revealed susceptibility to teichoplanin, an atypical finding for strains of *Enterococcus* with the *vanA* gene.<sup>386</sup>

For isolates susceptible to penicillin, the drug of choice is penicillin. For isolates that produce β-lactamase, oxacillin or nafcillin is preferred; alternatives include first-generation cephalosporins such as cephalothin and cefazolin, although these agents are sometimes less stable to β-lactamase, resulting in occasional reports of treatment failure. Vancomycin also is an alternative for β-lactamase-producing isolates but is less rapidly bactericidal than the β-lactam antibiotics and should be reserved for patients with hypersensitivity to β-lactams.<sup>387</sup> Isolates of *S. aureus* that test resistant to methicillin also are resistant to oxacillin and nafcillin and should be considered resistant to penicillin and all cephalosporins as well, even if in vitro susceptibility testing suggests otherwise. With these isolates, vancomycin usually is the antibiotic of choice, occasionally in conjunction with gentamicin or rifampin. Some methicillin-resistant isolates are susceptible to clindamycin, which therefore can be used for treatment of infection in such cases, especially if testing reveals no evidence of inducible resistance to clindamycin and infection is outside the central nervous system. Linezolid may be another option for treatment of infection in which methicillin-resistant isolates have been identified. Other antibiotics that often have activity against MRSA include trimethoprim-sulfamethoxazole and fluoroquinolones, although these agents generally are avoided in neonates. Treatment of infection involving isolates with reduced susceptibility to vancomycin should be guided by results of in vitro susceptibility testing, but potential agents generally include gentamicin, rifampin, and linezolid. In patients with endocarditis, other serious infections, or infections refractory to monotherapy, synergistic treatment with a β-lactam or vancomycin and either gentamicin or rifampin may be considered.

The pharmacokinetics of aqueous penicillin G, the semi-synthetic penicillins (oxacillin, nafcillin, and methicillin), and the first-generation cephalosporins (cephalothin and cefazolin) have been well characterized in newborns.<sup>104,388-400</sup> In general,

**Table 17-2 Drugs Useful in Treatment of Staphylococcal Disease in Term Neonates**

Agent	Dosage	
	Age Birth-1 Wk	Age 1-4 Wk
Penicillin G	25,000-50,000 units/kg q12h	Same dose q8h
Oxacillin	25-50 mg/kg q12h	25-40 mg/kg
Nafcillin	25-50 mg/kg q12h	q6-8h
Cefazolin	25 mg/kg q12h	Same dose q8h
Rifampin	5-10 mg/kg q12h	Same dose
Clindamycin	2.5-3.75 mg/kg q12h	Same dose q8h
Linezolid	10 mg/kg q12h	Same dose q8h
Synercid	7.5 mg/kg q12h	Same dose
Vancomycin	See Table 17-3	
Gentamicin	See Table 17-4	

**Table 17-3 Dosing of Vancomycin in Term and Preterm Neonates**

Postconceptional Age <sup>a</sup>	Postnatal Age	Dosage
<28 wk	0-14 d	15 mg/kg q8h
	>14 d	15 mg/kg q12h
28-34 wk	0-14 d	15 mg/kg q12h
	>14 d	15 mg/kg q8h
34-42 wk	0-7 d	15 mg/kg q12h
	>7 d	15 mg/kg q8h
>42 wk	All	15 mg/kg q8h

<sup>a</sup>Postconceptional age = gestational age at birth + postnatal age.

**Table 17-4 Dosing of Gentamicin in Term and Preterm Neonates**

Postconceptional Age <sup>a</sup>	Postnatal Age	Dosage
<26 wk	0-30 d	3 mg/kg q24h
	>30 d	5 mg/kg q24h
26-30 wk	0-21 d	3 mg/kg q24h
	21-45 d	5 mg/kg q24h
	45-60 d	2.5 mg/kg q12h
	>60 d	2.5 mg/kg q8h <sup>b</sup>
30-32 wk	0-14 d	3 mg/kg q24h
	14-45 d	5 mg/kg q24h
	>45 d	2.5 mg/kg q8h <sup>b</sup>
>32 wk	0-30 d	5 mg/kg q24h
	>30 d	2.5 mg/kg q8h <sup>b</sup>

<sup>a</sup>Postconceptional age = gestational age at birth + postnatal age.

<sup>b</sup>In patients with renal or cardiac dysfunction, use 2.5 mg/kg/dose q12-24h.

clearance of these antibiotics increases as postnatal age advances from birth to 4 weeks, and dosing intervals should be adjusted accordingly. Recommended doses and dosing intervals are summarized in Table 17-2.<sup>401</sup> Doses for both vancomycin and gentamicin are best calculated on the basis of postconceptional age (gestational age at birth plus postnatal age). Dosages of these agents used at St. Louis Children's Hospital are outlined in Tables 17-3 and 17-4. Even with careful dosing, serum concentrations of these antibiotics

exhibit significant patient-to-patient variability, potentially compounded by medications, such as indomethacin, that impair glomerular filtration and delay excretion.<sup>392</sup> Accordingly, to maximize therapeutic effect and minimize renal toxicity and ototoxicity, serum levels of gentamicin and probably vancomycin should be monitored, allowing modification of dosing as necessary. With gentamicin, peak levels of 4 to 15  $\mu\text{g}/\text{mL}$  and trough levels less than 2  $\mu\text{g}/\text{mL}$  are desirable. With vancomycin, the ideal levels are unclear, although some experts recommend peak levels between 20 and 40  $\mu\text{g}/\text{mL}$  and predose trough levels of 5 to 12  $\mu\text{g}/\text{mL}$ .

### Coagulase-Negative Staphylococci

As with infections due to *S. aureus*, antibiotic treatment is critical in the management of disease due to CoNS. Resistance to penicillin, the semisynthetic penicillins, and gentamicin is common among hospital-acquired isolates.<sup>18,20,393</sup> Resistance to vancomycin is rare but has been reported among isolates of *S. haemolyticus*.<sup>394,395</sup> With this information in mind, most experts recommend use of vancomycin as empirical therapy when CoNS infection is suspected or proved. The treatment regimen is then modified based on antibiotic susceptibility testing.

In considering antibiotic susceptibility results, several caveats are in order. First, as with *S. aureus*, penicillin resistance in CoNS frequently is mediated by production of  $\beta$ -lactamase.<sup>396</sup> Because this resistance often is not detected by routine microdilution methods, all isolates that appear susceptible to penicillin or ampicillin should be tested for  $\beta$ -lactamase production. Such testing involves first exposing organisms to oxacillin, which induces expression of  $\beta$ -lactamase. Second, although each organism in a population may have the genetic information necessary for resistance to semisynthetic penicillins, only a small minority express resistance under *in vitro* testing conditions.<sup>104</sup> To avoid overlooking these organisms, the clinical microbiology laboratory should attempt to optimize expression of resistance by culturing on salt-containing media at 30° C to 35° C.<sup>397</sup> Third, routine susceptibility testing sometimes indicates that an isolate resistant to methicillin is susceptible to cephalosporins. As described with *S. aureus*, however, cross-resistance is extensive; therefore, all isolates of CoNS found to be resistant to semisynthetic penicillins also should be considered resistant to cephalosporins for clinical purposes.<sup>398-400</sup>

For infection due to the few isolates that are rigorously established to be penicillin susceptible and  $\beta$ -lactamase negative, penicillin is a suitable antibiotic. With isolates that are resistant to penicillin but truly susceptible to the semisynthetic penicillins, therapy with oxacillin or nafcillin is appropriate. Vancomycin is the preferred antibiotic for infection due to CoNS that are resistant to semisynthetic penicillins and also for the rare neonate allergic to penicillin. One report indicates that the combination of rifampin and clindamycin is an alternative regimen for patients allergic to penicillin.<sup>402</sup> For multiresistant isolates, considerations include other glycopeptide antibiotics (for example, teicoplanin) or quinolone derivatives. Resistance to these agents has also been reported, however.

In patients with endocarditis or cerebrospinal fluid shunt infection, synergistic therapy may be indicated.<sup>403,404</sup> *In vitro* synergy studies have been performed with vancomycin in

combination with rifampin, gentamicin, or  $\beta$ -lactams (with isolates susceptible to each), and synergy has been demonstrated with all of these combinations.<sup>350,405</sup> In view of the high frequency of resistance to gentamicin and the  $\beta$ -lactams, vancomycin plus rifampin probably is the best regimen in most cases. Although rifampin alone also has good anti-staphylococcal activity, resistance emerges rapidly unless this antibiotic is used together with other antimicrobial agents.<sup>405</sup>

## PREVENTION

### *Staphylococcus aureus*

Control of nursery infection has been directed toward the three important links in the chain of events that leads to colonization of infants: the environment, nursery attendants, and the infants themselves.<sup>406-408</sup>

Staphylococci may be spread through the air; thus, overcrowding of infants in an NICU increases the risk of colonization and the potential for disease. In an outbreak situation, attempts to control the spread of staphylococci through remediation of overcrowding and isolation of infected or colonized patients have been shown to be effective in helping to curtail the outbreak.<sup>409</sup>

In the well-infant nursery, "rooming in," a practice of placing the neonate in a room with the mother, is utilized as a method of environmental control of staphylococcal transmission.<sup>410,411</sup> Because newborns may be colonized within the first few hours of life, however, and the usual rooming-in practice involves at least a short time in a common nursery, this approach has often failed. A variation of rooming in is "cohort isolation," which involves clustering a small number of infants born within 1 or 2 days of each other in the same nursery so that they can be discharged as a "cohort." The intent is to prevent contact between newly born, uncolonized neonates and older, contaminated infants. Several reports describe the successful interruption of epidemics using this technique.<sup>410,412,413</sup>

The primary determinant of infant colonization is nursing care. Maintaining an appropriate nurse-to-infant ratio is an important factor in reducing disease once a disease-associated *S. aureus* strain gains entrance to a nursery, especially in an NICU.<sup>23,30</sup> In addition, there are a variety of preventive maneuvers directed at nurses, including frequent mask, gown, and glove changes before handling of infants<sup>414,415</sup>; nasal application of antimicrobial or antiseptic ointment or spray<sup>415-418</sup>; and elimination of carriers from the nursery area.<sup>419,420</sup> In some situations, control of an epidemic requires removal of the nurse carrier from the nursery.<sup>421</sup> Fortunately, such situations are uncommon.

Proper hand hygiene among nursery health care providers is a fundamental factor in reducing colonization rates. Mortimer and associates achieved a reduction in infant colonization from 92% to 53% by insisting that attendants wash their hands.<sup>422</sup> Proper education and monitoring of hand hygiene practices are critical to the effectiveness of this intervention.<sup>423,424</sup> Hands must be cleansed before and after patient contact or contact with equipment that is used for patient care. Hands also should be cleansed after glove removal. Proper hand hygiene involves applying alcohol-based waterless rubs if hands are not soiled,<sup>425</sup> or washing

the hands for at least 10 to 15 seconds with either chlorhexidine gluconate or triclosan hand-washing agents.<sup>426</sup>

Because of the limited success in controlling transmission of staphylococci to infants, efforts have been made to protect the sites on the infant that are easily colonized and to eliminate colonization that has occurred. Protection from colonization has been attempted through anointing or otherwise covering the skin or umbilicus of the newborn with some protective material. Application of antimicrobial ointments<sup>24,29,427,428</sup> or antiseptic dyes<sup>27,429-431</sup> to the umbilicus or repeated washing of infants with hexachlorophene-containing powders or washes<sup>44,430,432-438</sup> has been attempted both to protect the infant from colonization and to reduce colonization that has occurred. All of these approaches have achieved varying degrees of success. Because very few organisms are necessary for colonization,<sup>429</sup> success or failure in particular instances probably is related to the strain involved and a variety of host and environmental factors.

Before the appearance of MRSA, some nursery epidemics were controlled with the use of systemic antibiotics.<sup>439</sup> Because health care-acquired MRSA isolates generally exhibit resistance to multiple antibiotics, it is doubtful that this approach will be successful if the epidemic strain is MRSA. Currently, the CDC recommends contact isolation for patients colonized or infected with MRSA.<sup>440</sup> This practice was shown to reduce nosocomial transmission of MRSA by 16-fold during an outbreak of MRSA in an NICU.<sup>441</sup>

In the early 1960s, attempts were made to stop virulent *S. aureus* epidemics in 10 NICUs throughout the United States using the technique of bacterial interference.<sup>442-446</sup> This technique involved deliberate implantation of an *S. aureus* strain of low virulence (502A) on the nasal mucosa and umbilicus of newborns to prevent colonization with the virulent *S. aureus* strain. Although this procedure was successful in curtailing all 10 epidemics,<sup>447</sup> it is not widely used or recommended currently.

It also was found in the early 1960s that meticulous hexachlorophene newborn infant body washes and cord care resulted in reduced colonization with *S. aureus*.<sup>433</sup> This approach was used as an interepidemic technique in many nurseries in an attempt to prevent *S. aureus* epidemics.<sup>432,435,436,438</sup> Although epidemics of *S. aureus* infection have been associated with high colonization rates, they also have occurred on occasion in NICUs with low colonization rates.<sup>448,449</sup> Furthermore, high colonization rates do not necessarily lead to the development of epidemic disease.<sup>449-451</sup>

If hexachlorophene is to be effective in reducing colonization rates, the application must be carried out in an almost ritualistic fashion and continued at home after hospital discharge.<sup>428,432,435,452</sup> Hexachlorophene washes have been shown to be neurotoxic, particularly in premature infants, however.<sup>375,453-460</sup> For these reasons, application of hexachlorophene is not recommended as a routine interepidemic newborn body cleansing preventive measure.

Several additional routine approaches to minimize interepidemic colonization of newborns have been investigated, including umbilical application of triple dye (brilliant green, proflavine hemisulfate, and crystal violet),<sup>461</sup> bacitracin,<sup>462</sup> silver sulfadiazine,<sup>463,464</sup> or mupirocin.<sup>24,29</sup> All have shown some effect in reducing *S. aureus* colonization. It remains to be seen whether the long-term application of these materials results in the development of resistant organisms.

A novel approach to the prevention of staphylococcal disease among hospitalized patients involves vaccination. Several vaccines that show some protective effect in animal models have been developed.<sup>465-468</sup> A recently conducted trial involving adult hemodialysis patients demonstrated a significant reduction in *S. aureus* bacteremia in patients who were vaccinated with *S. aureus* capsular polysaccharide vaccine compared with controls.<sup>469</sup> The efficacy and immunogenicity of staphylococcal vaccines in the neonatal population remain unknown.

## Coagulase-Negative Staphylococci

With the rise in prominence of CoNS as nosocomial pathogens, strategies for disease prevention have become increasingly important. Strict hand hygiene is of primary importance in minimizing staff-to-patient and patient-to-patient spread of CoNS. In addition, meticulous surgical technique to limit intraoperative bacterial contamination is critical in minimizing infection related to foreign bodies. Strict attention to protocols for the insertion and management of intravenous and intra-arterial catheters may decrease the risk of catheter-related infections. In patients who require intravenous access for prolonged periods of time, percutaneous placement of a small-diameter Silastic catheter is preferred when possible. In one study, these catheters were maintained for as long as 80 days, with an infection rate of less than 10% in infants weighing less than 1500 g.<sup>338</sup>

Studies of CoNS using scanning and transmission electron microscopy suggest that bacterial attachment to catheters is a dynamic process, dependent on properties intrinsic to the catheter surface.<sup>470-472</sup> Peters and co-workers have suggested that catheter components may even serve as a nutrient source for these organisms.<sup>470</sup> With this information in mind, a number of investigators have explored the possibility of developing catheters that are inert and resistant to bacterial colonization. Thus far, these attempts have been disappointing, however.

Over the years, clinicians have employed prophylactic antibiotic therapy during implantation of a foreign body, intending to prevent infection due to CoNS and other nosocomial pathogens. Although this practice is now routine during neurosurgical, cardiac, and orthopedic surgery, efficacy remains unproved, and selection for antibiotic resistance is a significant concern. More recent efforts have focused on the possibility of preventing infection by using catheters and other prosthetic materials that have been impregnated with antibiotics. Thus far, central catheters impregnated with cefazolin, minocycline-rifampin, or chlorhexidine-silver sulfadiazine have been studied in adults,<sup>473-476</sup> and these studies have generally shown a significant reduction in both catheter colonization and catheter-related bloodstream infection.<sup>477,478</sup> In one study comparing catheters impregnated with either minocycline-rifampin or chlorhexidine-silver sulfadiazine, impregnation with minocycline-rifampin was found to be superior.<sup>479</sup> Unfortunately, antibiotic-impregnated catheters are both unstudied and unavailable for use in the neonatal population.

In recent years, a number of investigators have examined the use of low-dose intravenous vancomycin to prevent nosocomial bacteremia due to CoNS in low-birth-weight infants. Spafford and associates performed a randomized,

double-blind, controlled study involving 70 neonates weighing less than 1000 g who had central venous catheters in place.<sup>480</sup> Among these infants, 35 received the standard total parenteral nutrition (TPN) solution, and the remaining 35 received a constant infusion of vancomycin (25 µg/mL) mixed with their total TPN solution. In infants receiving vancomycin, the rate of colonization of catheters by CoNS was reduced from 40% to 18%, and the rate of catheter-related sepsis was reduced from 15% to zero. Kacica and colleagues conducted a similar study in infants weighing less than 1500 g and found that gram-positive bacteremia developed in 1 of 71 infants receiving vancomycin, compared with 24 of 70 control infants.<sup>481</sup> Cooke and co-workers, employing a slightly different protocol, administered vancomycin in a dose of 5 mg/kg twice daily.<sup>482</sup> Among 72 neonates weighing less than 1500 g, 11 of 37 who received vancomycin, compared with 17 of 35 who received standard TPN, had one or more episodes of CoNS bacteremia. The results of these studies certainly are encouraging. On the other hand, the potential risks associated with prophylactic vancomycin, including ototoxicity, nephrotoxicity, and selection for resistant bacteria, remain poorly defined. At present, the routine use of prophylactic vancomycin is not recommended.

A collaborative approach to the reduction of nosocomial infections in the NICU has been shown to be effective in reducing rates of CoNS bacteremia in the NICU.<sup>483</sup> The development of this process involved collaboration among six neonatal intensive care units (members of the Vermont Oxford National Evidence-Based Quality Improvement Collaborative for Neonatology) to reduce rates of nosocomial infection. Through a critical review of the literature, review of internal practices, benchmark studies, and analysis of the experience with implemented changes, strategies were developed to decrease rates of nosocomial infections in the NICU.<sup>484</sup> Each participating institution made clinical changes related to three areas of consensus: hand hygiene, intravascular catheter care, and accuracy of diagnosis of CoNS bacteremia. With the intervention related to these three areas, the incidence of CoNS bacteremia decreased from 24.6% to 16.4%.<sup>485</sup>

Recently, an antistaphylococcal monoclonal antibody called BSYX-A110 has been developed for the prevention of CoNS sepsis. This antibody targets staphylococcal lipoteichoic acid and has been shown to be safe and tolerable when administered by intravenous infusion to high-risk neonates.<sup>485</sup> The efficacy of the antibody in preventing CoNS infections and related morbidity and deaths remains to be seen.

## CONCLUSION

Staphylococci continue to be common pathogens in both term and preterm infants. In recent years, our understanding of important staphylococcal virulence factors has expanded considerably. With the availability of the *S. aureus* and *S. epidermidis* genomes and advances in knowledge of neonatal immunity, it is likely that novel approaches to the treatment and prevention of staphylococcal disease will be forthcoming in the near future.

*Foetal syphilis is the malady that most medical men think of when reference is made to foetal disease. It has been studied in all its aspects and at very considerable length by a multitude of careful observers. It has been taken as the type of antenatal maladies, as the typical disease of the foetus; it may almost be said that, to some investigators, foetal pathology and foetal syphilis have been synonymous terms.*<sup>1</sup>

Many decades have passed since Ballantyne wrote his congenital syphilis treatise in 1902,<sup>1</sup> but despite a complete understanding of the disease and the transmission of the organism and the availability of effective therapy and prevention strategies, congenital syphilis remains a disease of the 21st century.

The first major work on syphilis, written by Francisco Lopez de Villalobos, appeared in 1498,<sup>2,3</sup> and in 1530, Hieronymus Fracastorius<sup>3,4</sup> wrote an epic poem that featured a shepherd named Syphilus, and described the disease. A generation later, Gale<sup>5</sup> introduced the word *syphilis* into the English language. Lopez and Fracastorius mentioned syphilis of the newborn, but they and others<sup>2,5,6</sup> thought that infants became infected through contact at delivery or post partum by ingestion of infected breast milk. Because many mothers of infants with congenital syphilis had no obvious signs of infection, some investigators believed that congenital disease was transmitted by the father. Nevertheless, by 1850, it was believed that an infant could not have syphilis unless the mother was infected.

A lengthy account of the signs of syphilis in infants was published in 1854 by Diday,<sup>5</sup> but he failed to recognize that children who were without symptoms by 6 months of age could still be infected. In 1858, Sir Jonathan Hutchinson<sup>7</sup> described the famous triad of late congenital syphilis: notched incisor teeth, interstitial keratitis, and eighth cranial nerve deafness. Rosebury<sup>8</sup> has provided an eminently readable account of the history of syphilis and other venereal diseases.

**THE ORGANISM**

Although given various names following its discovery, the causative organism of syphilis was ultimately named *Treponema* because of its resemblance to a twisted thread and *pallidum* because of its pale color. This species is a member of the order Spirochaetales, family Spirochaetaceae, and genus *Treponema*. The other five genera of the order are *Borrelia*, *Spirochaeta*, *Leptospira*, and *Cristispira*. Originally, the pathogenic treponemes that cause syphilis and yaws were designated as subspecies of *Treponema pallidum* because no differences were detected by electron microscopy, DNA analysis (greater than 95% homology), or polyacrylamide gel electrophoresis of outer membrane proteins. These subspecies designations are *T. pallidum* subsp. *pallidum* and *T. pallidum* subsp. *pertenue*.<sup>9-14</sup> Moreover, because the etiologic agent of endemic (nonvenereal) syphilis is a variant of *T. pallidum*, it has been designated *T. pallidum* subsp. *endemicum*. The designation for the causative agent of pinta remains *Treponema carateum*. Recently, a genetic signature was defined in the 5' flanking region of the 15-kilodalton (kDa) lipoprotein gene (*tpp15*) that distinguished *T. pallidum* subsp. *pallidum* from *T. pallidum* subsp. *pertenue*.<sup>13</sup> The genome of *T. pallidum* subsp. *pallidum* has been sequenced.<sup>14</sup>

Only *T. pallidum* and possibly *T. pertenue*<sup>15</sup> can cause congenital infection.<sup>16-18</sup> Neither of these organisms has been cultivated successfully in vitro, although the viability and virulence of *T. pallidum* can be maintained for days to weeks

in artificial media. A limited degree of replication has been documented, especially in the presence of mammalian cells.<sup>19-21</sup>

The fact that these virulent treponemes cannot be readily cultivated *in vitro* is, to a great extent, responsible for our incomplete understanding of their properties. The problem of elucidating the biology of *T. pallidum* is further compounded by the relative unavailability of good animal models for the study of syphilitic infection. Atypical lesions develop in guinea pigs after challenge with *T. pallidum*.<sup>16</sup> Vigorously immunosuppressed mice may be susceptible to infection.<sup>22</sup> Aside from primates, however, only the rabbit is readily infected with *T. pallidum*, with development of lesions that resemble those seen in humans, even progressing to secondary infection.

No animal model for tertiary syphilis exists. A nonhuman primate model of central nervous system (CNS) invasion by *T. pallidum* was developed for elucidation of the immune mechanisms responsible for clearance of the organism from the CNS.<sup>23</sup> Initial results demonstrated the participation of locally produced interferon- $\gamma$  in this process. Rabbit,<sup>24</sup> guinea pig,<sup>25</sup> and hamster<sup>26</sup> models for congenital infection have been described, but the relevance to human congenital syphilis is not yet defined. Vertical transmission of *T. pallidum* to various litters and generations of guinea pigs has been reported,<sup>27</sup> supporting the observation that a woman congenitally infected with syphilis that was never treated is able to transmit the disease to her fetus (third-generation syphilis).

## Morphology

*T. pallidum* varies in size, ranging from 0.10 to 0.18  $\mu\text{m}$  in diameter and from 6 to 20  $\mu\text{m}$  in length, making it below the resolution of the light microscope. These spirochetes can be detected by darkfield microscopy, revealing the characteristic pattern of motion. The organism has pointed ends and lacks the hook shape found in some commensal human spirochetes. Electron microscopy shows wavelike organisms with tapered ends. They have tight, regular spirals with a wavelength of 1.1  $\mu\text{m}$  and amplitude of 0.2 to 0.3  $\mu\text{m}$ .<sup>9,10</sup>

Morphologically, *T. pallidum* consists of an outer membrane that surrounds the endoflagella, cytoplasmic membrane, and protoplasmic cylinder of the organism.<sup>28,29</sup> Three sheathed flagella or axial fibrils emerge from each end of the organism. Although it might seem reasonable to assume that, by analogy to bacterial flagella, the axial fibrils are responsible for motility, their location within the outer membrane and the failure of anti-flagellar antibody to immobilize certain spirochetes make this less certain. A glycosaminoglycan layer that has been demonstrated *in vitro*<sup>19,30,31</sup> may function as an antiphagocytic capsule. Intra-cytoplasmic tubules are present, but their characteristics and function are as yet undefined.

## Composition

The development of polyacrylamide gel electrophoresis techniques allowed characterization of some of the major constituent proteins of *T. pallidum*; 16 major proteins have been described.<sup>30-32</sup> By phase partitioning analysis utilizing the nonionic detergent Triton X-114, integral membrane

proteins with apparent molecular masses of 47, 38, 36, 34, 32, 17, and 15 kDa have been identified.<sup>33-40</sup> These proteins, particularly the 47-, 34- and 17-kDa antigens, are proteolipids containing covalently linked fatty acids.<sup>35-37</sup> Cell fractionation studies of *T. pallidum* have demonstrated that the outer membrane consists of a lipid bilayer with a paucity of proteins.<sup>28</sup> Freeze-fracture and freeze-etch electron microscopy studies have provided more direct support for these findings.<sup>38,39</sup> Genomic analysis indicates 22 putative lipoproteins. Potential virulence factors are suggested by the presence of a large number of duplicated genes (tprA through tprL) that encode putative membrane proteins that may function as porins and adhesions.

The complete genome of *T. pallidum* subsp. *pallidum* (Nichols strain) has been sequenced by the whole-genome random sequencing method.<sup>14,41-44</sup> The *T. pallidum* genome is a circular chromosome containing 1,138,006 base pairs with 1041 predicted coding sequences (open reading frames). Systems for DNA replication, transcription, translation, and repair are intact, but catabolic and biosynthetic activities are minimized. Potential virulence factors include a family of 12 potential membrane proteins and several putative hemolysins. Motility-associated genes are highly conserved, consistent with the importance of this activity; 36 genes encode proteins in the flagellar structure.

## Metabolism

Most information on of the physiology and metabolism of *T. pallidum* is derived from the Nichols strain, which has been maintained in rabbits since 1912. In the past, *T. pallidum* was regarded as an anaerobe; however, this organism takes up oxygen<sup>45</sup> and degrades glucose aerobically to carbon dioxide and acetate, as well as anaerobically to pyruvate and lactate.<sup>46</sup> Of 22 carbon sources studied, only glucose and pyruvate were metabolized aerobically.<sup>47</sup> *T. pallidum* is better able to incorporate amino acids into proteins in the presence of 10% oxygen under anaerobic conditions.<sup>47</sup> The aerobic capabilities of *T. pallidum* have been substantiated by finding a functional flavoprotein-cytochrome electron transport system<sup>48</sup> and by demonstrating oxygen consumption with oxidative phosphorylation.<sup>49</sup> Studies of *in vitro* growth of *T. pallidum* generally have found best survival or slight replication, or both, at oxygen atmospheres of 3% to 6%.<sup>50,51</sup> Thus, *T. pallidum* should be considered microaerophilic.

## Immunity

Humoral immunity has been a subject of study in syphilis since the serendipitous discovery of antibody to cardiolipin by Wassermann early in this century. By the time patients seek medical attention for primary syphilis, antibodies to *T. pallidum* can be detected by immunofluorescence and hemagglutination techniques in 90% of cases and antibody to cardiolipin in 75% of cases.<sup>58</sup> Western blot techniques show both immunoglobulin M (IgM) and IgG class antibody responses to a wide repertoire of *T. pallidum* proteins,<sup>37</sup> the 47-kDa antigen being the most immunogenic.<sup>45</sup> A small percentage of patients have antibodies that, together with complement, inhibit motility and eliminate infectivity of the organism (*T. pallidum*-immobilizing antibodies).<sup>59,60</sup> Despite this ample evidence for an immune response, syphilis

progresses and secondary lesions develop in nearly all patients unless specific therapy is given. *T. pallidum*–immobilizing antibody is present in a majority of patients who have active secondary syphilis,<sup>59</sup> and one could argue either that this antibody is protective, on the verge of controlling the disease, or that it is not protective because active disease is still present. After 1 to 3 months of secondary lesions, spontaneous remission occurs; this condition is called *latency* because the organism persists in lymph and other tissues, and tertiary syphilis may appear at a later date. Moreover, in the preantibiotic era, relapse to active infection occurred in up to 25% of persons who received no treatment after their infection had become latent.<sup>61</sup> Most recurrences occur toward the end of the first year after infection; recurrence is rare after 2 years and presumably does not occur after 4 years. Accordingly, *early latent* syphilis has been designated as being 1 year or less in duration, and *late latent* syphilis as being greater than 1 year in duration. Passive immunization with large amounts of serum from rabbits (that have recovered from experimental infection and are immune to rechallenge with *T. pallidum*) delays and attenuates infection but does not prevent the ultimate development of syphilitic lesions.<sup>62–65</sup> Immune serum facilitates uptake of *T. pallidum* by human polymorphonuclear leukocytes.<sup>66</sup> What remains unclear is why the disease progresses despite abundant evidence for antibody responses; these observations all suggest that humoral immunity is insufficient and that cellular mechanisms play a significant role.

Although an overwhelming majority of treponemes in syphilitic lesions are found in extracellular spaces, treponemes occasionally have been found within macrophages and other cells.<sup>67</sup> Radolf and associates<sup>68</sup> have shown that *T. pallidum* lipoproteins induce macrophages to secrete tumor necrosis factor by a mechanism distinct from that of lipopolysaccharide. The direct interaction of *T. pallidum* with vascular endothelium may be an important early event in the initiation of the host immune response to syphilitic infection<sup>69</sup>; purified 47-kDa lipoprotein can activate human vascular endothelial cells to upregulate the expression of intercellular adhesion molecule-1 and procoagulant activity on its surface.<sup>70</sup> The enhanced adhesiveness and coagulability may result in the fibrin deposition and perivasculitis that are characteristic histopathologic findings in syphilis.

Delayed-type hypersensitivity to treponemal antigens appears late in secondary syphilis and may be related to the onset of latency. Although infection with *T. pallidum* stimulates acquired cellular resistance,<sup>71</sup> infection with unrelated organisms such as *Mycobacterium bovis* (bacille Calmette–Guérin) or *Propionibacterium acnes* does not protect animals against challenge with *T. pallidum*.<sup>72–74</sup> Schell and associates, however, have transferred resistance to infection with *T. pallidum* strain Bosnia by transfusing T cells from immune hamsters.<sup>75</sup> T lymphocytes responsive to *T. pallidum* appear in syphilitic lesions as the number of treponemes decreases,<sup>76</sup> which gives further evidence, albeit circumstantial, for a role of cellular immunity in controlling infection.

Some findings suggest that immune responses may be impaired early in syphilis. In early syphilis, (1) *in vitro* blastogenic transformation of lymphocytes after stimulation with a variety of antigens is depressed<sup>67</sup>; (2) paracortical (thymus-dependent) areas of lymph nodes are depleted<sup>77,78</sup>;

(3) delayed hypersensitivity to several antigens may be depressed<sup>79,80</sup>; and (4) ability to produce IgG in response to sensitization with sheep red blood cells (a T cell–dependent antigen) is markedly inhibited.<sup>81,82</sup> On the other hand, some authorities believe that the evolution of immunity is slow, albeit for unknown reasons, but that suppression of immunity is not responsible.<sup>36</sup>

It is even possible that true immunity to *T. pallidum* does not exist. Active lesions may be brought under control and animals may become resistant to rechallenge with *T. pallidum*, but the host is unable to rid itself completely of the infecting organism, which persists in lymph nodes. Premunition, resistance to rechallenge, or, in the case of syphilis, a “chancre-fast” state without biologic cure may best describe this situation. It is known that persons with untreated secondary syphilis or true latent infection are resistant to rechallenge with *T. pallidum*, as are those with untreated congenital syphilis.<sup>83</sup>

Some observations from studies of congenital syphilis helped to contribute to the understanding of immunity. Nineteenth-century physicians knew that a degree of maternal immunity is acquired during infection. Nabarro<sup>84</sup> observed that an infected infant did not infect the mother’s breast. Paré speculated that an infant who acquired the infection from a syphilitic wet nurse could pass infection to the mother through contact with contagious lesions.<sup>3</sup> In 1846, Kassowitz observed that the longer syphilis exists untreated in a woman before pregnancy occurs, the more likely it is that when she does become pregnant, her treponemes will be held in check, and the less likely it is that her fetus will die in utero or be born with congenital syphilis; this observation is called *Kassowitz’s law*.<sup>8,84</sup>

It remains unclear what factors determine which mothers, particularly those in the latent stage of infection, will pass disease to their fetuses. It also is not clear why some infants who are infected in utero are born without any clinical manifestations, with the subsequent development of overt disease in the first weeks or months of life or even later at puberty.

Modern immunology has only recently started to pay attention to the problem of congenital syphilis. As would be suspected by transplacental transfer of immunoglobulin, the IgG levels of infected infants largely match those of the mother. Moreover, by immunoblotting, the IgG reactivity of infant sera is indistinguishable from that of the mother, again indicating the transplacental nature of the IgG antibodies.<sup>85–88</sup> The range of IgM antibody responses to the proteins of *T. pallidum* in the sera of overtly infected newborns is comparable to that for disseminated (secondary) infection in adults.<sup>85</sup> The IgM response of the infant, however, is distinct from that of the mother and is uniformly directed against the 47-kDa membrane lipoprotein antigen.<sup>85,86,88</sup>

## TRANSMISSION

Humans are the natural host of *T. pallidum*. Sexual contact is almost exclusively the mode of transmission. Rarely is the disease passed to health care workers or others who accidentally come into contact with infectious lesions or to

laboratory personnel who handle infected animals. The newborn infant typically is infected in utero by transplacental passage of *T. pallidum* from an infected, untreated or inadequately treated mother, but the newborn also can be infected following contact with an active genital lesion at delivery. In utero transmission has been supported by isolation of the organism from umbilical cord blood and amniotic fluid,<sup>88-90</sup> detection of spirochetes in the placenta and umbilical cord with associated typical histopathologic changes,<sup>91,92</sup> and detection of IgM to *T. pallidum* in neonatal serum obtained at birth.<sup>85-88</sup> Lucas and associates<sup>90</sup> reported that *T. pallidum* can be isolated from approximately 74% of amniotic fluid samples from women with early syphilis; it is possible that *T. pallidum* can infect the fetus by traversing the fetal membranes to reach the amniotic fluid, resulting in fetal infection. Alternatively, infection may occur from contact with an infectious lesion during passage through the birth canal.<sup>1,84</sup> Centuries ago, when it was common for infants to be fed by a wet nurse, small epidemics of syphilis sometimes were caused by an infectious lesion on the nipple of the wet nurse. No recent data indicate that breast milk is associated with transmission of *T. pallidum*.

The risk of syphilis to the fetus or infant appears to vary considerably by interval when the mother acquired syphilis.<sup>93,94</sup> In 1951, Ingraham<sup>94</sup> described 220 women who had untreated early syphilis (up to 4 years duration); 41% of their infants were born alive and had congenital syphilis, 25% were stillborn, 14% died in the neonatal period, 21% weighed less than 2.3 kg at birth but had no evidence of congenital syphilis, and only 18% were healthy infants born at term gestation. By contrast, only 2% of infants born to 82 mothers with untreated late syphilis (longer than 4 years' duration) had congenital syphilis. Fiumara and colleagues<sup>93</sup> stated that when primary or secondary maternal syphilis went untreated, half of the infants were premature, stillborn, or died as neonates, and congenital syphilis developed in the other half; the chance of the mother's giving birth to a healthy full-term infant was very small. In the case of early latent syphilis, 20% to 60% of the infants were healthy, 20% were premature, and 16% were stillborn; 4% died as neonates, and 40% had congenital syphilis. In the case of untreated late syphilis, about 70% of the infants were healthy, 10% were stillborn, and approximately 9% were premature; about 1% died as neonates, and 10% had congenital syphilis.<sup>93</sup>

Recent data indicate that among women with untreated early syphilis, 40% of pregnancies result in spontaneous abortion, stillbirth, or perinatal death.<sup>95</sup> Infection can be transmitted to the fetus at any stage of disease, but the rate ranges from 60% to 100% during primary or secondary syphilis and slowly decreases with time. In a prospective cohort analysis of 428 women with untreated syphilis from 1988 to 1998, untreated primary syphilis at delivery resulted in a transmission rate of 29% (3% stillbirths and 26% live births with congenital syphilis). Untreated secondary syphilis at delivery resulted in congenital infection in 59% of the infants (20% stillborn, 39% live-born), whereas with early latent disease, the transmission rate was 50% (17% stillborn, 33% live-born). On the other hand, maternal late latent infection resulted in 5% stillbirths and only 8% live births with congenital syphilis.<sup>96</sup>

These statistical estimates put Kassowitz's law into epidemiologic terms. An interesting family study illustrating this law described a syphilitic mother who had five pregnancies resulting in eight children.<sup>97</sup> The first pregnancy produced a stillborn child; the second a full-term infant with congenital syphilis; the third, triplets, two of whom had congenital syphilis; the fourth, twins, one of whom had congenital syphilis; and the fifth, a healthy full-term infant. Although in keeping with Kassowitz's law, the effect of syphilis on the fetus was less severe with each succeeding pregnancy, the sobering point is that the mother, whose syphilis had escaped detection and treatment during the time she was delivering the syphilitic infants, was able to transmit congenital syphilis over the span of a decade. Two unusual aspects of this report are the unavailability of data to identify during which pregnancy the mother became infected and the fact that the diagnosis of infection in the parents occurred 4 years after the fifth pregnancy.

A majority of infants born to mothers with untreated or inadequately treated syphilis have no clinical or laboratory evidence of infection at birth. Nevertheless, manifestations of disease can develop a few weeks, months, or years later if these infants go untreated. The exact pathogenesis of this "late-onset" type of infection is unknown.

The effect of concurrent maternal infection with *T. pallidum* and human immunodeficiency virus (HIV) on the risk of fetal infection with *T. pallidum* and HIV is not fully understood.<sup>98-100</sup> Cellular immune dysfunction associated with HIV infection may permit a greater degree of treponemal proliferation and lead to a higher rate of fetal infection. HIV-infected women who acquire syphilis during pregnancy may not respond adequately to currently recommended benzathine penicillin therapy, thereby increasing the risk of fetal infection with *T. pallidum*.<sup>101</sup> Preliminary studies by Sanchez<sup>98</sup> indicate that infants born to co-infected mothers with early syphilis are significantly more likely to have clinical or laboratory evidence of congenital syphilis at delivery than infants born to women with early syphilis without HIV infection. Alternatively, untreated syphilis during a pregnancy complicated by maternal HIV may result in an increased risk of fetal HIV infection by producing a placentitis, allowing transmission of the virus from the maternal to fetal circulation.<sup>99</sup> The finding by Theus and colleagues<sup>102</sup> that virulent *T. pallidum* can directly promote the induction of HIV gene expression in macrophages, possibly resulting in increased systemic HIV levels with more rapid progression of the HIV infection, supports the notion of possible increased vertical transmission of HIV from a co-infected mother to the fetus.

*T. pallidum* is present in open, moist mucocutaneous lesions of primary or secondary syphilis, as well as in body fluids such as blood and cerebrospinal fluid (CSF), of infected infants. Health care workers should observe standard precautions when caring for infected infants, and infants and adults with infectious lesions should be placed in contact isolation for the first 24 hours of therapy. Once antimicrobial therapy has been initiated, the risk of transmission is virtually nonexistent because penicillin in sufficient dosage causes a complete disappearance of viable treponemes from syphilitic lesions within a few hours.<sup>103</sup> *T. pallidum* does not survive well outside the host and is easily killed by heat, drying, and soap and water.<sup>104,105</sup>

**Figure 18-1** Rates of congenital syphilis among infants (per 100,000 live-born infants) and primary and secondary syphilis among women (per 100,000 population) by year in the United States, 1981 to 2002. (From Centers for Disease Control and Prevention. Congenital syphilis—United States, 2002. *MMWR Morb Mortal Wkly Rep* 53:717, 2004.)

## EPIDEMIOLOGY

Early treatments for syphilis included mercury, first used in 1497; arsphenamine; other heavy metals; and malaria inoculation for paretic cases.<sup>106</sup> The breakthrough in treatment came in 1943 when Mahoney and colleagues<sup>107</sup> successfully used penicillin to treat primary syphilis in four patients. Because of the exquisite susceptibility of *T. pallidum* to penicillin, it was believed that use of this antimicrobial agent would lead to the virtual disappearance of syphilis. Indeed, a dramatic decline in the number of cases did occur, the incidence reaching a low point in the mid-1950s. Unfortunately, often when a disease approaches eradication, the control program rather than the disease is eradicated. As the incidence of syphilis decreased remarkably, the funding allocated for syphilis control was drastically reduced. By the early 1960s, the disease was resurgent, and more resources were again committed to control efforts. The incidence of syphilis subsequently declined in the 1970s, only to increase dramatically in the 1980s.<sup>108,109</sup> From 1986 to 1991, a steady increase was observed in the incidence of primary and secondary syphilis among women in the United States (Fig. 18-1).<sup>98</sup> This increase was greatest among blacks and Hispanic Americans in large urban centers such as New York City, Detroit, Miami, and Los Angeles.<sup>108,110-112</sup> The exchange of illegal drugs, particularly “crack cocaine,” for sex with multiple partners appears to play a major role in the transmission of syphilis.<sup>108,110,113-115</sup> Because the identities of sexual partners often are unknown among persons trading sex for drugs, partner notification, a traditional syphilis control strategy, is virtually impossible. Other factors implicated in the dramatic increase of syphilis included a reduction in resources for syphilis control programs that are coordinated in sexually transmitted disease clinics of local public health departments,<sup>116,117</sup> as well as the use of

spectinomycin for treatment of infections due to penicillinase-producing *Neisseria gonorrhoeae*, because spectinomycin is not effective against incubating syphilis.<sup>118,119</sup>

Between 1991 and 1996, the incidence of primary and secondary syphilis in the United States decreased by 86% (see Fig. 18-1). Several factors contributed to this significant decrease.<sup>120-126</sup> Awareness of the syphilis epidemic of the late 1980s has led to wider screening practices and identification of infected persons. Increased state and federal resources were invested in syphilis control programs for traditional (e.g., partner notification, clinical services) and nontraditional (e.g., community-based screening, outreach and risk-reduction counseling) activities.<sup>121,122</sup> These programs helped identify particular locations with a high prevalence of syphilis and with core populations at high risk for infection.<sup>121,122</sup> The recognition of these demographics allowed presumptive treatment of syphilis based on epidemiologic indications. Other reasons for the decline included a decrease in crack cocaine use and exchange of sex for drugs, major contributors to the epidemic, as well as the introduction of HIV prevention programs that target prevention of other sexually transmitted diseases. The development of acquired immunity to syphilis that occurred among high-risk populations when syphilis was more prevalent also may have played a role. In addition, changing the treatment recommendation for other STDs to ceftriaxone could have treated incubating syphilis.<sup>124</sup> By 1997, the incidence of reported cases of syphilis had fallen to the lowest ever reported, a rate of 3.2 cases per 100,000 persons.

Despite this decline, syphilis remains endemic in the United States.<sup>123,124</sup> Syphilis is a reportable disease; the number of reported cases of primary and secondary syphilis has varied, ranging between 6999 and greater than 45,000 cases per year,<sup>125,126</sup> although it is estimated that only about 1 of every 3 cases is reported.<sup>127</sup> Differences across race and

gender have been reported. African American and Hispanic races are strong markers for syphilis seroreactivity.<sup>128</sup> In 1998, the rate (number of cases per 100,000 population) of primary and secondary syphilis was substantially higher among blacks (17.1) than among Native American Indians or Alaskan Natives (2.8), Hispanic Americans (1.5), non-Hispanic whites (0.5), and Asians/Pacific Islanders (0.4).<sup>126</sup> People who live in "inner cities" on the East Coast and in the rural South<sup>129</sup> bear a disproportionate burden. In 1998, the rate of primary and secondary syphilis was higher in the South (5.1) than in the Midwest (1.9), West (1.0), and Northeast (0.8).<sup>126,130</sup> In fact, a majority of the total reported cases of primary and secondary syphilis occurred in the southeastern United States, which contains only 19% of the total U.S. population.<sup>120</sup>

Moreover, focal outbreaks of primary and secondary syphilis continue to occur, and these have been associated with illicit drug use, exchange of sex for drugs or money, and in certain groups of homosexual men with multiple partners.<sup>126,129</sup> Attention also has focused on the induced migration that results when public housing projects are dismantled and infected persons move to less impoverished areas that surround the inner city; this results in infection of new sexual partners, who often lack a history of drug use. These continuing outbreaks are disconcerting because cyclic national epidemics have occurred every 7 to 10 years; they underscore the need for syphilis elimination rather than enhanced control.<sup>128</sup>

Worldwide, syphilis remains a considerable public health problem, particularly in Eastern Europe and in the developing countries of Africa and Latin America.<sup>131</sup> In countries such as those of the former Soviet Union, the increase in syphilis has been related to changes in sexual behavior and in the patterns of provisions, use, and effectiveness of diagnostic treatment and contact tracing services.<sup>132</sup> In South America, the problem of syphilis and congenital syphilis only now is being unraveled. In a study in Buenos Aires, 10% of women with reactive serologic tests for syphilis had a history of stillbirth that was believed to be caused by syphilis.<sup>133</sup> In Bolivia, 26% of women in 1996 who were delivered of stillborn infants had syphilis, compared with only 4% of mothers of live-born infants.<sup>134</sup>

Nonetheless, in the United States, expectations currently are heightened for the possibility of the eventual control and elimination of endemic syphilis.<sup>128</sup> In 1998, the rate of primary and secondary syphilis declined to 2.6 cases per 100,000 population, the lowest rate ever reported in the United States.<sup>126</sup> No cases were reported in 78% of U.S. counties, and 90% of the counties had 4 or fewer cases per 100,000 population, reaching the Healthy People 2000 national objective. Moreover, syphilis today is occurring in fewer geographic areas, with 50% of new syphilis cases reported from less than 1% of U.S. counties. Because of these findings, the Centers for Disease Control and Prevention (CDC) has developed a National Plan for Elimination of Syphilis from the United States.<sup>126,128</sup> The CDC has defined syphilis elimination as the absence of sustained transmission. The national goal for syphilis elimination is to reduce primary and secondary syphilis cases to 1000 or less (rate: 0.4 per 100,000 population) and to increase the number of syphilis-free counties to 90% by 2005. The plan focuses on five key strategies: (1) enhanced community involvement

and partnerships at local, state, and national levels; (2) intensified surveillance; (3) rapid outbreak response; (4) expanded access to health care for persons infected with or exposed to syphilis; and (5) improved health promotion.

Gestational syphilis primarily affects women who are young, unmarried, and of low socioeconomic status and who receive inadequate prenatal care.<sup>112,135</sup> The incidence of congenital syphilis closely correlates with that of primary and secondary disease in women; it is not surprising that the incidence of congenital syphilis increased dramatically in the late 1980s, coincident with the rise in early syphilis among women of childbearing age.

The dramatic increase in the number of cases of congenital syphilis in 1990 to 1991 was due both to an increase in actual cases and to the use of revised reporting guidelines beginning in 1989, which broadened the surveillance definition for congenital syphilis.<sup>108,136,137</sup> Previous criteria for reporting cases of congenital syphilis were based on a clinical case definition.<sup>138</sup> A "confirmed case" was that of an infant or stillborn infant in whom *T. pallidum* was identified with darkfield microscopy or specific stains in specimens from lesions. A "presumptive case" was that of an infant or a stillborn infant who had a reactive test for syphilis and abnormalities on physical examination and on long bone radiographs, a reactive CSF Venereal Disease Research Laboratory (VDRL) test, an elevated CSF cell count or protein concentration without another cause, a nontreponemal serologic titer that was four times higher than that of the mother's, or, in the live-born infant, persistence of a reactive treponemal test beyond the age of 1 year. In 1989, a new surveillance case definition for reporting congenital syphilis was approved by the CDC (Table 18-1).<sup>108</sup> *Congenital syphilis* then included all cases in infants with clinical evidence of active syphilis, as well as infants without clinical manifestations and stillborn infants born to women with untreated or inadequately treated syphilis. Use of these guidelines increased the number of reported cases of congenital syphilis almost fourfold,<sup>98,139,140</sup> although clearly some cases were reported that actually were not infections. This current definition acknowledges the public health burden of the disease, because these infants require medical and public health interventions.

The persistence of congenital syphilis despite the wide availability of effective penicillin therapy has prompted close scrutiny of those cases still occurring. Mascola and associates<sup>141</sup> reviewed 50 Texas cases of congenital syphilis reported during 1 year for epidemiologic characteristics that might have led to their prevention. Their findings, including unpublished observations of 659 cases (C Beck-Sague, A Hadgu, L Frau, et al, unpublished data), are summarized in Table 18-2. Similar data have been reported from Miami,<sup>110</sup> Detroit,<sup>111</sup> and New York.<sup>142,143</sup> Lack of prenatal care was, by far, the single most important cause. Congenital syphilis is preventable, but only if prenatal care is available to, as well as sought by, those often hard-to-reach groups that are most at risk, such as teenage and/or unwed mothers, drug users, women who are sexually promiscuous, and members of disadvantaged minority groups (Table 18-3). Syphilis needs to be considered and ruled out with serologic tests in the first trimester of all pregnancies and with additional screenings at the beginning of the third trimester (28 weeks) and at delivery for mothers who live in areas with high incidences of infection.<sup>108,112,135,139,144,145</sup>

**Table 18–1 Surveillance Case Definitions for Congenital Syphilis**

A *confirmed case* of congenital syphilis is that in an infant in whom *Treponema pallidum* is identified by darkfield microscopy, fluorescent antibody testing, or use of other specific stains in specimens from lesions, placenta, umbilical cord, amniotic fluid, or autopsy material.

A *presumptive case* of congenital syphilis is that in either of the following:

- A. Any infant whose mother had untreated or inadequately treated<sup>a</sup> syphilis at delivery, regardless of findings in the infant; or
- B. Any infant or child who has a reactive treponemal test for syphilis AND any one of the following:
  1. Any evidence of congenital syphilis on physical examination; or
  2. Any evidence of congenital syphilis on long bone radiographs; or
  3. Reactive CSF VDRL test; or
  4. Elevated CSF cell count or protein content (without other defined cause); or
  5. Quantitative nontreponemal serologic titers that are four times higher than the mother's (both specimens drawn at time of birth)

A *syphilitic stillbirth* is defined as a death of a fetus weighing greater than 500 g or having reached a gestational age of greater than 20 weeks when the mother had untreated or inadequately treated syphilis.

<sup>a</sup>Inadequate treatment consists of any nonpenicillin therapy or penicillin therapy given less than 30 days before delivery.

CSF, cerebrospinal fluid; VDRL, Venereal Disease Research Laboratory.

**Table 18–2 Factors Contributing to Occurrence of Congenital Syphilis**

Factor	No. of Cases	% of Total
No prenatal care, STS result positive at delivery	301	46
Prenatal care received, STS result negative at first trimester, not repeated	96	15
No STS performed during prenatal care	27	4
Negative result on maternal STS at delivery	44	7
Laboratory error in testing	2	0.3
Delay in treatment	50	8
Prenatal treatment failures	95	14
Insufficient data	36	6
Other	8	1
TOTAL	659	

STS, serologic test for syphilis.

Data from Mascola L, Pelosi R, Blout JH, et al. Congenital syphilis.

Why is it still occurring? JAMA 252:1719-1722, 1984 and

C Beck-Sagne et al, unpublished data.

The CDC has identified factors contributing to the occurrence of congenital syphilis in 2002.<sup>146</sup> From 2000 to 2002 the rate of congenital syphilis decreased 21%, from 14.2 to 11.2 cases per 100,000 population. Primary and secondary syphilis rates among women during this same interval declined 35.3%, from 1.7 to 1.1 cases per 100,000. Thus, every year since 1991, congenital syphilis rates and primary and secondary syphilis rates in women have declined (see Fig. 18-1). Furthermore, congenital syphilis rates declined in all ethnic minority populations; rates declined 50.6% among Native American Indian/Alaskan Natives, 22.4% among Hispanic Americans, 21.4% among Asians/Pacific Islanders and 19.8% among non-Hispanic black infants. Rates also decreased in every region of the United States except the Northeast, where the rate increased by 0.9%. In 2002, only 4.4% of U.S. countries reported cases of congenital syphilis, compared with 5.4% in 2000.

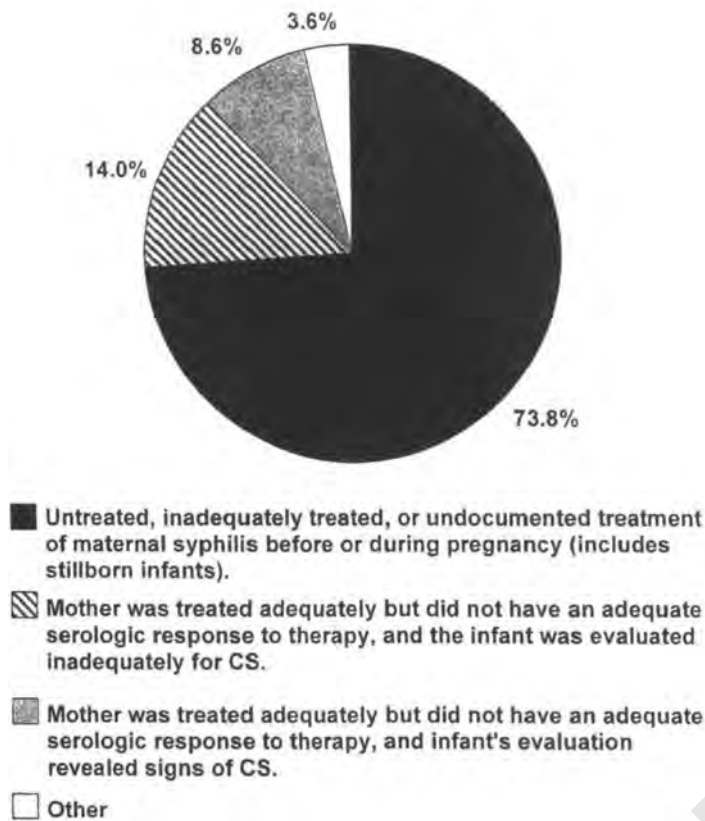

**Table 18–3 Epidemiologic Factors Associated with High Risk for Syphilis Exposure**

- Being an unmarried or teenage mother
- Inadequate or no prenatal care
- Illicit drug use in the mother or sexual partner
- Multiple sexual partners
- History of sexually transmitted disease<sup>a</sup>
- Sexual contact with anyone known to have a sexually transmitted disease<sup>a</sup>
- Racial/ethnic minority mothers of low socioeconomic status

<sup>a</sup>Including human immunodeficiency virus infection.

Among the 451 cases of congenital syphilis reported during 2002, 333 (73.8%) occurred because the mother received either no penicillin or inadequate treatment before or during pregnancy (Fig. 18-2).<sup>146</sup> In 130 cases (28.8%), the mother received no prenatal care. Of the 288 mothers who received prenatal care, 86 initiated care during the first trimester, 93 during the second trimester, and 59 during the third trimester; 30.5% of the those initiating care in the third trimester did so less than 30 days before delivery. Of the 451 infants with congenital syphilis, 18 (4%) were stillborn, and 8 (1.8%) died within 30 days of delivery (overall case-fatality ratio, 5.8%). These mortality data represent a modest improvement from those reported from 1982 to 1998 by Gust and colleagues.<sup>147</sup> In that study, the case-fatality ratio was 6.4% (stillborns and neonatal deaths) for 14,627 infants with congenital syphilis. More than half of the deaths occurred when the infant was born before 30 weeks of gestation. Also, an inverse relationship was noted between number of prenatal visits and risk of fatal outcome.<sup>147</sup>

Several investigators have called attention to problems with antenatal management and communication crucial to the prevention of congenital syphilis.<sup>148,149</sup> These problems include failure to (1) obtain an appropriate and complete maternal history, (2) perform routine screening at appropriate times during the pregnancy, (3) correctly interpret

**Figure 18-2** Diagnosis of congenital syphilis (CS) in the United States, 2002. (From Centers for Disease Control and Prevention. Congenital syphilis—United States, 2002. *MMWR Morb Mortal Wkly Rep* 53:717, 2004.)

serologic results, (4) recognize signs of maternal syphilis, (5) provide treatment for the pregnant sexual partner of an acutely infected man, and (6) communicate pertinent maternal history and results of screening tests to the infant's health care practitioner. Local health departments and clinicians must improve the exchange of information between obstetric and pediatric services. These issues further underscore the need for education of health care providers on the management of sexually transmitted diseases.

Sexually transmitted infections potentially threaten everyone regardless of demographic probabilities. As shown in Table 18-2, 44 cases occurred in women who were incubating syphilis at the time of delivery, which highlights the limitation of the screening serologic tests to detect early cases. Serologic tests are poor diagnostic tools during the incubation or early primary stage of syphilis. During those times, results of the nontreponemal (rapid plasma reagin [RPR] or VDRL) tests may not show reactivity because reactivity occurs 4 to 8 weeks after the infection is acquired and several days to 1 week after the development of a chancre.<sup>150,151</sup> In primary syphilis, nonreactivity on nontreponemal testing is reported to occur in one fourth to one third of cases.<sup>152,153</sup> Nonreactivity on the microhemagglutination-*T. pallidum* (MHA-TP) assay and the fluorescent treponemal antibody (FTA) test occurs in as many as 36% and 18% of cases of primary syphilis, respectively.<sup>155</sup> A prenatal prevention strategy that uses only currently available serologic tests, therefore, cannot eliminate all congenital syphilis,<sup>155</sup> and contact tracing of sexual partners, careful physical examination of women in labor for evidence of

primary syphilis, and additional testing of postpartum women at 4 weeks after delivery will be necessary.<sup>98,120,156,157</sup> Moreover, if a woman with an infant younger than 1 year is diagnosed with early syphilis, that infant should be evaluated serologically and receive appropriate treatment.<sup>156</sup>

## **PATHOLOGY AND PATHOGENESIS**

Controversy about the pathogenesis of congenital syphilis is ongoing. Historically, it was taught that infection of the fetus by a syphilitic mother could not occur before the fifth month of pregnancy, because pathologic changes in fetal tissue could not be demonstrated before this point in gestation. It was thought that the Langhans' cell layer of the cytotrophoblast formed a placental barrier against *T. pallidum* invasion of the fetus.<sup>158,159</sup> This theory was disproved by the electron microscopic demonstration of persistence of the Langhans' cell layer throughout pregnancy.<sup>160</sup> Moreover, using silver stains and immunofluorescence techniques, Harter and Benirschke<sup>161</sup> demonstrated spirochetes in fetal tissue from spontaneous abortions at 9 and 10 weeks of gestation. Infectivity testing that would have proved the presence of *T. pallidum* conclusively was not performed by these investigators, however. The lack of pathologic changes in fetal tissues earlier than the fifth month of pregnancy could be a result of fetal immunoincompetence during early gestation.<sup>162</sup> Moreover, viable spirochetes in amniotic fluid obtained by amniocentesis from a woman with early syphilis have been reported as early as 14 weeks of gestation, proving that the fetus can be exposed to *T. pallidum* early in pregnancy.<sup>163</sup>

Pathologic changes in congenital syphilis are similar to those that occur in acquired syphilis, except for the absence of a primary or chancre stage. Because infection involves the placenta<sup>164</sup> and spreads hematogenously to the fetus, widespread involvement is characteristic. No matter which organ is involved, the essential microscopic appearance of lesions is that of perivascular infiltration of lymphocytes, plasma cells, and histiocytes, with obliterative endarteritis and extensive fibrosis.<sup>165-167</sup> These typical histopathologic features of the inflammatory response to invasion by *T. pallidum* in tissues and blood vessels suggest an important role for cytokines as mediators of immunopathogenesis during syphilis.<sup>68</sup> Radolf and associates<sup>68</sup> have shown that *T. pallidum* lipoproteins induce macrophages to secrete tumor necrosis factor, as well as to activate vascular endothelium.

In addition, Brightbill and colleagues<sup>168</sup> have shown that the 47-kDa lipoprotein of *T. pallidum* induced production of interleukin-12 (IL-12) messenger RNA from human macrophages, a key signal of the innate immune system. The spirochete also has been shown to activate human promyelomonocytic cell line THP-1 cells in a CD14-dependent manner.<sup>169</sup> These findings lend further support to the concept that lipoproteins are the principal components of intact spirochetes and that they are responsible for monocyte activation, indicating that surface exposure of lipoproteins is an important determinant of a spirochetal pathogen's pro-inflammatory capacity.

## Placenta

The infected placenta is larger, thicker, and paler than normal.<sup>170</sup> Histopathologic examination of the placenta, especially if unexpectedly large, and of the umbilical cord is a useful adjunct for the diagnosis of congenital syphilis.<sup>112,170-175</sup> The histologic features consist of focal villitis with endovascular and perivascular proliferation and relative immaturity of the villi, which become enlarged and hypercellular and have bullous projections<sup>171,172</sup>; these larger villi, with respect to the amount of blood in the capillaries, are the cause of the pallor. Sheffield and colleagues<sup>175</sup> have correlated villous enlargement as well as placental erythroblastosis with stillbirth due to congenital syphilis. In addition, an increased amount of connective tissue surrounds the capillaries and also makes up the stroma.

Treponemes are demonstrable with silver stains,<sup>164,171,172</sup> although tissue membrane artifacts may in fact be difficult to distinguish from these organisms. Necrotizing funisitis, a deeply seated inflammatory process within the matrix of the umbilical cord, has been associated with congenital syphilis and can provide a diagnostic clue to its presence at birth.<sup>173-175</sup> Spirochetes have been identified within the umbilical cord lesions by silver stain. Bromberg and co-workers<sup>176</sup> have detected *T. pallidum* in umbilical specimens by an immunofluorescent antigen detection assay (IFA). Using polymerase chain reaction (PCR) assay to detect *T. pallidum* DNA, Genest and colleagues<sup>91</sup> confirmed the strong association between the placental histopathologic features (enlarged hypercellular villi, proliferative fetal vascular changes, and acute or chronic villitis) and congenital syphilis and suggested that PCR assay may identify additional cases of histologically unidentified congenital syphilis.

## The Fetus and Newborn

A stillborn syphilitic infant often has a macerated appearance, with a collapsed skull and protuberant abdomen. The skin shows vesicular or bullous lesions, which have a fluid rich in treponemes. Guarner and associates<sup>177</sup> reported that a constant feature throughout the tissues was concentric macrophage (CD68-positive) infiltrate around vessels, giving an onionskin appearance. Immunohistochemical analyses have identified macrophages as the prime immune response to congenital syphilis. The liver and spleen are enlarged and show fibrosis and extramedullary hematopoiesis.<sup>178</sup> Roentgenographs of long bones show evidence of osteochondritis and periostitis.<sup>179</sup>

A divergence of opinion exists as to the nature and extent of hepatic involvement in congenital syphilis. The traditional view has been that diffuse interstitial inflammation is present and can progress to disrupt the normal hepatic architecture by extensive scarring.<sup>180,181</sup> Oppenheimer and Hardy<sup>178</sup> found that 15 of 16 livers from infants who died before 9 weeks of age were abnormal; lesions varied considerably in severity but included inflammation in the interstitial stroma and perivascular network, especially in the area of the portal triads, with diffuse hepatitis and excessive extramedullary hematopoiesis.<sup>178</sup> When Wright and Berry<sup>182</sup> reviewed liver sections from which Nabarro<sup>84</sup> had previously described intercellular fibrosis, they found that 50 of 59 sections stained with hematoxylin and eosin were histologically normal, although silver stains revealed heavy infiltration with treponemes. The discrepancies in the observations of these workers may be related to the different ages of the patients and the severity of the infections. The patients described by Wright and Berry were as old as 1 year of age. Rarely, gummas have been described in the liver in infants with congenital syphilis; cirrhosis appears to be an uncommon complication.<sup>178</sup> The spleen is enlarged because of an extensive nonspecific inflammatory reaction<sup>183</sup>; it also demonstrates extramedullary hematopoiesis.

The "pneumonia alba" of congenital syphilis is characterized grossly by yellowish white, heavy, firm, and grossly enlarged lungs.<sup>167,183</sup> A marked increase in the amount of connective tissue in the interalveolar septa and the interstitium associated with collapse and loss of alveolar spaces explains the increased weight and density of the lung. This obliterative fibrosis of the lung is now reported only rarely,<sup>178</sup> most probably owing to treatment of mothers earlier in gestation.

Attention has been called to the unique submucosal inflammation and fibrosis of the gastrointestinal tract in infants who died during the first 2 months of life.<sup>178</sup> An initial mucosal and submucosal infiltration with mononuclear cells is associated with a striking submucosal fibroblastic proliferation, resulting in a remarkable increase in the width of the submucosa. These changes are found more often in the small intestine than in the colon and stomach.<sup>177,184</sup> An intense pancreatitis<sup>178</sup> is present, with a perivascular inflammatory infiltrate, obliteration of ductules and acini, reduction in the number of islets, and extensive fibrosis.

Renal involvement appears to be the consequence of injury to the glomeruli by immune complex deposition,<sup>185</sup> just as has been described for the glomerulitis of secondary syphilis in adults.<sup>186</sup> An epimembranous glomerulopathy<sup>187</sup> is common and is associated with two different forms of

immune complex injury, one involving complement deposition in addition to IgA, IgM, and IgG and the other involving immune complexes without complement deposition along the basement membrane.<sup>185</sup> A perivascular inflammatory infiltrate, consisting of plasma cells and lymphocytes involving the interstitial tissues, is prominent. The visceral and parietal epithelial cells of the glomeruli are swollen and increased in number. Increased matrix, collagen, and cells broaden axial regions in each tuft. Numerous electron-dense nodular deposits are noted on the epithelial aspect of the thickened glomerular basement membrane.<sup>185,187</sup> Elution studies have demonstrated the presence of antitreponemal antibodies in the eluate and of treponemal antigen in the eluted sections.<sup>188</sup> A seemingly more rare proliferative glomerulonephritis also has been described, with mesangio-endothelial proliferation and crescent formation.<sup>189</sup>

The neuropathologic features of congenital syphilis are comparable with those of acquired syphilis, except that the parenchymatous processes (general paresis, tabes dorsalis) that were infrequently described in the older literature now are extremely rare.<sup>190</sup> Meningeal involvement is apparent as a discoloration and thickening of the basilar meninges,<sup>167,190</sup> especially around the brain stem and the optic chiasm. Microscopically, endarteritis typically is present; depending on the severity and chronicity of the infection as well as on the blood vessels involved, various degrees of neuronal injury can ensue. As the infection resolves, fibrosis can occur, with formation of adhesions that obliterate the subarachnoid space, leading to an obstructive hydrocephalus or to a variety of cranial nerve palsies.<sup>190</sup> Interstitial inflammation and fibrosis of the anterior lobe of the pituitary gland, at times accompanied by focal necrosis, also have been reported among infants with congenital syphilis.<sup>191</sup> The posterior lobe remains unaffected. An evolving anterior pituitary gumma was noted at autopsy in a 3-day-old infant with congenital syphilis that did not respond to treatment.<sup>192</sup>

Widespread involvement of bones is characteristic of congenital syphilis. Osteochondritis, periostitis, and osteomyelitis are present, especially in the long bones and ribs. The osteochondritis is recognized grossly by the presence of a moderate and irregular yellow line in the zone of provisional calcification.<sup>193</sup> The trabeculae are irregular, discontinuous, and variable in size and shape. The excessive fibrosis occurring at the osseous-cartilaginous junction is referred to as syphilitic granulation tissue and contains numerous blood vessels surrounded by the inflammatory infiltrate.<sup>167,194,195</sup> The characteristic saw-toothed appearance described historically is now uncommonly found in radiographs<sup>196</sup>; however, xeroradiography of long bones of still-born infants with congenital syphilis often demonstrates this classic pattern,<sup>179</sup> which is produced by irregularity in the provisional zone of calcification, corresponding to an irregularity in growth of capillaries. Small islands of cartilage may persist in the ossified bone.<sup>178</sup>

A subperiosteal deposit of osteoid, which can completely encircle the shaft of the long bone, is a feature of the periostitis.<sup>84,197</sup> An associated osteomyelitis (osteitis) usually is present and, when it involves the long bones, is called *diaphysitis*.<sup>196</sup> Microscopically, an inflammatory infiltrate with erosion of the trabeculae and prominent fibrosis is seen.<sup>196</sup> In the skull, the periosteal reaction eventually can lead to the radiographic feature of frontal bossing. The basic process of

the osseous disturbance seems to involve a failure to convert cartilage in the normal sequence to mature bone. Controversy about the pathogenesis of these bone changes has been ongoing for years.<sup>186,198</sup> One view is that they are specific results of local infection by the spirochete; the other is that they represent nonspecific trophic changes on endochondral bone formation caused by severe generalized disease. The fact that they heal without specific antibiotic therapy tends to favor the latter view.

Pathologic observations do not provide a basis for hematologic manifestations of congenital syphilis, which are thought to reflect physiologic changes of unknown pathogenesis (discussed later in the chapter). Adequate numbers of megakaryocytes are present.<sup>199</sup> Severe anemia initially represents an acute hemolytic process, compounded by splenomegaly and excessive cellular destruction. This is followed by a chronic progressive anemia, accentuated by physiologic marrow hypoplasia.<sup>200</sup>

## CLINICAL MANIFESTATIONS

### General Considerations

The spectrum of perinatal syphilis is similar in many ways to that of other infections in which the infecting organism spreads hematogenously from the pregnant woman to involve the placenta and infect the fetus. The extent of damage to the fetus presumably depends on the stage of development when infection occurs and elapsed time before treatment. With early infection and in the absence of therapy, miscarriage, stillbirth, premature delivery, or neonatal death can occur.<sup>84,94,95,147,164,170,201-203</sup> Infection can be clinically recognizable or silent at birth; if the infection goes untreated, its expression is delayed for several months to years.<sup>159,204,205</sup>

Congenital syphilis has been divided somewhat arbitrarily into early and late stages.<sup>166</sup> Clinical manifestations appearing within the first 2 years of life are designated *early*, and those occurring after this time are called *late*. The clinical manifestations of early congenital syphilis are a direct result of active infection and inflammation. The clinical manifestations of late congenital syphilis represent the scars induced by initial lesions of early congenital syphilis or reactions to persistent and ongoing inflammation. These so-called stigmata of late congenital syphilis reflect the delayed expression of a prenatal insult in a fashion comparable with the occurrence of deafness beyond infancy that is related to congenital rubella.<sup>206</sup>

### Syphilis in the Pregnant Woman

Clinical manifestations of acquired syphilis<sup>131,135</sup> are not altered by pregnancy. Genital chancres, the principal manifestation of primary infection, occur about 3 weeks after contact. They often are unrecognized in women because they cause no symptoms, and their location within the vagina or on the cervix, labia, or the perineum makes detection difficult. Extragenital chancres can occur (e.g., lips, tongue, tonsil, nipple, finger, anus). Syphilitic chancres are painless, clearly demarcated ulcers 0.5 to 2 cm in diameter and generally associated with enlargement of the regional lymph nodes. Multiple lesions are not uncommon.<sup>207</sup> Because these lesions are painless and may be hidden, the diagnosis of primary

syphilis in women often is not made until the secondary or latent stage. Accordingly, ulcerating lesions always warrant evaluation by darkfield microscopy and serologic tests. If untreated, syphilitic chancres heal spontaneously 3 to 8 weeks after their appearance. The mechanism for healing is obscure; it is believed that local immunity is partly responsible, because secondary lesions appear during or after the regression of the primary one.

Lesions of secondary syphilis result from the dissemination of *T. pallidum* from syphilitic chancres, and the term *disseminated syphilis* probably is more appropriate.<sup>19,208</sup> More than 3 weeks elapse between the deposition of *T. pallidum* in the dermis and emergence of these lesions; this delay in development and failure of affected sites to evolve into lesions that resemble primary chancres probably reflect a degree of humoral or cellular immunity, or both. Thus, secondary syphilis manifests 4 to 10 weeks after the initial primary lesion; however, in some patients who present with disseminated lesions, a careful search leads to discovery of the primary chancre. The rash of secondary syphilis is macular, papular, follicular, papulosquamous, or pustular<sup>166,209</sup>; the vesiculobullous eruption that is common in congenital syphilis rarely occurs in adults. Lesions are symmetrical and generally involve the trunk, where they tend to follow skin lines, and the palms and soles. The rash has been misidentified as an allergic reaction, even though it seldom is pruritic. Mucous patches that appear as white plaques on erythematous bases represent superficial mucosal erosions and can involve the oral cavity, vulva, vagina, or cervix.<sup>166</sup> In warm, moist areas of the body such as the anogenital region and intertriginous surfaces, the papules enlarge and become exuberant, raised, wartlike lesions that are the highly infectious condylomata lata.<sup>209</sup>

Secondary syphilis is a systemic disease, and interest in the dermatologic manifestations should not prevent the physician from recognizing the presence of constitutional symptoms such as fever, weight loss, anorexia, headache, fatigue, and arthralgia that can precede or accompany the dermatologic manifestations. Generalized nontender lymphadenopathy usually is present. A variety of other complications occur, including hepatitis,<sup>210,211</sup> glomerulonephritis or nephrotic syndrome,<sup>212-215</sup> osteitis,<sup>216-218</sup> iritis, and meningitis (Table 18-4).<sup>208</sup> *T. pallidum* has been isolated from the CSF of 30% of adults with untreated primary and secondary

syphilis.<sup>101</sup> With or without treatment, the lesions of secondary syphilis heal and infection enters a subclinical or latent phase that lasts for years and can be diagnosed only by serologic testing.<sup>219,220</sup> Too often its protean clinical manifestations are overlooked and misdiagnosed.<sup>221-223</sup>

Latent syphilis is subdivided into early (1 year or less from onset of infection) and late (later than 1 year from onset) latent stages based on the time when mucocutaneous lesions can recur and infection can still be transmitted.<sup>156,166</sup> Patients are diagnosed with early latent syphilis if, within the year preceding the evaluation, they had a documented seroconversion, symptoms or signs of primary or secondary syphilis, or a sexual partner who had primary, secondary, or early latent syphilis. If the time of infection cannot be ascertained, a diagnosis of syphilis of unknown duration is made and the patient is managed as if she had late latent syphilis.

A high index of suspicion (see Table 18-3) is needed by the obstetrician or perinatologist to consider the diagnosis of syphilis in pregnancy and to prevent adverse outcomes. Two caveats should be heeded: Any ulcer, regardless of location, that is painless, indurated, and indolent and fails to heal within 2 weeks warrants exclusion of syphilis as a diagnosis. Similarly, any generalized eruption, regardless of its morphology, should be viewed as secondary (disseminated) syphilis until proved otherwise. One of the most common sequelae of untreated syphilis during pregnancy that is recognized worldwide is spontaneous abortion during the second and early third trimesters.<sup>92</sup> Furthermore, untreated maternal syphilis can result in preterm delivery, perinatal death, and congenital infection. Antenatal ultrasonography can be helpful in the diagnosis of fetal syphilis; hydramnios, fetal hydrops, enlarged placenta, hepatosplenomegaly, and bowel dilatation have been described.<sup>224,225</sup> Ultrasonography performed in pregnant women with early syphilis has suggested that fetal hepatosplenomegaly can be an important early indicator of congenital infection.<sup>225</sup>

### Early Congenital Syphilis

The diagnosis of early congenital syphilis should be entertained in any infant who is born at less than 37 weeks of gestation with no other apparent explanation, or if unexplained hydrops fetalis or an enlarged placenta is present. In infancy, failure to move an extremity (pseudoparalysis of Parrot), persistent rhinitis (snuffles), a maculopapular or papulosquamous rash (especially in the diaper area), unexplained jaundice, hepatosplenomegaly or generalized lymphadenopathy, or an anemia or thrombocytopenia of uncertain cause should raise consideration of congenital syphilis (Table 18-5).

**Hepatosplenomegaly.** Hepatomegaly is present in nearly all infants with congenital syphilis and may occur in the absence of splenomegaly, although the reverse is not true.<sup>226</sup> Jaundice, which has been recorded in 33% of patients,<sup>226</sup> can be caused by syphilitic hepatitis (with elevated direct and indirect bilirubin levels) or by the hemolytic component of the disease. It may be the only manifestation of the disease. Hepatic dysfunction in the form of elevated serum aminotransferases, alkaline phosphatase,<sup>227</sup> and direct bilirubin<sup>227-229</sup> initially can worsen with initiation of penicillin therapy and can persist for several weeks.<sup>228,229</sup>

**Table 18-4 Clinical Manifestations of Early Syphilis in the Pregnant Woman**

Asymptomatic
Symptomatic
Chancre(s), genital and extragenital
Mucocutaneous lesions
Macular, papular, follicular, papulosquamous, pustular
Condylomata lata
Mucous patches
Lymphadenopathy
Constitutional symptoms
Less common manifestations (alopecia, hepatitis, glomerulonephritis or nephrotic syndrome, osteitis, iritis, meningitis)
Preterm labor (spontaneous abortion, stillbirth, preterm delivery)

**Table 18–5 Clues That Suggest a Diagnosis of Congenital Syphilis<sup>a</sup>**

Epidemiologic Background	Clinical Findings
Untreated early syphilis in the mother	Osteochondritis, periostitis
Untreated latent syphilis in the mother	Snuffles, hemorrhagic rhinitis
An untreated mother who has contact with a known syphilitic during pregnancy	Condylomata lata Bullous lesions, palmar/plantar rash
Mother treated for syphilis during pregnancy with a drug other than penicillin	Mucous patches Hepatomegaly, splenomegaly
Mother treated for syphilis during pregnancy without follow-up to delivery	Jaundice Nonimmune hydrops fetalis
Any high-risk factor given in Table 18-3	Generalized lymphadenopathy Central nervous system signs; elevated cell count or protein in cerebrospinal fluid Hemolytic anemia, diffuse intravascular coagulation, thrombocytopenia Pneumonitis Nephrotic syndrome Placental villitis or vasculitis (unexplained enlarged placenta) Intrauterine growth restriction

<sup>a</sup>Arranged in decreasing order of confidence of diagnosis.

Data from Rathbun KC. Congenital syphilis: a proposal for improved surveillance, diagnosis and treatment. *Sex Transm Dis* 10:102, 1983.

**Generalized Lymphadenopathy.** Generalized lymphadenopathy usually occurs in association with hepatosplenomegaly and has been described in up to 50% of patients.<sup>226</sup> The lymph nodes themselves can be as large as 1 cm in diameter and typically are nontender and firm. Generalized enlargement of the lymph nodes can occur in other systemic illnesses but is quite uncommon in neonates and young infants. If an infant has palpable epitrochlear nodes, the diagnosis of syphilis is highly probable.

**Hematologic Manifestations.** Major hematologic findings include anemia, jaundice, leukopenia or leukocytosis, and thrombocytopenia. A characteristic feature in the immediate newborn period is that of a Coombs'-negative hemolytic anemia. After the neonatal period, chronic nonhemolytic anemia can develop, accentuated by the usual physiologic anemia of infancy.<sup>199,200</sup> The pathogenesis of this anemia is not known. Other findings include polychromasia and erythroblastemia with up to 500 nucleated red blood cells per 100 leukocytes. This pattern of anemia and erythropoietic response historically led to confusion with erythroblastosis fetalis.<sup>84</sup> Although the leukocyte count usually falls within the normal range,<sup>199</sup> leukopenia, leukocytosis, or a leukemoid reaction<sup>226</sup> can occur. Lymphocytosis and monocytosis may be features. Thrombocytopenia, related to decreased platelet survival rather than to insufficient production of platelets,

often is present and can be the only manifestation of congenital infection. Hemophagocytosis has been described and may play an important role in the pathogenesis of anemia and thrombocytopenia.<sup>230</sup>

Hydrops fetalis also is a manifestation of congenital syphilis in newborns.<sup>231</sup> A negative Coombs' test result in a hydropic infant with hemolytic anemia should suggest this diagnosis. Paroxysmal cold hemoglobinuria, a disease mediated by an antibody to erythrocytes that meets even the most rigorous definition of an autoantibody, may develop in a few patients with congenital syphilis.<sup>232,233</sup>

**Mucocutaneous Manifestations.** Mucocutaneous manifestations occur in 15% to 60% of infants with syphilis.<sup>226,234</sup> Rhinitis (snuffles) can be an early feature, developing after the first week of life and usually before the end of the third month. It was reported in two thirds of patients in the early literature<sup>234</sup> but now is less common.<sup>226</sup> A mucous discharge develops, with character similar to that of discharge in upper respiratory tract infections. The discharge, which is teeming with spirochetes and is highly infectious, can become progressively more profuse and occasionally is blood-tinged. Secondary bacterial infection can occur, causing the discharge to become purulent. If ulceration of the nasal mucosa is sufficiently deep and involves the nasal cartilage, a "saddle nose" deformity, one of the later stigmata of congenital syphilis, can result. Snuffles also has been associated with laryngitis and an aphonic cry.<sup>234</sup> Mucous patches can appear in the mouth and are more prevalent in infants with severe systemic disease.

The most common cutaneous lesion is a maculopapular eruption that is oval and pink or red, subsequently becoming coppery brown.<sup>235</sup> As the rash changes color, very fine superficial desquamation or scaling can occur, particularly on the palms and soles. The lesions are more common on the posterior portion of the body (especially the buttocks, back, thighs, and soles) than on the anterior surface but also can involve the perioral area and palms. Other maculopapular types of eruptions uncommonly are found in early congenital syphilis. The lesions can be annular or circinate or can have the appearance of any other kind of lesion seen in acquired secondary syphilis.<sup>209</sup>

Pemphigus syphiliticus occurs most often in the neonatal period and is characterized by a widely disseminated vesiculobullous eruption that involves the palms and soles.<sup>235</sup> The lesions vary in size and can contain a cloudy hemorrhagic fluid that teems with treponemes. When these bullae rupture, they leave a denuded area that can undergo extensive maceration and crusting.

After the first 2 or 3 months of life, the perioral area, especially the nares and the angles of the mouth, and the perianal area can be affected by condylomata lata.<sup>202,235</sup> These highly infective areas are flat or wartlike and moist. The condylomata can be single or multiple and frequently accompany no other signs of infection. They can lead to deep fissures radial to the affected orifices and can result in fine scars designated *rhagades*. Comparable eruptions also can be found in other body folds or intertriginous areas but are considered to be more characteristic of the later stage of early congenital syphilis.

Other dermatologic manifestations of congenital syphilis have been described. Petechial lesions can result from

thrombocytopenia. Generalized edema can be present<sup>199,226</sup> as a result of hypoproteinemia related to renal or hepatic disease.

**Bone Lesions.** Bone lesions are perhaps the most frequently encountered abnormalities in untreated early congenital syphilis. Most bone lesions are not clinically discernible (see “Radiographic Diagnosis” section) except in pseudoparalysis of Parrot.<sup>236,237</sup> Pseudoparalysis of Parrot, a syndrome in which pain is associated with a bone lesion or a superimposed fracture, or both, occurs infrequently in infants with congenital syphilis.<sup>238</sup> Clinically, it can manifest as irritability in an infant a few weeks of age who does not move one of the limbs.<sup>239</sup> The upper extremities are affected more frequently than lower extremities, and unilateral involvement predominates. This clinical picture can mimic Erb’s palsy but rarely is present at birth. The correlation between the clinical and the radiologic findings is poor, inasmuch as other areas of bone involvement can look more severely affected on radiographs even though no clinical signs suggest their presence.

**Renal Manifestations.** The clinical picture of nephrotic syndrome usually appears at 2 or 3 months of age, the predominant manifestation being generalized edema, including pretibial, scrotal, and periorbital areas, together with ascites.<sup>240-244</sup> Rarely, the infant can have hematuria with less severe proteinuria but more profound azotemia, which suggests that a glomerulitis predominates.

**Central Nervous System Manifestations.** According to Platou, clinically inapparent involvement of the brain and spinal cord revealed by CSF abnormalities occurred in 60% of infants with congenital syphilis in 1949.<sup>234</sup> Of note, however, he empirically defined an abnormal CSF as having greater than 5 white blood cells per mm<sup>3</sup> and a protein content greater than 45 mg/dL. The overall incidence of neurosyphilis by these criteria could be challenged, because the CSF of neonates contains up to 25 white blood cells per mm<sup>3</sup>, and a protein content as high as 150 mg/dL in full-term infants and 170 mg/dL in preterm infants can be considered normal.<sup>245</sup> Furthermore, the significance of a reactive CSF VDRL test in the absence of other diagnostic evidence of congenital syphilis is suspect, inasmuch as non-treponemal IgG can pass from the serum to the CSF.<sup>246</sup> Experiments using rabbit inoculation of CSF from infants born to mothers with untreated early syphilis documented a prevalence of spirochetal invasion of the CSF in 6 of 7 (86%) infants with clinical and laboratory evidence of congenital syphilis, but only 1 of 12 (8%) infants born to mothers with untreated early syphilis and whose findings on physical examination and laboratory evaluation were normal.<sup>88</sup> Neurologic manifestations, although well documented in the earlier literature,<sup>190</sup> are now infrequently reported. The clinical types of CNS involvement have been separated arbitrarily into supposedly well-defined groups, but frequently overlap exists.

Acute syphilitic leptomeningitis appears during the first year of life, usually between the ages of 3 and 6 months. Signs can suggest acute bacterial meningitis, including a stiff neck, progressive vomiting, Kernig’s sign, bulging fontanelles, separation of the suture, and hydrocephalus.<sup>247</sup> In contrast with this clinical picture, CSF reveals abnormalities consistent

with an aseptic meningitis, with up to 200 mononuclear cells per mm<sup>3</sup>, a modest increase in protein (50 to 200 mg/dL), and a normal glucose value. The CSF VDRL test is positive. This is the one form of CNS involvement that always responds to specific therapy.<sup>234</sup>

Chronic meningovascular syphilis can have a protracted course, resulting in progressive hydrocephalus, cranial nerve palsies or vascular lesions of the brain, and gradual intellectual deterioration.<sup>247</sup> These complications develop toward the end of the first year. The hydrocephalus is of low grade, progressive, and communicating as a result of obstruction in the basilar cisterns. Cranial nerve palsies can complicate the picture.<sup>190</sup> The seventh nerve most often is involved, but the third, fourth, and sixth cranial nerves also can be affected. Optic atrophy can be preceded by papilledema.

A variety of cerebrovascular syndromes have been described, but they are rare.<sup>190</sup> Cerebral infarction results from syphilitic endarteritis and can occur between the first and second years of life, commonly manifesting as acute hemiplegia. Convulsions frequently complicate this clinical picture.

**Ocular Manifestations.** The occurrence of syphilitic involvement of the eye in early congenital syphilis is rare. Chorioretinitis, salt-and-pepper fundus, glaucoma, uveitis, cataract,<sup>248</sup> and chancres of the eyelid have been described.<sup>84</sup> Involvement by syphilis leads to a granular appearance of the fundus; pigmentary patches of various shapes and colors<sup>84</sup> are seen in the periphery of the retina. The young infant rarely manifests the signs of photophobia and diminution in vision that occur in older patients. Congenital glaucoma can occur<sup>84</sup> and should be a diagnostic consideration in the presence of blepharospasm, cloudy cornea, enlarged cornea (diameter exceeding 12 mm), and excessive tearing.

Inflammation of the uveal tract (including the iris and ciliary body anteriorly and the choroid posteriorly) affects the retina because of the close anatomic relationship of the cornea to the structures of the uveal tract. Consequently, chorioretinitis rather than uveitis is the more commonly diagnosed ocular problem in infancy. In a recent report, however, pathologic examination of an eye from a 3-day-old infant who died of congenital syphilis revealed a focal granulomatous reaction involving the anterior uvea and lens.<sup>248</sup> Rarely, a chancre of the eyelid appears 4 weeks after birth, presumably resulting from recently developed syphilitic lesions of the maternal genitalia.<sup>84</sup>

**Intrauterine Growth Restriction.** The effect of syphilis on the growth of the fetus in utero is likely to be related to the timing and severity of the fetal infection. In a carefully performed quantitative morphologic study, Naeye<sup>249</sup> demonstrated that syphilitic infection in utero did not seem to have a significant effect on the growth of the fetus, as manifested by a study of 36 perinatal deaths. Naeye’s findings were similar to his previous results that showed a relative lack of effect on fetal growth from toxoplasmosis, contrasting with the intrauterine growth restriction associated with rubella and cytomegalovirus infections.<sup>250</sup> Case reports have indicated that infected newborns were small for their gestational age.<sup>239</sup> Whether this growth retardation is the result of syphilitic infection or other co-factors (e.g., use of illicit intravenous drugs by the mother<sup>251</sup>) that affect fetal growth is not known.

**Other Findings.** The classic historical description of the infant with congenital syphilis is a severely infected premature infant with marasmus, a pot belly, "old man" facies, and withered skin.<sup>84,235</sup> The degree of failure to thrive can be correlated with the frequently encountered pathologic finding of intense pancreatitis<sup>178</sup> and inflammation of the gastrointestinal tract.<sup>178</sup> Rectal bleeding due to syphilitic ileitis with ulcer formation and associated with intestinal obstruction has been reported.<sup>185</sup> Involvement of the anterior pituitary gland in congenital syphilis is manifested by persistent hypoglycemia beyond the early neonatal period.<sup>191</sup> Evaluation of pituitary function, including tests for thyroid function, and determination of growth hormone and cortisol levels, combined with magnetic resonance imaging of the pituitary, confirms the diagnosis of hypopituitarism.<sup>191</sup>

Other uncommon manifestations of congenital syphilis include pneumonia alba, or syphilitic pneumonitis, which is an obliterative fibrosis of the lung tissue. Myocarditis<sup>178</sup> has been found at autopsy in approximately 10% of infants who die, although the clinical significance of this finding is not clear. Fever has been reported to accompany other signs of congenital syphilis in infants beyond the immediate newborn period.<sup>111,227</sup>

### Late Congenital Syphilis

As noted earlier, the clinical manifestations of late congenital syphilis are stigmata that represent scars induced by the initial lesions of early congenital syphilis or reactions to persistent and ongoing inflammation. In patients older than 2 years of age, late congenital syphilis can be manifested by (1) the stigmata of the disorder that represent the scars of initial lesions or developmental changes induced by the early infection; (2) ongoing inflammation that causes interstitial keratitis, nerve deafness, and Clutton's joints (although *T. pallidum* is not demonstrable); or (3) a persistently positive result on treponemal serologic tests for syphilis in the absence of apparent disease.<sup>166</sup> In reviewing the manifestations of late congenital syphilis (Table 18-6), Fiumara and Lessell<sup>252</sup> concluded that only Hutchinson's triad (Hutchinson's teeth, interstitial keratitis, and eighth nerve deafness), mulberry molars, or Clutton's joints are specific enough to confirm the diagnosis.

**Table 18-6 Clinical Manifestations of Late Congenital Syphilis**

<b>Dentition:</b>	Hutchinson's teeth, mulberry molars (Moon's, Fournier's)
<b>Eye:</b>	interstitial keratitis, healed chorioretinitis, secondary glaucoma (uveitis), corneal scarring
<b>Ear:</b>	eighth nerve deafness
<b>Nose and face:</b>	"saddle nose," protuberant mandible
<b>Skin:</b>	rhagades
<b>Central nervous system:</b>	mental retardation, arrested hydrocephalus, convulsive disorders, optic nerve atrophy, juvenile general paresis, cranial nerve palsies
<b>Bones and joints:</b>	"saber shins," Higouménakis' sign, Clutton's joints

**Dentition.** Vasculitis that occurs around the time of birth damages the developing tooth bud, which then leads to a number of dental abnormalities that appear in late congenital syphilis. The deciduous teeth do not seem to be affected, except for a possible increase in the incidence of dental caries.<sup>84</sup> Hutchinson's teeth are abnormalities of the permanent upper central incisors; these teeth are peg shaped and notched, usually with obvious thinning and discoloration of enamel in the area of the notching. The teeth are widely spaced and shorter than the lateral incisors. The width of the biting surface is less than that of the gingival margin.<sup>252</sup>

A diagnostic lesion, the mulberry molar (also known as Moon's or Fournier's molar) is always the first lower molar.<sup>252</sup> Characteristically, the tooth's grinding surface, which is narrower than that at the gingival margin, has many small cusps instead of the usual four well-formed cusps. The enamel itself tends to be poorly developed. Putkonen<sup>253</sup> examined 30 children whose infected mothers had received penicillin during the latter half of pregnancy and an additional 36 children whose initial therapy for congenital syphilis was initiated during the first few months of life. He noted distinct syphilitic dental changes in 7 of 15 children whose treatment began at age 4 months or later, but in none of the children whose mothers had received treatment during the last half of pregnancy or before age 3 months. He concluded that early treatment prevented the dental changes of syphilis.

**Eye.** Interstitial keratitis is the second manifestation of Hutchinson's triad. This lesion can be detected in patients between 5 and 20 years of age. A severe inflammatory reaction begins in one eye, generally becoming bilateral during the ensuing weeks or months. Spirochetes have not been found to be present.<sup>201</sup> Symptoms include photophobia, pain, excessive lacrimation, and blurred vision. Patients can have conjunctival injection, miosis, keratitis, or anterior uveitis, or a combination of these findings. Interstitial keratitis is considered preventable if treatment is given before age 3 months.<sup>253</sup> Interstitial keratitis usually appears at puberty and is not affected by penicillin therapy but responds transiently to corticosteroid treatment.<sup>254</sup> Keratitis often has a relapsing course that can result in secondary glaucoma or corneal clouding.

**Ear.** Eighth nerve deafness is the least common component of Hutchinson's triad, occurring in only 3% of patients with late congenital syphilis.<sup>252,255,256</sup> The histopathologic features of luetic involvement of the temporal bone include mononuclear leukocytic infiltration and obliterative endarteritis, with involvement of the periosteal, endochondral, and endosteal layers of bone. Osteochondritis affecting the otic capsule can lead to cochlear degeneration and fibrous adhesions, resulting in eighth nerve deafness as well as vertigo. Although the deafness usually occurs in the first decade, it may not appear until the third or fourth decade of life. The initial involvement can be unilateral or bilateral; deafness initially involves the higher frequencies, and normal conversational tones are affected later. It may respond to long-term corticosteroid therapy.

**Nose and Face.** The sequelae of syphilitic rhinitis include failure of the maxilla to grow fully, resulting in a concave

configuration in the middle section of the face with relative protuberance of the mandible and an associated high palatal arch. Inflammation of the nasal mucosa can affect the cartilage, leading to destruction of the underlying bone and perforation of the nasal septum. The resulting depression of the roof of the septum gives the appearance of a “saddle nose.”

**Skin.** An infrequent sign of late congenital syphilis is linear scars that become fissured or ulcerated, resulting in deeper scars called rhagades. These scars are located around body orifices, including the mouth, nostrils, and anus.<sup>84</sup>

**Central Nervous System.** The reported incidence of neurologic involvement in late congenital syphilis varies considerably, according to different authors. Some report that as many as one third of patients more than 2 years of age have CSF abnormalities that would justify a diagnosis of late asymptomatic neurosyphilis.<sup>234</sup> The neurologic manifestations can include mental retardation, arrested hydrocephalus, convulsive disorders, juvenile general paresis, and cranial nerve abnormalities, including deafness and blindness, which is due to optic nerve atrophy.<sup>190,247</sup> These findings are uncommon in cases described during the last 50 years.<sup>252</sup> Use of single photon emission computed tomography (SPECT) in a 5-year-old patient with late neurosyphilis clinically manifested as seizures demonstrated areas of hypoperfusion that closely agreed with abnormalities seen in the electroencephalogram.<sup>257</sup> Findings on cranial computed tomography, magnetic resonance imaging, and cerebral angiography, however, were normal.

**Bones and Joints.** Bone involvement in late congenital syphilis is relatively infrequent in comparison with the frequent occurrence of abnormalities in early congenital syphilis.<sup>84</sup> The sequelae of periosteal reactions can involve the skull, resulting in frontal bossing; the tibia, resulting in “saber shin”; or the sternoclavicular portion of the clavicle, resulting in a deformity called Higouménakis’ sign.<sup>252</sup> For unknown reasons, the last-named finding tends to occur only on the side of dominant handedness.

Joint involvement is rare. Clutton’s joints were found in only 1 of 271 patients described by Fiumara and Lessell.<sup>252</sup> In this condition, synovitis occurs with hydrarthrosis, local tenderness, and limitation of motion<sup>258</sup>; the knee is the most commonly affected joint. Roentgenograms do not show involvement of the bones, and examination of the joint fluid reveals a few mononuclear cells.

## DIAGNOSIS

The ideal for the diagnosis of congenital syphilis would be to easily and accurately delineate the following groups: (1) infected mothers giving birth to infected infants with clinical manifestations of infection, (2) infected mothers giving birth to infected infants with no clinical signs of infection, (3) infected mothers giving birth to uninfected infants who appear healthy, (4) infected but seronegative mothers giving birth to infected infants who appear healthy, and (5) uninfected mothers. The problem of distinguishing among the latter four groups is a recurring problem in discussing identification of the infected infant and underscores the

need for an “evaluate and treat when uncertain” approach to congenital syphilis.

A definitive diagnosis of congenital syphilis can be made in the unusual situation in which the organism can be identified by darkfield microscopy, histologic examination, or rabbit infectivity test (RIT) of specimens from suspicious lesions or amniotic fluid.<sup>89,92,156,163,225,259</sup> Seroconversion or a fourfold rise in titer on a syphilis serologic test, either the RPR or the VDRL test, with a positive result on a treponemal test (fluorescent treponemal antibody absorption [FTA-ABS] test or hemagglutination tests) also is sufficient for a definitive diagnosis to be made (Table 18-7).<sup>88</sup>

In most infants, the presence of one or more clinical features of congenital syphilis plus positive results on syphilis serologic testing usually is sufficient for a diagnosis of probable congenital syphilis (see Table 18-7).<sup>260</sup> The early manifestations of congenital syphilis (e.g., hepatosplenomegaly with or without jaundice or generalized lymphadenopathy), hematologic manifestations (e.g., hemolytic anemia or thrombocytopenia), nonimmune hydrops fetalis, mucocutaneous manifestations (vesiculobullous rash, snuffles, condylomata lata), bone involvement (osteochondritis), renal manifestations, or CNS or CSF abnormalities prompts serologic testing that will establish or refute probable infection. The diagnosis of possible congenital syphilis is made when a serologic test result is positive but clinical manifestations of infection are absent. The diagnosis of congenital syphilis can be excluded if both the RPR and FTA-ABS tests become nonreactive before the age of 6 months in an infant who has not received treatment, or if these serologic tests are nonreactive in the mother and the infant, barring the situation in which the mother is

**Table 18-7 Suggested Diagnostic Categories of Congenital Syphilis Relative to Confidence of Diagnosis**

### Definite Diagnosis

1. Confirmation of presence of *T. pallidum* by darkfield microscopic or histologic examination or rabbit infectivity test (RIT)
2. STS (RPR, VDRL) titer increased fourfold or greater than maternal STS titer (both specimens drawn at time of evaluation)

### Probable Diagnosis

1. STS (RPR or VDRL) reactive in presence of snuffles, condylomata lata, pemphigus syphiliticus, hepatosplenomegaly, or osseous lesions
2. STS (RPR or VDRL) reactive in presence of other clinical manifestations given in Table 18-5
3. STS (VDRL) reactive in cerebrospinal fluid
4. Reactive treponemal antibody test after the age of 15 months

### Possible Diagnosis

STS (RPR or VDRL, FTA-ABS) reactive in absence of clinical disease

### Unlikely Diagnosis

STS nonreactive before the age of 6 months

FTA-ABS, fluorescent treponemal antibody absorption (test); RPR, rapid plasma reagin (test); STS, serologic test for syphilis; VDRL, Venereal Disease Research Laboratory (test).

seronegative because she is in the incubation period of early syphilis.<sup>157,227</sup>

Because of the infrequent occurrence of congenital syphilis in most newborn infants and its protean clinical manifestations, the physician must be alert to the possibility of this diagnosis. Adding to the challenge is that the diagnosis of syphilis in the mother also can be difficult. Routine use of a serologic test for syphilis is recommended in the first trimester of pregnancy,<sup>144,145</sup> again at the beginning of the third trimester, and at delivery in women with demographic or behavioral factors placing them at risk for acquiring syphilis (see Table 18-3).<sup>108,135,156</sup> The diagnosis of syphilis in the first few weeks of life depends on epidemiologic evidence, careful physical examination, documentation of radiologic abnormalities consistent with the diagnosis, and confirmation of infection by appropriate serologic testing or, if possible, demonstration of spirochetes in suspicious lesions or amniotic fluid (such demonstration is rare, however).<sup>89,156,163,225,259,261,262</sup>

### Radiographic Diagnosis

Bone involvement, the most common pathologic manifestation of congenital syphilitic infection,<sup>234,263</sup> involves multiple bones and is symmetrical. The metaphyses and diaphyses most often are involved, especially the long bones. The radiographic abnormalities include osteochondritis (metaphyseal dystrophy), osteomyelitis (osteitis-like dystrophy), and periostitis (periosteal dystrophy).

Characteristically, bone involvement is widespread; besides the long bones, the cranium, spine, and ribs also are affected. The earliest and most characteristic changes are found in the metaphysis, with sparing of the epiphysis.<sup>198</sup> The changes are nonspecific and variable, ranging from radiopaque bands to actual fragmentation and apparent destruction with mottled areas of radiolucency. Frequently, an enhanced zone of provisional calcification (radiopaque band) is associated with osteoporosis immediately beneath the dense zone. Variations of these paretic changes are seen, including peripheral (lateral) paretic only and alternating bands of density sandwiching a paretic zone (Fig. 18-3).<sup>196</sup> The classic saw-toothed appearance of the bone now is uncommon, although it can be seen on xeroradiographs of stillborn infants with congenital syphilis.<sup>179</sup> Metaphysitis or metaphyseal dystrophy (the choice of term depends on the concept of pathogenesis) of the long bones manifests at birth or can first appear after the first month of life.

In many of the long bones, the lesions are located on the lateral aspects of the metaphyses.<sup>198</sup> The tibia often exhibits metaphyseal defects on its upper medial aspect; bilateral presence of such defects is called Wimberger's sign (Fig. 18-4). Rarely, similar changes may occur at the upper ends of the humeri. Although Wimberger's sign formerly was thought to be pathognomonic of congenital syphilis,<sup>264</sup> it has been described<sup>265</sup> in other disease states, including osteomyelitis, hyperparathyroidism, and infantile generalized fibromatosis.

Focal areas of patchy cortical radiolucency with spreading of the medullary canal and irregularity of the endosteal and periosteal aspects of the cortex can be seen on radiographs. In severe cases, the radiolucent areas can appear as columns, giving a "celery stick" appearance of alternating bands of longitudinal translucency and relative density, a finding also

**Figure 18-3** The patient was a 1-month-old male infant who presented with a respiratory illness and a positive result on VDRL testing. The radiograph of the forearm and distal humerus shows evidence of irregular metaphyseal demineralization associated with periosteal new bone formation. The changes are most marked in the distal radius and ulna, but the radial aspect of the distal humerus also is involved. The dense bands in the distal metaphysis of the radius and ulna as well as the distal humerus are nonspecific findings. Although these metaphyseal bands of density are seen in a significant number of infants with congenital syphilis, they are not diagnostic. The presence of symmetrical metaphyseal lesions is more typical and helps to differentiate the long bone lesions of congenital syphilis from other causes of osteomyelitis or osseous dysplasia associated with disseminated infection.

seen in rubella and cytomegalovirus infection that probably represents a growth arrest abnormality.<sup>196</sup>

The inflammatory reaction in the diaphysis stimulates the periosteum to lay down new bone. The single or multiple layers of periosteal new bone extend along the cortex of the entire diaphysis. Unlike the other two forms of osseous involvement (metaphyseal dystrophy and osteitis-like dystrophy), diaphyseal abnormalities are less often present at birth. Osteochondritis is evident radiographically 5 weeks after fetal infection has occurred; periostitis requires 16 weeks for radiographic diagnosis.<sup>266</sup> Obstetric radiography<sup>267</sup> allows for the in utero diagnosis of fetal syphilis by demonstrating periosteal cloaking. Although maternal treatment has been associated with radiologic resolution of these lesions, the radiographic signs of congenital syphilis also resolve without therapy. Periostitis usually occurs during the early months of life and must be distinguished from that seen in healing rickets, battered child syndrome, infantile cortical hyperostosis, a variety of poorly understood disorders presumed

**Figure 18-4** An anteroposterior film of both lower extremities of the same patient as in Figure 18-3 demonstrates demineralization and osseous destruction of the proximal medial tibial metaphysis bilaterally. These lesions are features of Wimberger's sign. Note the diffuse symmetrical periostitis and irregular demineralization of the metaphyses of the distal tibiae and femurs.

to be related to nutritional deficiencies, occasionally pyogenic osteomyelitis,<sup>198</sup> and prostaglandin-induced periostitis.<sup>268</sup>

Involvement of the metacarpals, metatarsals, or proximal phalanges of the hand is rare. Dactylitis appears radiologically as a spindle-shaped enlargement of the bone and can occur from the ages of 3 to 24 months.<sup>198</sup> Unusual osseous manifestations also have been reported. A case of syphilitic arthritis of the hip and elbow in association with osteomyelitis of the femur and humerus has been described in the immediate newborn period.<sup>269,270</sup> Single bone involvement is unique, but solitary involvement of the radius has been described.<sup>271</sup> Solomon and Rosen<sup>272,273</sup> reported that in more than one third of 112 infants with congenital syphilis, radiographic findings were consistent with trauma of bone made more fragile by syphilitic infection. Bone scans have been performed in very few patients; they reveal diffuse abnormalities when performed,<sup>274-276</sup> but such scans are neither helpful nor recommended.

### Demonstration of the Organism

The "gold standard" for the identification of *T. pallidum* in clinical specimens is inoculation into rabbits—the RIT.<sup>88,89,101,277,278</sup> RIT has excellent sensitivity, permitting detection of as few as 5 to 10 organisms. Within 30 to

60 minutes of collection, the clinical sample (serum, blood, CSF, or amniotic fluid) is injected into the testicle of a seronegative adult male rabbit. While housed at 10° C to 20° C, each animal is regularly examined over 3 months for evidence of infection by *T. pallidum* (orchitis) and also by serologic testing (RPR and treponemal tests). If after 3 months evidence of orchitis is lacking and the serologic test is nonreactive, the rabbit is considered to be noninfected and the specimen negative for viable *T. pallidum*. When treponemal infection in the rabbit is suspected because of seroconversion or development of orchitis, the rabbit is sacrificed, popliteal lymph nodes and testicular tissue are removed and minced in sterile saline, and the tissue extract is examined by darkfield microscopy. Positive findings on darkfield examination (i.e., visualization of spirochetes) of testicular extract are confirmatory. If the darkfield examination findings again are negative, 2 mL of the testicular homogenate is then injected into a second seronegative rabbit, and the previous procedure is repeated.

The RIT is performed only in research laboratories; in clinical situations, the definitive diagnosis of syphilis is made by detecting characteristic treponemes by darkfield microscopy.<sup>279</sup> Bullae can be aspirated with a sterile syringe and needle. Papules or condylomata can be abraded with a gauze square until oozing occurs. A sterile glass slide is applied to the exudate, which then is covered by a drop of normal saline and a coverslip and promptly examined. Negative findings on examination do not exclude the diagnosis of syphilis, and examinations should be repeated if the clinical findings are suggestive. The scaly eruption of syphilis is not a good source of material for darkfield microscopy.

Another definitive diagnostic test for the diagnosis of syphilis is darkfield microscopy of body fluid specimens. This procedure requires a darkfield microscope and specially trained personnel but usually is available in clinics for patients who have sexually transmitted infections. Although not evaluated for use in specimens from newborns, a modification called the "dark ground" microscopy method has been used in adults with primary and secondary syphilis, with sensitivities of 97% and 84%, respectively, and with good specificity.<sup>280</sup> This is a rapid and sensitive test but also requires a darkfield microscope and trained personnel.

### Hematology

Blood should be obtained for determination of hematocrit and hemoglobin, red blood cell count, reticulocyte count, platelet count, and white blood cell count, as well as for a differential smear, direct Coombs' test, and serologic testing (RPR or VDRL). Performance of a serum treponemal test such as the FTA-ABS test is not necessary in the newborn period if the mother is known to have a reactive result (see later).

### Serology

#### General Considerations

Serologic tests<sup>155</sup> have played a prominent role in the clinical diagnosis of syphilis since the early 1900s, when antibody to the mammalian membrane lipid cardiolipin (diphosphatidylglycerol) was serendipitously detected by Wassermann

**Table 18–8 Serologic Tests for Syphilis**

Tests to Detect Antibodies to Cardioliipin	
1.	VDRL (Venereal Disease Research Laboratory): usually done by reference laboratories
2.	RPR (rapid plasma reagin): now used in offices and small laboratories
Tests to Detect Antibody to <i>T. pallidum</i>	
1.	TPI ( <i>T. pallidum</i> –immobilizing): no longer available for diagnostic purposes
2.	FTA-ABS (fluorescent treponemal antibody, absorbed with non-pallidum treponemes [ <i>T. phagedenis</i> ])
3.	TP-PA ( <i>T. pallidum</i> particle agglutination): hemagglutination test that detects antibody to <i>T. pallidum</i> components; hemagglutination assays have largely replaced FTA-ABS testing
4.	ELISA (enzyme-linked immunosorbent assay): IgG and IgM antibody tests
5.	FTA-ABS-IgM (fluorescent <i>T. pallidum</i> antibody-absorbed IgM): not recommended (see text)
6.	Immunoblotting (IgG, IgM, IgA): not yet adapted for clinical use in diagnosing syphilis

IgA, IgG, IgM, immunoglobulins A, G, M.

in the serum of patients with active syphilis (Table 18-8). The test used to detect this antibody went through a number of modifications (by Kolmer, Kahn, and Mazzini), culminating in that of the Venereal Disease Research Laboratory (i.e., VDRL) of the Communicable Disease Center (as the CDC then was designated). Antibody to cardioliipin also was called reagin, a term that should be replaced because of potential confusion with IgE. The serologic test that has remained in use, however, is one that rapidly and easily detects antibody to cardioliipin, the RPR test, which has replaced the VDRL test in many laboratories. RPR results are reported as dilutions or *titers* so that the degree of reactivity can be determined; a high titer in the absence of treatment and especially a rising titer (a fourfold increase or greater) indicate the presence of active infection. The RPR titer often is one to two dilutions higher than results obtained from the VDRL test; therefore, caution must be exercised when making clinical decisions on the basis of results of these two different tests for the same patient. For similar reasons, so that appropriate comparisons can be made, the same nontreponemal test should be performed in the mother and her infant.<sup>156</sup> Because the RPR test generally is more sensitive than the VDRL test, it is the preferred test for screening pregnant women. The VDRL test is recommended for use with CSF.

Infection with *T. pallidum* causes the host to produce antitreponemal antibodies, which are detected by FTA testing. The more recently developed *T. pallidum* hemagglutination test—the *T. pallidum* particle agglutination (TP-PA) test—is easy to perform and can be done with small volumes of serum in an automated system. The micro-hemagglutination assay for *T. pallidum* antibody (MHA-TP) has similar performance characteristics but no longer is available commercially. The TP-PA provides results that are comparable with those of the FTA, although the FTA is slightly more sensitive and specific.<sup>279</sup> When syphilis is suspected in a patient who has a reactive RPR test but a

**Table 18–9 Seroreactivity of More Common Tests for Untreated Syphilis**

Test <sup>a</sup>	% Positive			
	Primary Stage	Secondary Stage	Latent Stage	Tertiary Stage
VDRL or RPR	75	100	75	75
FTA-ABS, TP-PA	90	100	100	100

<sup>a</sup>See Table 18-8 for full test names.

negative TP-PA test result, an FTA test should be performed to exclude early syphilis as a diagnosis.

**Nontreponemal Antibody Tests: Rapid Plasma Reagin and Venereal Disease Research Laboratory Tests.** The VDRL and RPR tests often are called “nontreponemal antibody tests.” Actually, the antigenic stimulus is uncertain. Diphosphatidylglycerol constitutes a small proportion of the lipids of *T. pallidum*,<sup>281</sup> but these organisms may be unable to synthesize this substance, and it is possible that they incorporate it from damaged host tissues. Thus, production of RPR antibody could reflect an autoimmune host response to a slightly altered or a differently presented cardioliipin. In this context, it is interesting that anticardioliipin antibody reflects ongoing tissue damage, its detection correlating closely with the amount of activity in the early stages of syphilis infection. These observations may explain why patients with autoimmune diseases, such as systemic lupus erythematosus, characteristically have positive RPR test results. The RPR test result also can be positive, generally not exceeding a titer of 1:8, in nonsyphilitic patients who have infections caused by viruses (especially Epstein-Barr and hepatitis viruses), *Mycoplasma*, or protozoa.<sup>67,150,282</sup> A reactive RPR test also is found in the absence of syphilis in heroin addicts, in elderly persons, and in patients with cirrhosis, malignancy (especially if associated with production of excess IgM), and autoimmune disease or, rarely, in pregnancy itself.<sup>67,150,283-287</sup> VDRL reactivity in these conditions has acquired the unfortunate designation “biologic false positive,” to indicate an etiologic process other than *T. pallidum* infection.

The VDRL test is reactive in about 75% of adults at the time they seek medical attention for primary syphilis (Table 18-9). Secondary syphilis always is associated with a reactive VDRL, usually at a dilution greater than 1:16.<sup>58,279</sup> Persistence of a positive VDRL result after appropriate antibiotic therapy, sometimes called the serofast state, apparently is uncommon. The VDRL result usually becomes negative within 2 years of treatment.<sup>155,288,289</sup> Even without treatment, the VDRL titer slowly declines and is, in fact, negative in one third of patients with late syphilis.<sup>58</sup>

From 1% to 2% of sera from patients with secondary syphilis will exhibit a prozone phenomenon.<sup>150-153</sup> This phenomenon is due to presence of an excess amount of reagin antibody in the patient’s undiluted serum. The excess in antibody prevents flocculation, resulting in a falsely negative test result. The prozone effect can be overcome by diluting the serum before testing, after which the serum

usually will exhibit titers of 1:16 or greater. Failure to recognize a prozone effect in maternal serum tested during pregnancy has resulted in failure to diagnose congenital syphilis.<sup>153</sup>

**Treponemal Antibody Tests.** Other serologic tests detect an interaction between serum immunoglobulins and surface antigens of *T. pallidum*; these tests are distinguished from those for cardiolipin antibody and from all so-called treponemal antibody tests. The *T. pallidum*–immobilizing test was, for many years, foremost among these, being used as the “gold standard” to determine whether the patient had been infected with *T. pallidum*. This test was difficult to perform, required a source of viable organisms (usually obtained from an infected rabbit), a darkfield microscope, and a substantial investment of time; it no longer is available.

Antibody to treponemal antigens from lyophilized *T. pallidum* also can be detected by the FTA test. Because all of the antigens of *T. pallidum* are not unique and antibody reactivity with some of them may exist in normal serum, an absorption step was needed that used a nonpathogenic treponeme (*Treponema reiteri*, now called *Treponema phagedenis*). This gave rise to the more specific FTA-ABS test. Except for the rare instance in which antibody to DNA causes a positive FTA-ABS reaction in serum from a patient with lupus erythematosus or rheumatoid arthritis, this test is regarded as specific, and it essentially has replaced the *T. pallidum*–immobilizing test as the standard for determining whether prior infection with *T. pallidum* had ever occurred.<sup>287</sup> The FTA-ABS test, however, requires a fluorescence microscope and a highly trained technician.

The development of hemagglutination tests—for example, the TP-PA and MHA-TP—has provided specific assays that can be performed easily in most laboratories and require less specialized equipment. These tests use a lysate of pathogenic *T. pallidum* and yield results that are very similar to those obtained by the FTA-ABS. They largely have replaced the FTA-ABS as the most efficient and specific test to detect antibody to *T. pallidum*.<sup>60,154,286,290-293</sup> The MHA-TP, however, no longer is commercially available. The TP-PA test uses the same treponemal antigen as was required in the MHA-TP but utilizes gelatin particles rather than sheep red blood cells, which eliminates nonspecific reactions with serum or plasma samples. The TP-PA test was developed in Japan; its performance has been comparable with that of FTA-ABS tests.<sup>294</sup> Physicians out of habit continue to request an FTA-ABS test, although at present most laboratories perform a hemagglutination test; these terms—FTA-ABS assay and hemagglutination reaction—are used interchangeably throughout this chapter.

Immunoblotting has been studied by several investigators for detection of IgG and IgM antibodies to specific *T. pallidum* proteins in sera of adults with syphilis.<sup>35,37,45</sup> The sensitivity and specificity of immunoblotting are excellent; however, it has not been feasible to transfer this diagnostic method into the clinical laboratory.<sup>295</sup> Enzyme-linked immunosorbent assays (ELISAs)<sup>295-300</sup> are under study; some of them use *T. pallidum* outer membrane proteins that have been generated by recombinant techniques. For example, Van Voorhis and colleagues<sup>300</sup> studied six recombinant *T. pallidum* antigens in ELISA for their sensitivities and

specificities in sera from patients with syphilis, Lyme disease, or leptospirosis as well as from uninfected patients. Two antigens (Tp0453 and Tp92) had sensitivities and specificities of 98% to 100% and 97% to 100%, respectively.

Another method recently evaluated is the immunochromatographic strip test.<sup>301</sup> This test detects antibodies specific for *T. pallidum* without reacting with the reagent in sera from patients with biologically false-positive tests. These newer tests ultimately should be helpful: Their sensitivity is sufficient to detect early syphilis cases, in which the currently used tests can be nonreactive, and they are now available commercially.

In approximately 90% of patients with a primary syphilitic chancre, the hemagglutination test result is positive by the time they seek medical attention.<sup>60,279,285,286,288</sup> All patients with secondary syphilis or late infection demonstrate a positive reaction. These tests are highly specific, as well as being extremely sensitive. A few disease states, such as systemic lupus erythematosus, polyarteritis or related conditions, and, in one report, even pregnancy, are said to cause a false-positive FTA-ABS result, but these diagnoses should be apparent, and the sophisticated observer often can detect a distinctive beaded pattern of fluorescence in these reactions.<sup>67</sup> Historically it was believed that, once positive results have been obtained on these tests, such results will remain so for life, even if the infection has been cured. Romanowski and co-workers,<sup>302</sup> however, found that 24% of first-episode primary syphilis patients exhibited a nonreactive result on FTA-ABS testing and 13% had a nonreactive result on MHA-TP testing at 36 months after treatment. Nevertheless, positive reactions are not helpful in determining whether active infection is present. Despite the exquisite sensitivity and specificity of these tests, therefore, a positive result may not be helpful diagnostically in an individual patient; a negative result excludes a diagnosis of all but early primary infection.

### Serologic Diagnosis in the Infant

**Rapid Plasma Reagin and Fluorescent Treponemal Antibody Absorption Tests.** Maternal RPR and FTA-ABS test reactivity can be found in both IgG and IgM antibody isotypes.<sup>37,303,304</sup> If the placenta is intact, IgG is passively transferred to the newborn. Thus, a reactive serologic test in the neonate can be due to maternally derived IgG and does not necessarily indicate that the infant is infected. Furthermore, maternal antibody could have arisen from untreated, inadequately treated, or adequately treated disease. If the antibody titer is higher in the infant than in the mother by the same nontreponemal test (a fourfold or greater difference is required to exclude laboratory variation), this finding would signify congenital infection.<sup>88</sup> If the infant's reactive RPR test is caused by passively transferred antibody, the reactivity progressively declines as time passes and should disappear by 6 months of age. A persistently reactive RPR test in the infant beyond 12 to 15 months of age suggests an active infection, and a rising titer makes this diagnosis certain.

The CDC has recommended that serum from blood specimens drawn from the infant, rather than from umbilical cord blood obtained at birth, be used for serologic testing because the rates of false-positive and false-negative results are lower.<sup>156</sup> Owing to its ease of collection, however,

umbilical cord blood continues to be a readily available specimen. Appropriate care in collection of umbilical cord blood should be taken to avoid contamination with maternal blood. Serologic testing of umbilical cord blood can be performed with either the RPR assay or the VDRL test. The RPR assay is more sensitive,<sup>305</sup> although false-positive reactions due to contamination of the sample with Wharton's jelly can occur. Both tests, however, may be nonreactive when the maternal serologic titer is low. It is best to screen the mother, rather than the newborn<sup>306</sup>; routine screening of umbilical cord blood is discouraged.<sup>307</sup>

If the mother has a false-positive RPR test result, the relevant antibody can be passively transferred to the infant. Naturally, in such a case, neither the mother nor the infant will have a reactive treponemal test. If the mother has a reactive treponemal test because of untreated or previously treated syphilis, the antibody also appears in the newborn by passive transfer. Thus, detection of such reactivity in the newborn indicates that the mother had at some point encountered *T. pallidum*, but it does not indicate whether her infection was treated, and it certainly does not diagnose active infection of the infant. Because the FTA-ABS test is performed without dilutions in the United States, sequential use of this test is not useful in infants suspected of having syphilis. Eventually, of course, any passively transferred maternal IgG antibody causing reactivity in a normal infant is catabolized until it is no longer detectable. Persistence of antibody beyond 12 to 18 months of age can be considered a reliable, but often retrospective, diagnostic finding, which is seen in 50% to 70% of infants with congenital syphilis.<sup>308,309</sup>

**Fluorescent Treponemal Antibody Immunoglobulin M Test.** Detection of IgM by FTA-ABS theoretically should be helpful in diagnosing congenital infection because IgM is not transferred across the placenta. In clinical studies, however, false-negative results have been obtained in 20% to 39% of cases, and false-positive results, perhaps related to rheumatoid factor,<sup>310</sup> in up to 10%. Prospective clinical investigations using rigorous case definitions and standardized methods have not been performed, and the place of the FTA IgM test in the clinical practice of pediatrics remains in question.<sup>311</sup> Stoll and associates<sup>312</sup> modified the original FTA-ABS IgM test by using the IgM fraction of neonatal serum. This FTA-ABS 19S IgM test had a sensitivity of 73% and a specificity of 100% among at-risk infants.

**Enzyme-Linked Immunosorbent Assay.** IgM ELISAs have been developed to detect both nontreponemal<sup>87,313</sup> and treponemal antibodies.<sup>174,312,313</sup> As currently marketed, these assays are of limited usefulness in diagnosis of congenital syphilis, owing to less than optimal sensitivity and specificity. Stoll and associates<sup>312</sup> used an IgM capture ELISA for *T. pallidum* and found a sensitivity of only 88% among infants with clinical and laboratory manifestations of congenital syphilis. Further refinement and evaluation of these assays will be important because the ELISA has the potential for rapid diagnosis of congenitally infected infants. Moreover, many clinical laboratories already are experienced with this technique.

**Immunoglobulin M and Immunoglobulin A Immunoblotting.** Immunoblotting has been used to detect and characterize the specific neonatal IgM and IgA<sup>314</sup> antibody

responses to *T. pallidum*. Specific IgM antibody directed against *T. pallidum* membrane lipoprotein antigens with apparent molecular masses of 72, 47, 45, 42, 37, 17, and 15 kDa has been detected among sera of infants with clinical manifestations of congenital syphilis; reactivity against the 47-kDa antigen was uniformly present in all of the neonatal serum IgM immunoblots with a positive result.<sup>85-88,315,316</sup> Fractionation of sera into IgG and IgM components by high-performance liquid chromatography confirmed that serum reactivity to these treponemal antigens was not due to rheumatoid factors.<sup>86</sup> Similar IgA reactivity to a variety of *T. pallidum* antigens has been detected by immunoblotting in infants with possible congenital syphilis.<sup>314</sup>

IgM reactivity to the 47-kDa antigen also has been found in sera of 20% to 42% of subclinically infected infants born to mothers with untreated syphilis.<sup>88,316</sup> It has been detected in fetal blood obtained by cordocentesis at 24 weeks of gestation; the positive serum IgM immunoblot result was validated by the simultaneous detection of viable spirochetes in the blood of this hydropic fetus by RIT.<sup>89</sup> Moreover, 14 weeks later at delivery, after appropriate maternal therapy, the neonatal serum lacked IgM reactivity, suggesting that the fetal infection also had been successfully treated in utero. Dobson and colleagues<sup>85</sup> reported disappearance of neonatal IgM reactivity to *T. pallidum* 1 to 3 months after appropriate treatment.

The ability to detect IgM reactivity in neonatal sera has been enhanced when the antigen source for immunoblotting comprised the subset of membrane proteins selectively extracted by Triton X-114 phase partitioning (detergent-phase proteins), rather than whole-cell lysates of *T. pallidum*.<sup>88</sup> This improvement was particularly evident in evaluation of IgM reactivities to the 15- and 17-kDa immunogens, which are known to be present in *T. pallidum* in relatively low abundance. Recently, Sanchez and co-workers showed that immunoblot analysis with a recombinant form of the highly immunogenic 47-kDa lipoprotein of *T. pallidum* appeared to be even more sensitive than immunoblotting with native *T. pallidum* antigens.<sup>317</sup> In some infants with congenital syphilis, IgM reactivity was apparent only when the recombinant 47-kDa lipoprotein was used as the antigen source.

Similarly, IgM reactivity to the 47-kDa antigen also has been found in CSF of infants with congenital syphilis.<sup>88,316,318</sup> Lewis and associates<sup>316</sup> found 82% reactive CSF IgM immunoblots in infants with clinical and laboratory evidence of congenital syphilis, but 4% reactivity among infants at risk of having congenital infection with *T. pallidum* but with normal findings on clinical and laboratory evaluations. Sanchez and co-workers<sup>88</sup> detected IgM reactivity to the 47-kDa antigen in CSF of two of seven infants in whom findings on physical and laboratory examinations were consistent with a diagnosis of congenital syphilis; the significance of the reactive IgM immunoblot was confirmed by the finding of viable treponemes in the CSF by RIT.

**Polymerase Chain Reaction Techniques.** PCR tests for detection of specific *T. pallidum* DNA in tissues and body fluids have been developed.<sup>319-324</sup> PCR assay is said to be capable of detecting an amount of purified treponemal DNA equivalent to that of only a few organisms (about 0.01 pg).<sup>319</sup> Sanchez and co-workers<sup>88</sup> have reported on the use of PCR

assay for congenital syphilis diagnosis; they compared results of PCR assay on neonatal serum and CSF with those obtained by RIT, the current reference standard.<sup>88,324,325</sup> Results for 5 CSF samples from 19 infants born to mothers with untreated early syphilis were positive by both PCR assay and RIT, were negative for 12 by both tests, and were positive for 2 by RIT but negative by PCR assay; none were positive by PCR assay and negative by RIT. Thus, the sensitivity of PCR assay relative to RIT was 71% for CSF, and the specificity was 100%. When the results of PCR assay and RIT on 29 serum and CSF samples were combined, 9 were positive by both tests, 17 were negative by both tests, and 3 were positive by RIT but negative by PCR assay; none that was negative by RIT was positive by PCR assay. Similarly, for amniotic fluid obtained from 12 pregnant women with early syphilis, 7 of 7 samples were positive by both tests, and all 5 that were negative by RIT were negative by PCR assay. The excellent agreement between results of RIT and of PCR assay substantiates the future use of PCR assay as a surrogate for RIT.

### Cerebrospinal Fluid Examination

Using RIT of neonatal CSF, Sanchez and co-workers<sup>88</sup> studied the prevalence of CNS invasion by *T. pallidum* among 19 infants born to mothers with early syphilis. Seven of the infants had clinical and laboratory evidence of congenital syphilis, and 12 had no clinical or laboratory findings suggestive of congenital infection. These investigators found the prevalence of spirochetal invasion of the CSF to be 86% (6 of 7) among infants with clinically recognizable congenital syphilis, but only 8% (1 of 12) among infants who lacked clinical and laboratory evidence. The sensitivity and specificity of a reactive CSF VDRL test, presence of pleocytosis, and elevated CSF protein content were 71% and 92%, 43% and 92%, and 43% and 92%, respectively. All infants with a positive CSF RIT had a reactive serum IgM immunoblot (100% sensitivity) and a positive serum PCR assay result (100% sensitivity). No infant with a negative serum IgM immunoblot and a negative serum PCR assay result had a positive result on CSF RIT, leading the investigators to conclude that the diagnosis of congenital syphilis, particularly in the infant without clinical and laboratory evidence of infection, will ultimately require a comprehensive approach using assays for both specific neonatal IgM and *T. pallidum* DNA in serum and CSF. In a more recent study, Michelow and colleagues<sup>326</sup> evaluated 76 infants with untreated congenital syphilis using RIT. These investigators found spirochetes in the CSF of 17 of these 76 infants; all but one had clinical or laboratory findings suggestive of neurosyphilis. IgM immunoblotting of serum identified all infants who had *T. pallidum* infection of the CNS.

With use of currently available methodologies, leukocytosis (25 white blood cells per mm<sup>3</sup> or less) and elevated protein content (greater than 150 mg/dL in full-term and greater than 170 mg/dL in preterm infants) in the CSF in an infant who exhibits any features suggestive of congenital syphilis should be regarded as supportive of the diagnosis. Also, an infant with reactive CSF on VDRL testing should receive presumptive treatment for neurosyphilis, although such a result in the absence of other evidence of congenital

syphilis is suspect, inasmuch as nontreponemal IgG can pass from serum to the CSF in neonates.<sup>246</sup>

An unsettling element has been introduced by the use of various modifications of the serum FTA technique to study CSF from syphilitic patients. Conflicting results have been obtained in adults,<sup>327-329</sup> and systematic studies have yet to be done for congenital syphilis. Thus, at present, the FTA-ABS and hemagglutination tests should not be done using CSF in infants suspected of having congenital syphilis; the results cannot be interpreted properly, and other means must be used to establish or exclude the diagnosis.

### DIFFERENTIAL DIAGNOSIS

A diagnosis of syphilitic infection is highly likely in the presence of snuffles, a vesiculobullous eruption, hepatosplenomegaly, generalized lymphadenopathy, condylomata lata, symmetrical metaphyseal lesions, and a positive result on an RPR or VDRL test. Many of these findings, however, are features of multiple other disorders or closely resemble such features.

### Dermatologic Manifestations

The vesiculobullous manifestations of congenital syphilis may be confused with other infections or with congenital disorders of the skin that can present as vesiculobullous eruptions.<sup>330</sup> Infection caused by *Staphylococcus aureus* can produce vesicles or bullae on any part of the body. Severe infection may result in confluent bullae with erythema and desquamation (Ritter's disease). Examination of aspirated fluid reveals many polymorphonuclear leukocytes and, on occasion, gram-positive cocci in clusters, and culture will yield the organism.

*Pseudomonas aeruginosa* septicemia can be accompanied by a cutaneous eruption consisting of clustered pearly vesicles on an erythematous background, which rapidly becomes purulent green or hemorrhagic.<sup>331</sup> When the lesion ruptures, a circumscribed ulcer with a necrotic base appears and may persist, surrounded by a purplish cellulitis. Culture of the lesion and the blood confirms the diagnosis.

In the septicemic early-onset form of listeriosis, a cutaneous eruption consisting of miliary lesions resembling papules, pustules, or papulopustules can occur over the entire body, with a predilection for the back.<sup>332</sup> Culture of these lesions and blood usually reveals *Listeria monocytogenes* as the etiologic agent. Additional infectious causes of vesicular or bullous lesions of the skin of the newborn include group B streptococci,<sup>333</sup> *Haemophilus influenzae* type b,<sup>334</sup> *Mycobacterium tuberculosis*,<sup>335</sup> and cytomegalovirus.<sup>336</sup>

In virus-induced eruptions, the vesicles are located in the mid-epidermis. In herpesvirus infection, vesicles are the most common dermatologic manifestation. They tend to be sparsely disseminated throughout the body, or they may occur in crops or clusters. Involvement of the palms and soles has been recorded, as has the formation of bullae. Recurrence of these skin lesions is not unusual. Scrapings from the base of these lesions, when fixed in alcohol and stained with Papanicolaou stain, may show intranuclear inclusions or multinucleated giant cells compatible with the diagnosis of herpes simplex or varicella-zoster infection, and

cultures may yield the offending virus. The latter infection rarely occurs in the newborn period, and the diagnosis may be discarded on epidemiologic or clinical grounds. Variola and vaccinia can affect the fetus or newborn and cause vesicular eruptions. Appropriate epidemiologic evidence should be sought to exclude these diagnoses.

Mucocutaneous candidiasis may manifest as a vesicular dermatitis at the end of the first week of life. The vesicles usually become confluent and rupture, leaving a denuded area surrounded by satellite vesicles or pustules. Congenital candidiasis with skin manifestations also has been described, and severe systemic involvement may accompany this intra-uterine infection.<sup>337</sup>

A variety of hereditary disorders of the skin appear at birth or in early infancy as vesiculobullous eruptions.<sup>330</sup> Epidermolysis bullosa is a group of specific genetic disorders. Erythema toxicum, miliaria rubra, incontinentia pigmenti, urticaria pigmentosa, epidermolytic hyperkeratosis, acrodermatitis enteropathica, Langerhans' cell histiocytosis (histiocytosis X), transient neonatal pustular melanosis, infantile acropustulosis, and aplasia cutis congenita should be included in the differential diagnosis.<sup>338</sup>

### Hepatosplenomegaly

When the clinical presentation is that of hepatosplenomegaly with or without jaundice, the list of possibilities in the differential diagnosis is extensive and includes all causes of elevated direct and indirect bilirubin. The physician should consider isoimmunization (e.g., Rh incompatibility, ABO incompatibility), other infectious diseases (early-onset sepsis, cytomegalovirus infection, congenital rubella, herpes simplex infection, coxsackievirus B or other enteroviral infections, toxoplasmosis), neonatal hepatitis, diseases of the biliary tract (e.g., extrahepatic biliary atresia or choledochal cyst), and genetic and metabolic disorders (e.g., cystic fibrosis, galactosemia, and  $\alpha_1$ -antitrypsin deficiency).<sup>339</sup>

### Hydrops Fetalis

Hydrops fetalis can be caused by chronic anemia (isoimmunization disorder, homozygous  $\alpha$ -thalassemia, fetomaternal or fetofetal transfusions), cardiac or pulmonary failure due to causes other than anemia (large arteriovenous malformations, premature closure of the foramen ovale, cystic adenomatoid malformation, pulmonary lymphangiectasia), perinatal tumors (neuroblastoma, chorioangioma), achondroplasia, renal disorders (congenital nephrosis, renal vein thrombosis), and infections, such as congenital cytomegalovirus infection, toxoplasmosis, parvovirus B19 infection,<sup>340</sup> and congenital hepatitis.<sup>339</sup>

Most cases of hydrops are caused by isoimmunization disorders, which can be excluded as a cause by a negative direct Coombs' test result. A normal hemoglobin electrophoresis pattern excludes the diagnosis of  $\alpha$ -thalassemia. The Kleihauer-Betke technique of acid elution for identifying fetal cells in the maternal circulation can aid in ruling out the diagnosis of fetomaternal transfusion. Other diagnostic considerations can be discarded on the basis of appropriate radiographic studies, placental examination, urinalysis with microscopy, biopsy, and immunologic studies.

### Renal Disease

In the neonate and young infant, the nephrotic syndrome and acute nephritis occur infrequently. The former more often is associated with infantile microcystic disease, minimal-lesion nephrotic syndrome, or renal vein thrombosis than with congenital syphilis. Neonatal nephritis can occur as a manifestation of congenital syphilis, hereditary nephritis, hemolytic-uremic syndrome, and, rarely, pyelonephritis. The clinical signs that distinguish syphilitic renal involvement from the other conditions mentioned include the presence of other manifestations of early congenital syphilis, a positive result on serologic tests for syphilis, elevated levels of IgG (in infantile microcystic disease, the levels of IgG are low), and the response to specific therapy for syphilis.

### Ophthalmologic Involvement

Neonatal buphthalmos, an uncommon finding in syphilis, occurs as an isolated genetic disorder and may be associated with a variety of syndromes (e.g., aniridia, Hallermann-Streiff syndrome, Reiger's anomaly, Lowe's syndrome, Sturge-Weber syndrome, oculodentodigital syndrome, Pierre Robin syndrome); it also is associated with rubella.<sup>341</sup> Nasolacrimal duct obstruction is a more frequent cause of excessive lacrimation in the newborn period and early infancy.

## THE THERAPY

### The Pregnant Woman

A pregnant woman who has a suspicious lesion and a negative RPR test result may be in an early stage of infection. Detection of treponemes by darkfield microscopy should lead to therapy without regard to results of serologic tests; an RPR test should be repeated in 3 to 6 weeks (Table 18-10). A patient who has neither lesions nor positive results of serologic studies but who has been exposed sexually to a person who has syphilis should receive treatment for syphilis on the 25% to 50% likelihood that she has acquired syphilis and is in the early phase of the infection and able to infect the fetus.<sup>157,227</sup>

The finding of a positive RPR reaction should lead to a careful and complete evaluation of the pregnant patient for evidence of primary or secondary syphilis. If signs of active disease are not found and the treponemal test result also is reactive, then a diagnosis of latent syphilis is made, with the diagnosis being early latent disease if she was known to have a negative RPR result within the previous 1 to 2 years.

Failure of nontreponemal serologic titers to decrease appropriately is reason for CSF examination and retreatment unless reinfection can be established as the cause.<sup>116</sup> Moreover, persons with no decrease in titer should be reevaluated for HIV infection. In late latent syphilis or syphilis of unknown duration, a lumbar puncture is recommended in patients who are seropositive for antibody to HIV to exclude neurosyphilis.<sup>156</sup>

If the pregnant woman had positive results on RPR and treponemal tests before this pregnancy and it is certain that she received appropriate treatment, observation during the

**Table 18–10 Therapeutic Decisions Involving the Pregnant Woman in Relation to Rapid Plasma Reagin (RPR) Status<sup>a,b,c</sup>**

RPR Status	Decision
<b>Negative RPR Result</b>	
Signs of clinical disease	Treat <sup>d,e</sup>
No signs of clinical disease	<i>High risk</i> Repeat RPR at 28 wk and at term <i>Low risk</i> Repeat RPR at term
<b>Positive RPR Result</b>	
Signs of clinical disease <sup>e</sup>	Treat
No signs of clinical disease	
Known positive syphilis tests in past	Observe <sup>f</sup>
Adequate treatment	Treat
Untreated	
New positive TP-PA test	
<i>If positive<sup>e</sup></i>	Evaluate and treat
<i>If negative</i>	Perform FTA-ABS <i>If positive</i> : Evaluate and treat <sup>e</sup> <i>If negative</i> : Observe <sup>g</sup> and repeat TP-PA in 3 wk <i>If positive</i> : Evaluate and treat <sup>e</sup> <i>If negative</i> : Observe <sup>g</sup>

<sup>a</sup>Positive result on RPR is the most common reason for medical evaluation.

<sup>b</sup>See text.

<sup>c</sup>See Table 18-8 for full test names.

<sup>d</sup>Test for possible prozone effect.

<sup>e</sup>Test for HIV antibody.

<sup>f</sup>Treat if RPR titer is greater than 1:4 (VDRL titer greater than 1:2) in a woman with a history of pre-pregnancy therapy—possible reinfection.

<sup>g</sup>Assume a biologically false-positive result (see text).

HIV, human immunodeficiency virus.

pregnancy, with clinical evaluation and RPR testing repeated in the third trimester and at delivery, constitutes adequate management. Serologic titers may be checked monthly in women at high risk for reinfection or in geographic areas in which the prevalence of syphilis is high.<sup>156,342</sup> Although it is expected that the nontreponemal test will eventually become nonreactive after appropriate treatment, some patients may have persistence of nontreponemal antibodies at a low titer for an extended period of time. This response is referred to as the *serofast reaction*, and the patient is not infectious.

If the pregnant woman has a positive RPR result but a nonreactive treponemal test, the result is referred to as a “biologically false-positive” result. Caution must be exercised to rule out the presence of early syphilis, because the RPR test becomes reactive earlier than do the treponemal tests. In cases of early syphilis, a second treponemal test performed 3 to 6 weeks later will be reactive, and the patient should be given treatment as noted earlier.

### Penicillin

Parenteral penicillin G remains the drug of choice for the treatment of syphilis (Table 18-11).<sup>156,343-345</sup> A regimen of benzathine penicillin G (2.4 million units given as 1.2 million units in each buttock) appropriate for the stage of syphilis cures maternal infection and prevents or cures fetal infection.<sup>156,343</sup> For women with early syphilis, a second dose of benzathine penicillin (2.4 million units intramuscularly) can be administered 1 week after the initial dose, to minimize the occurrence of a fetal treatment failure.<sup>156</sup>

Failure rates for prevention of fetal infection ranging from 2%<sup>270</sup> to as high as 14% (see Table 18-2) have been reported. A majority of fetal treatment failures seem to occur after maternal treatment for secondary syphilis.<sup>346</sup> Treatment failure in such cases may be explained in part by the marked spirochetemia that occurs during secondary syphilitic infection. Other reasons for the presumptive treatment

**Table 18–11 Recommended Treatment of Syphilis in Pregnant Patient<sup>a</sup>**

Stage of Syphilis	Drug (Penicillin)	Route	Dose (units)
<b>Early</b> (duration less than 1 yr) Primary, secondary, or early latent HIV antibody–negative	<i>Recommended</i>		
	Benzathine	IM	2.4 million single dose; possibly repeat in 1 wk
	Benzathine	IM	2.4 million single dose; possibly repeat weekly × 3
<b>Latent</b> (duration longer than 1 yr) <sup>d</sup>	<i>Alternative</i>		
	Penicillin desensitization <sup>c</sup>		
	<i>Recommended</i> Benzathine	IM	2.4 million weekly × 3 wk
<b>Neurosyphilis</b>	<i>Alternative</i>		
	Penicillin desensitization		
	<i>Recommended</i> Aqueous	IV	3-4 million every 4 hr × 10-14 days
	<i>Alternative</i> Procaine <sup>e</sup>	IM	2.4 million daily × 10-14 days

<sup>a</sup>See text.

<sup>b</sup>With normal cerebrospinal fluid findings, if performed.

<sup>c</sup>For details, see MMWR Morb Mortal Wkly Rep 51(RR-6):1, 2002.

<sup>d</sup>Lumbar puncture to exclude neurosyphilis is recommended for HIV antibody–positive patients.

<sup>e</sup>Probenecid, 500 mg orally qid × 10-14 days, also should be prescribed.

HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous.

failures have been related to possibly altered penicillin pharmacokinetics in pregnancy<sup>347</sup> or to advanced fetal disease.<sup>348</sup> Problems exist in the interpretation of these data because, by currently available methodologies, the accurate identification of an infected newborn is problematic at best. The clinical and laboratory manifestations of congenital syphilis may require several weeks to months for resolution despite adequate penicillin therapy. Likewise, the fetus may be adequately treated in utero by maternal penicillin therapy yet have persistent abnormalities that are detected at birth because insufficient time has elapsed for complete disappearance of the physical and laboratory abnormalities. Such a case would be erroneously classified as a treatment failure. Moreover, the improper use of the CDC surveillance case definitions as diagnostic criteria for congenital syphilis has led to the misclassification of infants as infected when the diagnosis is not certain.

Invasion of the CNS by *T. pallidum* can occur during any stage of syphilis.<sup>101</sup> Currently recommended therapy for neurosyphilis is aqueous crystalline penicillin G, 18 to 24 million units daily, administered as 3 to 4 million units intravenously every 4 hours for 10 to 14 days. If compliance can be ensured, an alternative regimen consists of procaine penicillin G, 2.4 million units intramuscularly daily, plus probenecid, 500 mg orally four times a day, both given for 10 to 14 days.<sup>208,293</sup> Benzathine penicillin G, 2.4 million units intramuscularly weekly for up to 3 weeks, often is provided after completion of either of these two neurosyphilis treatment regimens.<sup>156</sup>

Syphilis can be more difficult to eradicate in the presence of concurrent HIV infection.<sup>101,344,349</sup> Nevertheless, current recommendations include a regimen similar to that for patients who lack HIV antibody (see Table 18-11), along with careful and frequent clinical and serologic follow-up.<sup>156</sup> For HIV-infected patients with primary or secondary syphilis, some authorities recommend up to three once-weekly doses of 2.4 million units of benzathine penicillin G or other supplemental antibiotics,<sup>156</sup> in addition to a single intramuscular dose of benzathine penicillin G. HIV-infected patients who have either late latent syphilis or syphilis of unknown duration require a CSF examination before treatment. If nontreponemal antibody titers have not declined fourfold by 6 months with primary or secondary syphilis, or by 6 to 12 months in early latent syphilis, or if the titer has increased fourfold at any time, a CSF examination should be performed and the patient re-treated with 7.2 million units of benzathine penicillin G (administered as three once-weekly doses of 2.4 million units each) if CSF examination findings are normal. Patients who have CSF abnormalities consistent with neurosyphilis should receive treatment for neurosyphilis as described earlier (see Table 18-11).

### Alternative Drugs

The pregnant syphilitic patient who has a history of penicillin allergy should be skin tested and, if necessary, desensitized according to the protocol of Wendel and co-workers.<sup>350</sup> Desensitization can be accomplished by providing the patient with gradually increasing doses of oral or intravenous penicillin during several hours until the objective of full tolerance is achieved. Such an approach must be attempted only under expert guidance and under circumstances in which emergency treatment is available.<sup>156</sup>

Multiple-dose regimens of ceftriaxone for treatment of primary and secondary syphilis, as well as for neurosyphilis, have been efficacious in limited studies.<sup>351-357</sup> A 10-day course of ceftriaxone is an alternative regimen for the nonpregnant, penicillin-allergic patient with early syphilis. Data are insufficient to recommend ceftriaxone treatment during pregnancy. In rabbits, a 7- to 10-day course of ceftriaxone failed to clear CNS infection with *T. pallidum* in a consistent fashion.<sup>358</sup> An occasional patient who is allergic to penicillin also is allergic to the cephalosporins, and cephalosporins should not be used if the penicillin allergy is potentially life-threatening.<sup>156,352-357</sup>

Erythromycin, which is effective in syphilis,<sup>343,359</sup> crosses the placenta in an unpredictable fashion, often poorly.<sup>345</sup> Erythromycin does not reliably cure the infected fetus, and it should not be used.<sup>360</sup>

Tetracycline given in a dosage of 28 g orally over a 14-day period (2 g per day in four doses) compares favorably in effectiveness with penicillin.<sup>156,361</sup> Because of its potential for damage to the liver of the pregnant woman,<sup>362,363</sup> and its adverse effects on the teeth and long bones of the fetus,<sup>364</sup> tetracycline should not be used in pregnancy.

Preliminary data on use of azithromycin for treatment of syphilis in nonpregnant adults have shown efficacy.<sup>365,366</sup> Azithromycin treatment failures have occurred, however.<sup>365,367</sup> A mutation in ribosomal RNA recently has been described that confers azithromycin resistance to *T. pallidum*.<sup>368</sup> Caution is advised with use of azithromycin for therapy of syphilis; no data regarding its use in pregnancy are available to ensure its effectiveness in the prevention of fetal syphilis.

During a shortage of intravenous aqueous penicillin G in the United States,<sup>369</sup> the CDC recommended that for treatment of neurosyphilis, procaine penicillin G plus probenecid (see Table 18-11) be administered when intravenous penicillin is not available.<sup>370</sup> For persons with neurosyphilis who do not tolerate intramuscular procaine penicillin G, intravenous ampicillin (12 to 16 g per day in four divided doses for 10 to 14 days) or, alternatively, intravenous ceftriaxone (2 g daily, given as a single dose, for 10 to 14 days) could be considered for use only if careful clinical and serologic follow-up evaluation was ensured. For persons with neurosyphilis who are allergic to penicillin, desensitization to penicillin followed by treatment with either aqueous penicillin or procaine penicillin is preferred. These regimens for neurosyphilis can be followed by a single dose of benzathine penicillin G (see Table 18-11).

### The Infant

Treatment for newborns with a reactive serologic test for syphilis is required in the following situations (Table 18-12)<sup>156,371,372</sup>:

- If the infant has clinical, laboratory, or radiographic abnormalities, or a combination of these, compatible with congenital syphilis
- If no maternal treatment before delivery was documented
- If maternal treatment was inadequate or unknown
- If maternal treatment was with drugs other than penicillin

**Table 18–12 Therapeutic Decisions Involving the Infant in Relation to Rapid Plasma Reagin (RPR) Status**

RPR Status	Decision
<b>Negative RPR Result</b>	
Possible early syphilis	
Without clinical findings	Treat
With clinical findings	Evaluate for other congenital infection; if none apparent, treat
<b>Positive RPR Result</b>	
With clinical manifestations	Treat
Without clinical manifestations, perform the following:	
1. Quantitative RPR in mother and infant—if infant titer fourfold higher	Treat
2. Hematologic studies—if abnormal	Treat
3. Bone radiography—if abnormal	Treat
4. Lumbar puncture—if abnormal	Treat
5. If mother	
a. Has no, inadequate, or undocumented treatment	Treat
b. Was treated with nonpenicillin	Treat
c. Was treated within 4 wk of delivery	Treat
d. Or if adequate follow-up of newborn in doubt	Treat

- If the mother received treatment within 4 weeks of delivery
- If the mother received treatment for early syphilis during the pregnancy with the appropriate penicillin regimen, but nontreponemal antibody titers did not decrease at least fourfold
- If the mother had serologic evidence of relapse or reinfection after treatment (a fourfold or greater increase in nontreponemal antibody titer)
- If adequate follow-up of the infant is uncertain

A practical approach is to provide treatment for congenital syphilis for all newborns who have a positive RPR test result even if the mother is not thought to have an active infection. This recommendation is based on a number of pragmatic considerations: (1) it may be difficult to document that the mother received adequate therapy and has a falling RPR titer; (2) a low-titer RPR test result may be compatible with untreated latent maternal syphilis; (3) the newborn, if infected, may not have any clinical manifestations at birth; and (4) compliance with follow-up visits is a monumental problem. Clearly, if the infant has a positive RPR test result and any signs consistent with congenital syphilis, treatment should be administered. If no clinical findings are present, however, a quantitative RPR test should be performed on blood from the mother and her newborn. Treatment is indicated if the infant has a titer four or more times higher than that of the mother.

In infants in whom findings on physical examination are normal and the quantitative RPR titer is not significantly higher than in the mother, the maternal history of infection

with *T. pallidum* and treatment for syphilis must be considered in evaluation and treatment for the infant. If the infant may be infected, then hematologic investigation, skeletal radiographic survey, and lumbar puncture should be performed. If any of these reveal abnormalities that are consistent with the diagnosis of congenital syphilis, the infant must receive appropriate treatment.<sup>156,372</sup>

In the previous 2 decades, the need for examination of CSF obtained at lumbar puncture and for long bone radiographic evaluation has been questioned.<sup>373,374</sup> Beeram and colleagues<sup>373</sup> have reported that among infants who had normal findings on physical examination but were born to mothers with untreated or inadequately treated syphilis, a reactive CSF VDRL test was found in only 0.6% of evaluated infants. Mean CSF white blood cell count and protein content did not differ significantly from those in a control population of healthy infants who had negative evaluations for bacterial infection, including sterile cultures of blood and CSF. Using the stricter criteria of Platou (white blood cell count greater than 5 cells/mm<sup>3</sup>; protein content greater than 40 mg/dL) in determination of abnormal CSF indices, 44% and 95% of control infants had CSF pleocytosis and elevated protein content, respectively. This study supports the recent recommendation by the CDC (see later) that if treatment for possible neurosyphilis is provided to infants at risk of being infected with *T. pallidum*, performance of a lumbar puncture is not necessary.<sup>156</sup> This study also highlights the need to use appropriate reference values in the evaluation of neonatal CSF.

Similarly, long bone radiographic findings frequently are abnormal among infants with clinical signs of congenital syphilis.<sup>374</sup> These infants require prolonged penicillin therapy irrespective of the results of the skeletal survey, and both the CDC and American Academy of Pediatrics no longer require that such surveys be routinely performed in these circumstances.<sup>156,372</sup> Nevertheless, because as many as 6% of normal infants born to mothers with untreated syphilis may have bone abnormalities as the sole manifestation of possible congenital syphilis,<sup>374</sup> radiographic examination should be performed before the decision to manage at-risk infants with only a single dose of benzathine penicillin therapy.<sup>156</sup>

If the meaning of a positive RPR test result in an otherwise normal infant is in doubt and the results of all other tests are negative, repeated quantitative RPR testing should be done. When antibody is passively acquired from the mother, serial quantitative tests show a declining titer. A falling titer suggests that the infant is free of infection; on the other hand, a stable or rising titer implies the presence of infection. The decision concerning treatment or observation of such a newborn depends on the clinical setting; whether the mother has received antibiotic therapy; the results of other tests such as skeletal radiography, liver function tests, and hematologic studies; and the opportunity for adequate follow-up. Antisyphilitic therapy is indicated in any circumstance in which the mother is unreliable and compliance with the therapeutic regimen and adequate follow-up care cannot be ensured.

It should not be forgotten that in the newborn, a negative RPR test result may not exclude incubating syphilis if maternal infection was in the earliest clinical stage and antibodies had not reached detectable levels.<sup>157,227</sup> Thus,

**Table 18-13 Recommended Treatment of the Newborn<sup>a, b</sup>**

Maternal Rx <sup>c</sup>	Clinical Findings in Newborn	Drug (Penicillin G)	Route	Dose (50,000 units/kg)
None or inadequate <sup>d</sup>	Present	Aqueous or Procaine	IM or IV	Daily × 10-14 days in two (<7 days), three (8-30 days), or four (>1 mo) doses
None or inadequate <sup>d</sup>	Absent	Aqueous or Procaine	IM or IV	Daily dose × 10-14 days
Adequate (during pregnancy)	Absent	Benzathine Benzathine (CDC) or Follow-up only (AAP)	IM IM	Single dose Single dose
Adequate (before pregnancy)	Absent	Follow-up only or Benzathine (only if follow-up cannot be ensured)	IM	Single dose

<sup>a</sup>Close and frequent follow-up, including serologic test for syphilis, is essential.

<sup>b</sup>Test mother for HIV antibody.

<sup>c</sup>Inadequate maternal treatment: not documented, within 4 weeks of delivery, or with erythromycin or nonpenicillin drug; or serologic antibody titers do not fall appropriately (see text).

<sup>d</sup>Some experts would not treat if follow-up is ensured.

HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous.

such an infant without clinical abnormalities should undergo a second RPR test within 3 to 4 weeks. If the risk of exposure to the infant is considerable (e.g., if the child was born to a known syphilitic with no documented treatment history), a reasonable case can be made for immediate penicillin therapy. If the newborn has clinical manifestations that are thought to be consistent with the diagnosis of congenital syphilis, a negative RPR test result makes this clinical diagnosis highly questionable; reevaluation is indicated. Finally, the appearance of secondary or tertiary syphilis in the mother within the year after delivery should prompt a thorough reevaluation of the infant for the possibility of congenital syphilis.

### Penicillin

Penicillin remains the drug of choice for treatment of congenital syphilis (Table 18-13).<sup>88,98,136,156,359,371,372,375</sup> Infants who are 4 weeks of age or younger and who have proven or highly probable disease are likely to have CNS invasion by *T. pallidum*.<sup>88</sup> These include (1) infants with physical findings compatible with congenital syphilis; (2) infants who lack such physical findings but have abnormalities on CSF examination, on bone radiographs, or on laboratory evaluation; (3) infants who have a serum quantitative nontreponemal serologic titer that is four times greater than the mother's titer; and (4) infants who have a positive result on darkfield or fluorescent antibody test of body fluids. The evaluation<sup>156,372</sup> of these infants should begin with CSF analysis to detect evidence of possible neurosyphilis and to establish a baseline for follow-up evaluation. A complete blood cell count and platelet count also should be

performed, because anemia and thrombocytopenia may not be readily detected by physical examination only. Other tests such as chest radiography, cranial ultrasound study, ophthalmologic examination, and auditory-evoked brain-stem response evaluation should be performed as clinically indicated.

Infants with proven or highly probable disease should receive treatment for 10 days with either (1) aqueous crystalline penicillin G, 50,000 units/kg intravenously every 12 hours for the first week of life and every 8 hours beyond 1 week of age or (2) aqueous procaine penicillin G, 50,000 units/kg administered intramuscularly once daily for 10 days.<sup>156,372</sup> If more than 1 day of therapy is missed, the entire course of penicillin be restarted.<sup>156</sup> Although the CSF levels of penicillin are higher in infants who receive intravenous aqueous penicillin G than in those given intramuscular procaine penicillin, the significance of this finding remains unclear, because both therapies have resulted in clinical and laboratory cure.<sup>376</sup> Similarly, infants and children who are identified as having congenital syphilis after the neonatal period (beyond 4 weeks of age) should receive aqueous penicillin G, 50,000 units/kg intravenously every 6 hours for 10 days.<sup>156</sup> For older children, the amount of penicillin should not exceed that recommended for adults (see Table 18-11). The efficacy of a 10-day course of penicillin for eradication of spirochetes from neonatal CSF has been documented.<sup>88,326</sup>

For infants who have normal findings on physical examination and a serum quantitative nontreponemal serologic titer that is the same as or less than four times the maternal titer, the evaluation is dependent on the maternal treatment history, maternal stage of infection, and planned

infant treatment (see Table 18-13).<sup>156</sup> If maternal treatment for syphilis was not given, was undocumented, was a nonpenicillin regimen, or was administered 4 weeks or less before delivery, or if the adequacy of maternal treatment for early syphilis cannot be evaluated because the nontreponemal serologic titer has not decreased fourfold, or relapse or reinfection is suspected because of a fourfold increase in the maternal nontreponemal serologic titer, then the infant should receive the following treatment: (1) aqueous penicillin G or procaine penicillin G for 10 days or (2) benzathine penicillin G, 50,000 units/kg (single dose intramuscularly) with close serologic follow-up studies.<sup>156,372</sup> If the infant receives a 10-day course of parenteral penicillin, then a complete evaluation consisting of a lumbar puncture, complete blood cell count and platelet count, and bone radiographs may not be necessary, because the infant will receive adequate therapy for proven or highly probable disease (see earlier), including possible neurosyphilis.<sup>116</sup> Nevertheless, abnormalities found on these tests may further support a diagnosis of congenital syphilis, and performance of a lumbar puncture may document CSF abnormalities that would prompt close follow-up. On the other hand, if the infant is to receive a single intramuscular injection of benzathine penicillin G, then a complete evaluation (lumbar puncture, complete blood cell count with platelet count, and bone radiographs) is mandatory.<sup>156,372</sup> Using RIT as the diagnostic standard, Michelow and colleagues<sup>326</sup> have shown that most infants with *T. pallidum* infection of the CNS can be identified by this combination of tests. If any test has an abnormal result, or if any part of the evaluation is not done, then a 10-day course of penicillin is recommended.

The decision by both the CDC<sup>116</sup> and the American Academy of Pediatrics<sup>372</sup> to allow the expanded use of a single intramuscular dose of benzathine penicillin G is based on the finding that, in contrast with the infant with clinical manifestations of congenital syphilis, the prevalence of CNS invasion by *T. pallidum* as documented by RIT is very low in infants who lack physical, radiographic, or laboratory evidence of congenital infection.<sup>88</sup> Single-dose benzathine penicillin therapy has been widely used in the past, and its use allows for earlier hospital discharge of the infant with subsequent improved maternal-infant interaction and decrease in hospitalization costs.<sup>377</sup> This regimen has been supported by two small clinical studies.<sup>378,379</sup>

Nonetheless, failure of a single injection of benzathine penicillin G administered to three infants has been reported.<sup>380,381</sup> These infants were born to mothers with early syphilis and were not fully evaluated for evidence of congenital syphilis at delivery. These treatment failures have been attributed to the inability of benzathine penicillin G to adequately penetrate and achieve treponemocidal concentration in certain sites, such as the aqueous humor and CNS.<sup>382,383</sup> Michelow and colleagues<sup>325</sup> have documented the presence of spirochetes in the CSF of three infants without clinical manifestations who received a single injection of benzathine penicillin; at follow-up evaluation, findings on CSF examination were normal and the results of RIT for spirochetes were negative. These investigators recommend that if the evaluation for congenital syphilis is not complete or not performed, the infant should receive empirical therapy that will eradicate *T. pallidum* from the CNS.

For infants who appear healthy on physical examination and have a serum quantitative nontreponemal serologic titer that is the same as or less than four times the maternal titer, evaluation is unnecessary if during pregnancy the maternal treatment was appropriate for the stage of infection, and (1) it was given more than 4 weeks before delivery, (2) it was for early syphilis and the nontreponemal serologic titers decreased fourfold after appropriate therapy, or (3) it was for late latent syphilis, the nontreponemal titers remained stable and low, and evidence of maternal reinfection or relapse is lacking.<sup>156</sup> The CDC recommends that in these situations, a single intramuscular dose of benzathine penicillin G 50,000 units/kg be administered to the infant.<sup>156</sup> Some experts, however, would not treat these infants but would provide close serologic follow-up only.<sup>156,372</sup>

For infants who have normal findings on physical examination and a serum quantitative nontreponemal serologic titer that is the same as or less than four times the maternal titer, evaluation and treatment are unnecessary if the maternal treatment was before pregnancy and the nontreponemal serologic titers remained low and stable before and during the pregnancy and at delivery.<sup>156</sup> If compliance with follow-up is uncertain, a single intramuscular dose of benzathine penicillin G, 50,000 units/kg, may be given.

Infants born to mothers co-infected with syphilis and HIV do not require different evaluation or therapy for syphilis from that recommended for all infants.<sup>156</sup> These infants born to co-infected women may be at higher risk of infection with *T. pallidum*<sup>98,100</sup>; however, it is not known whether co-infected infants respond to treatment for congenital syphilis differently from infants uninfected with HIV. Close serologic follow-up evaluation of these infants is mandatory.

### Alternative Drugs

Very few alternative regimens are available for infants with congenital syphilis. Clinical studies of the treatment of congenital syphilis with ampicillin or ceftriaxone, or other new cephalosporins that readily penetrate the blood-brain barrier, have not been reported, although theoretically these drugs should be effective.<sup>384</sup>

Infants with congenital syphilis should receive procaine penicillin or benzathine penicillin G for treatment (see Table 18-13).

The lack of adequate CNS penetration by erythromycin or oral tetracycline makes these drugs inappropriate for the treatment of congenital syphilis. In addition, tetracycline and doxycycline are not advised for children younger than 8 years of age because they may stain the teeth and possibly cause bone toxicity.

### Jarisch-Herxheimer Reaction

The Jarisch-Herxheimer reaction, a common occurrence in the treatment of acquired early syphilis in adults,<sup>385</sup> consists of chills, fever, generalized malaise, hypotension, tachycardia, tachypnea, accentuation of the cutaneous lesions, leukocytosis, and, exceedingly rarely, death. It begins within 2 hours of treatment, peaks at approximately 8 hours, and disappears in 24 to 36 hours. The cause of the reaction is not known,<sup>386</sup> although release of *T. pallidum* membrane lipoproteins that stimulate pro-inflammatory cytokines likely explains this clinical phenomenon.<sup>387</sup>

**Table 18-14 Follow-up after Treatment or Prophylaxis for Congenital Syphilis**

Patient Category	Follow-up Procedures
Infants diagnosed as having congenital syphilis	<ol style="list-style-type: none"> <li>1. RPR testing every 2-3 mo until negative or decreased fourfold. If RPR titer is stable or increasing after 6-12 mo after treatment, reevaluate and re-treat.</li> <li>2. Perform treponemal antibody test after age of 15 mo.</li> <li>3. If initial CSF was abnormal or infant showed signs of CNS disease, repeat CSF evaluation every 6 mo until normal. With abnormal CSF not due to intercurrent illness on re-testing, re-treat.</li> <li>4. Careful developmental evaluation, vision testing, and hearing testing are indicated.</li> </ol>
Infants who received treatment in utero or at birth because of maternal syphilis	<ol style="list-style-type: none"> <li>1. RPR testing at birth and then every 3 mo until result is negative.</li> <li>2. Treponemal antibody test after age of 15 mo.</li> </ol>
Women who received treatment for syphilis during pregnancy	<ol style="list-style-type: none"> <li>1. RPR testing as often as monthly until delivery, then every 6 mo until negative result obtained or titer decreased fourfold.</li> <li>2. Re-treatment any time there is a fourfold rise in RPR titer.</li> </ol>

CNS, central nervous system; CSF, cerebrospinal fluid; RPR, rapid plasma reagin.

Modified from Rathbun KC. Congenital syphilis: a proposal for improved surveillance, diagnosis and treatment. *Sex Transm Dis* 10:102, 1983, with permission; and *MMWR Morb Mortal Wkly Rep* 51(RR-6):1, 2002.

Approximately 40% of pregnant women who receive treatment for syphilis demonstrate a Jarisch-Herxheimer reaction.<sup>388,389</sup> In addition, these women may experience the onset of uterine contractions and preterm labor, with decreased fetal activity and fetal heart rate changes, including late decelerations, which last up to 24 to 48 hours and may lead to fetal death. These manifestations of the Jarisch-Herxheimer reaction in pregnancy possibly are mediated by the prostaglandin pathway. No prophylactic measure or treatment currently is available. Abnormal ultrasonographic findings in the fetus, as well as fetal monitoring for 24 hours, may identify pregnancies at highest risk.

In congenital syphilis, the incidence of the Jarisch-Herxheimer reaction is low, although it may be more common when treatment occurs later in infancy<sup>227</sup>; when it does occur, it varies in severity, ranging from fever to cardiovascular collapse and seizures.<sup>88</sup> In Platou's series,<sup>234</sup> almost half of the infants sustained a febrile reaction during the first 36 hours after initiation of penicillin therapy. No relationship was observed between the severity or the outcome of the infection and this temperature elevation.

### Post-treatment Follow-up

Recommendations for follow-up evaluation are summarized in Table 18-14. It is advisable to monitor the outcome of therapy by repeated RPR testing. Patients responding to therapy should have falling titers (fourfold or better decrease), and as many as 70% to 93% should become seronegative within 1 year.<sup>234,309</sup> Re-treatment should be considered if signs persist or recur, if any increase in the titer of a non-treponemal test is noted, if an initially high-titer non-treponemal test fails to decrease fourfold in the first year, or if the repeated lumbar puncture plus CSF analysis at 6 months shows persistent abnormalities, including a positive VDRL test result.<sup>156</sup> The recommendation of a second treponemal test beyond 15 months as a way of retrospectively diagnosing congenital syphilis<sup>308</sup> is not merely for epidemiologic use—an established diagnosis can help in medical and developmental follow-up evaluation of the child.

### PROGNOSIS

Although treatment can cure the infection, the prognosis in treated congenital syphilis depends on the degree of damage before the initiation of therapy. In general, the earlier treatment is initiated, the more likely it is that a satisfactory response can be obtained.<sup>390</sup> If marked damage to the fetus has occurred, treatment in utero may not prevent abortion, stillbirth, or neonatal death, and even if treatment keeps the newborn infant alive, stigmata can remain. If the treatment is provided prenatally or within the first 3 months of life, and such stigmata have not yet become apparent, they generally can be prevented.<sup>253</sup> Interstitial keratitis is an exception; this complication does not seem to be responsive to specific antibiotic therapy. On occasion, dramatic relief has been afforded by the use of corticosteroids and mydriatics, although relapses have occurred with cessation of corticosteroid therapy. The osseous lesions seem to heal independently of specific therapy. Treatment of congenital syphilis in the late stage does not reverse the stigmata.<sup>194</sup>

A number of reports describe the persistence of treponemes after therapy for syphilis in both humans and animals.<sup>391-394</sup> *T. pallidum* has been shown to survive in the lymph nodes, eye, and CSF after doses of penicillin that are presumed adequate. Silverstein<sup>162,395</sup> observed that monkeys inoculated in utero with *T. pallidum* had a significant number of viable treponemes in the aqueous humor of their clinically normal eyes 6 months after birth. Hardy and associates<sup>396</sup> described a newborn with congenital syphilis treated with penicillin in whom the aqueous humor contained virulent treponemes, and a number of cases of recrudescence of neurosyphilis in adults have been described after treatment with recommended doses of penicillin.<sup>397-399</sup> Survival of the organism in the eye or CSF is ascribed to inadequate penetration of penicillin, but this explanation does not account for persistence of treponemes in lymph nodes after treatment.

## PREVENTION

Congenital syphilis is a preventable disease. To minimize the likelihood of its occurrence, every woman who becomes pregnant should undergo at least one serologic test for syphilis during the first trimester.<sup>112,144,307,400</sup> For communities and populations in which the prevalence of syphilis is high or for women in high-risk groups (see Table 18-3), repeated testing at the beginning of the third trimester (at 28 weeks of gestation)<sup>135,139</sup> and at delivery is recommended.<sup>156,342</sup> Sanchez and associates<sup>139</sup> have documented the importance of maternal serologic screening for syphilis at delivery in a high-risk inner-city population. During the years 1987 to 1990, approximately 3% of 58,387 pregnant women had reactive serologic tests for syphilis; in 5% of these women, an antepartum RPR test was nonreactive, but an RPR test at delivery was reactive.

Screening tests at delivery should be performed in mothers and not in infants.<sup>112,156,306</sup> An infant's serologic titer often is one to two dilutions less than that of the mother's; thus, an infant may have a nonreactive umbilical cord VDRL test but have a mother with a reactive serologic test for syphilis at delivery. From 1987 to 1990, Sanchez and co-workers<sup>139</sup> compared results of maternal serologic studies at delivery with those obtained from VDRL testing of umbilical cord blood. These investigators documented 534 cases with reactive maternal serologic tests at delivery but negative umbilical cord blood VDRL test results. Eighty-seven, or 16%, of these infants were born to mothers with untreated syphilis at delivery and were therefore at risk for infection if treatment was not given. It is clear that these infants would not have been identified if only the umbilical cord blood had been screened. No infant should be discharged from the nursery before results of maternal serologic screening have been documented. With the practice of early discharge at 48 hours or less, it becomes the responsibility of the health care provider to arrange for adequate follow-up in infants who are discharged before the result of the maternal serologic test is known.

In most clinical facilities, prenatal testing is required by law or as a matter of institutional procedure. Some states also mandate serologic screening at delivery for all women. The alternative of targeted testing is impractical to implement and would save little money, even as rates of syphilis decline in women and infants.<sup>401</sup> Printed requirements do not eliminate human error, and prenatal testing requirements are not applicable to a woman who does not enter the medical care system until the moment before delivery.

In an infant born to a woman who is incubating syphilis at delivery and whose serologic tests are nonreactive, congenital syphilis is, by current methods, impossible to prevent.<sup>157,227</sup> In areas with a high incidence of congenital syphilis, a postpartum serologic test for syphilis at 6 weeks can be helpful in detecting infants in this high-risk group.

Reporting of cases to the local health department will allow rapid-contact investigation of named sexual partners and appropriate follow-up for infected persons. Patients who have had sexual contact with an untreated person should have clinical evaluation, serologic testing, and treatment. The time periods before treatment used for identifying at-risk sexual partners are (1) 3 months plus duration of symptoms for primary syphilis; (2) 6 months plus duration

of symptoms for secondary syphilis; and (3) 1 year for early latent syphilis.<sup>156</sup> Persons who were exposed within 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in a sexual partner might be infected even if seronegative and should receive presumptive treatment.

As partner notification has become more challenging because of anonymous sex and the inability to locate sexual partners, attention has focused on identifying core environments and populations in which syphilis transmission is occurring.<sup>402</sup> Such knowledge has resulted in provision of prophylactic syphilis treatment to groups of people in high-risk populations. Recently, the CDC has designed a strategy to assist public health providers at both state and local levels to design interventions for targeted at-risk populations that are locally identified.<sup>403</sup> Called the rapid ethnographic community assessment process (RECAP), the assessment is a package of activities and tools designed to use ethnographic methods for improving community involvement, as well as developing interventions that fit a population's social and behavioral context. It has been used in North Carolina with success.<sup>403</sup> Ultimately, prevention of congenital syphilis will be accomplished only if elimination of syphilis becomes a reality.

## Conclusion 596

Tuberculosis is a classic familial disease.<sup>1</sup> The household is the main setting throughout the world for the person-to-person spread of *Mycobacterium tuberculosis*. With the recent resurgence of tuberculosis in many industrialized nations, issues concerning pregnant women and their children have been reexamined by practitioners of tuberculosis control.

Before 1985, tuberculosis in the pregnant woman and newborn had become an infrequent event in the United States. Although specific statistics concerning tuberculosis in pregnancy are not reported, the increase in total tuberculosis cases in the late 1980s and 1990s and the shift in numbers to young adults and children suggested that tuberculosis in pregnancy may become a more prevalent problem.<sup>2,3</sup> This problem disproportionately affects minority urban populations because they have very high tuberculosis case rates, a greater relative shift in cases to adults of childbearing age, and, in general, less access to prenatal care and screening for disease and infection caused by *M. tuberculosis*.

The influence of pregnancy on the occurrence and prognosis of tuberculosis has been discussed and debated for centuries. At various times, pregnancy has been thought to improve, worsen, or have no effect on the prognosis of tuberculosis. This controversy has lost much of its importance since the advent of effective antituberculosis chemotherapy. The greatest areas of debate at present concern (1) the use of chemotherapy to prevent the progression of *M. tuberculosis* infection to tuberculosis during pregnancy and the postpartum period and (2) the treatment of exposed infants to prevent the development of serious tuberculosis.<sup>4</sup>

## TERMINOLOGY

A practical approach to tuberculosis terminology is to follow the natural history of the disease, which can be divided into three stages: exposure, infection, and disease.<sup>5</sup> Exposure implies that the patient has had recent (less than 3 months) and significant contact with an adult with suspected or confirmed contagious pulmonary tuberculosis. For example, an infant born into a family in which an adult has active tuberculosis would be in the exposure stage. In this stage, the child's tuberculin skin test is negative, the chest radiograph result is normal, and the child is free of signs and symptoms of tuberculosis. Unfortunately, it is impossible to know whether a young child in the exposure stage is truly infected with *M. tuberculosis*, because the development of delayed-type hypersensitivity to a tuberculin skin test for tuberculin may take up to 3 months after the organisms have been inhaled.

*M. tuberculosis* infection is present if an individual has a positive tuberculin skin test result but lacks signs or symptoms of tuberculosis. In this stage, findings on the chest radiograph either are normal or reveal only granuloma or calcification in the lung parenchyma or regional lymph nodes. The purpose of treating *M. tuberculosis* infection is to prevent future disease. In newborns, the progression from infection to disease can occur very rapidly, within several weeks to months.

Tuberculosis disease occurs if signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. Because 25% to 35% of children with tuberculosis have extrapulmonary involvement, a thorough physical examination, in addition to a high-quality chest radiograph, is essential to rule out disease.<sup>5</sup> Genitourinary tuberculosis in women often causes only subtle symptoms until it is far advanced. Ten to 20% of immunocompetent adults and children with the disease initially have a negative tuberculin skin test result, usually because of immunosuppression by tuberculosis itself. The rate of negative skin test results with disease due to *M. tuberculosis*, however, is much higher in newborns and small infants, especially if they have life-

threatening forms of tuberculosis such as disseminated disease or meningitis.

## MYCOBACTERIOLOGY

Mycobacteria are nonmotile, non-spore-forming, pleomorphic, weakly gram-positive rods that are 1 to 5  $\mu\text{m}$  long, usually slender, and slightly curved. *M. tuberculosis* may appear beaded or clumped. The cell wall constituents of mycobacteria determine their most striking biologic properties. The cell wall is composed of 20 to 60% lipids bound to proteins and carbohydrates. These and other properties make mycobacteria more resistant than most other bacteria to light, alkali, acid, and the bactericidal activity of antibodies. Growth of *M. tuberculosis* is slow, with a generation time of 12 to 24 hours on solid media.

Acid-fastness, the capacity to form stable mycolate complexes with certain aryl methane dyes that are not removed even by rinsing with 95% ethanol plus hydrochloric acid, is the hallmark of mycobacteria. The cells appear red when stained with carbol fuchsin (Ziehl-Neelsen or Kinyoun stains) or purple with crystal violet, or they exhibit yellow-green fluorescence under ultraviolet light when stained with auramine and rhodamine (Truant stain). Truant stain is considered the most sensitive stain, especially when small numbers of organisms are present. Approximately 10,000 cells per  $\text{mm}^3$  must be present in a sample for them to be seen in an acid-fast stained smear.

Identification of mycobacteria depends on their staining properties and their biochemical and metabolic characteristics. Mycobacteria are obligate aerobes with simple growth requirements. *M. tuberculosis* can grow in classic media, whose essential ingredients are egg yolk and glycerin (Löwenstein-Jensen or Dorset media), or in simple synthetic media (Middlebrook, Tween-albumin). Isolation on solid media takes 2 to 6 weeks, followed by another 2 to 4 weeks for drug-susceptibility testing. More rapid isolation (7 to 21 days) can be achieved using a synthetic liquid medium in an automated radiometric system, the most common one being BACTEC (Becton, Dickinson, and Co. [BD], Sparks, Md). A specimen is inoculated into a bottle of medium containing carbon-14-labeled palmitic acid as a substrate. As mycobacteria metabolize the palmitic acid, carbon dioxide-14 accumulates in the head space of the bottle, where radioactivity can be measured. Unfortunately, because bottles are often analyzed in series by repetitive needle aspiration in an automated, single-needle system, cross-contamination leading to a false-positive culture can occur. Drug susceptibility testing can be performed on the same system using bottles with antimicrobial agents added to the medium. In this radiometric system, identification and drug-susceptibility testing often can be completed in 2 to 3 weeks, depending on the concentration of organisms in the patient sample.

Unfortunately, it is often difficult to isolate *M. tuberculosis* from infants and toddlers with tuberculosis.<sup>6,7</sup> Infants and children with pulmonary tuberculosis rarely produce sputum, the usual culture material for adults. The preferred source of culture for children is the gastric aspirate, performed early in the morning before the stomach has been emptied of the respiratory secretions swallowed overnight. For older children, the culture yield from gastric aspirates obtained on three

consecutive mornings is 20% to 40%.<sup>8</sup> The yield from infants is usually higher, up to 75%.<sup>9</sup> For many infants with congenital pulmonary tuberculosis, *M. tuberculosis* can be cultured from a tracheal aspirate owing to the large number of organisms in the lungs.

Several types of nucleic acid amplification have been developed to detect *M. tuberculosis* in patient samples. The main form of nucleic acid amplification studied in children with tuberculosis is the polymerase chain reaction (PCR), which uses specific DNA sequences as markers for microorganisms. Various PCR techniques, most using the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms, have a sensitivity and specificity of more than 90% compared with sputum culture for detecting pulmonary tuberculosis in adults. However, test performance varies even among reference laboratories. The test is relatively expensive and requires fairly sophisticated equipment and scrupulous technique to avoid cross-contamination of specimens.

Use of PCR in childhood tuberculosis has been limited. Compared with a clinical diagnosis of pulmonary tuberculosis in children, the sensitivity of PCR has varied from 25 to 83% and specificity has varied from 80% to 100%.<sup>10</sup> The PCR of gastric aspirates may be positive in a recently infected child even when the chest radiograph result is normal, demonstrating the occasional arbitrariness of the distinction between *M. tuberculosis* infection and disease in children. The PCR may have a useful but limited role in evaluating children for tuberculosis. A negative PCR result never eliminates tuberculosis as a diagnostic possibility, and a positive result does not confirm it. The major use of PCR will be in evaluating children with significant pulmonary disease when the diagnosis is not established readily on clinical or epidemiologic grounds. PCR particularly may be helpful in evaluating immunocompromised children with pulmonary disease, especially children with human immunodeficiency virus (HIV) infection, although published reports of its performance in such children are lacking. PCR also may aid in confirming the diagnosis of extrapulmonary tuberculosis, although only a few case reports have been published. No information has been published concerning the accuracy of PCR or other techniques of nucleic acid amplification in samples from pregnant women or neonates with congenital or postnatally acquired tuberculosis.

Relatedness of strains of *M. tuberculosis* was determined in the past by analysis of bacteriophages, a cumbersome and difficult task. A newer technique, restriction fragment length polymorphism analysis of mycobacterial DNA, has become an accurate and powerful tool for determining strain relatedness.<sup>11</sup> It is used frequently in some communities and may help determine whether an infant with tuberculosis has true congenital infection or was infected by another source.

## EPIDEMIOLOGY

Tuberculosis remains the leading infectious disease in the world.<sup>12</sup> The World Health Organization (WHO) estimates that during the 1990s 90 million individuals developed tuberculosis and 30 million people died of the disease worldwide. The WHO also estimates that, in the developing world, there are 1.3 million cases of tuberculosis and 400,000 tuberculosis-

related deaths annually among children younger than 15 years of age. In most developing countries, the highest rates of tuberculosis occur among young adult men and women. Although much attention has been given recently to the growing number of children orphaned in developing countries by their parents' deaths from HIV-related illnesses, many orphans also are being created by tuberculosis.

In the United States from 1953 through 1984, the incidence of tuberculosis disease declined an average of 5% per year. From 1985 through 1992, there was a 20% increase in total cases of tuberculosis in the United States and a 40% increase in tuberculosis cases among children.<sup>13</sup> Most experts cite four major factors contributing to this increase: (1) the co-epidemic of HIV infection,<sup>14</sup> which is the strongest risk factor known for development of tuberculosis disease in an adult infected with *M. tuberculosis*<sup>15</sup>; (2) the increase in immigration of people to the United States from countries with a high prevalence of tuberculosis, enlarging the pool of infected individuals<sup>16,17</sup>; (3) the increased transmission of *M. tuberculosis* in congregate settings, such as jails, prisons, hospitals, nursing homes, and homeless shelters; and (4) the general decline in tuberculosis-related public health services and access to medical care for the indigent in many communities.<sup>18</sup> Fortunately, in 2003, the approximately 15,500 cases of tuberculosis in the United States was a 40% decline from the peak number of cases in 1992.

In the early 20th century in the United States, when tuberculosis was more prevalent, the risk of becoming infected with *M. tuberculosis* was high across the entire population. Currently, tuberculosis has retreated into fairly well-defined pockets of high-risk individuals, such as foreign-born persons from or persons who travel to high-prevalence countries, inmates of correctional institutions, illicit drug users, unprotected health care workers who care for high-risk patients, migrant families, homeless persons, and anyone likely to encounter people with contagious tuberculosis. One must distinguish the risk factors for becoming infected with *M. tuberculosis* from those that increase the likelihood that an infected individual will develop disease. A compromised immune system and recent infection with *M. tuberculosis* are the major risk factors for progression of infection to disease. Although tuberculosis occurs throughout the United States, cases are disproportionately reported from large urban areas. Cities with populations exceeding 250,000 account for only 18% of the nation's population but almost 50% of its tuberculosis cases.

The number of tuberculosis cases in the United States is increasing among foreign-born persons from countries with a high prevalence of tuberculosis. The percentage of total cases of tuberculosis in the United States that occurs in foreign-born individuals had increased from 22% in 1986 to more than 50% in 2003.<sup>17</sup> In previous estimates, two thirds of foreign-born individuals with tuberculosis were younger than 35 years of age when entering the United States, and in many cases their disease could have been prevented if they had been identified as infected after immigration and given appropriate treatment for *M. tuberculosis* infection. Unfortunately, new immigrants to the United States older than 15 years of age are required to have a chest radiograph but no tuberculin skin test to detect asymptomatic infection; children younger than 15 years old receive no tuberculosis testing as part of immigration.<sup>19</sup> Studies have estimated that

30% to 50% of the almost 1 million annual new immigrants to the United States are infected with *M. tuberculosis*.<sup>17</sup> Clearly, foreign-born women and adolescents of childbearing age should be one group targeted for appropriate tuberculosis screening and prevention.<sup>20</sup>

Another factor that has had a great impact on tuberculosis case rates in the United States has been the epidemic of HIV infection.<sup>15</sup> The proportion of women with HIV infection is increasing, and because risk factors for HIV infection intersect with those for tuberculosis the number of co-infected women will increase.<sup>21-23</sup> In most locales experiencing recent increases in tuberculosis cases, the demographic groups with the greatest tuberculosis morbidity rates are the same as those with high morbidity rates from HIV infection. HIV-infected persons with a reactive tuberculin skin test develop tuberculosis at a rate of 5% to 10% per year compared with a historical average of 5% to 10% for the lifetime of an immunocompetent adult. There is controversy concerning the infectiousness of adults with HIV-associated pulmonary tuberculosis. Although some studies have indicated dually infected adults are as likely as non-HIV-infected adults with tuberculosis to infect others, some studies have shown less transmission from HIV-infected adults.<sup>24</sup>

The current epidemiology of tuberculosis in pregnancy is unknown. From 1966 to 1972, the incidence of tuberculosis during pregnancy at New York Lying-In Hospital ranged from 0.6% to 1.0%.<sup>25</sup> During this time, 3.2% of the patients with culture-proven pulmonary tuberculosis were first diagnosed during pregnancy, a rate equal to that of nonpregnant women of comparable age. There have been only two series of pregnant women with tuberculosis reported from the United States in the past 2 decades.<sup>26,27</sup> Increased risk of tuberculosis is most striking for foreign-born women, who have high rates of tuberculosis infection, and poor minority women. In the United States, almost 40% of tuberculosis cases in minority women occur before 35 years of age. Approximately 80% of tuberculosis cases among children in the United States occur in minority populations.<sup>13</sup> Most of these cases occur after exposure to an ill family member. In all populations, whether the disease incidence is high or low, tuberculosis infection and disease tend to occur in clusters, often centered on the close or extended family, meaning that minority newborns are at greatly increased risk of congenital and postnatally acquired tuberculosis infection and disease.

## TUBERCULOSIS IN PREGNANCY

### Pathogenesis

The pathogenesis of tuberculosis infection and disease during pregnancy is similar to that for nonpregnant individuals.<sup>28,29</sup> The usual portal of entry for *M. tuberculosis* is the lung through inhalation of infected droplet nuclei discharged by an infectious individual. The inoculum of organisms necessary to establish infection is unknown but is probably fewer than 10.<sup>30</sup> Once tubercle bacilli are deposited in the lung, they multiply in the nonimmune host for several weeks. Usually, this uninhibited replication produces no symptoms, but a patient may experience low-grade fever, cough, or mild pleuritic pain. Shortly after infection, some organisms are carried from the initial pulmonary focus within macrophages

**Figure 19-1** Chest radiograph of the mother of the child shown in Figure 19-2. This radiograph reveals early miliary tuberculosis.

to the regional lymph nodes.<sup>31</sup> From there, organisms enter lymphatic and blood vessels and disseminate throughout the body; the genitalia, endometrium, and, if the woman is pregnant, the placenta may be seeded.<sup>32</sup> By 1 to 3 months after infection, the host usually develops cell-mediated immunity and hypersensitivity to the tubercle bacillus, reflected by the development of a reactive tuberculin skin test.<sup>33</sup> As immunity develops, the primary infection in the lung and foci in other organs begin to heal through a combination of resolution, fibrosis, and/or calcification.<sup>34</sup> Although walling-off of these foci occurs, viable tubercle bacilli persist. If the host's immune system later becomes suppressed, these dormant bacilli may become active, leading to "reactivation" tuberculosis.<sup>35</sup>

There are two major ways that tuberculosis infection in the mother can lead to infection of the fetus in utero. If dissemination of organisms through the blood and lymphatic channels occurs during pregnancy, the placenta may be infected directly. This can occur either during the asymptomatic dissemination that is part of the mother's initial infection or during pulmonary, miliary, or disseminated tuberculosis disease in the mother.<sup>36-50</sup> Miliary tuberculosis in women can arise from a long-standing dormant infection but more often complicates a recent infection (Fig. 19-1). Therefore, infection with *M. tuberculosis* that occurs during pregnancy, as opposed to dormant infection that occurred before the pregnancy, probably poses a greater risk to the fetus. This is a major reason why pregnant women with new onset of *M. tuberculosis* infection usually should be treated

carefully during the pregnancy; delay could result in disease in the mother, the infant, or both.

The second mechanism by which a fetus can become infected with *M. tuberculosis* is directly from established genitourinary tuberculosis in the mother. Genital tuberculosis is most likely to start around the time of menarche and can have a very long and relatively asymptomatic course. The fallopian tubes most often are involved (in 90%-100% of women), followed by the uterus (50%-60%), ovaries (20%-30%), and cervix (5%-15%).<sup>25,32</sup> Sterility often is the presenting complaint of tuberculosis endometritis, which diminishes the likelihood of congenital tuberculosis occurring.<sup>51,52</sup> If infection of the placenta occurs, it results more frequently from disseminated tuberculosis in the mother than from a local endometritis. Tuberculous endometritis, however, can lead to congenital infection of the newborn.<sup>32,53-56</sup> Tuberculosis in the mother as a complication of in vitro fertilization has been described.<sup>57</sup>

### Effect of Pregnancy on Tuberculosis

Over the past 2 millennia, medical opinions regarding the interaction of pregnancy and tuberculosis have varied considerably. Hippocrates believed that pregnancy had a beneficial effect on tuberculosis, a view that persisted virtually unchallenged well into the 19th century.<sup>58</sup> In 1850, Grisolle reported 24 cases of tuberculosis that developed during pregnancy.<sup>59</sup> In all patients the progression of tuberculosis during pregnancy was more severe than that usually seen in nonpregnant women of the same age. Shortly thereafter, several other papers were published that implied that pregnancy had a deleterious effect on tuberculosis. This view gained so much support that by the early 20th century, the practice of induced abortion to deal with the consequences of tuberculosis during pregnancy became widely accepted.

The opinion that pregnancy had a deleterious effect on tuberculosis predominated until the late 1940s. In 1943, Cohen<sup>60</sup> detected no increased rate of progression of tuberculosis among 100 pregnant women with abnormal chest radiograph results. In 1953, Hedvall<sup>59</sup> presented a comprehensive review of published studies concerning tuberculosis in pregnancy. He cited studies totaling more than 1000 cases that reported deleterious effects of pregnancy on tuberculosis. He discovered a nearly equal number of reported cases, however, in which a neutral or favorable relationship between pregnancy and tuberculosis was observed. In his own study of 250 pregnant women with abnormal chest radiograph results thought to be due to tuberculosis, he noted that 9% improved, 7% worsened, and 84% remained unchanged during pregnancy. During the first postpartum year, 9% improved, 15% worsened, and 76% were stable. Cromie<sup>61</sup> noted that 31 of 101 pregnant women with quiescent tuberculosis experienced relapse after delivery. Twenty of the 31 relapses occurred in the first postpartum year. Several other investigators observed the higher risk of relapse during the puerperium. Several theories were proposed to explain this phenomenon, including postpartum descent of the diaphragm, nutritional stress of pregnancy and lactation, insufficient sleep for the new mother, rapid hormonal changes, and depression in immunity in late pregnancy and the postpartum period. A similar number of other studies, however, failed to support an increased risk of progression of tuber-

culosis in the postpartum period.<sup>62-66</sup> A study by Cohen and colleagues failed to demonstrate an increase in activity of tuberculosis during pregnancy or any postpartum interval.<sup>62</sup> Rosenbach and Gangemi<sup>64</sup> and Cohen and colleagues<sup>62</sup> showed that only 9% to 13% of women with long-standing tuberculosis had progression of disease during the pregnancy or first postpartum year, a rate thought to be comparable to that in nonpregnant women. Few of these studies had adequate control populations. From all the studies reported, it became clear that the anatomic extent of disease, the radiographic pattern, and the susceptibility of the individual patient to tuberculosis were more important than the pregnancy itself in determining the course and prognosis of the pregnant woman with tuberculosis.

The controversy concerning the effect of pregnancy or the postpartum period on tuberculosis has lost most of its importance with the advent of effective chemotherapy.<sup>67,68</sup> With adequate treatment, pregnant women with tuberculosis have the same excellent prognosis as nonpregnant women. Several studies document no adverse effects of pregnancy, birth, the postpartum period, or lactation on the course of tuberculosis in women receiving chemotherapy.<sup>69,70</sup>

Most studies have dealt with the risk of reactivation of tuberculosis among women with abnormal chest radiograph results but no evidence of active tuberculous lesions. It is not clear whether women with asymptomatic *M. tuberculosis* infection but no radiographic findings are at increased risk of developing tuberculosis during pregnancy or the postpartum period. In 1959, Pridie and Stradling<sup>71</sup> found that the incidence of pulmonary tuberculosis among pregnant women was the same as that in the nonpregnant female population of the area. From 1966 to 1972, Schaefer and associates<sup>25</sup> found that the annual pulmonary tuberculosis case rate among pregnant women in New York Lying-In Hospital was 18 to 29 per 100,000 population, comparable to the incidence of tuberculosis during the same period in women of childbearing age in all New York City. Although no definitive study has been reported, it appears unlikely that progression from asymptomatic *M. tuberculosis* infection to tuberculosis disease is accelerated during pregnancy or the postpartum period.

### Effect of Tuberculosis on Pregnancy

In the prechemotherapy era, active tuberculosis at an advanced stage carried a poor prognosis for both mother and child. Schaefer and associates<sup>25</sup> reported that the infant and maternal mortality rates from untreated tuberculosis were between 30% and 40%. In the chemotherapy era, the outcome of pregnancy rarely is altered by the presence of tuberculosis in the mother, except in the rare cases of congenital tuberculosis. One study from Norway revealed a higher incidence of toxemia, postpartum hemorrhage, and difficult labor in mothers with tuberculosis compared with that in control subjects.<sup>72</sup> The incidence of miscarriage was almost 10 times higher in the tuberculous mothers, but there was no significant difference in the rate of congenital malformations in children born to mothers with and without tuberculosis. Another study reported an incidence of prematurity for infants born to untreated mothers in a tuberculosis sanitarium ranging from 23% to 64%, depending on the severity of tuberculosis in the mother.<sup>73</sup> Most experts now believe,

however, that with proper treatment of the pregnant woman with tuberculosis, the prognosis of the pregnancy should not be affected adversely by the presence of tuberculosis. Because of the excellent prognosis for the mother and child, the recommendation for therapeutic abortion has been abandoned.

### Screening for Tuberculosis in Pregnancy

For all pregnant women, the history obtained in an early prenatal visit should include questions about a previously positive tuberculin skin test result, previous treatment for *M. tuberculosis* infection or disease, current symptoms compatible with tuberculosis, and known exposure to other adults with the disease.<sup>74-76</sup> Membership in a high-risk group is a sufficient reason for a tuberculin skin test. For many high-risk women, prenatal or peripartum care represents their only contact with the health care system, and the opportunity to test them for tuberculosis infection or disease should not be lost. Some experts believe that all pregnant women should receive a tuberculin skin test.<sup>77</sup> Most experts believe, however, that only women with specific risk factors for *M. tuberculosis* infection or disease should be tested. It must be emphasized that women co-infected with HIV and *M. tuberculosis* may show no reaction to a tuberculin skin test. Pregnant women with high risk for or with known HIV infection should have a thorough investigation for tuberculosis.

Changes in the interpretation of the Mantoux tuberculin skin test have been promoted by the Centers for Disease Control and Prevention, the American Thoracic Society, and the American Academy of Pediatrics.<sup>76,78</sup> The rationale for using different sizes of induration as representing a positive result in different populations has been discussed thoroughly in many publications. The current recommendation is that for individuals at the highest risk of having *M. tuberculosis* infection progress to tuberculosis—contacts of adults with infectious tuberculosis, patients with an abnormal chest radiograph result or clinical evidence of tuberculosis, or persons with HIV infection or other immunocompromise—a Mantoux tuberculin skin test reaction of at least 5 mm is classified as positive, indicating infection with *M. tuberculosis*. For other high-risk groups, a reaction of at least 10 mm is positive. For all other persons deemed at low risk for tuberculosis, a reaction of at least 15 mm is positive. Obviously, this classification scheme depends on the ability and willingness of the family and health care provider to develop a thorough epidemiologic history of tuberculosis exposures and risk. It also depends on accurate interpretation of the skin test result. One recent study implied that pediatricians tend to under-read induration in tuberculin skin tests.<sup>79</sup>

There have been no studies to verify whether the classification scheme for the Mantoux tuberculin skin test is valid in pregnant women, but there is no reason to suspect otherwise.<sup>80,81</sup> The effect of pregnancy on tuberculin hypersensitivity as measured by the tuberculin skin test is controversial.<sup>82</sup> Some studies have shown a decrease in in vitro lymphocyte reactivity to purified protein derivative during pregnancy.<sup>83</sup> In vivo studies using patients as their own controls, however, have demonstrated no effect of pregnancy on cutaneous delayed hypersensitivity to tuberculin.<sup>84,85</sup> Most experts believe the tuberculin skin test by the Mantoux technique is valid throughout pregnancy. There is no evidence that the

tuberculin skin test has adverse effects on the pregnant mother or fetus or that skin testing reactivates quiescent foci of tuberculosis infection.<sup>86</sup>

One of the most difficult problems in the interaction of tuberculosis and pregnancy is deciding whether a pregnant woman with *M. tuberculosis* infection should receive immediate treatment or whether the treatment should be postponed until after the child is delivered.<sup>87</sup> Not all infected individuals have the same chance of developing tuberculosis during a short period of time. Individuals who were infected remotely (more than 2 years previously) have a low chance of developing tuberculosis during a given 9-month period. Individuals who have been infected more recently, however, particularly if their infection is discovered during a contact investigation of an adult with active tuberculosis, are at much higher risk; about half of the lifetime risk of progression of infection to disease occurs during the first 1 to 2 years after infection. Other vulnerable adults, particularly those co-infected with HIV, also are at greatly increased risk of having progression of infection to disease. In general, treatment for tuberculosis infection should be initiated during pregnancy if the woman likely has been infected recently (especially in the setting of a contact investigation of a recently diagnosed case) or if she is at increased risk of rapid development of tuberculosis. Although isoniazid (INH) is not thought to be teratogenic, some experts recommend waiting until the second trimester of pregnancy to begin treatment. Unfortunately, patient adherence to INH treatment for tuberculosis infection appears to be very low if the initiation of treatment is delayed until after the child is delivered. The reason for this low adherence is not clear, but several problems include the perception of nonimportance because a treatment delay of many months is allowed, transfer of care from one segment of the health care system to another, and, perhaps, the lack of reinforcement by health care professionals concerning the importance of the treatment. Although screening and treatment of high-risk pregnant women may seem to be an effective strategy to prevent future cases of tuberculosis, it has not yet been demonstrated that this strategy is successful in the U.S. health care system.<sup>88</sup>

Routine chest radiography is not advisable as a screening tool for pregnant women because the prevalence of tuberculosis remains fairly low.<sup>89,90</sup> With appropriate shielding, however, pregnant women with positive tuberculin skin test results should have chest radiographs to rule out tuberculosis.<sup>91</sup> In addition, a thorough review of systems and physical examination should be carried out to exclude extrapulmonary tuberculosis.

## CONGENITAL TUBERCULOSIS

### Tuberculosis in the Mother

In general, the clinical manifestations of tuberculosis in the pregnant woman are the same as those in nonpregnant individuals. The most important determinants of the clinical presentation are the extent and anatomic location of disease. In one series of 27 pregnant and postpartum women with pulmonary tuberculosis, the most common clinical findings were cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%).<sup>27</sup> Almost 20% of

patients had no significant symptoms; other studies also have found less significant symptoms in pregnant women with tuberculosis.<sup>26</sup> The tuberculin skin test result was positive in 26 of 27 patients. The diagnosis was established in all cases by culture of sputum for *M. tuberculosis*. Sixteen of the patients in this series had drug-resistant tuberculosis; their clinical course was marked by more extensive pulmonary involvement, a higher incidence of pulmonary complications, longer sputum conversion times, and a higher incidence of death. In other series, 5% to 10% of pregnant women with tuberculosis have had extrapulmonary disease, a rate comparable with nonpregnant women of the same age.<sup>26</sup>

Although the female genital tract may be the portal of entry for a primary tuberculosis infection, more often infection at this site originates by continuity from an adjacent focus of disease or by blood-borne seeding of the fallopian tubes.<sup>51</sup> Progression of disease usually is by descent in the genital tract. Mucosal ulceration within the fallopian tube develops, and pelvic adhesions occur frequently. Many patients are asymptomatic. The most common complaints are sterility and menstrual irregularity with menorrhagia or amenorrhea. These findings greatly diminish the likelihood of congenital tuberculosis. Other less frequent signs and symptoms include lower abdominal pain and tenderness, weight loss, fever, and night sweats. Diagnosis in the nonpregnant woman is usually established by culture and histologic examination of tissue recovered after uterine curettage. The highest recovery rates of *M. tuberculosis* are obtained from scrapings obtained just before or during menstruation.

Tuberculosis mastitis is very rare in the United States but occurs almost exclusively in childbearing-aged women.<sup>92-94</sup> The most common finding is a single breast mass, with or without a draining sinus. Nipple retraction and peau d'orange skin changes suggestive of carcinoma also may be present. The ipsilateral axillary lymph nodes usually are enlarged. Diagnosis is confirmed by biopsy of the mass or axillary node and culture of the tissue for *M. tuberculosis*. Transmission of *M. tuberculosis* to the infant through breast milk is exceedingly rare, if it occurs at all.

### In Utero Routes of Transmission

Tuberculosis in the neonate can be either truly congenital (i.e., acquired in utero) or truly neonatal (i.e., acquired early in life from the mother, contagious members of the family, family friends, or caretakers). Each of these two kinds of perinatal tuberculosis may be subdivided. *Congenital tuberculosis* can be acquired in any one of three ways: (1) from the infected placenta via the umbilical vein, (2) by inhalation of infected amniotic fluid, and (3) by ingestion of infected amniotic fluid. *Neonatal tuberculosis* can be acquired in four different ways: (1) by inhalation of infected droplets, (2) by ingestion of infected droplets, (3) by ingestion of infected milk (theoretical), and (4) by contamination of traumatized skin or mucous membranes.

It is not always possible to be sure of the route of infection in a particular neonate, and, with effective chemotherapy at hand, it is not essential for the care of the infant. However, it is important to try to identify the source of infection so that the person infecting the infant can be treated and further transmission can be prevented.<sup>95</sup>

**Table 19-1 Modes of Inoculation of the Fetus or Newborn with *Mycobacterium tuberculosis***

Maternal Focus	Mode of Spread
Placentitis	Hematogenous (umbilical vessel)
Amniotic fluid	Aspiration
Cervicitis	Direct contact
Pneumonitis	Airborne (postnatal)

The potential modes of inoculation of the fetus or newborn infant with *M. tuberculosis* from the mother are shown in Table 19-1.<sup>96</sup> Infection of the fetus through the umbilical cord has been rare, with fewer than 350 cases reported in the English-language literature.<sup>97</sup> These infants' mothers frequently suffer from tuberculous pleural effusion, meningitis, or disseminated disease during pregnancy or soon after.<sup>39,42,44,47,98</sup> In some series of congenital tuberculosis, however, fewer than 50% of the mothers were known to be suffering from tuberculosis at the time of delivery and beginning of symptoms in the newborn.<sup>99,100</sup> In most of these cases, diagnosis of the child led to the discovery of the mother's tuberculosis. The intensity of lymphohematogenous spread during pregnancy is one of the factors that determines whether congenital tuberculosis will occur. Hematogenous dissemination in the mother leads to infection of the placenta with subsequent transmission of organisms to the fetus. *M. tuberculosis* has been demonstrated in the decidua, amnion, and chorionic villi of the placenta. The organisms also have been shown to reach the placenta through direct extension from a tuberculous salpingeal tube. Even massive involvement of the placenta with tuberculosis, however, does not always give rise to congenital tuberculosis.<sup>101</sup> It is not clear whether the fetus can be infected directly from the mother's bloodstream without a caseous lesion forming first in the placenta, although this phenomenon has been demonstrated in experimental animal models.<sup>102</sup>

In hematogenous congenital tuberculosis, the organisms reach the fetus through the umbilical vein. If bacilli infect the liver, a primary focus develops with involvement of the periportal lymph nodes. The bacilli can pass through the liver, however, into the main circulation through the patent foramen ovale. Alternately, they can pass through the right ventricle into the pulmonary circulation, leading to a primary focus in the lung. The organisms in the lung often remain dormant until after birth when oxygenation and circulation increase significantly, leading to the growth of organisms and pulmonary tuberculosis in the young infant. In many children with congenital tuberculosis, multiple lesions occur throughout the body; it is not possible to determine whether they represent multiple primary foci or some occur secondary to primary lesions in the lung or liver. The only lesion of the neonate that is unquestionably associated with congenital infection is a primary complex in the liver.

Congenital infection of the infant also can occur through aspiration or ingestion of infected amniotic fluid.<sup>103</sup> If the caseous lesion in the placenta ruptures directly into the amniotic cavity, the fetus can inhale or ingest the bacilli. Inhalation or ingestion of infected amniotic fluid is the most

likely cause of congenital tuberculosis if the infant has multiple primary foci in the lung, gut, or middle ear.<sup>104</sup> In congenital tuberculosis caused by aspiration, the primary complex can be in the liver, the lung, or both organs.

The pathology of congenital tuberculosis in the fetus and newborn usually demonstrates the predisposition to dissemination ensured by the modes of transmission, particularly through the umbilical vein. The liver and lungs are the primary affected organs, with bone marrow, bone, gastrointestinal tract, adrenal glands, spleen, kidneys, abdominal lymph nodes, and skin also frequently affected.<sup>105,106</sup> The histologic patterns of involvement are similar to those in adults; tubercles and granulomas are common. Central nervous system involvement occurs in fewer than 50% of cases.<sup>99,106</sup> In most recent series, the mortality rate of congenital tuberculosis has been close to 50%, primarily because of the failure to suspect the correct diagnosis. Most fatal cases are diagnosed at autopsy.<sup>99,100</sup>

Postnatal acquisition of *M. tuberculosis* through airborne inoculation is the most common route of infection of the neonate.<sup>107-109</sup> It may be impossible to differentiate postnatal infection from prenatal acquisition on clinical grounds alone.<sup>110</sup> Any adult in the neonate's environment can be a source of airborne tuberculosis, including health care workers.<sup>111,112</sup> Up to 40% of infants with untreated *M. tuberculosis* infection develop tuberculosis disease within 1 to 2 years. There are few data concerning the time of onset of tuberculosis when the infection is acquired at or shortly after birth. In one series of 48 infants exposed postnatally to mothers with pulmonary tuberculosis in the pretreatment era, 21 became infected; of those who became ill, signs such as fever, tachypnea, weight loss, and hepatosplenomegaly developed in 4 to 8 weeks.<sup>113</sup> Because newborns infected with the organism are at extremely high risk for developing severe forms of disease, investigation of an adult with tuberculosis whose household contacts include a pregnant woman or newborn should be considered a public health emergency. In addition, all adults in contact with an infant suspected of having *M. tuberculosis* infection or disease should undergo a thorough investigation for disease.

The skin and mucous membranes are rare portals of entry for *M. tuberculosis* in neonates. Infection through the skin has been mentioned several times in association with lesions of the head and face, very likely related to minor traumatic lesions being infected by kissing. Primary lesions of the mucous membranes of the mouth also have been recognized, although usually in infants beyond the newborn period. In both of these situations, the primary lesion was insignificant, but the enlarged regional lymph nodes called attention to the problem.

A previously well-known form of skin and mucous membrane infection was tuberculosis of the male genitalia after circumcision, in the years when it was customary for the individual performing the circumcision to suck the blood around the incision. This procedure was obviously dangerous if that individual happened to have bacilli in the sputum. The primary focus of inoculation on the penis was often inconspicuous, but within 1 to 4 weeks, ulceration, suppuration, and bilateral inguinal lymphadenopathy would develop. At first firm and nontender, the nodes might later break down with sinus formation to the exterior. Holt,<sup>114</sup> in his review of circumcision tuberculosis, described a case with

extensive ulceration of the penis and scrotum, greatly swollen lymph nodes, a generalized rash resembling varicella, hepatosplenomegaly, fever, cough, rales, and a positive tuberculin test result, with recovery of tubercle bacilli from sputum and penile discharge. Of the 41 patients described by Holt, 16 died and 6 recovered, with the outcome of the others unknown.<sup>114</sup>

### Criteria for Diagnosis of Congenital Tuberculosis

In 1935, Beitzke<sup>115</sup> suggested criteria for diagnosis of congenital tuberculosis in a thoughtful, detailed, and often-quoted review of the reported cases up to that time:

1. Tuberculosis in the child must be firmly established;
2. A primary complex in the liver is proof of congenital tuberculosis because this complex could arise only through perfusion of the liver with tubercle bacilli contained in umbilical cord blood;
3. If a primary complex is lacking in the liver, then tuberculosis can be considered to be congenital only if tuberculous lesions are present in a fetus or in a newborn only a few days old; or in an older infant, extra-uterine infection can be excluded with certainty, that is, if the child was removed from the tuberculous mother at birth to a tuberculosis-free environment.

A study by Cantwell and co-workers,<sup>97</sup> based on a review of cases of congenital tuberculosis published before and after 1980, proposed the following modification of Beitzke's criteria: the infant must have proven tuberculous lesions and at least one of the following: (1) lesions in the first week of life; (2) a primary hepatic complex or caseating hepatic granulomas; (3) tuberculosis infection of the placenta or maternal genital tract, or both; or (4) exclusion of postnatal transmission by a thorough contact investigation. Although Beitzke's criteria are in fact fully met by many of the 350 or so reported cases of congenital tuberculosis, in other cases it is impossible to be certain whether infection was transmitted in utero or was acquired during the early days or weeks of life. In many cases of true congenital tuberculosis, the mother was not known to be suffering from active tuberculosis. Two articles contain tables with detailed information on 26 cases and 15 cases.<sup>99,100</sup> In only 10 of the 26 cases was tuberculosis diagnosed in the mother ante partum, although it became apparent in another 15 after diagnosis in the infant.<sup>99</sup> Five of the 26 mothers died of tuberculosis, an indirect confirmation of the fact that the diagnosis was made very late. In the series of 15 cases, 7 mothers were thought to be well at the time of delivery, but all 15 were subsequently found either to have had pleural effusion antepartum (four cases) or to have developed endometrial, miliary, or meningeal tuberculosis post partum.<sup>100</sup>

### Clinical Features and Diagnosis of Congenital Tuberculosis

The clinical manifestations of tuberculosis in the fetus and newborn vary in relation to the site and size of the caseous lesions. Symptoms may be present at birth but more commonly begin by the second or third week of life. The most frequent signs or symptoms of true congenital tuberculosis

**Table 19-2 Most Frequent Signs and Symptoms of Congenital Tuberculosis**

Symptom or Sign	Frequency (%)
Hepatosplenomegaly	76
Respiratory distress	72
Fever	48
Lymphadenopathy	38
Abdominal distention	24
Lethargy or irritability	21
Ear discharge	17
Papular skin lesions	14
Vomiting, apnea, cyanosis, jaundice, seizures, petechiae	<10 each

**Figure 19-2** Chest radiograph of a 1-month-old infant with congenital tuberculosis.

are listed in Table 19-2.<sup>97,99,116-147</sup> Most infants have an abnormal chest radiograph result, with about half having a miliary pattern.<sup>148</sup> Some infants with a normal chest radiograph result early in the course develop profound radiographic abnormalities as the disease progresses (Fig. 19-2). The most common abnormalities are adenopathy and parenchymal infiltrates. Occasionally, the pulmonary involvement progresses very rapidly, leading to cavitation.<sup>149,150</sup> Tuberculosis of the middle ear in children with congenital tuberculosis has been described fairly often.<sup>99,108,149,151-154</sup> The eustachian tube in newborns permits ready access to infected pharyngeal fluids or vomitus. Multiple perforation or total destruction of the tympanic membrane, otorrhea, enlarged cervical lymph nodes, and facial paralysis are all possible sequelae.

Table 19-3 Antituberculosis Drugs in Children

Drugs	Dosage Forms	Daily Dose (mg/kg)	Twice-Weekly Dose (mg/kg/per dose)	Maximum Dose
Isoniazid	Scored tablets: 100 mg 300 mg Syrup: 10 mg/ml	10-15	20-40	Daily: 300 mg Twice weekly: 900 mg
Rifampin	Capsules: 150 mg 300 mg Syrup: formulated in syrup from capsules	10-20	10-20	600 mg
Pyrazinamide	Scored tablets: 500 mg	20-40	50-70	2 g
Streptomycin	Vials: 1 g, 4 g	20-40 (IM)	20-40 (IM)	1 g
Ethambutol	Scored tablets: 100 mg 400 mg	15-25	50	2.5 g

The clinical presentation of tuberculosis in the newborn is similar to that caused by bacterial sepsis<sup>139-141</sup> and congenital infections with syphilis and cytomegalovirus.<sup>9</sup> Abnormalities of liver function are common.<sup>142,144</sup> The diagnosis of congenital tuberculosis should be suspected in any infant with signs and symptoms of sepsis or viral infection who does not respond to vigorous antibiotic therapy and whose evaluation for other congenital infections is unrevealing. Of course, suspicion also should be high if the mother has or has had tuberculosis or if she is in a high-risk group for tuberculosis. The importance of obtaining an adequate history for the presence of risk factors for tuberculosis in the mother cannot be overemphasized. Suspicion should increase if the mother has suffered from unexplained pneumonia, bronchitis, pleural effusion, meningeal disease, or endometritis during, shortly before, or even after pregnancy. Evaluation of both parents and other family members can yield important clues about the presence of tuberculosis within the family.

The timely diagnosis of congenital or neonatal tuberculosis is often difficult.<sup>95,155,156</sup> Whenever possible, the placenta should be examined and cultured for *M. tuberculosis*. The tuberculin skin test result is always negative initially, although it may become positive after 1 to 3 months of treatment. The diagnosis must be established by finding acid-fast bacilli in body fluids or tissue or by culturing *M. tuberculosis*. A positive acid-fast bacilli smear of an early morning gastric aspirate obtained from a newborn should be considered indicative of tuberculosis, although false-positive results can occur.<sup>8</sup> Direct acid-fast bacilli smears from middle-ear fluid, bone marrow, tracheal aspirate, or biopsy tissue can be useful and should be obtained more often.<sup>144,157</sup> Hageman and colleagues<sup>99</sup> found positive cultures for *M. tuberculosis* in 10 of 12 gastric aspirates, three of three liver biopsies, three of three lymph node biopsies, and two of four bone marrow aspirations from children with congenital tuberculosis. Open-lung biopsy also has been used to establish the diagnosis.<sup>158</sup> The cerebrospinal fluid should be examined and cultured, although the yield for isolating *M. tuberculosis* is less than 20% and meningitis occurs in only one third of cases of congenital tuberculosis.

## TREATMENT OF TUBERCULOSIS

The drugs used most commonly to treat *M. tuberculosis* infection and disease, their dosage forms, and doses are listed in Table 19-3.<sup>159</sup> Detailed discussion of the pharmacokinetics of each drug is beyond the scope of this chapter. No published study has examined in detail the pharmacokinetics of drugs used as antituberculosis agents in premature or term neonates.<sup>160</sup>

INH is the mainstay of treatment for tuberculosis infection and disease in infants, children, and adults. It is inexpensive, highly effective in preventing the multiplication of tubercle bacilli, of low molecular weight and therefore readily diffusible to all tissues in the body, and relatively nontoxic to children. It can be administered orally or intramuscularly. When it is taken orally, high plasma, sputum, and cerebrospinal fluid levels are reached within a few hours and persist for at least 6 to 8 hours. Because of the slow multiplication of *M. tuberculosis*, the total daily dose can be given at one time. The principal toxic effects of INH are peripheral neuritis and hepatitis. Peripheral neuritis, resulting from competitive inhibition of pyridoxine, is almost unknown in North American children because both cow's milk (or formula) and meat are the main dietary sources of pyridoxine. In some well-nourished children, serum pyridoxine concentrations are mildly depressed by INH, but clinical signs are not apparent. For most children, therefore, it is not necessary to use supplementary pyridoxine. However, in pregnancy, in teenagers whose diets may be inadequate, in children from ethnic groups with a low milk and meat intake, and in breast-fed babies, pyridoxine supplementation (25 to 50 mg/day) is important.

Hepatotoxicity from INH, rare in children, increases in frequency with age. Monitoring serum aspartate aminotransferase and serum alanine aminotransferase sometimes reveals transient increases during treatment with INH, but the levels usually return to normal spontaneously without interruption of treatment. Liver enzyme abnormalities in adolescents receiving INH likewise are rather common and usually disappear spontaneously, but severe hepatitis can

occur. Although neonates usually tolerate INH well, some experts recommend routine biochemical monitoring in the first several months of therapy. The usual dosage of INH in children is 10 to 20 mg/kg per day, to a maximum of 300 mg per day. INH is available in tablets of 100 and 300 mg. A syrup of INH in sorbitol (10 mg/mL) appears to be satisfactory; however, it is unstable at room temperature and should be kept cool. Many children develop significant gastrointestinal intolerance (nausea, vomiting) while taking the INH suspension, but neonates and infants tolerate the lower required volume of suspension well. If tablets are used, they are easily crushed in a dessert spoon and given with some soft food such as applesauce, mashed banana, thawed undiluted frozen orange juice, or another palatable medium. The crushed tablets should not be added to the nursing bottle or offered in milk or water because they will be ingested only partially.

Rifampin (RIF) is a semisynthetic drug derived from *Streptomyces mediterranei*. The drug is absorbed readily from the gastrointestinal tract in the fasting state. Excretion mainly is through the biliary tract; however, effective levels are achieved in the kidneys and urine. In many patients receiving RIF treatment, the tears, saliva, urine, and stool turn orange as a result of a harmless metabolite, and the patient and parents always must be warned of this in advance. RIF can be made into a suspension easily for use in children. RIF is very well tolerated by neonates and infants. The incidences of hepatitis, leukopenia, and thrombocytopenia are extremely low. RIF should be used alone only when treating *M. tuberculosis* infection due to an INH-resistant organism. If one uses INH, 20 mg/kg, and RIF, 15 to 20 mg/kg, there is an appreciable incidence of hepatotoxicity. Therefore, when using the two together, one would be wise to approximate INH, 10 mg/kg, and RIF, 15 to 20 mg/kg.

Pyrazinamide (PZA) contributes to the killing of *M. tuberculosis*, particularly at a low pH such as that within macrophages. The exact mechanism of action of PZA is a subject of controversy. PZA has no effect on extracellular tubercle bacilli in vitro but clearly contributes to the killing of intracellular bacilli. Primary resistance is very rare, except that *Mycobacterium bovis* is resistant. The drug diffuses readily into all areas, including the cerebrospinal fluid. The usual adult daily dose is 20 to 40 mg/kg. The optimal dose for infants and children has not been established firmly because no formal pharmacokinetic studies have been reported. The adult dose is tolerated well by infants and children, results in high cerebrospinal fluid concentrations, and clearly is effective in therapy trials for active tuberculosis in children. PZA appears to exert its maximum effect during the first 2 months of therapy. Hepatotoxicity can occur at high doses but is rare at the usual dose. PZA routinely causes an increase in the serum uric acid concentration by inhibiting its excretion through the kidneys. Toxic reactions in adults include flushing, cutaneous hypersensitivity, arthralgia, and overt gout; however, the considerable experience with this drug in children in Latin American countries, Hong Kong, and the United States has revealed few problems.

Ethambutol (EMB) has been used for many years as a companion drug for INH in adults. The usual oral dose is 15 mg/kg per day. At this dose, the drug primarily is bacteriostatic, its major role being to prevent emergence of resistance to other drugs. However, at doses of 25 mg/kg per

day or 50 mg/kg given twice a week, EMB has some bactericidal action. Unfortunately, at these higher doses, optic neuritis or red-green color blindness has occurred in some adults. Although the incidence of ophthalmologic toxicity in children is extremely low, if it occurs at all, EMB is not recommended for routine use in young children in whom visual field and color discrimination tests are difficult and inaccurate. However, it is used frequently and safely in children with life-threatening forms of tuberculosis or with drug-resistant tuberculosis.

Streptomycin (STM) is a valuable drug to be used in conjunction with INH and RIF in life-threatening forms of tuberculosis. It is bactericidal and tolerated well by children in the usual dose of 20 to 40 mg/kg per day intramuscularly up to 1 g. Usually, STM can be discontinued within 1 to 3 months if clinical improvement is definite.

## General Principles

The tubercle bacillus can be killed only during replication, which occurs among organisms that are active metabolically. In one model, bacilli in a host exist in different populations.<sup>5</sup> They are active metabolically and replicate freely when oxygen tension is high and the pH is neutral or alkaline. Environmental conditions for growth are best within cavities, leading to a large bacterial population. Older children with pulmonary tuberculosis and patients of all ages with only extrapulmonary tuberculosis are infected with a much smaller number of tubercle bacilli because the cavitory population is not present. However, neonates with congenital tuberculosis tend to have a large burden of organisms at diagnosis.

Naturally occurring drug-resistant mutant organisms occur within large populations of tubercle bacilli even before chemotherapy is started. All known genetic loci for drug resistance in *M. tuberculosis* are located on the chromosome; no plasmid-mediated resistance is known. The rate of resistance within populations of organisms is related to the rate of mutations at these loci. Although a large population of bacilli as a whole may be considered drug susceptible, a subpopulation of drug-resistant organisms occurs at a fairly predictable rate. The mean frequency of these drug-resistant mutations is about  $10^{-6}$  but varies among drugs: STM,  $10^{-5}$ ; INH,  $10^{-6}$ ; and RIF,  $10^{-7}$ . A cavity containing  $10^9$  tubercle bacilli has thousands of single drug-resistant mutant organisms, whereas a closed caseous lesion contains few, if any, resistant mutants.

The population size of tubercle bacilli within a patient determines the appropriate therapy. For patients with a large bacterial population (adults with cavities or extensive infiltrates), many single drug-resistant mutants are present and at least two antituberculosis drugs must be used. Conversely, for patients with *M. tuberculosis* infection but no disease, the bacterial population is very small (about  $10^3$  to  $10^4$  organisms), drug-resistant mutants are rare, and a single drug can be used. Older children with pulmonary tuberculosis and patients of all ages with extrapulmonary tuberculosis have medium-sized populations in which drug-resistant mutants may or may not be present. In general, these patients should be treated with at least two drugs. Neonates and infants with tuberculosis disease have large mycobacterial populations, and several drugs are required to effect a cure.

## Pregnant Women

The only drug with well-documented efficacy against *M. tuberculosis* infection in pregnant women is INH. Infants and children tolerate INH very well, and adverse reactions are rare. However, adverse reactions are more common in adults. Between 5% and 10% of young adults taking INH have an asymptomatic increase in serum liver transaminase levels; 1% to 2% suffer from symptomatic hepatitis, which is reversible if the medication is stopped immediately. For most young adults, monitoring for hepatitis is done clinically. Routine or periodic evaluation of serum liver enzyme tests is reserved for adults with underlying liver disease or those taking other potentially hepatotoxic drugs. However, some experts think that all pregnant women taking INH should have routine biochemical monitoring for hepatitis. Serum liver enzyme elevations of three to four times normal are common and do not necessitate discontinuation of the drug. There is no evidence that giving INH to a pregnant woman adversely affects the liver of the fetus. The other important adverse reaction of INH is peripheral neuritis caused by inhibition of pyridoxine metabolism. Pyridoxine should be given to pregnant adolescents or women and breast-feeding infants because breast milk has low concentrations of pyridoxine, even if the mother is receiving vitamin supplements.<sup>161</sup>

The current recommendation of the Centers for Disease Control and Prevention is to treat adults and children infected with *M. tuberculosis* with INH for 9 months.<sup>76</sup> Usually, the medication is taken daily under self-supervision. If poor patient adherence is likely and resources are available, INH can be given twice weekly using directly observed therapy.<sup>162</sup> Directly observed therapy requires that a health care worker, often from the local health department, observe the patient take antituberculosis medications. In general, directly observed therapy should be used for all patients with tuberculosis disease because of the difficulty in predicting patient adherence and the consequences of poor adherence (relapse and development of drug resistance). Directly observed therapy is often used for high-risk newborns with tuberculosis exposure or infants with *M. tuberculosis* infection.

For patients who cannot take INH for treatment of *M. tuberculosis* infection either because of side effects of the medication or because they are infected with an INH-resistant but RIF-susceptible strain of *M. tuberculosis*, the treatment of choice for *M. tuberculosis* infection is RIF, which also can be given daily or twice a week under directly observed therapy.<sup>163</sup> If the mother is known to be infected with a strain of tuberculosis that is resistant to both INH and RIF (multidrug-resistant tuberculosis), an expert should be consulted for the management of the mother and the child after delivery.<sup>164</sup>

Although treatment of a woman with active tuberculosis during pregnancy is unquestioned, treatment of a pregnant woman who has an asymptomatic *M. tuberculosis* infection is more controversial. Some clinicians prefer to delay therapy until after delivery, because pregnancy does not seem to increase the risk of developing active tuberculosis. Others believe that because recent infection can be accompanied by hematogenous spread to the placenta, it is preferable to treat without delay or to wait until the second trimester to start chemotherapy. A report by Franks and colleagues<sup>165</sup> suggests

that the risk of INH-associated hepatitis and death is higher in women than in men and that women in the postpartum period are slightly more vulnerable to INH hepatotoxicity. These investigators suggest that it might be prudent to avoid INH during the postpartum period or at least to monitor postpartum women taking INH with frequent examinations and laboratory studies. The possible increased risk of INH hepatotoxicity must be weighed against the risk of developing active tuberculosis as well as the consequences to both mother and infant should active tuberculosis develop.

The indications for treatment and the basic principles of management for the pregnant woman with tuberculosis disease are no different from those for the nonpregnant patient. The recommendations for which drugs to use and how long to give them are slightly different, however, mostly because of possible effects of several of the drugs on the developing fetus.

The currently recommended treatment for drug-susceptible pulmonary tuberculosis in the United States in nonpregnant individuals is 6 months of INH and RIF, supplemented during the first 2 months with PZA and either EMB or STM.<sup>159,166</sup> With any of the regimens, the drugs usually are given every day for the first 2 weeks to 2 months; then they can be given daily or twice a week (under directly observed therapy) for the remainder of therapy with equal effectiveness and rates of adverse reactions.<sup>167</sup>

There is no doubt that untreated tuberculosis represents a far greater risk to a woman and her fetus than does appropriate treatment of the disease.<sup>68,168-172</sup> Extensive experience with the use of INH in pregnancy has been reported. Even though it crosses the placenta, it is not teratogenic even when given during the first 4 months of gestation.<sup>173</sup> EMB also appears to be safe during pregnancy. In 650 cases in which pregnant women were treated with EMB, no evidence of fetal malformations, including eye abnormalities, was found.<sup>86,174-176</sup> The action of RIF to inhibit DNA-dependent RNA polymerase combined with its ability to cross the placental barrier has created some concern about its use in pregnancy.<sup>177</sup> Only 3% of 446 fetuses exposed in utero to RIF had abnormalities, however, compared with 2% for EMB and 1% for INH.<sup>86</sup> The noted abnormalities included limb reductions, central nervous system abnormalities, and hypoprothrombinemia. Hemorrhagic disease of the newborn also has been described after the use of RIF in the mother. The incidence of abnormalities in fetuses not exposed to anti-tuberculosis medications ranges from 1% to 6%. In general, the powerful antituberculosis effect of RIF outweighs concern about its effect on the fetus. Nonpregnant women receiving RIF should receive contraception counseling because receiving RIF can impair the efficacy of oral contraceptives, leading to unintended pregnancy in a tuberculous woman.<sup>178</sup>

Several antituberculosis drugs generally are not used in pregnant women because of possibly toxicity to the fetus.<sup>179-182</sup> STM has variable passage across the placental barrier. Its use in pregnancy is now limited by the availability of better drugs and its effect on the fetus.<sup>181-184</sup> In a review of 206 infants exposed in utero to STM, 34 (17%) had significant eighth nerve damage, the abnormalities ranging from mild vestibular damage to profound bilateral deafness.<sup>86</sup> The deleterious effects of STM are independent of the critical periods earlier in embryogenesis, and it is potentially hazardous throughout gestation. It is assumed that capreomycin,

kanamycin, and amikacin, other aminoglycosides with anti-tuberculosis activity, could have the same toxic potential as STM. Little is known about the specific effects of PZA on the fetus. Although there are no data, an increasing number of experts are using PZA during pregnancy with no reported adverse reactions. Nonspecific teratogenic effects have been attributed to ethionamide.<sup>185</sup> The central nervous system effects of cycloserine and the gastrointestinal effects of para-aminosalicylic acid in adults make their use in pregnancy undesirable.

The currently recommended initial treatment of drug-susceptible tuberculosis disease in pregnancy is INH and RIF daily, with the addition of EMB initially, under directly observed therapy.<sup>186,187</sup> Pyridoxine (50 mg daily) always should be given with INH during pregnancy because of the increased requirements for this vitamin in pregnant women. After drug susceptibility testing of the isolate of *M. tuberculosis* reveals it to be susceptible to both INH and RIF, the EMB can be discontinued. If PZA is not used in the initial regimen, INH and RIF must be given for 9 months instead of 6 months. After the first 2 weeks to 2 months of daily treatment, the drugs can be given twice a week under directly observed therapy, which is the preferred method of treatment by most experts. The treatment of any form of drug-resistant tuberculosis during pregnancy is extraordinarily difficult and should be handled by an expert with great experience with the disease.<sup>188,189</sup>

Because treatment of tuberculosis in pregnant women often continues after delivery, there is concern as to whether it is safe for the mother to breast-feed her infant. Snider and Powell<sup>190</sup> concluded that a breast-feeding infant would have serum levels of no more than 20% of the usual therapeutic levels of INH for infants and less than 11% of other antituberculosis drugs. Potential toxic effects of drugs delivered in breast milk have not been reported. Because pyridoxine deficiency in the neonate can cause seizures, however, and because breast milk has relatively low levels of pyridoxine, infants who are taking INH or whose breast-feeding mothers are taking INH should receive supplemental pyridoxine.<sup>191</sup>

### Neonates and Infants

The optimal treatment of congenital tuberculosis has not been established, because the rarity of this condition precludes formal treatment trials. It would appear that the basic principles for treatment of other diseases in children and adults also apply to the treatment of congenital tuberculosis.<sup>159,167,192</sup> All children with suspected congenital tuberculosis should be started on four antituberculosis medications (INH, RIF, PZA, plus either EMB or STM) until the diagnostic evaluation and susceptibility testing of isolated organisms is concluded. Although the optimal duration of therapy has not been established, many experts treat infants with congenital or postnatally acquired tuberculosis for a total duration of 9 to 12 months because of the decreased immunologic capability of the young infant. INH given alone is known to be safe in neonates, including premature infants. There are no comparable data for INH given in combination with other drugs or for other drugs alone.

Several studies have shown that RIF can be given safely to premature infants for indications other than tuberculosis. In addition, anecdotal information supports the notion that PZA, STM, and kanamycin are safe in neonates. Young infants taking these drugs should have biochemical monitoring of serum liver enzymes and uric acid (for PZA) performed on a regular basis. Although the pharmacokinetics of anti-tuberculosis drugs in the neonate are essentially unknown, extensive clinical experience suggests that the doses listed in Table 19-3 are effective and safe. All neonates and infants with tuberculosis should be treated by directly observed therapy.

### Following the Infant on Therapy

Follow-up of children treated with antituberculosis drugs has become somewhat more streamlined in recent years. While receiving chemotherapy, the patients should be seen monthly, both to encourage regular taking of the prescribed drugs and to check, by a few simple questions (concerning appetite, well-being) and a few observations (weight gain; appearance of skin and sclerae; palpation of liver, spleen, and lymph nodes), that the disease is not spreading and that toxic effects of the drugs are not appearing. Repeat chest radiographs probably should be obtained 1 to 2 months after the onset of chemotherapy to ascertain the maximal extent of disease before chemotherapy takes effect; thereafter, radiographs rarely are necessary. Chemotherapy has been so successful that follow-up beyond its termination is not usually necessary, except for children with serious disease, such as congenital tuberculosis or meningitis, or those with extensive residual chest radiographic findings at the end of chemotherapy.

Every case of definite or suspected tuberculosis must, by law, be reported immediately by telephone to the health department to ensure (1) prompt contact investigation<sup>193-199</sup> and (2) free antituberculosis drugs, which are available for diagnosed cases and for intimate contacts in almost every state of the United States.

### Prognosis

The prognosis for congenital tuberculosis was dismal in the prechemotherapy era.<sup>200</sup> In Hughesdon's report,<sup>104</sup> 3 infants died on the first day of life, 8 between 18 and 30 days, 15 between 31 and 60 days, and 3 between 65 and 112 days. Hageman and associates<sup>99</sup> reviewed 26 patients born since the introduction of INH in 1952: 12 died, and 9 of these were untreated, the diagnosis being established only at autopsy. The results in survivors were good, but the follow-up was usually short.<sup>152,201</sup> The child reported by Nemir and O'Hare,<sup>100</sup> who was treated intensively with INH, STM, and aminosalicylic acid in the 1950s, recovered, was followed for 27 years, and is herself the mother of two tuberculin-negative children.

There is little question that today's multidrug, short-course chemotherapeutic regimens should be extremely effective in bringing the disease under rapid and permanent control, if it is due to drug-susceptible organisms. Experience with treatment of disease due to drug-resistant organisms is so limited as to preclude prognosis.

## VACCINATION AGAINST TUBERCULOSIS— BACILLE CALMETTE-GUÉRIN

Bacille Calmette-Guérin (BCG) vaccines are the oldest of the vaccines used throughout the world. They have been given to 4 billion people and have been used routinely since the 1960s in every country of the world except the United States and the Netherlands. However, despite their widespread use, tuberculosis remains among the most destructive infectious diseases in the world, indicating that the BCG vaccines alone will not be sufficient to eliminate or even control the disease.

### History and Development of Bacille Calmette-Guérin Vaccines

The BCG vaccines are attenuated strains of *M. bovis*. Starting in 1908, the original strain was subcultured every 3 weeks for 13 years.<sup>202</sup> The genotype changes that resulted at various stages cannot be determined because the original cultures and subcultures were not preserved. This long process was marked by a loss of virulence first for calves, then for guinea pigs. In 1948, despite the complete lack of reported controlled trials or case-control studies, the First International BCG Congress stated that the BCG vaccines were effective and safe. After World War II, the WHO and UNICEF organized campaigns to promote vaccination with BCG in several countries. The seed lot system for BCG was established in 1956,<sup>201</sup> and the WHO developed requirements for freeze-dried BCG in 1966.<sup>203</sup> By the end of 1974, more than 1.5 billion individuals had received a BCG vaccination. Since 1977, BCG vaccination has been included in the WHO Expanded Programme on Immunization. Approximately 100 million children receive a BCG vaccination each year, expanding the total number of individuals who have received it to more than 4 billion.

The original strain of *M. bovis* used to make BCG was maintained by serial passage at the Pasteur Institute until it was lost or discarded. It previously was distributed to dozens of laboratories, each of which produced and maintained its own BCG strain. It soon became apparent that the conditions for culture used in the various laboratories resulted in the production of many “daughter” BCG strains that differed widely in growth characteristics, biochemical activity, ability to induce delayed hypersensitivity, and animal virulence.<sup>204-207</sup> The patterns of large restriction fragments created by the digestion of BCG DNA vary among strains.<sup>208</sup> In the 1960s, the WHO recommended stabilization of the biologic characteristics of the derivative strains by lyophilization and storage at low temperatures.<sup>209</sup>

Interlaboratory studies and genomic evaluation have shown that the BCG strains in use today vary widely in many characteristics.<sup>210,211</sup> However, the possible consequences on vaccine efficacy and adverse effects are not known. When comparing the various published clinical trials and case-control series, it is difficult to demonstrate that one strain of BCG is superior to another in the protection of humans against tuberculosis. Some laboratory and clinical observations have suggested that BCG strains can be separated into “strong” (Pasteur 1173 P2, Danish 1331) and “weak” (Glaxo 1077, Tokyo 172) groups. Although the relative efficacy of these two groups has been inconsistent, the strong strains have been associated with a higher rate of adverse reactions

in neonates, including lymphadenitis and osteitis.<sup>212-215</sup> There is no consensus about which strain of BCG is optimal for general use. It has been postulated that investigators and public health authorities have selected BCG strains by their desire to maximize tuberculin reactivity and minimize adenitis, which may create strains that are the inverse of the ideal vaccine. It also appears that some BCG strains have lost efficacy over time.<sup>216</sup>

### Vaccine Preparation and Administration

Seed lots are lyophilized bacilli that are part of the original harvest of the various BCG strains. The bacilli usually are grown in Sauton medium and are harvested early (day 6 to 9) to ensure good survival of organisms after lyophilization. The mass of mycobacterial cells is filtered, pressed, homogenized, diluted, then freeze dried. Reconstituted vaccines contain both live bacilli and dead bacteria. Regulating the ratio of live to dead organisms is an important aspect of quality control, and can affect both efficacy and rates of adverse reactions.

Most BCG vaccine programs favor the intradermal route of administration using a syringe and needle. Japan and most of South Africa use percutaneous administration with a multipuncture device. It is generally accepted that the intradermal method is more accurate and consistent because the dose is measured precisely and the administration is controlled. The deltoid region of the arm is the most common injection site, although many other body sites are used in individual patients. More than 90% of patients receiving their first BCG vaccination develop a local reaction (erythema, induration, tenderness) followed by healing and scar formation within 3 months.

Other methods of administration were developed to try to address problems of local reactions created by intradermal administration. Subcutaneous injection appears to be effective but often produces retracted scars. Other techniques, such as scarification, jet injection, and use of bifurcated needles, have yielded highly variable and, in some cases, inadequate results.<sup>217</sup> There have been no conclusive reported trials that compared the various techniques of BCG administration for protection against tuberculosis, but local complication rates generally are lowest with the multipuncture devices.

### Adverse Reactions to Bacille Calmette-Guérin Vaccination

Local ulceration and regional lymphadenitis are the most common complications, occurring in less than 1% of immunocompetent recipients after intradermal administration of BCG.<sup>218,219</sup> These lesions usually occur within a few weeks to months after vaccination but can be delayed for months in immunocompetent persons and for years in immunocompromised hosts.<sup>220</sup> Axillary, cervical, or supraclavicular nodes may be involved on the ipsilateral side of vaccination. Outbreaks of lymphadenitis after BCG vaccination have followed the introduction of a new BCG strain into the vaccination program.<sup>221,222</sup> There is no evidence that children who experience local complications are more likely to have immune deficits or to have enhanced or diminished protection against tuberculosis.<sup>221,222</sup> Because the risk of lymphadenitis is significantly higher when newborns are

given a full dose of BCG, the WHO recommends using a reduced dose in children younger than 30 days of age.

The treatment of local adenitis as a complication of BCG vaccination is controversial, ranging from observation to surgical drainage to administration of antituberculosis chemotherapy to a combination of surgery and chemotherapy.<sup>223</sup> Nonsuppurative lymph nodes usually resolve spontaneously, although resolution may take several months.<sup>224,225</sup> The WHO recommends drainage and direct instillation of an anti-tuberculosis drug into the lesion for adherent or fistulated lymph nodes.<sup>226</sup> However, one study of 120 patients with BCG-induced lymphadenitis treated for 6 months with an oral antituberculosis drug showed that medical therapy was no better than observation and that the rate of spontaneous drainage of lymph nodes was higher among children who received isoniazid than among those who were only observed.<sup>227</sup> Most experts now agree that nonsuppurative adenitis associated with BCG vaccination should be managed by observation only.

Other complications of BCG vaccination are far less frequent. The mean risk of osteitis after BCG vaccination has varied from 0.01 per million in Japan to 300 per million in Finland.<sup>228-230</sup> As with lymphadenitis, osteitis rates occasionally have increased dramatically after introduction of a new vaccine strain into a vaccination program. Other very rare complications of BCG vaccination include lupus vulgaris, erythema nodosum, iritis, and osteomyelitis. In general, these complications should be treated with antituberculosis medications (except pyrazinamide, to which *M. bovis* is resistant).

Generalized BCG infection is extremely rare in immunocompetent hosts.<sup>231-233</sup> However, overall rates of fatal disseminated BCG disease in recently vaccinated persons have been reported at 0.19 to 1.56 cases per million vaccinated, most cases occurring in children with severe defects in cellular immunity, such as severe combined immunodeficiency, malnutrition, cancer, Di George syndrome, interferon- $\gamma$  receptor deficiency, or symptomatic HIV infection.<sup>218,234-240</sup> It is likely that the real incidence of disseminated BCG infection is higher, as some cases undoubtedly are misdiagnosed as disseminated tuberculosis. The exact safety of BCG vaccination in children and adults with HIV infection is unknown. Disseminated BCG infection has been described in an HIV-infected adult 30 years after he received BCG.<sup>241</sup> One French study showed that 9 of 68 HIV-infected children given BCG vaccine developed complications: 7 had large satellite adenitis and 2 developed disseminated lesions.<sup>242</sup> The WHO recommends giving BCG vaccination to asymptomatic HIV-infected infants who live in high-risk areas for tuberculosis. BCG vaccine is not recommended for symptomatic HIV-infected children, even if local tuberculosis case rates are high.

Despite the presence of live BCG organisms in ulcerated vaccination sites, person-to-person transmission of BCG has never been documented.

### Effect of Bacille Calmette-Guérin Vaccination on Tuberculin Skin Test Results

Although BCG vaccines have an effect on the result of the tuberculin skin test, the effect is variable, and no reliable method can distinguish tuberculin reactions caused by BCG vaccination from those caused by infection with *M. tuber-*

*culosis*. In various studies with different populations, the proportion of individuals who were vaccinated with BCG previously who have had significant skin test reactions has varied from 0% to 90%.<sup>243-247</sup> The size of the skin test reaction after BCG vaccination varies with the strain and dose of the vaccine,<sup>245,248</sup> the route of administration,<sup>247,249</sup> the age at vaccination,<sup>244,250</sup> the child's nutritional status, the time interval since vaccination,<sup>244,250</sup> and the frequency of skin testing.<sup>251</sup>

Several studies have demonstrated that when newborns are given a BCG vaccination, up to 50% have a negative tuberculin skin test reaction at 6 months of age and the vast majority have a negative reaction by 2 to 5 years of age.<sup>244,252</sup> However, interpretation of the skin test result in BCG-vaccinated children may be complicated by the booster phenomenon. The booster effect is the increase in reaction size caused by repetitive testing in a person sensitized to mycobacterial antigens.<sup>253</sup> Skin test reactions can be boosted in children who previously received a BCG vaccination, giving the false impression of "conversion" of a skin test from negative to positive, which usually indicates a new tuberculosis infection.<sup>254</sup>

Strong or severe reactions to a tuberculin skin test are rare in individuals who have been vaccinated with BCG previously who are *not* also infected with *M. tuberculosis*. Prior receipt of a BCG vaccine is never a contraindication for tuberculin skin testing. Most skin reactions due to BCG vaccination are less than 10 mm in size. In general, the tuberculin skin test should be interpreted in the same manner for an adult or child who has received a BCG vaccination as it is for a person with similar epidemiologic characteristics who has not received BCG.

### Effectiveness of the Bacille Calmette-Guérin Vaccines

A detailed discussion of the effectiveness of the BCG vaccines and the variables that may have an impact on effectiveness is beyond the scope of this chapter. There have been eight major controlled trials conducted in a variety of populations and many published case-control and cohort studies of various BCG preparations.<sup>255,256</sup> Investigators at the Harvard School of Health found 15 prospective trials and 12 case-control studies that met their criteria for adequacy in study design and controls against potential bias. In the prospective trials, the protective effect of BCG vaccines against tuberculosis disease was 51%.<sup>256</sup> Analysis of eight studies involving only vaccination of newborns revealed a protective effort of 55%.<sup>255</sup> For trials that measured these outcomes, BCG vaccines showed 71% protection against death from tuberculosis, 64% protection against tuberculosis meningitis, and 72% protection against disseminated tuberculosis. Different BCG preparations and strains used in the same population gave similar levels of protection, whereas genetically identical BCG strains gave different levels of protection in different populations.<sup>255,256</sup> The duration of any protective effect is poorly studied and unknown but probably short-lived (less than 10 years at best).

It appears that BCG vaccines have worked well in some circumstances but poorly in others. Because only a small percentage of infectious cases of tuberculosis in adults are prevented by childhood BCG vaccination, BCG vaccination

as currently practiced is not an effective instrument of disease control. The best use of BCG is the prevention of life-threatening forms of tuberculosis—meningitis and disseminated, severe pulmonary disease—in infants and young children.

### MANAGEMENT OF A NEONATE BORN TO A MOTHER WITH A POSITIVE TUBERCULIN SKIN TEST RESULT

If the mother is well and her chest radiograph result is normal, no separation of the mother and infant is required. Although the mother is a candidate for treatment of *M. tuberculosis* infection, the infant does not need special evaluation or therapy. Other family members should have a tuberculin skin test and further evaluation, if indicated. The local health department, however, often does not have the resources to do this testing, which should be performed by the treating physicians. It is not necessary to delay discharge of the infant from the newborn nursery pending the results of this family investigation. The need for further skin testing of the infant depends on whether disease is found in the family or cannot be excluded within the family's environment.

If the radiograph result is abnormal, the mother and child should be separated until the mother has been evaluated thoroughly. If active tuberculosis is present in the mother, she should be started on effective antituberculosis medications right away. Examination of the mother's sputum for acid-fast organisms always is necessary even if obtaining a sample requires vigorous measures. All other household members and frequent visitors should be investigated for *M. tuberculosis* infection and disease.

If the mother's chest radiograph result is abnormal but the history, physical examination, sputum smear, and evaluation of the radiograph reveal no evidence of active tuberculosis, it is reasonable to assume that the infant is at low risk for infection and that the radiographic abnormality is due to another cause or a quiescent focus of previous infection with *M. tuberculosis*. If the mother remains untreated, however, she may develop reactivation tuberculosis and subsequently expose her infant. The mother, if not previously treated, should receive appropriate therapy, and she and her infant should receive frequent follow-up care. In this situation, the infant does not need chemotherapy. All household members should be evaluated for tuberculosis by a clinician.

If the mother has clinical and radiographic evidence of active, possibly contagious, tuberculosis, the local health department should be informed immediately about the mother so that a contact investigation can be performed. The infant should be evaluated for congenital tuberculosis with a physical examination and high-quality posteroanterior and lateral chest radiographs. If possible, serologic testing for HIV should be performed on the mother and her infant. The mother and infant should be separated until the infant is receiving chemotherapy or the mother is judged to be noncontagious.<sup>257</sup> Prophylactic INH (10 mg/kg per day) for newborns born to mothers with tuberculosis has been so efficacious that separation of the mother and infant is no longer considered mandatory once therapy is started.<sup>258-260</sup> Separation should occur only if the mother is ill enough to require hospitalization, if she has been or is expected to

become nonadherent to her treatment, or if she is thought to be infected with a drug-resistant strain of *M. tuberculosis*. INH therapy should be continued in the infant at least until the mother has been shown to be culture negative for 3 months. At that time, a Mantoux tuberculin skin test is done on the child. If the result is positive, the infant should be investigated for the presence of tuberculosis with a physical examination and chest radiograph and further appropriate workup if disease is suggested. If disease is absent, the infant should continue INH for a total of 9 months. If the follow-up skin test result is negative and the mother or contact with tuberculosis has good adherence and response to treatment, INH may be discontinued in the infant. The infant needs close follow-up, and it is prudent to repeat a tuberculin skin test after 6 to 12 months.

If the mother or other family member with contagious tuberculosis has disease caused by a multidrug-resistant strain of *M. tuberculosis* or has poor adherence to treatment and better supervision of therapy for the adult and infant is not possible, the Centers for Disease Control and Prevention recommends that the infant be separated from the contagious adult and BCG vaccination be considered.<sup>261,262</sup> Vaccination with BCG appears to decrease the risk of tuberculosis in exposed infants, but the effect is variable.<sup>263,264</sup> Kendig<sup>265</sup> reported 117 infants born to mothers with active tuberculosis around the time of delivery; none of the 30 BCG-vaccinated infants developed tuberculosis, and 38 cases of tuberculosis and three deaths occurred among the 75 infants who received neither BCG vaccine nor INH therapy. However, 24 of the 30 infants who received BCG vaccine also were separated from their mother for at least 6 weeks; it is impossible to determine what degree of protection was conferred by this separation. Similar studies in England and Canada also describe the apparent efficacy of BCG given to neonates.<sup>266</sup> Usually, the child must be kept out of the household, away from the contagious case, until the skin test result becomes reactive (marking protection from infection). However, some infants who receive a BCG vaccination do not develop a reactive tuberculin skin test. It is unknown whether developing a reactive skin test correlates with protection. It is also unknown whether a second BCG vaccination given to a child who maintains a negative tuberculin skin test reaction after the first BCG vaccination will cause an enhanced level of protection. Although BCG vaccines have some protective effect for the exposed newborn, most experts in the United States feel that ensuring appropriate separation and taking whatever steps are necessary to provide adequate chemotherapy for the child and the contagious adult are a better approach than BCG vaccination. The use of directly observed therapy has made the need for BCG vaccination of infants in the United States almost nonexistent.

### MANAGEMENT OF NEONATES AFTER POSTNATAL EXPOSURE

From time to time, workers in nurseries have been found to have infectious tuberculosis.<sup>112,267</sup> These experiments of nature provide useful data on the risk to the infants. In general, risk of infection of neonates in a modern hospital nursery appears to be low. Most nurseries have large air volumes, flows, and adequate air exchanges to decrease the

risk of infection. Also, the minute volume of neonates is low, diminishing the risk of infection after a brief time of exposure. Light and co-workers<sup>259</sup> followed 437 infants exposed to a nurse with a cough and a sputum smear that was positive for tuberculosis. Of these infants, 160 were considered to be at greatest risk and received daily INH for 3 months; all infants remained tuberculin-negative. However, Steiner and colleagues<sup>112</sup> observed development of miliary tuberculosis in 2 of 1647 infants exposed in a nursery. Thus, infection is rare under nursery conditions, but it can and does occur. Strict control measures should prevent such episodes. Nursery personnel should undergo Mantoux testing before starting work and, if the result is negative, yearly thereafter. If the skin test is positive, a prospective employee should have a chest radiograph. If the radiograph result is normal, appropriate therapy for *M. tuberculosis* infection should be given, accompanied by careful medical follow-up. Prospective employees with positive skin tests and abnormal chest radiographs must be carefully and thoroughly evaluated. Many require antituberculosis therapy.

Theoretically, these same guidelines apply to workers in licensed and unlicensed daycare facilities, but in many cases they have not yet been implemented.

Children with primary tuberculosis are rarely contagious because of the nature of their pulmonary disease, absence of forceful cough, and small number of organisms in the diseased tissue.<sup>268,269</sup> Infants with congenital tuberculosis often have extensive pulmonary involvement with positive acid-fast stains of tracheal aspirates and large numbers of tubercle bacilli in the lungs and airways.<sup>270,271</sup> In several cases, there has been evidence of transmission of *M. tuberculosis* from congenitally infected infants to health care workers; transmission to other infants has not been reported.<sup>272-276</sup> Neonates with suspected congenital tuberculosis should be placed in appropriate isolation until it can be determined that they are not infectious, by acid-fast stain and culture of respiratory secretions.

If a member of the household other than the mother is found to have or to have had tuberculosis recently, the roles of chemotherapy and BCG vaccine for the infant remain controversial. If the tuberculous family member has completed treatment in the past, that individual should undergo a checkup before the infant enters the home. If the family member is still being treated, he or she should have been sputum culture negative for at least 3 months before contact with the infant. If the infant must return to a home in which one of the family members has only recently started treatment, he or she should receive daily INH for at least 3 to 4 months, which Dormer and associates<sup>258</sup> showed to be very effective in preventing the development of tuberculosis in infants born to mothers in a sanatorium. If the family cannot be relied on to administer daily medication, if directly observed therapy is impossible, or if there are a number of household members who may have tuberculosis, BCG vaccination of the neonate should be considered.

## CONCLUSION

Perinatal tuberculosis, although rare, will continue to occur, particularly among high-risk groups such as blacks, Hispanics, Asian or Pacific Islanders, Native Americans Alaskan natives, and particularly among recent immigrants to the United

States. Intrauterine transmission to the unborn child occurs particularly in pregnant women experiencing initial *M. tuberculosis* infection and disease such as pleural effusion or miliary tuberculosis; less often it is a complication of endometrial tuberculosis. Postnatal tuberculosis, on the other hand, is usually acquired from a mother, another close family member, or a caregiver with cavitary tuberculosis. Only by keeping the possibility of tuberculosis in mind and by carrying out appropriate history taking and tuberculin testing of pregnant patients, particularly those from high-risk groups, can tuberculosis be diagnosed and treated in time in the mother and newborn. If it does occur and is diagnosed in time, intensive treatment should result in an excellent outcome.

At the beginning of the 21st century, diarrheal disease continues to be a significant cause of morbidity and mortality worldwide. During the period of 1986 to 2000, an estimated 1.4 billion children younger than 5 years suffered an episode of acute diarrhea every year in developing countries; among these, 123.6 million required outpatient medical care, and 9 million required hospitalization. Approximately 2 million diarrhea-associated deaths occurred in this age group annually, primarily in the most impoverished areas of the world.<sup>1</sup> These estimates are somewhat lower than the more than 3 million annual deaths from diarrhea reported in the prior 10 years,<sup>2</sup> indicating progress in prevention and treatment of acute diarrhea. In the United States, approximately 400 childhood deaths per year were reported during the late 1980s,<sup>3,4</sup> although the actual number may be higher.<sup>4</sup>

Accurate incidence rates for acute diarrhea in neonates from different populations are not readily available. The relative sparing of the newborn probably results from low exposure to enteropathogens and protection associated with breast-feeding.<sup>5-8</sup> After the first few months of life, increasing interaction with other individuals and the environment, including introduction of artificial feeding, increases the risk of exposure to enteropathogens. For most pathogens, the incidence of acute diarrhea peaks in children between 6 months and 4 years old.<sup>9</sup> Neonatal diarrhea is more common in underdeveloped areas, where low educational levels, crowding, and poor standards of medical care, environmental sanitation, and personal hygiene favor early contact with enteropathogens. As the incidence of neonatal gastroenteritis rises, there is a proportional increase in neonatal deaths because medical care for the poor often is inadequate.<sup>10,11</sup> For very low birth

weight infants (<1500 g), the death rate from diarrhea is 100-fold greater than for higher-birth-weight infants.<sup>12</sup>

This chapter discusses the pathogenesis, diagnosis, treatment, and prevention of gastroenteritis based on the available knowledge about pathogens that can cause neonatal diarrhea. Pathogens that rarely or never cause acute diarrhea in neonates are not discussed. After an overview of host defense mechanisms and protective factors in human milk, the remainder of the chapter is devoted to specific pathogens that cause inflammatory or noninflammatory diarrhea.

## ENTERIC HOST DEFENSE MECHANISMS

The neonate is a host that is uniquely susceptible to enteric infections. Neonates have not had the opportunity to develop local or systemic immune responses, and in the first few days of life, they have not acquired the highly important enteric flora that protects the normal adult gastrointestinal tract.<sup>13-18</sup> Still less is known about the barrier effect of the neonate's gastric acidity,<sup>19</sup> intestinal mucus,<sup>20</sup> or motility,<sup>21,22</sup> each of which provides protection against gastrointestinal tract infections in older infants, children, and adults.

The gastric acid barrier appears to be least effective during the first months of life. The average gastric pH level of the newborn is high (pH 4 to 7; mean, 6).<sup>23,24</sup> Although the pH falls to low levels by the end of the first day of life (pH 2 to 3),<sup>23</sup> it subsequently rises again; by 7 to 10 days of life, the hydrochloric acid output of the neonatal stomach is far less than that of older infants and children.<sup>24,25</sup> The buffering action of frequent milk feedings and the short gastric emptying time<sup>26-29</sup> interpose additional factors in the neonate that would be expected to permit viable ingested organisms to reach the small intestine.

The intestinal epithelium serves as a nutrient absorptive machine, barrier to pathogen entry, and regulator of inflammation. Intestinal epithelial cells have receptors for bacterial products and produce chemokines (e.g., interleukin [IL]-8, monocyte chemoattractant protein type 1 [MCP-1], granulocyte macrophage-cell stimulating factor [GM-CSF]) and pro-inflammatory cytokines (e.g., IL-6, tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ], IL-1) in response to invasion by enteropathogens.<sup>30</sup> The gut epithelium orchestrates the immune response. However, in the newborn, phagocytic, chemotactic, and complement functions are immature. B and T lymphocyte functions are impaired, resulting in a preferential IgM production in response to antigenic stimulation. IgG is actively transferred from mother to infant across the placenta at about 32 weeks' gestation and peaks by about 37 weeks; premature neonates, especially those born before 28 weeks' gestation, are deficient in these maternally derived serum antibodies.<sup>31</sup>

## PROTECTIVE FACTORS IN HUMAN MILK

The importance of breast-feeding infants for the prevention of diarrheal disease has long been emphasized.<sup>13,32-45</sup> Published studies reporting the association between breast-feeding and diarrhea are extensive and suggest that infants who are breast-fed suffer fewer episodes of diarrhea than those who are not. This protection is greatest during a child's

**Table 20-1 Association between Antibodies in Human Milk and Protection against Enteropathogens**

Organism	Antibody
<i>Vibrio cholerae</i>	Lipopolysaccharide, enterotoxin
<i>Campylobacter jejuni</i>	Surface proteins

Enterotoxigenic <i>E. coli</i>	Enterotoxin, adherence proteins
Shigatoxin producing <i>E. coli</i>	Adherence proteins
<i>Shigella</i>	Lipopolysaccharide, virulence plasmid-associated antigens
<i>Giardia lamblia</i>	Surface proteins

first 3 months of life and declines with increasing age. During the period of weaning, partial breast-feeding confers protection that is intermediate between that gained by infants who are exclusively breast-fed and that by those who are exclusively bottle-fed.

A striking demonstration of the protection afforded by breast-feeding of newborns has been provided by Mata and Urrutia<sup>13</sup> in their studies of a population of infants born in a rural Guatemalan village. Despite extremely poor sanitation and the demonstration of fecal organisms in the colostrum and milk of almost one third of mothers,<sup>46</sup> diarrheal disease did not occur in any newborns. The incidence of diarrhea rose significantly only after these infants reached 4 to 6 months old, at which time solids and other fluids were used to supplement the human milk feedings. At that time, *Escherichia coli* and gram-negative anaerobes (e.g., *Bacteroides*) were found to colonize the intestinal tract.<sup>13</sup> In contrast, urban infants of a similar ethnic background who were partly or totally artificially fed frequently acquired diarrheal disease caused by enteropathogenic *E. coli* (EPEC).

Multiple mechanisms by which breast-feeding protects against diarrhea have been postulated. Breast-feeding confers protection by active components in milk and by decreased exposure to organisms present on or in contaminated bottles, food, or water. Many protective components have been identified in human milk and generally are classified as belonging to the major categories of cells, antibody, anti-inflammatory factors, and glycoconjugates and other nonantibody factors.<sup>47-50</sup> Examples of milk antibodies are summarized in Table 20-1. For any given pathogen, multiple milk factors may help protect the infant. Human milk typically targets a major pathogenic mechanism using multiple, redundant strategies. Redundancy of milk protective factors and targeting of complex virulence machinery have created a formidable barrier to enteropathogens. Despite the fact that pathogens can rapidly divide and mutate, milk continues to protect infants. For example, human milk has secretory antibodies to *Shigella* virulence antigens and lipopolysaccharides,<sup>51,52</sup> neutral glycolipid Gb3 to bind Shiga toxin,<sup>53,54</sup> and lactoferrin to disrupt and degrade the surface-expressed virulence antigens.<sup>55-57</sup> In a similar way, milk contains antibodies directed toward the surface expressed virulence antigens of EPEC,<sup>58</sup> oligosaccharides that block cell attachment,<sup>59</sup> and lactoferrin that disrupts and degrades the surface expressed EPEC antigens.<sup>60</sup> Human milk can initiate and

maintain the growth of *Bifidobacterium* and low pH in the feces of newborn infants, creating an environment antagonistic to the growth of *E. coli*.<sup>13,17,18,61</sup>

The protective effect of human milk antibodies against enteropathogen-specific disease has been described for *Vibrio cholerae*,<sup>62</sup> *Campylobacter jejuni*,<sup>63</sup> EPEC,<sup>59</sup> enterotoxigenic *E. coli* (ETEC),<sup>64,65</sup> *Shigella*,<sup>66,67</sup> and *Giardia lamblia*.<sup>68,69</sup> and for bovine milk concentrate against ETEC,<sup>70</sup> rotavirus,<sup>71</sup> and *Shigella*.<sup>72</sup>

In 1933, the nonlactose carbohydrate fraction of human milk was found to consist mainly of oligosaccharides.<sup>73</sup> In 1960, Montreuil and Mullet<sup>74</sup> determined that up to 2.4% of colostrum and up to 1.3% of mature milk are oligosaccharides. Human milk contains a larger quantity of the oligosaccharides than does milk from other mammals, and its composition is singularly complex.<sup>75</sup> The metabolic fate of the oligosaccharides is of interest. Only water, lactose, and lipids are present in greater amounts than the oligosaccharides. Despite the fact that substantial energy must be expended by the mother to synthesize the many hundreds of different milk oligosaccharides, the infant does not use them as food. Most of the oligosaccharides pass through the gut undigested.<sup>76,77</sup> It is thought that they are present primarily to serve as receptor analogues that misdirect enteropathogen attachment factors away from gut epithelial carbohydrate receptors. Likewise, enteropathogens use the oligosaccharide portion of glycolipids and glycoproteins as targets for attachment of whole bacteria and toxins. Evidence is emerging that these glycoconjugates may have an important role in protection of the breast-fed infant from disease.<sup>48</sup>

Human milk protects suckling mice from the heat-stable enterotoxin (ST) of *E. coli*; on the basis of its chemical stability and physical properties, the protective factor has been deduced to be a neutral fucosyloligosaccharide.<sup>79,80</sup> Experiments have shown that EPEC attachment to HEp-2 cells can be inhibited by purified oligosaccharide fractions from human milk.<sup>59</sup> Oligosaccharides also may be relevant to protection from Norwalk virus and other caliciviruses, because these viruses attach to human ABO, Lewis, and secretor blood group antigens.<sup>80,81</sup> Human milk contains large amounts of these carbohydrates. The ganglioside fraction in human milk has been shown to inhibit the action of heat-labile toxin (LT) and cholera toxin on ileal loops more effectively than secretory IgA.<sup>82,83</sup> Lactadherin in human milk has been shown to bind rotavirus and to inhibit viral replication in vitro and in vivo.<sup>84</sup> A study of infants in Mexico showed that lactadherin in human milk protected infants from symptoms of rotavirus infection.<sup>72</sup>

## ESCHERICHIA COLI

*E. coli* organisms promptly colonize the lower intestinal tracts of healthy infants in their first few days of life<sup>85-88</sup> and constitute the predominant aerobic coliform fecal flora throughout life in humans and in many animals. The concept that this species might cause enteric disease was first suggested in the late 19th and early 20th centuries, when several veterinary workers described the association of diarrhea (i.e., scours) in newborn calves with certain strains of *E. coli*.<sup>89-94</sup>

In 1905, Moro<sup>95</sup> observed that *Bacterium* (now *Escherichia coli*) was found more often in the small intestines of children

with diarrhea than in children without diarrhea. Adam<sup>96,97</sup> confirmed these findings and noted the similarity with Asiatic cholera and calf scours. He further extended these observations by suggesting that *E. coli* strains from patients with diarrhea could be distinguished from normal coliform flora by certain sugar fermentation patterns. Although he called these disease-producing organisms *dyspepsicoli* and introduced the important concept that *E. coli* could cause enteric disease, biochemical reactions have not proved to be a reliable means of distinguishing nonpathogenic from pathogenic *E. coli* strains. There are now at least six recognized enteric pathotypes of *E. coli*.<sup>98</sup> The pathotypes can be distinguished clinically, epidemiologically, and pathogenetically (Table 20-2).<sup>98-104</sup>

ETEC organisms are defined by their ability to secrete the LT or the ST enterotoxin, or both. LT is closely related to cholera toxin and similarly acts by means of intestinal adenylate cyclase,<sup>105,106</sup> prostaglandin synthesis,<sup>107,108</sup> and possibly platelet activating factor.<sup>109,110</sup> ST (particularly the variant STa) causes secretion by specifically activating intestinal mucosal guanylate cyclase.<sup>111-113</sup> The STb toxin causes noncyclic, nucleotide-mediated bicarbonate secretion and appears to be important only in animals.<sup>114-116</sup> Enteroinvasive *E. coli* (EIEC) has the capacity to invade the intestinal mucosa, thereby causing an inflammatory enteritis much like shigellosis.<sup>117,118</sup> EPEC elicits diarrhea by a signal transduction mechanism,<sup>98-102,119,120</sup> which is accompanied by a characteristic attaching-and-effacing histopathologic lesion in the small intestine.<sup>121</sup> Enterohemorrhagic *E. coli* (EHEC) also induces an attaching-and-effacing lesion, but in the colon.<sup>98</sup> EHEC also secretes Shiga toxin, which gives rise to the sequela of hemolytic-uremic syndrome (HUS). Diffusely adherent *E. coli*<sup>122</sup> executes a signal transduction effect, which is accompanied by the induction of long cellular processes.<sup>123</sup> Enteroaggregative *E. coli* (EAEC) adheres to the intestinal mucosa and elaborates enterotoxins and cytotoxins.<sup>98,103,125</sup>

A major problem in the recognition of ETEC, EIEC, EPEC, and EHEC strains of *E. coli* is that they are indistinguishable from normal coliform flora of the intestinal tract by the usual bacteriologic methods. Serotyping is of value in recognizing EPEC serotypes<sup>126</sup> and EIEC, because these organisms tend to fall into a limited number of specific serogroups (see Table 20-2).<sup>126,127</sup> EIEC invasiveness is confirmed by inoculating fresh isolates into guinea pig conjunctivae, as described by Sereny.<sup>128</sup> The ability of organisms to produce enterotoxins (LT or ST) is encoded by a transmissible plasmid that can be lost by one strain of *E. coli* or transferred to a previously unrecognized strain.<sup>129-131</sup> Although the enterotoxin plasmids appear to prefer certain serogroups (different from EPEC or invasive serogroups),<sup>132</sup> ETEC is not expected to be strictly limited to a particular set of serogroups. Instead, these strains can be recognized only by examining for the enterotoxin. This is done in ligated animal loops,<sup>133</sup> in tissue culture,<sup>134,135</sup> or by enzyme-linked immunosorbent assay (ELISA)<sup>136</sup> for LT or in suckling mice for ST.<sup>137,138</sup> Specific DNA probes also are available for LT and ST.<sup>98</sup> Whether there are other mechanisms involved in the ability of the versatile *E. coli* species to cause enteric disease, such as by producing other types of enterotoxins<sup>139</sup> or by fimbriate adherence traits alone,<sup>140,141</sup> remains to be elucidated.

ETEC, enterotoxigenic *Escherichia coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; EHEC, enterohemorrhagic *E. coli*; EAEC, enteroaggregative *E. coli*; LT, heat-labile toxin; ST, heat-stable toxin.

### Enterotoxigenic *Escherichia coli*

Although early work on the recognition of *E. coli* as a potential enteric pathogen focused on biochemical or serologic distinctions, there followed a shift in emphasis to the enterotoxins produced by previously recognized and entirely “new” strains of *E. coli*. Beginning in the mid-1950s with work by De and colleagues<sup>142,143</sup> in Calcutta, *E. coli* strains from patients with diarrhea were found to cause a fluid secretory response in ligated rabbit ileal loops analogous to that seen with *V. cholerae*. Work by Taylor and associates<sup>144,145</sup> showed that the viable *E. coli* strains were not required to produce this secretory response and that this enterotoxin production correlated poorly with classically recognized EPEC serotypes. In São Paulo, Trabulsi<sup>146</sup> made similar observations with *E. coli* isolated from children with diarrhea, and several veterinary workers demonstrated that ETEC was associated with diarrhea in piglets and calves.<sup>147–150</sup> A similar pattern was described in 1971 with acute undifferentiated diarrhea in adults in Bengal from whom *E. coli* could be isolated from the upper small bowel only during acute illness.<sup>151,152</sup> These strains of *E. coli* produced a nondialyzable, LT, ammonium sulfate–precipitable enterotoxin.<sup>153</sup> Analogous to the usually short-lived diarrheal illnesses of *E. coli* reported by several workers, a short-lived course of the secretory response to *E. coli* culture filtrates compared with the secretory response of cholera toxin was described.<sup>154</sup> However, like responses to cholera toxin, secretory responses to *E. coli* were associated with activation of intestinal mucosal adenylate cyclase that paralleled the fluid secretory response.<sup>155,156</sup>

The two types of enterotoxins produced by *E. coli*<sup>157–159</sup> have been found to be plasmid-encoded traits that are potentially separable from each other and from the equally important plasmid-encoded adherence traits for pathogenesis.<sup>129–131,160</sup> ST causes an immediate and reversible secretory response,<sup>133</sup> whereas the effects of LT (e.g., cholera toxin) follow a lag period necessitated by its intracellular site of action.<sup>105,106,134</sup> Only LT appears to cause fluid secretion by activating adenylate cyclase, which is accomplished by toxin-induced ADP-ribosylation of the G<sub>s</sub>α signaling protein.<sup>98,105</sup> The activation of adenylate cyclase by LT and by cholera toxin is highly promiscuous, occurring in many cell types and resulting in development of nonintestinal tissue culture assay systems such as the Chinese hamster ovary (CHO) cell assay<sup>134</sup> and Y1 adrenal cell assay.<sup>135</sup> The antigenic similarity of LT and cholera toxin and their apparent binding to the monosialoganglioside GM<sub>1</sub> have enabled development of ELISAs for detection of LT and cholera toxin.<sup>138,161–163</sup>

ST is a much smaller molecule and is distinct antigenically from LT and cholera toxin.<sup>134,137,138</sup> Although it fails to alter cAMP levels, ST increases intracellular intestinal mucosal cyclic guanosine monophosphate (cGMP) concentrations and specifically activates plasma membrane-associated intestinal guanylate cyclase.<sup>111–113</sup> Like cAMP analogues, cGMP analogues cause intestinal secretion that mimics the response to ST.<sup>111</sup> The receptor for STa responds to an endogenous ligand called *guanylin*, of which STa is a structural homologue.<sup>164</sup> Because the capacity to produce an enterotoxin may be transmissible between different organisms by a plasmid or even a bacteriophage,<sup>129,131</sup> interstrain gene transfer

may be expected to be responsible for occasional toxigenic non-*E. coli*. Enterotoxigenic *Klebsiella* and *Citrobacter* strains have been associated with diarrhea in a few reports, often in the same patients with ETEC.<sup>165,166</sup> Likewise, certain strains of *Salmonella* appear to produce an LT, CHO cell-positive toxin that may play a similar role in the pathogenesis of the watery, noninflammatory diarrhea sometimes seen with *Salmonella enteritidis* infection.<sup>167,168</sup> At least equally important as enterotoxigenicity for *E. coli* to cause disease is the ability of these organisms to colonize the upper small bowel, where the enterotoxin produced has its greatest effect. A separable, plasmid-encoded colonization trait was first recognized in porcine *E. coli*. Veterinary workers demonstrated that the fimbriate K-88 surface antigen was necessary for ETEC to cause disease in piglets.<sup>160</sup> An autosomal dominant allele appears to be responsible for the specific intestinal receptor in piglets. In elegant studies by Gibbons and co-workers,<sup>169</sup> the homozygous recessive piglets lacked the receptor for K-88 and were resistant to scours caused by ETEC. At least 15 analogous colonization factors have been described for human *E. coli* isolates<sup>98,170,171</sup> against which local IgA antibody may be produced. These antigens potentially may be useful in vaccine development.

### Epidemiology and Transmission

Data on the epidemiology and transmission of ETEC remain scanty for the neonatal period. In the past 2 decades, these strains have been recognized among adults with endemic, cholera-like diarrhea in Calcutta, India, and in Dacca, Bangladesh,<sup>105,151</sup> and among travelers to areas such as Mexico and Central Africa.<sup>173-175</sup>

The isolation of ETEC is uncommon in sporadic diarrheal illnesses in temperate climates where sanitation facilities are good and where winter viral patterns of diarrhea predominate. ETEC is commonly isolated from infants and children with acute watery summer diarrhea in areas where sanitary facilities are less than optimal.<sup>35,165,175-187</sup> These include areas such as Africa,<sup>165</sup> Brazil,<sup>35,175,181,186,187</sup> Argentina,<sup>177</sup> Bengal,<sup>178,179</sup> Mexico,<sup>180</sup> and Native American reservations in the southwestern United States.<sup>182,183</sup> In a multicenter study of acute diarrhea in 3640 infants and children in China, India, Mexico, Myanmar, and Pakistan, 16% of cases (versus 5% of 3279 controls) had ETEC.<sup>184</sup> A case-control study from northwestern Spain showed a highly significant association of ETEC with 26.5% of neonatal diarrhea, often acquired in the hospital.<sup>185</sup> Although all types of ETEC (LT and/or ST producers) are associated with cholera-like, non-inflammatory, watery diarrhea in adults in these areas, they probably constitute the major cause (along with rotaviruses) of dehydrating diarrhea in infants and young children in these areas. In this setting, peaks of illnesses tend to occur in the summer or rainy season, and dehydrating illnesses may be life threatening, especially in infants and young children.<sup>35,181,186</sup> Humans are probably the major reservoirs for the human strains of ETEC, and contaminated food and water probably constitute the principal vectors.<sup>188,189</sup> Although antitoxic immunity to LT and asymptomatic infection with LT-producing *E. coli* tends to increase with age, ST is poorly immunogenic, and ST-producing *E. coli* continues to be associated with symptomatic illnesses into adulthood in endemic areas.<sup>183,187</sup>

The association of ETEC with outbreaks of diarrhea in newborn nurseries is well documented. Ryder and colleagues<sup>190</sup> isolated an ST-producing *E. coli* from 72% of infants with diarrhea, from the environment, and in one instance, from an infant's formula during a 7-month period in a prolonged outbreak in a special care nursery in Texas. Another ST-producing *E. coli* outbreak was reported in 1976 by Gross and associates<sup>191</sup> from a maternity hospital in Scotland. ETEC and EPEC were significantly associated with diarrhea among infants younger than 1 year in Bangladesh.<sup>192</sup>

An outbreak of diarrhea in a newborn special care nursery that was associated with enterotoxigenic organisms that were not limited to the same serotype or even the same species has been reported.<sup>193</sup> The short-lived ETEC, *Klebsiella*, and *Citrobacter* species in this outbreak raised the possibility that each infant's indigenous bowel flora might become transiently toxigenic, possibly by receiving the LT genome from a plasmid or even a bacteriophage.

### Clinical Manifestations

The clinical manifestations of ETEC diarrhea tend to be mild and self-limited, except in small or undernourished infants, in whom dehydration may constitute a major threat to life. In many parts of the developing world, acute diarrheal illnesses are the leading recognized causes of death. There is some suggestion that the diarrheal illnesses associated with ST-producing ETEC may be particularly severe.<sup>179</sup> Most probably the best definition of the clinical manifestations of ETEC infection comes from volunteer studies with adults. Ingestion of  $10^8$  to  $10^{10}$  human ETEC isolates that produce LT and ST or ST alone resulted in a 30% to 80% attack rate of mild to moderate diarrheal illnesses within 12 to 56 hours that lasted 1 to 3 days.<sup>117</sup> These illnesses, typical for traveler's diarrhea, were manifested by malaise, anorexia, abdominal cramps, and sometimes explosive diarrhea. Nausea and vomiting occur relatively infrequently, and up to one third of patients may have a low-grade fever. Although illnesses usually resolve spontaneously within 1 to 5 days, they occasionally may persist for 1 week or longer. The diarrhea is non-inflammatory, without fecal leukocytes or blood. In outbreaks in infants and neonates, the duration has been in the same range (1 to 11 days), with a mean of approximately 4 days.

### Pathology

As in cholera, the pathologic changes associated with ETEC infection are minimal. From animal experiments in which Thiry-Vella loops were infected with these organisms and at a time when the secretory and adenylate cyclase responses were present, there was only a mild discharge of mucus from goblet cells and otherwise no significant pathologic change in the intestinal tract.<sup>106</sup> Unless terminal complications of severe hypotension ensue, ETEC organisms rarely disseminate beyond the intestinal tract. Like cholera, ETEC diarrhea is typically limited to being an intraluminal infection.

### Diagnosis

The preliminary diagnosis of ETEC diarrhea can be suspected by the epidemiologic setting and the non-inflammatory nature of stool specimens, which reveal few or no leukocytes. Although the ability of *E. coli* to produce enterotoxins may be lost or transmitted to other strains, there is a tendency for the enterotoxin plasmids to occur among certain predominant

serotypes, as shown in Table 20-2.<sup>132</sup> These serotypes differ from EPEC or invasive serotypes, but their demonstration does not prove that they are enterotoxigenic. The only definitive way to identify ETEC is to demonstrate the enterotoxin itself by a specific gene probe for the toxin codon, by a bioassay such as tissue culture or ileal loop assays for LT or the suckling mouse assay for ST, or in the case of LT, by immunoassay such as ELISA. However, even these sensitive bioassays are limited by the unavailability of any selective media for detecting ETEC by culture. Even though substantial improvements have been made in enterotoxin assay (particularly for LT), the necessary random selection of *E. coli* from a relatively nonselective stool culture plate resulted in a sensitivity of only 43% of epidemiologically incriminated cases in an outbreak when 5 to 10 isolates were randomly picked and tested for enterotoxigenicity.<sup>189</sup> By also examining paired serum samples for antibody against LT, only 36% demonstrated significant serum antibody titer rises, for a total sensitivity of ETEC isolation or serum antibody titer rises of only 64%. Some have suggested that isolates may be pooled for LT or ST assay. The capacity to prove with radiolabeled or enzyme-tagged oligonucleotide gene sequences for the enterotoxins (LT or ST) further facilitates the identification of enterotoxigenic organisms.<sup>194,195</sup> A novel method of combining immunomagnetic separation (using antibody-coated magnetic beads) followed by DNA or polymerase chain reaction (PCR) probing may enhance the sensitivity of screening fecal or food specimens for ETEC or other pathogens.<sup>196,197</sup>

### Therapy and Prevention

The mainstay of treatment of any diarrheal illness is rehydration.<sup>198</sup> This principle especially pertains to ETEC diarrhea, which is an intraluminal infection. The glucose absorptive mechanism remains intact in *E. coli* enterotoxin-induced secretion, much as it does in cholera, a concept that has resulted in the major advance of oral glucose-electrolyte therapy. This regimen can usually provide fully adequate rehydration in infants and children able to tolerate oral fluids, replacing the need for parenteral rehydration in most cases.<sup>199,200</sup> Its use is particularly critical in rural areas and developing nations, where early application before dehydration becomes severe may be lifesaving.

The standard World Health Organization solution contains 3.5 g NaCl, 2.5 g NaHCO<sub>3</sub>, 1.5 g KCl, and 20 g glucose per liter of clean or boiled drinking water.<sup>198</sup> This corresponds to the following concentrations: 90 mmol/L of sodium, 20 mmol/L of potassium, 30 mmol/L of bicarbonate, 80 mmol/L of chloride, and 110 mmol/L of glucose. A variety of recipes for homemade preparations have been described,<sup>201</sup> but unless the cost is prohibitive, the premade standard solution is preferred. Each 4 ounces of this solution should be followed by 2 ounces of plain water. If there is concern about hypertonicity, especially in small infants in whom a high intake and constant direct supervision of feeding cannot be ensured, the concentration of salt can be reduced.<sup>202</sup> A reduced osmolality solution with 60 mmol/L of sodium and 84 mmol/L of glucose and a total osmolality of 224 (instead of 311) mOsm/kg has been found to reduce stool output by 28% and illness duration by 18% in a multicenter trial involving 447 children in four countries.<sup>203</sup> Commercially available rehydration solutions are increasingly available worldwide.<sup>198</sup>

The role of antimicrobial agents in the treatment or prevention of ETEC is controversial. This infection usually resolves within 3 to 5 days in the absence of antibacterial therapy.<sup>198</sup> Moreover, there is concern about the potential for coexistence of enterotoxigenicity and antibiotic resistance on the same plasmid, and co-transfer of multiple antibiotic resistance and enterotoxigenicity has been well documented.<sup>204</sup> Widespread use of prophylactic antibiotics in areas where antimicrobial resistance is common has the potential for selecting for rather than against enterotoxigenic organisms. The prevention and control of ETEC infections would be similar to those discussed under EPEC serotypes. The use of breast-feeding should be encouraged.

### Enteroinvasive *Escherichia coli*

EIEC causes diarrhea by means of *Shigella*-like intestinal epithelial invasion (discussed later).<sup>117,118</sup> The somatic antigens of these invasive strains have been identified and seem to fall into 1 of 10 recognized O groups (see Table 20-2). Most, if not all, of these bacteria share cell wall antigens with one or another of the various *Shigella* serotypes and produce positive reactions with antisera against the cross-reacting antigen.<sup>118</sup> However, not all strains of *E. coli* belonging to the 10 serogroups associated with dysentery-like illness are pathogenic, because a large (140 MDa) invasive plasmid is also required.<sup>205</sup> Additional biologic tests, including the guinea pig conjunctivitis (Sereny) test or a gene probe for the plasmid, are used to confirm the property of invasiveness.<sup>117</sup>

Although an outbreak of foodborne EIEC diarrhea has been well documented among adults who ate an imported cheese,<sup>118</sup> little is known about the epidemiology and transmission of this organism, especially in newborns and infants. Whether the infectious dose may be as low as it is for *Shigella* is unknown; however, studies of adult volunteers suggest that attack rates may be somewhat lower after ingestion of even large numbers of EIEC than would be expected with *Shigella*. The outbreak of EIEC diarrhea resulted in a dysentery-like syndrome with an inflammatory exudate in stool and invasion and disruption of colonic mucosa.<sup>118</sup> Descriptions of extensive and severe ileocolitis in infants dying with *E. coli* diarrhea indicate that neonatal disease also can be caused by invasive strains capable of mimicking the pathologic features of shigellosis.<sup>206</sup> The immunofluorescent demonstration of *E. coli* together with an acute inflammatory infiltrate<sup>207</sup> in the intestinal tissue of infants tends to support this impression, although it has been suggested that the organisms may have invaded the bowel wall in the postmortem period.<sup>117</sup> There is still little direct evidence concerning the role of invasive strains of *E. coli* in the cause of neonatal diarrhea.<sup>175</sup> The infrequency with which newborns manifest a dysentery-like syndrome makes it unlikely that this pathogen is responsible for a very large proportion of the diarrheal disease that occurs during the first month of life.

The diagnosis should be suspected in infants who have an inflammatory diarrhea as evidenced by fecal polymorphonuclear neutrophils or even bloody dysenteric syndromes from whom no other invasive pathogens, such as *Campylobacter*, *Shigella*, *Salmonella*, *Vibrio*, or *Yersinia*, can be isolated. In this instance, it may be appropriate to have the fecal *E. coli* isolated and serotyped or tested for invasiveness in the Sereny test. Plasmid pattern analysis and chromosomal restriction

endonuclease digestion pattern analysis by pulsed-field gel electrophoresis have been used to evaluate strains involved in outbreaks.<sup>208</sup> The management and prevention of EIEC diarrhea should be similar to those for acute *Shigella* or other *E. coli* enteric infections.

### Enteropathogenic *Escherichia coli*: Classic Serotypes

The serologic distinction of *E. coli* strains associated with epidemic and sporadic infantile diarrhea was first suggested by Goldschmidt in 1933<sup>209</sup> and confirmed by Dulaney and Michelson in 1935.<sup>205</sup> These researchers found that certain strains of *E. coli* associated with institutional outbreaks of diarrhea would agglutinate with antisera on slides. In 1943, Bray<sup>211</sup> isolated a serologically homogeneous strain of *E. coli* (subsequently identified as serogroup O111) from 95% of infants with summer diarrhea in England. He subsequently summarized a larger experience with this organism isolated from only 4% of asymptomatic controls but from 88% of infants with diarrhea, one half of which was hospital acquired.<sup>212</sup> This strain (initially called *E. coli-gomez* by Varela in 1946) also was associated with infantile diarrhea in Mexico.<sup>213</sup> A second type of *E. coli* (called *beta* by Giles in 1948 and subsequently identified as O55) was associated with an outbreak of infantile diarrhea in Aberdeen, Scotland.<sup>214,215</sup>

From this early work primarily with epidemic diarrhea in infants has developed an elaborate serotyping system for certain *E. coli* strains that were clearly associated with infantile diarrhea.<sup>216-218</sup> These strains first were called enteropathogenic *E. coli* by Neter and colleagues<sup>219</sup> in 1955, and the association with particular serotypes can still be observed.<sup>220</sup> As shown in Table 20-1, these organisms are distinct from the enterotoxigenic or enteroinvasive organisms or those that inhabit the normal gastrointestinal tract. They exhibit localized adherence to HEp-2 cells, a phenotype that has been suggested to be useful for diagnosis and pathogenesis research.<sup>119</sup>

### Epidemiology and Transmission

EPEC is an important cause of diarrhea in infants in developing or transitional countries.<sup>98,221-223</sup> Outbreaks have become rare in the United States and other industrialized countries, but they still occur.<sup>224</sup> Some have attributed the rarity of this recognition of illness in part to the declining severity of diarrheal disease caused by EPEC within the past 30 years, resulting in fewer cultures being obtained from infants with relatively mild symptoms.<sup>98,225</sup> However, several other variables influence the apparent incidence of this disease in the community. A problem arises with false-positive EPEC on the basis of the nonspecific cross-reactions seen with improper shortening of the serotyping procedure.<sup>226,227</sup> Because of their complexity and relatively low yield, neither slide agglutination nor HEp-2 cell adherence or DNA probe tests are provided as part of the routine identification of enteric pathogens by most clinical bacteriology laboratories. Failure to recognize the presence of EPEC in fecal specimens is the inevitable consequence.

The apparent incidence of EPEC gastroenteritis also varies with the epidemiologic circumstances under which stool cultures are obtained. The prevalence of enteropathogenic strains is higher among infants from whom cultures are obtained during a community epidemic compared with those

obtained during sporadic diarrheal disease. Neither reflects the incidence of EPEC infection among infants involved in a nursery outbreak or hospital epidemic.

EPEC gastroenteritis is a worldwide problem, and socioeconomic conditions play a significant role in determining the incidence of this disease in different populations.<sup>228</sup> For instance, it is unusual for newborn infants born in a rural environment to manifest diarrheal disease caused by EPEC; most infections of the gastrointestinal tract in these infants occur after the first 6 months of life.<sup>5,229</sup> Conversely, among infants born in large cities, the attack rate of EPEC is high during the first 3 months of life. This age distribution reflects in large part the frequency with which EPEC causes cross-infection outbreaks among nursery populations<sup>191,230-237</sup>; however, a predominance of EPEC in infants in the first 3 months of life also has been described in community epidemics<sup>238-240</sup> and among sporadic cases of diarrhea acquired outside the hospital.<sup>241-247</sup> The disparity in the incidence of neonatal EPEC infection between rural and urban populations has been ascribed to two factors: the trend away from breast-feeding among mothers in industrialized societies and the crowding together of susceptible newborns in nurseries in countries in which hospital deliveries predominate over home deliveries.<sup>5,229,248</sup> Although the predominant serogroup can vary from year to year,<sup>239,242,243,246,249,250</sup> the same strains have been prevalent during the past 40 years in Great Britain,<sup>251</sup> Puerto Rico,<sup>252</sup> Guatemala,<sup>5</sup> Panama,<sup>205</sup> Israel,<sup>247</sup> Newfoundland,<sup>240</sup> Indonesia,<sup>244</sup> Thailand,<sup>254</sup> Uganda,<sup>255</sup> and South Africa.<sup>256</sup>

When living conditions are poor and overcrowding of susceptible infants exists, there is a rise in the incidence of neonatal diarrhea in general<sup>257</sup> and EPEC gastroenteritis in particular.<sup>215,238,258</sup> A higher incidence of asymptomatic family carriers is found in such situations.<sup>238,239</sup>

Newborn infants can acquire EPEC during the first days of life by one of several routes: (1) organisms from the mother ingested at the time of birth; (2) bacteria from other infants or toddlers with diarrheal disease or from asymptomatic adults colonized with the organism, commonly transmitted on the hands of nursery personnel or parents; (3) airborne or droplet infection; (4) fomites; or (5) organisms present in formulas or solid food supplements.<sup>259</sup> Only the first two routes have been shown conclusively to be of any real significance in the transmission of disease or the propagation of epidemics.

Most neonates acquire EPEC at the time of delivery through ingestion of organisms residing in the maternal birth canal or rectum. Stool cultures taken from women before, during, or shortly after delivery have shown that 10% to 15% carry EPEC at some time during this period.<sup>85,86,88,260,261</sup> Use of fluorescent antibody techniques<sup>261</sup> or cultures during a community outbreak of EPEC gastroenteritis<sup>88</sup> revealed twice this number of persons excreting the organism. Virtually none of the women carrying pathogenic strains of *E. coli* had symptoms referable to the gastrointestinal tract.

Many of the mothers whose stools contain EPEC transmit these organisms to their infants,<sup>85,88</sup> resulting in an asymptomatic infection rate of 2% to 5% among newborns cultured at random in nursery surveys.<sup>85,86,191,262</sup> These results must be considered conservative and are probably an artifact of the sampling technique. One study using 150 O antisera to identify as many *E. coli* as possible in fecal cultures showed a

correlation between the coliform flora in 66% of mother-infant pairs.<sup>263</sup> Of particular interest was the observation that the O groups of *E. coli* isolated from the infants' mucus immediately after delivery correlated with those subsequently recovered from their stools, supporting the contention that these organisms were acquired orally at the time of birth. In mothers whose stools contained the same O group as their offspring, the mean time from rupture of membranes to delivery was about 2 hours longer than in those whose infants did not acquire the same serogroups, suggesting that ascending colonization before birth also can play a role in determining the newborn's fecal flora.

The contours of the epidemiologic curves in nursery<sup>238,264-269</sup> and community<sup>238-240</sup> outbreaks are in keeping with a contact mode of spread. Transmission of organisms from infant to infant takes place by way of the fecal-oral route in almost all cases, most likely on the hands of persons attending to their care.<sup>86,267,269,270</sup> Ill infants represent the greatest risk to those around them because of the large numbers of organisms found in their stools<sup>271-274</sup> and vomitus.<sup>275-277</sup> Cross-infection also has been initiated by infants who were healthy at the time of their admission to the nursery.<sup>264,272,278-280</sup>

A newborn exposed to EPEC is likely to acquire enteric infection if contact with a person excreting the organism is intimate and prolonged, as in a hospital or family setting. Stool culture surveys taken during outbreaks have shown that between 20% and 50% of term neonates residing in the nursery carry EPEC in their intestinal tracts.<sup>102,230,231,234</sup> Despite descriptions of nursery outbreaks in which virtually every neonate or low-birth-weight infant became infected,<sup>262,264,281</sup> there is ample evidence that exposure to pathogenic strains of *E. coli* does not necessarily result in greater likelihood of illness for premature infants than for term infants.<sup>261,272,279,282</sup> Any increased prevalence of cross-infections that may exist among premature infants can be explained more readily by the prolonged hospital stays, their increased handling, and the clustering of infants born in different institutions than by a particular susceptibility to EPEC based on immature defense mechanisms.
